c. **Anticonvulsant therapy.** Use of routine anticonvulsants for hyponatremic seizures may not be effective and can be associated with severe apnea.

C. **General management.** Always treat the underlying disorder.

1. **Hyponatremia with hypervolemia.** Sodium and water restriction while maintaining an effective circulating volume.

2. **Hyponatremia with hypovolemia.** Volume expansion with sodium and water to replace losses.

3. **Hyponatremia with euvoolemia.** Water restriction.

D. **Specific management**

1. **Volume overload (dilutional hyponatremia).** Treat with fluid restriction. The total maintenance fluids can be decreased by 20 mL/kg/d, and serum sodium

levels should be monitored every 6 to 8 hours. The underlying cause must be investigated and treated.

2. **Inadequate sodium intake.** See Table 69–1 for recommended sodium intake.
 - a. **The maintenance sodium requirement for term infants is 2 to 4 mEq/kg/d and higher in premature infants.** Calculate the amount of sodium the patient is receiving using the equations in Chapter 10. Readjust the IV sodium intake if it is the cause of hyponatremia.
 - b. **If the infant is receiving oral formula only, check the formula being used.** Low-sodium formulas such as Similac PM 60/40 or breast milk (which is low in sodium) may contribute to hyponatremia. Use of supplemental sodium chloride or a formula with higher sodium content may be necessary.
 - c. **Calculate the total sodium deficit using the following equation.** The result will be the amount of sodium needed to correct the hyponatremia. Usually, **only half of this amount** is given over 12 to 24 hours.

$$\text{Total sodium deficit} = (\text{Desired sodium [135 mEq/L]} - \text{Infant's sodium value}) \times (\text{Weight [kg]} \times 0.6)$$

3. **Increased sodium losses.** Treat the underlying cause and increase the sodium administered to replace the losses.
4. **Drug-induced hyponatremia.** If a renal salt-wasting medication such as **furosemide** is being given, serum sodium levels will be low even though an adequate amount of sodium is being given in the diet. An increase in sodium intake may be required, as is often the case in infants with BPD/CLD who are receiving diuretics. Most are also receiving oral feedings, so an oral sodium chloride supplement can be used. Start with 1 mEq 3 times per day with feedings and adjust as needed. Some infants may require 12 to 15 mEq/d. Sodium levels should be kept in the low 130s because higher levels may result in fluid retention when diuretics are used. **Indomethacin-induced hyponatremia** is treated with fluid restriction.
5. **Syndrome of inappropriate secretion of antidiuretic hormone. Prevention is the best management** by monitoring infants at risk for SIADH. If diagnosed, the goal is to **identify and treat the underlying cause of SIADH**. The cause of SIADH is usually obvious; if it is not, further investigation is needed (eg, ultrasonography of the head or chest radiograph to rule out lung disease). The treatment is to gradually increase the sodium level by promoting free water excretion by fluid restriction. During treatment, monitor the serum sodium, osmolality, and urine output to determine whether the patient is responding.
 - a. **Seizures present or serum sodium is <120 mEq/L**
 - i. **Hypertonic saline solution (3% sodium chloride) is the treatment of choice.** See Section V.B.1.a. and b.
 - ii. **Fluid restriction.** Usually 40 to 60 mL/kg/d free water. There are no clear recommendations on fluid restriction. Some recommend decreasing free water by 20%.
 - iii. **Furosemide (Lasix).** Administer 1 mg/kg IV every 6 hours. Loop diuretics inhibit free water absorption.
 - iv. **Anticonvulsant therapy if seizing (controversial).** Treatment of hyponatremic seizures with anticonvulsants may be ineffective and associated with apnea.
 - v. **Urea administration** increases water excretion and is associated with a decrease in urinary sodium excretion.
 - vi. **Vaptans** inhibit vasopressin receptor and increase free water excretion. Tolvaptan (oral vasopressin receptor antagonist) has been used successfully in limited reports. Dose is 0.1 to 0.6 mg/kg/d; crush the tablets and mix with water.

- b. **Serum sodium is >120 mEq/L without seizures.** Treat underlying cause.
 - i. **Fluid restriction.** Usually 40 to 60 mL/kg/d; some recommend decreasing free water by 20%. This regimen does not allow for fluid loss that accompanies the use of a radiant warmer or phototherapy.
 - ii. **Other therapies include:** Furosemide, sodium supplementation, increase solute load (fortified breast milk/formula, oral urea powder [0.1–2 g/kg/d], urea treatment for chronic SIADH).

70 Hypotension and Shock

I. **Problem.** The nurse reports that an infant is hypotensive and may be showing signs of shock. **Hypotension is defined as a decreased blood pressure.** There is no consensus on the exact definition of a normal blood pressure range or a clear accepted definition of hypotension in the term or preterm neonate. Hypotension can occur in a neonate with normal tissue perfusion or poor perfusion and overwhelming shock. Hypotension is very common in premature infants; however, the blood pressure that indicates end-organ damage in the very low birthweight (VLBW) infant is unknown.

A. **Hypotension.** Data are conflicting on the exact blood pressure that requires treatment based on gestational age, postnatal age, and infant weight. There are many definitions of hypotension:

1. **Mean blood pressure <5th to 10th percentile of normative blood pressure** values from a reference population for the infant's gestational age, birth weight, or postnatal age (term).
2. **Mean blood pressure that is less than the gestational age of the infant in weeks** (preterm infants during the first 3–5 days of life). For example, in a 28-week-old neonate, hypotension would be a mean blood pressure <28 mm Hg.
3. **Mean blood pressure <30 mm Hg.**
4. **For a rapid reference of premature and term infant blood pressure ranges, see Table 70-1 and Figure 70-1,** and for more detailed blood pressure values, see Appendix C.

B. **Shock is a clinical syndrome** of inadequate tissue perfusion that frequently accompanies hypotension. The types of shock are: **hypovolemic, cardiogenic, obstructive, distributive, and dissociative.** Some clinical scenarios may constitute many types of shock such as sepsis (distributive, hypovolemic, and cardiogenic), necrotizing enterocolitis (NEC) (hypovolemic and distributive), or pulmonary hypertension (obstructive and cardiogenic).

II. Immediate questions

A. **What is the method of measurement?** Blood pressure can be measured by invasive and noninvasive techniques. The invasive technique is considered the gold standard and is performed by transducing an indwelling arterial or umbilical artery catheter. A dampened waveform suggests air in the system or inappropriate position of the transducer and may result in inaccurate measurements. Because small bubbles in the system can affect the systolic and diastolic values, **the mean blood pressure is considered the most accurate measurement of systemic perfusion pressure.** The noninvasive technique most commonly performed is the oscillometric method using a blood pressure cuff on an extremity. Ensure that the cuff size is appropriate and that the cuff is applied properly to the extremity. Other noninvasive techniques include auscultation, Doppler ultrasound, and palpation, all of which are less accurate in infants.

Table 70–1. RAPID REFERENCE BLOOD PRESSURE RANGES IN PREMATURE INFANTS ACCORDING TO BODY WEIGHT AND TERM INFANTS BASED ON DAY OF LIFE (DETAILED BLOOD PRESSURE VALUES ARE FOUND IN APPENDIX C)

Birthweight (g)	Mean (mm Hg)	Systolic (mm Hg)	Diastolic (mm Hg)
Premature infants^a			
501–750	38–49	50–62	26–36
751–1000	35.5–47.5	48–59	23–36
1001–1250	37.5–48	49–61	26–35
1251–1500	34.5–44.5	46–56	23–33
1501–1750	34.5–45.5	46–58	23–33
1751–2000	36–48	48–61	24–35
Term infants^b			
Day 1	31–63	46–94	42–57
Day 2	37–68	46–91	27–58
Day 3	36–70	51–93	26–61
Day 4	41–65	60–88	34–57

FIGURE 70–1. Currently suggested lower and upper limits for normal blood pressure in neonates. (Reproduced with permission from Nuntnarumit P, Yang W, Bada-Ellzey HS: Blood pressure measurements in the newborn, *Clin Perinatol*. 1999 Dec;26(4):981-996.)

- B. Are signs of shock present?** Signs of shock include lethargy, poor tone, respiratory distress, tachypnea, apnea and bradycardia, tachycardia, narrow pulse pressure, weak pulses, prolonged capillary refill time (>3–4 seconds), pallor, and cold extremities (with a normal core temperature). Hypothermia is typically seen in infants with shock since they have an impaired autonomic nervous system. **Systolic hypotension** is a marker for decreased cardiac output secondary to impaired preload, contractility, and/or afterload. **Diastolic hypotension** is a marker for decreased systemic vascular resistance (SVR).
- C. Is the urine output acceptable?** Normal urine output is >1 to 2 mL/kg/h and is decreased in shock due to decreased renal perfusion. If the blood pressure is low but the urine output is adequate, aggressive treatment may not be necessary as renal perfusion is adequate (indirect measure of end-organ function). An exception would be the infant with septic shock and hyperglycemia resulting in osmotic diuresis and increased urine output.

III. Differential diagnosis

- A. Hypotension.** Low blood pressure can occur in term or preterm infants. It is very common in premature infants and managed differently from term infants. It can also be drug induced.
- 1. Drug-induced hypotension** may cause vasodilation resulting in low blood pressure. Common types of medications include vasodilators, opiates, sedatives, and maternal antihypertensive agents. Some examples are, tubocurarine, nitroprusside, magnesium sulfate, digitalis, and barbiturates. Others include exogenous surfactant, topical timolol for infantile hemangioma, and intravitreal bevacizumab for the treatment of retinopathy of prematurity in premature infants.
 - 2. Extreme prematurity.** Hypotension is very common in extremely low birth-weight (ELBW) infants (60%–100% at 24–26 weeks' gestation) and VLBW infants (40% at 27–29 weeks' gestation) and is associated with an increased incidence of mortality and morbidity (specifically bronchopulmonary dysplasia, intraventricular hemorrhage [IVH]/periventricular leukomalacia, and neurodevelopmental delay). Etiology of hypotension in the immediate postnatal period is multifactorial and usually transient with improvement during the first few days of life. During this transitional period, hypotension in this group of infants is rarely secondary to hypovolemia and more likely due to the maladaptive transition to extrauterine circulation, immature preterm myocardium, delayed closure of the patent ductus arteriosus (PDA), adrenocortical insufficiency, poor vascular tone, immature catecholamine responses, and transient left ventricular (LV) dysfunction. After the immediate postnatal period, hypotension is usually secondary to an identifiable cause such as NEC, PDA, sepsis, or surgery.

B. Shock

- 1. Hypovolemic shock.** Decreased intravascular volume causes decreased venous return, stroke volume, cardiac output, and tissue perfusion. It can be secondary to hemorrhagic shock (antepartum or postpartum blood loss) or nonhemorrhagic shock (fluid and electrolyte losses). The most common cause of hypovolemia in the neonate is hemorrhage. The majority of VLBW infants who are hypotensive are not hypovolemic.
 - a. Antepartum/intrapartum blood loss** is often associated with asphyxia.
 - i. Abruptio placentae**
 - ii. Placenta previa**
 - iii. Twin-twin transfusion**
 - iv. Fetomaternal hemorrhage**
 - v. Umbilical cord tear/prolapse/rupture**
 - vi. Birth injury** (rupture of spleen or liver, adrenal hemorrhage, subgaleal hemorrhage, subdural hematoma)

- b. Postpartum blood loss**
 - i. Coagulation disorders** (disseminated intravascular coagulation [DIC], coagulopathies)
 - ii. Vitamin K deficiency bleeding**
 - iii. Iatrogenic** (accidental dislodgement of vascular catheter)
 - iv. Pulmonary hemorrhage**
 - v. Intracranial hemorrhage**
 - vi. Surgical blood loss** (eg, circumcision-associated frenular artery bleed)
 - vii. Tumor-associated hemorrhage** (sacroccygeal teratoma)
 - viii. Massive internal bleeding** (any major organ such as gastrointestinal [GI] tract)
- c. Fluid and electrolyte losses**
 - i. Insensible water loss**
 - ii. Diuretic use**
 - iii. Heat stress**
 - iv. Gastrointestinal abnormalities** (vomiting, diarrhea)
 - v. Polyuria** (diabetes insipidus, osmotic diuresis)
 - vi. Capillary leak syndrome** (third space losses)
- 2. Cardiogenic shock.** Myocardial dysfunction causes a decrease in cardiac output, resulting in inadequate tissue perfusion.
 - a. Severe intrapartum or birth asphyxia,** chronic fetal hypoxemia.
 - b. Congenital heart disease** with left-sided lesions (systemic outflow obstruction) is the most common condition to present with shock after the PDA closes. Examples include hypoplastic left heart syndrome, congenital aortic stenosis, coarctation of the aorta, and interruption of the aortic arch. Other congenital heart diseases can present with shock but are not as common.
 - c. Congenital cardiomyopathy** is rare and may present with hydrops fetalis. Other associations include inborn errors of metabolism (see Chapter 100) and infant of a diabetic mother.
 - d. Patent ductus arteriosus** can cause cardiac failure and hypotension due to a steal of systemic blood flow, which may cause decreased perfusion to postductal organs (intestine, kidneys). Increased left atrial pressure, pulmonary venous hypertension, and pulmonary edema/hemorrhage may occur.
 - e. Cardiac dysrhythmias** can cause poor cardiac output. Examples include supraventricular tachycardia, ventricular tachycardia, ventricular fibrillation, complete atrioventricular block, and atrial flutter. Complete congenital heart block can be due to Sjögren type A and B antigens in maternal Lupus and Sjögren syndrome.
 - f. Myocarditis** can cause cardiac failure in addition to septic shock and is usually secondary to a viral infection, most commonly coxsackievirus, in a neonate.
 - g. Large arteriovenous malformation** can cause shunting of blood.
 - h. Congenital hypothyroidism** can present with refractory cardiogenic shock (rare).
- 3. Obstructive shock.** Obstruction of the great vessels of the heart can lead to decreased cardiac output and can be associated with cardiogenic shock. Causes include tension pneumothorax, cardiac tamponade, pulmonary embolism (air or thrombus), severe pulmonary hypertension, and pneumopericardium.
- 4. Distributive shock.** Abnormalities within the vascular beds cause blood volume to be distributed inadequately to organs and tissues. There is no definitive volume loss, but rather inappropriate vasodilatation, dysfunction of the endothelium with capillary leak, loss of vascular tone, or a combination of these. Because the intravascular fluid volume is maldistributed, signs of shock appear.

- a. **Septic shock** is the most common cause of distributive shock and results from endotoxins released by various organisms. This can be complicated by DIC and the normal transition from fetal to neonatal circulation. With increased pulmonary vascular resistance (PVR) and the presence of a PDA, persistent pulmonary hypertension of the newborn (PPHN) results with increased right ventricular work. The incidence of hypotension in infants (any gestation) with sepsis is 38% to 69%. Neonatal herpes simplex virus infection can cause a rapid deterioration and should be considered in the setting of abnormal liver function tests and severe coagulopathy.
 - b. **Neurogenic shock** is secondary to decreased sympathetic activity and lack of vascular tone, leading to vasodilation with decreased tissue perfusion. Although rare in neonates, it may occur with birth asphyxia or intracranial hemorrhage.
 - c. **Anaphylactic shock** is caused by a hypersensitivity response with vasodilation, increased capillary permeability, and fluid shifts resulting in severe hypotension and circulatory collapse. Infants can become sensitized by antigens transferred through breast milk (peanuts, egg, cow's milk). Additional triggers include medications (β -lactam antibiotics, antipyretics), intravenous immune globulin, vaccinations, and natural rubber latex (bottle nipples, pacifiers).
 - d. **Adrenal shock** is caused by adrenal insufficiency. The most common cause is congenital adrenal hyperplasia, whereby 21-hydroxylase deficiency accounts for the majority of cases (95%). Other causes include the nonclassical form of congenital adrenal hyperplasia, adrenal hemorrhage/infarction, and X-linked adrenal hypoplasia congenita (usually males). Clinical signs are hyponatremia, hypoglycemia, hyperkalemia, and masculinization of the external genitalia in females. Those with bilateral adrenal hemorrhage/infarction may not respond to volume resuscitation or inotropic medications.
 - e. **Neonatal toxic shock syndrome** and neonatal toxic shock syndrome–like exanthematous disease are commonly caused by methicillin-resistant *Staphylococcus aureus*.
5. **Dissociative shock.** Cardiac function is preserved with intact and responsive blood vessels and adequate blood volume. However, poor perfusion results from inadequate ability to carry or release oxygen to tissues, such as in **severe anemia** (see Chapter 88) or **methemoglobinemia** (see Chapter 56).
 6. **Mimics of shock in the neonate.** Some **inborn errors of metabolism** resulting in hypoglycemia or hyperammonemia can **mimic the presentation of shock** by unexplained neonatal collapse (galactosemia, urea cycle defects, and others; see Chapter 100). Signs and symptoms of a possible inborn error of metabolism include hypoglycemia, vomiting, jaundice, seizures, hepatosplenomegaly, and cardiomyopathy. Appropriate laboratory tests should be obtained to rule out these conditions.

IV. Database

A. History

1. **What is the gestational age?** VLBW and ELBW infants have low cardiac output due to poor myocardial contractility and relative adrenal insufficiency.
2. **What is the birth history?** Birth asphyxia may be associated with myocardial dysfunction and cardiogenic shock. Maternal bleeding or birth trauma may result in fetal hemorrhage and significant hypovolemia. Maternal intraamniotic infection can increase the risk for neonatal sepsis.
3. **Is there known congenital heart disease?** Structural abnormalities or dysrhythmias can result in cardiogenic shock.
4. **What medications are administered to the infant?** A common side effect of many drugs is hypotension.

B. Physical examination

1. **Significant weight loss, sunken eyes, poor skin turgor, dry/cracked skin, immature skin, use of phototherapy or radiant warmer:** Consider insensible fluid losses (see Chapter 10).
2. **Peripheral edema, heart murmur, hepatomegaly:** Consider cardiogenic shock
3. **Tachycardia, poor urine output, cool extremities, skin mottling:** Consider sepsis.
4. **Warm shock (early stage, warm extremities).** Loss of vascular tone resulting in peripheral vasodilation, capillary leak, tachycardia, increased cardiac output, bounding peripheral pulses, and hypotension (usually low diastolic blood pressure).
5. **Cold shock (late stage, cool extremities).** Increase in vascular tone resulting in peripheral vasoconstriction, prolonged capillary refill time (>3 seconds), decreased peripheral pulses, depressed cardiac output, and hypotension (usually low systolic blood pressure or combined hypotension).
6. **Compensated shock** maintains blood flow to vital organs.
7. **Uncompensated shock** compromises blood flow to vital organs, resulting in tissue damage and multisystem organ failure.
8. **Irreversible shock** results in death with irreversible damage to vital organs.

C. Laboratory studies

1. **Complete blood count with differential** can assess for anemia and sepsis.
2. **Coagulation studies (prothrombin time/partial thromboplastin time) and platelet count** if DIC is suspected.
3. **Serum glucose, electrolytes, and calcium levels** may reveal a metabolic disorder.
4. **Cultures** (blood, cerebrospinal fluid, urine if indicated) can assess for sepsis.
5. **Kleihauer-Betke test** may reveal a suspected fetomaternal transfusion. The test detects the presence of fetal erythrocytes in the mother's blood by a slide elution technique. It causes adult hemoglobin to be eluted from erythrocytes, but fetal hemoglobin resists elution. After the slide is stained, fetal hemoglobin cells appear dark, whereas maternal erythrocytes appear clear. Ask the obstetrician to order this test on the mother.
6. **Arterial blood gases** can assess for hypoxia and acidosis.
7. **Serum lactate**, if increased, may signify anaerobic metabolism, sepsis, and poor tissue perfusion.
8. **Serum histamine or tryptase levels** can be elevated with anaphylactic shock.
9. **Baseline cortisol level** if considering hydrocortisone therapy.
10. **Serum ammonia level** to rule out hyperammonemia in inborn errors of metabolism.

D. Imaging and other studies

1. **Chest radiograph** can assess for a mechanical cause of shock (pneumothorax; transillumination may also be helpful), volume status (small cardiac silhouette suggests volume depletion), or cardiac disease (cardiomegaly may suggest a congenital heart defect).
2. **Ultrasonography of the head** can identify intracranial hemorrhage.
3. **Electrocardiogram** can assess for cardiac dysrhythmias.
4. **Echocardiogram** can assess cardiac anatomy, cardiac output, right ventricular and LV function, and systemic and pulmonary blood flow. Decreased LV output or left ventricle underfilling may suggest hypovolemia. **Targeted neonatal echocardiography** is a shorter, more focused echocardiogram done at the bedside to assess a specific clinical problem and monitor the response to treatment.
5. **Central venous pressure** is measured in the central veins near the heart and can be obtained via umbilical venous catheter placed at the junction of the inferior vena cava and right atrium. It approximates right atrial pressure and is an estimate of right ventricular preload. Normal values are 4 to 6 mm Hg (VLBW) and 5 to 8 mm Hg (newborn), with some sources reporting wider ranges of 2.8 to 13.9 mm Hg in VLBW infants. **Low values suggest hypovolemia, and high values suggest cardiogenic shock.**

6. **American College of Critical Care Medicine hemodynamic parameters for pediatric and neonatal septic shock**
 - a. **Central venous oxygen saturation** is measured by a special catheter in the superior vena cava with goal levels >70%. **Less than 70%** is abnormal and indicative of shock.
 - b. **Superior vena cava flow** can be obtained by Doppler echocardiography. **Less than 40 mL/kg/min** is abnormal and indicative of shock.
 - c. **Cardiac index** measures the heart performance based on LV cardiac output in relation to body surface area. **Less than 3.3 L/min/m²** is abnormal and indicative of shock.
7. **Near-infrared spectroscopy** provides a noninvasive measurement of venous oxygen saturation in the skin tissues to assess oxygen delivery to the brain, renal, and mesenteric regions (see Chapter 25).

V. Plan

- A. **Follow the ABCDs** (airway, breathing, circulation, drugs). Immediately stabilize the infant's airway and respiratory status. Provide **adequate respiratory support** based on clinical exam, chest radiograph, and/or blood gas using noninvasive or invasive measures depending on the severity of respiratory failure. **Establish vascular access** and consider central venous and arterial access for invasive blood pressure monitoring and frequent blood draws. **Initiate fluid resuscitation** and **begin antibiotics** after obtaining cultures.
- B. **Is treatment of hypotension necessary?** If the infant is hypotensive without clinical signs of shock and poor end-organ perfusion, aggressive treatment is usually not necessary, regardless of the blood pressure (consider permissive hypotension, especially in ELBW infants). Close observation and frequent reevaluation are important because the clinical picture may change quickly. Some clinicians recommend only treating hypotension if it is prolonged or associated with hypoxia, hypocapnia, hypercapnia, metabolic acidosis, or any condition associated with impaired cerebral autoregulation. If the infant is hypotensive with clinical signs of shock, early aggressive treatment should be considered.
- C. **Immediate treatment based on etiology.** Remember to start prostaglandin infusion in the setting of shock with hepatomegaly, murmur, cyanosis, or upper/lower extremity blood pressure differential until an echocardiogram is performed to rule out ductal-dependent congenital heart disease.
 1. **Tension pneumothorax.** Use needle decompression and/or chest tube placement (see Chapter 75).
 2. **Pericardial effusion.** Manage with pericardiocentesis (see Chapter 41).
 3. **Anaphylaxis.** Remove source if possible and administer epinephrine.
 4. **Hemorrhage/anemia.** Give blood transfusion, see below.
 5. **Congenital heart disease.** Prostaglandin E₁ for ductal-dependent lesions.
 6. **Tachyarrhythmia.** Adenosine for supraventricular tachycardia.
 7. **Bradyarrhythmia.** Pacemaker for congenital heart block.
 8. **Critically large patent ductus arteriosus** should be considered for PDA closure.
 9. **Hypovolemia** is initially managed by fluid administration.
 10. **Sepsis** should be managed by empiric antibiotics within 1 hour.
 11. **Adrenal crisis/hypoadrenalism** treated by fluids, glucocorticoids, and mineralocorticoids.
 12. **Hypothyroidism.** Thyroid hormone replacement.
- D. **Unknown etiology.** Consider empiric volume expansion with 10 mL/kg crystalloid (normal saline) given intravenously over 10 to 30 minutes.
 1. **If there is a response,** continue volume expansion to increase preload and improve cardiac output.
 2. **If there is no response or hypotension worsens,** consider cardiogenic shock and treatment with inotropic agents.

3. **If there is no response to volume or inotropic agents**, consider treatment with glucocorticoids.
 4. **Preterm infants are known to have transient hypotension** secondary to relative adrenal insufficiency. Without a history of blood loss or evidence of hypovolemia, fluid administration is not recommended. Excess or unwarranted fluid in these infants is associated with increased mortality and morbidity (PDA, IVH, NEC, and abnormal neurodevelopment), and there is no evidence of benefit.
- E. Supportive therapy**
1. **Correct hypothermia.**
 2. **Correct metabolic acidosis, electrolyte abnormalities** (hypoglycemia, hypocalcemia), and hormonal deficiencies (thyroid).
 3. **Correct coagulopathy and thrombocytopenia.**
 4. **Consider hydrocortisone at stress doses** if requiring >10 mcg/kg/min of vasopressors. It has been shown to hasten the weaning of vasopressors in VLBW infants.
- F. Blood replacement**
1. **Consider transfusion** for hematocrit <35% to 40% with severe cardiopulmonary disease or hematocrit <30% with moderate cardiopulmonary disease.
 2. **Administer packed red blood cells** cautiously based on volume status of infant (5–10 mL/kg aliquots).
 3. **Consider fresh-frozen plasma, cryoprecipitate, and fibrinogen replacement** for DIC.
 4. **The following formula can be used to calculate the volume of packed red blood cells** required to achieve a desired hematocrit assuming the total blood volume is 80 mL/kg and the packed red blood cell (PRBC) hematocrit (Hct) is 70%.

$$\text{PRBC volume} = \frac{(\text{Weight [kg]} \times \text{Total blood volume}) \times (\text{Desired Hct} - \text{Patient Hct})}{\text{PRBC Hct}}$$

G. Medications

1. **Commonly used medications for hypotension and shock** are listed in Table 70–2. Choose agent based on etiology and preferred effect.

VI. Management of specific conditions

- A. Extreme prematurity (very low birthweight).** National Association of Neonatal Nurse Practitioners guidelines (American Academy of Pediatrics endorsed; Figure 70–2) recommend the following for hypotension in VLBW infants in the first 3 days of life:
1. **Treat based on etiology.**
 2. **Use of volume expansion is not recommended** unless there is evidence of placenta previa, abruption, umbilical cord blood loss, fetal anemia, or fetal maternal transfusion. Treat with normal saline, lactated Ringer's, or O-/Rh-negative blood at 10 mL/kg over 5 to 10 minutes and repeat if necessary.
 3. **Dopamine alone should be used prior to dobutamine when the cause of hypotension is unknown.** In a VLBW infant with hypotension and low systemic blood flow during the first postnatal day, use dobutamine since it promotes systemic vasodilation, improves low systemic blood flow, and may increase cardiac output.
 4. **If the VLBW infant has hypotension and an infection, use dopamine** as first-line treatment and then epinephrine if it is not effective.
 5. **For VLBW infants with refractory hypotension, use hydrocortisone.** Obtain a baseline serum cortisol level. The use of hydrocortisone with indomethacin is associated with a high risk of GI perforation, and early postnatal use of dexamethasone is associated with cerebral palsy.

Table 70–2. COMMONLY USED MEDICATIONS FOR HYPOTENSION AND SHOCK

Vasopressor (Drug Class)	Dose	Receptors and Location	Effect	Clinical Use
Dopamine (adrenergic agonist)	Low: 1–5 mcg/kg/min	Dopamine (renal, mesenteric, coronary arteries)	Vasodilation in kidneys, intestines, coronary arteries ↑renal perfusion, urine output	First line for most clinical scenarios - PPHN without cardiac dysfunction - VLBW infant
	Intermediate: 5–15 mcg/kg/min	Beta (heart)	Positive inotropy Positive chronotropy ↑HR, ↑BP, renal perfusion, cardiac output	- Septic shock - Neurogenic shock - Perinatal hypoxic ischemia - Infusion via central line is strongly advised (vesicant)
	High: 15–20 mcg/kg/min	Alpha (vascular smooth muscle, heart) Beta (heart)	Vasoconstriction, Positive inotropy and chronotropy ↑HR, ↑BP, ↑SVR	
Dobutamine (adrenergic agonist)	2–20 mcg/kg/min	Beta (heart)	Positive inotropy Positive chronotropy Peripheral vasodilation ↑HR, ↑BP, ↑myocardial oxygen demand	- Hemodynamically significant PDA - Post-PDA ligation syndrome - Second/third line in cardiogenic shock - Infusion via large vein
Epinephrine (adrenergic agonist)	Low <0.3 mcg/kg/min	Beta (heart)	Positive inotropy Positive chronotropy Peripheral vasodilation ↑HR, ↑BP, ↑myocardial oxygen demand	- Anaphylactic shock - PPHN with cardiac dysfunction - Second line in septic shock - Third line in VLBW infants - Infusion via central line is strongly advised (vesicant)
	High >0.3 mcg/kg/min	Alpha (vascular smooth muscle, heart)	Vasoconstriction Positive inotropy ↑BP, ↑SVR, ↑PVR	

(Continued)

Table 70–2. COMMONLY USED MEDICATIONS FOR HYPOTENSION AND SHOCK (CONTINUED)

Vasopressor (Drug Class)	Dose	Receptors and Location	Effect	Clinical Use
Norepinephrine (adrenergic agonist)	0.02–2 mcg/kg/min	Alpha (vascular smooth muscle, heart)	Vasoconstriction Positive inotropy ↑BP, ↑SVR, ↑PVR	- Second or third line in cardiogenic shock - Infusion via central line is strongly advised (vesicant)
Vasopressin (antidiuretic hormone analog)	0.0001–0.0004 units/kg/min 0.17–10 milliunits/kg/min Caution: units of measure vary by indication and age	V1 (vascular smooth muscle) V2 (renal collecting duct system)	Vasoconstriction ↑BP, ↑SVR, ↑urine output	- PPHN without cardiac dysfunction - Hypertrophic obstructive cardiomyopathy - Rescue therapy if failed catecholamines and steroids - Infusion via central line is strongly advised (vesicant)
Milrinone	0.25–0.75 mcg/kg/min +/- loading dose	Phosphodiesterase 3 inhibitor (vascular smooth muscle, heart)	Positive inotropy Vasodilation Improved diastolic dysfunction ↓SVR, ↓PVR	- Post-PDA ligation syndrome - Omitting loading dose may decrease risk of hypotension
Hydrocortisone (glucocorticoid)	25 mg/m ² /d divided every 6–8 hours OR 1 mg/kg/dose IV every 8 hours (physiologic dose) OR 50–100 mg/m ² /d divided every 6–8 hours (stress dose)	Upregulates adrenergic receptors Treats adrenal insufficiency	↑BP, ↑urine output	- Adrenal shock - Second line in VLBW infants - Suspected or confirmed adrenal insufficiency (peak cortisol after ACTH stimulation: <18 mcg/dL or basal cortisol <4 mcg/dL or basal cortisol <18 mcg/dL with inotropic support)

ACTH, adrenocorticotropic hormone; BP, blood pressure; HR, heart rate; IV, intravenous; PPHN, persistent pulmonary hypertension of the newborn; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance; VLBW, very low birthweight.

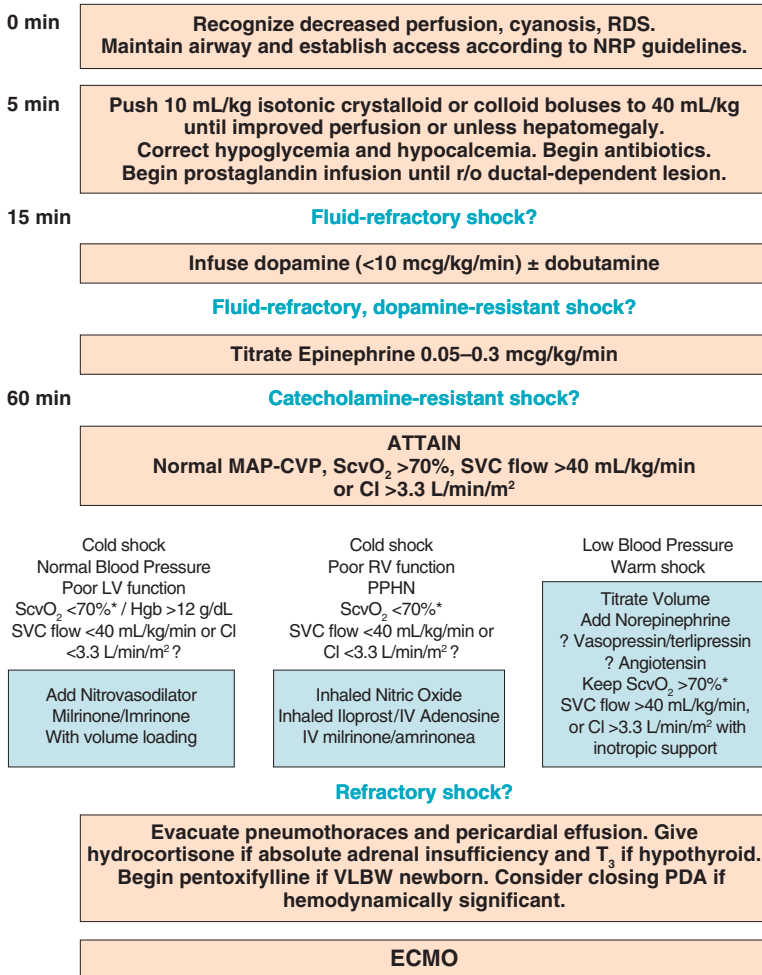

FIGURE 70–2. National Association of Neonatal Nurse Practitioners Guidelines for the treatment of transitional hypotension in very low birthweight infants (VLBW). (Data from Vargo L, *Seri I: New NANN Practice Guideline: the management of hypotension in the very-low-birth-weight infant*, *Adv Neonatal Care*. 2011 Aug;11(4):272-278.)

6. **Use of milrinone in VLBW infants is not recommended** because it is not supported by evidence.
- B. Patent ductus arteriosus**
1. **Hypotension is common** due to systemic steal of blood flow to the pulmonary circulation, low diastolic pressure, and eventual systemic hypoperfusion and end-organ dysfunction.
 2. **Prophylactic indomethacin (first 24 hours of birth)** to facilitate PDA closure decreases vasopressor-dependent hypotension and the need for escalating respiratory support in infants <28 weeks' gestation at the end of the first postnatal week.
 3. **For hypotension related to a hemodynamically significant patent ductus arteriosus**, consider modest fluid restriction, optimal ventilation, inotropic agent (dobutamine is first line), and PDA closure.
- C. Post-patent ductus arteriosus ligation syndrome**
1. **After ligation**, the decline in pulmonary blood flow results in a decline in LV preload. SVR and LV afterload increase with the elimination of the low-resistance pulmonary circuit. Myocardial function decreases after ligation but usually improves within 24 hours.
 2. **The goal of therapy** is to improve LV systolic function and reduce LV afterload with agents such as dobutamine and milrinone.
- D. Persistent pulmonary hypertension of the newborn**
1. **The goal of therapy** is to reduce PVR and improve left atrial filling.
 2. **Optimal ventilation, oxygen, and inhaled nitric oxide** are the first treatments of choice, with inotropic agents, sedation, and muscle relaxation used as needed. Consider sildenafil, inhaled iloprost, and milrinone as additional therapies.
 3. **ECLS** has been used in term infants with refractory PPHN.
- E. Sepsis** (see also Chapter 146)
1. **Hypotension is primarily caused by a decrease in SVR**, which increases heart rate and stroke volume. Acidosis, hypoperfusion, and high myocardial oxygen demand impair myocardial contractility.
 2. **Obtain cultures (blood, urine if indicated, cerebrospinal fluid)** and initiate empiric antibiotics within the first hour.
 3. **Volume expansion is the first-line treatment for septic shock** to optimize cardiac preload. If fluid-refractory shock persists, consider inotropic agents.
 4. **Most common inotropic agents for treatment of septic shock** are dopamine, epinephrine, and hydrocortisone for refractory hypotension.
 5. **Intravenous immune globulin** has not been found to be beneficial in infants with suspected or proven infection.
 6. **Recombinant human activated protein** should not be used for severe neonatal sepsis due to lack of evidence showing benefit and increased risk of bleeding in adults resulting in withdrawal from the market.
 7. **ECLS is a viable therapy for refractory septic shock** with 80% survival.
 8. **Adjunctive therapies with unclear evidence of benefit.** Double-volume exchange transfusion, granulocyte/neutrophil transfusion (Cochrane review found inconclusive evidence to support or refute the use in neutropenic septic neonates), granulocyte colony-stimulating factor, pentoxifylline (Cochrane review found low-quality evidence to suggest it may decrease mortality in VLBW infants as an adjunct to antibiotics), continuous renal replacement therapy, and therapeutic plasma exchange.
 9. **Term newborn septic shock algorithm.** Based on American College of Critical Care Medicine 2017 Clinical Practice Guidelines (Figure 70–3).
 - a. **Time-sensitive, goal-directed stepwise management of hemodynamic support** in newborns with septic shock.
 - b. **Proceed to next step** if shock persists.

American College of Critical Care Medicine algorithm for time-sensitive, goal directed stepwise management of hemodynamic support in newborns. Proceed to next step if shock persists. 1) First hour goals-restore and maintain heart rate thresholds, capillary refill ≤ 2 s, and normal blood pressure in the first hours. 2) Subsequent ICU goals-restore normal perfusion pressure (mean arterial pressure-central venous pressure) preductal and postductal oxygen saturation difference <5% and either ScvO₂ >70% (*except congenital heart patients with mixing lesions), superior vena cava flow >40 mL/kg/min, or cardiac index >3.3 L/min/m² in NICU.

FIGURE 70–3. Term newborn septic shock algorithm based on the American College of Critical Care Medicine 2017 Clinical Practice Guidelines. CI, cardiac index; CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; IV, intravenous; LV, left ventricular; MAP, mean arterial pressure; NRP, Neonatal Resuscitation Program; PDA, patent ductus arteriosus; PPHN, persistent pulmonary hypertension of the newborn; RDS, respiratory distress syndrome; RV, right ventricular; ScvO₂, central venous oxygen saturation; SVC, superior vena cava; T₃, triiodothyronine; VLBW, very low birthweight. (Reproduced with permission from Davis AL, Carcillo JA, Aneja RK, et al: American College of Critical Care Medicine Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Septic Shock, Crit Care Med. 2017 Jun;45(6):1061-1093.)

- c. **First-hour goals:** Restore and maintain heart rate thresholds, capillary refill ≤ 2 seconds, and normal blood pressure
 - d. **Subsequent intensive care unit goals:** Restore normal perfusion pressure (mean arterial pressure – central venous pressure), preductal and postductal oxygen saturation difference $< 5\%$, and any of the following: central venous oxygen saturation $> 70\%$ (except in cardiac mixing lesions), superior vena cava flow > 40 mL/kg/min, or cardiac index > 3.3 L/min/m².
- F. Term infant of diabetic mother**
1. **Along with an increased risk of respiratory distress syndrome and persistent pulmonary hypertension of the newborn**, these infants may have congenital heart disease, specifically septal hypertrophy resulting in hypertrophic obstructive cardiomyopathy.
 2. **Septal hypertrophy leads to left ventricular diastolic dysfunction** and impaired LV filling. Consider volume initially to improve preload and overcome systemic outflow obstruction. β -Blockers (esmolol, propranolol) can be used for chronic management to improve LV filling. Inotropes may worsen hypotension and cardiac dysfunction.
- G. Perinatal hypoxic ischemia**
1. **Asphyxia causes transient myocardial ischemia**, resulting in cardiogenic shock due to decreased LV output. Pulmonary hypertension and adrenal insufficiency may also occur.
 2. **Use inotropic agents for hypotension.** First-line medication is dopamine. If refractory hypotension is present, consider epinephrine and hydrocortisone.
 3. **If severe pulmonary hypertension with right ventricular dysfunction**, consider inhaled nitric oxide and prostaglandin to offload pressure on the right ventricle.
- H. Neurogenic shock.** Consider volume expansion and inotropic agents.
- I. Anaphylactic shock.** Intravenous epinephrine is the first-line treatment. Other therapies include antihistamines, steroids, and albuterol for bronchospasm.
- J. Adrenal shock**
1. **Consider volume expansion** with blood replacement and corticosteroids for adrenal hemorrhage.
 2. **Treat congenital adrenal hyperplasia** with hydrocortisone and sodium supplementation along with pediatric endocrinologist recommendations.
- K. Methemoglobinemia.** Treat with methylene blue therapy unless the infant has glucose-6-phosphate dehydrogenase deficiency.

71 Is the Infant Ready for Discharge?

- I. Problem.** An infant in the newborn nursery or the neonatal intensive care unit (NICU) is ready to be discharged home. How can we ensure that discharge from the hospital is smooth, safe, and complete? **The American Academy of Pediatrics (AAP) has developed specific guidelines for discharge for the following infant types: high risk, late preterm, and healthy term.** The following section reviews the evaluation of infants prior to discharge.
- II. Immediate questions**
- A. What is the gestational age of the infant? Does the infant fit in a high-risk category?** It is important to accurately determine the gestational age of an infant to use the correct AAP guidelines. The guidelines for the late preterm infant differ from those for the healthy term infant. High-risk category guidelines are very specific for

4 subcategories: preterm infant, infant with special care needs or who is dependent on technology, infant at risk because of family issues, or infant with anticipated early death.

B. Does the infant meet discharge criteria (infant readiness)? The decision to discharge any infant is often a very complex decision. Careful preparation for discharge by ensuring infant readiness and other factors may decrease the incidence of readmission and reduce the risks of morbidity and mortality. These guidelines are only a framework for guiding decisions, as the final decision should be **individualized for each infant**. Historically, preterm infants were only discharged when they achieved a specific weight; now preterm infants are discharged based on physiologic criteria and not weight. In fact, the first, most important factor in deciding on discharge is infant readiness. Other considerations include family, community, and health-care provider readiness; risk factors of the mother and infant; and safety concerns, among others.

- 1. Are the vital signs stable?** Most discharge criteria require vital signs be documented within normal reference ranges for the infant for 12 hours preceding discharge. For late preterm and term infants, this includes a respiratory rate <60 breaths/min, a heart rate of 100 to 160 beats/min, and an axillary temperature of 36.5°C to 37.4°C in an open crib. For high-risk neonates, criteria include physiologic mature and stable cardiorespiratory function and adequate maintenance of normal body temperature in an open bed with normal ambient temperature. Most preterm infants are able to maintain normal body temperature at home between 36 and 37 weeks of postmenstrual age (PMA) but lag in achieving maturation of respiratory control, sometimes until up to 44 weeks of PMA.
- 2. Have there been any recent episodes of apnea and bradycardia?** Episodes of apnea of prematurity along with associated bradycardia and desaturation typically resolve at approximately postconception age of 34 to 36 weeks, although infants born less than 28 weeks gestation may have prolonged apnea beyond term. If such episodes persist at 36 weeks of age, the infants may not yet be safe for discharge. Many NICUs will wait for an event-free period of time (typically 5–7 days) before considering these infants ready for discharge home. If events persist beyond term (42–44 weeks), some institutions will send infants home on varying combinations of cardiopulmonary event monitoring, respiratory stimulants (eg, theophylline or caffeine), and supplemental oxygen. In this situation, infant cardiopulmonary resuscitation training and monitor and oxygen use training are arranged for the parents. Complete caregiver understanding of the prescribed outpatient therapies must be verified before discharge. **It is important to note that the use of a home monitor** does not negate the fact that the infant still needs to show maturity of respiratory control prior to discharge. Home monitors do not prevent sudden infant death syndrome and should not be used to justify discharge of an infant with apnea or at risk of apnea.
- 3. Is the infant feeding satisfactorily?** The ability of the infant to breast or bottle feed satisfactorily without cardiorespiratory compromise (ie, to be able to coordinate sucking and swallowing and breathing while taking in an adequate number of calories [120 kcal/kg/d] in reasonable frequency [every 3–4 hours], with each feed not taking >30–40 minutes) is of major importance. By 36 to 37 weeks of PMA, most preterm infants are able to feed satisfactorily. Gavage feeding and gastrostomy tube are alternative feeding practices that are used in infants who are not able to feed by breast or bottle. In addition, many premature infants require fortification of their milk to provide adequate nutrition even after discharge from the NICU. When preparing for the transition home, consideration must be given to the type and caloric content of the fortification that will continue after discharge.
- 4. Is the infant showing consistent and sufficient weight gain (especially for the preterm, late preterm, and high-risk infants)?** At discharge, the infant should

be gaining weight steadily on breast or bottle feeds. Most healthy preterm or term infants with no ongoing problems show an average weight gain of 15 to 30 g/d. Sustained weight gain is more important than specific weight criteria for discharge.

5. **Has the late preterm and term infant passed 1 stool spontaneously and urinated regularly?** Delayed stooling and urination can indicate a serious medical problem (see Chapters 72 and 73).
 6. **Is there any active bleeding from the circumcision site?** Make sure there has been no active bleeding for a minimum of 2 hours prior to discharge.
- C. **Is the family ready for the infant's discharge?** The housing environment, caregiver comfort level, and access to community resources all play an important part in the successful transition to home.
1. **Has the family received discharge training?** Before discharge home, at least 2 family caregivers for the high-risk neonate and the mother and any other caregivers for the preterm and term infant should have received training in feeding, basic infant care (eg, bathing, skin cord and genital care, proper temperature measurement, comforting), and techniques to identify signs and symptoms of an acute illness; review of infant safety guidelines (eg, sleep safety, smoke-free environment, car seat use) is also needed.
 2. **Are there medications that need to be continued after discharge?** Infants discharged on medications usually have the first prescription filled before discharge. Before the infant leaves the hospital, the caregivers should be trained in safely administering the medications. Caregivers are briefed on the duration of administration, importance of the medication, and probable duration of treatment, as well as side effects and risks of discontinuing too soon.
 3. **Are any special feeding techniques necessary?** If clinical grounds indicate the need for a prolonged tube feeding or gastrostomy tube feeding, caregivers must be trained to carry out the feedings at home. Training on the specific method of feeding with the actual equipment the caregivers will be using at home is essential for safe discharge.
 4. **Will the infant be discharged with technologic support?** If infants have bronchopulmonary dysplasia/chronic lung disease (BPD/CLD), a history of bradycardia, or other complications associated with prematurity, they may be sent home with a monitoring device, home oxygen, or both. Caregivers must have completed training on the specific devices they will be using in the home, and proper use of the devices should be verified before discharge. Rarely, infants will be discharged with more complex technologic support (eg, ventilators). The home environment must be safe for and supportive of all levels of support. If necessary, a home environmental assessment can be done to ensure appropriateness before discharge.
 5. **Have the caregivers received training in cardiopulmonary resuscitation?** All caregivers should be aware of the procedures for emergency intervention. Parents of high-risk infants being discharged from the NICU should have infant cardiopulmonary resuscitation reviewed with them before discharge.
 6. **Are there any risk factors in the family that require social services or child protective services to be involved?** These include mental illness in a parent at home, history of child abuse, neglect, untreated parenteral substance abuse or positive urine drug testing in the mother or infant, lack of social support for the mother, history of domestic violence, adolescent mother, mother who lives in a shelter or on the street, or person with a communicable disease living in the home. Discharge should be delayed until risk factors are resolved or a plan is in place for the infant to be safe.
- D. **Is the community ready for the infant's discharge?** Identification of key local providers and support systems for both the infant and family is necessary before discharge of any infant but especially for the high-risk neonate.

1. **Has a primary care provider been identified and contacted?** Information on the name, location, and appointment time for the follow-up physician should be available at the time of discharge. In any given case, the specialty physician should personally contact the primary care physician by telephone to discuss the patient or to make arrangements for a preliminary discharge summary to be faxed to the primary physician. Most infants should be seen within 48 hours of discharge from the NICU.
2. **Will specialists be involved in outpatient care?** Caregivers should be made aware of all the clinical conditions that require outpatient follow-up as well as be given specific names and contact information for making follow-up appointments. In many cases, the inpatient team may be more successful at arranging follow-up than the caregivers, and every attempt should be made to solidify appointments before discharge. It is imperative that caregivers understand the importance of follow-up with subspecialists (eg, ophthalmologists, pediatric surgeons, pediatric cardiologists).
3. **Is the infant at high risk for neurodevelopmental disability?** High-risk NICU infants need comprehensive neurodevelopmental evaluations and appropriate intervention services. The initial examination and evaluation for developmental assessment are done in the NICU before discharge to assess the need for early interventional services. Early intervention is extremely important to beneficial long-term outcome in infants at highest risk for disability. There is a growing body of evidence suggesting that early detection can take advantage of periods of the most active neuroplasticity after brain injury. Many states have early intervention programs that are available to NICU graduates at high risk. These resources should be accessed before discharge in preparation for outpatient follow-up. Appointments at a neonatal follow-up clinic for monitoring growth and development, with input from a dietitian, social worker, physiotherapist, occupational therapist, and developmentalist, are mandatory for very-high-risk infants.
4. **Is the infant a candidate for in-home health visits?** At the request of the physician, follow-up home visits by a home health nurse to check clinical status, to repeat tests, and to ensure weight gain should be arranged for finite periods, depending on the needs of the individual infant and family. If the infant has an **anticipated early death**, has hospice care been notified and bereavement support been given?
5. **Have all screening tests, laboratory evaluations, radiologic evaluations, and appropriate immunizations been completed?**
 - a. **Is the audiology screening complete?** An initial newborn hearing screen (either otoacoustic emissions [OAE] assessment, measuring the sound waves in the inner ear, or auditory brainstem response [ABR] assessment, measuring how the brain responds to sound) is recommended for all infants before discharge and no later than 1 month of age. Note that if OAE testing is done, it does not pick up neural dysfunction (eighth nerve or auditory brainstem pathway). All infants who do not pass the screen and subsequent rescreening need to have a medical evaluation including an audiologic evaluation no later than 3 months of age. The birth hospital and the state early hearing detection and intervention coordinator are responsible to convey the hearing screening results to the parents and medical home. Results are recorded in the patient's record and the discharge summary and are also mailed to each state's Newborn Hearing Screening Program. **ABR assessment** is essential in other clinical conditions in which there is an increased risk for hearing loss and for which progressive losses are possible. **Risk factors for hearing loss** include family history of permanent childhood hearing loss, in utero TORCHZ (toxoplasmosis, other infections, rubella virus, cytomegalovirus [CMV], herpes simplex virus, and Zika virus infection), ear

and craniofacial anomalies, hyperbilirubinemia requiring exchange transfusion, persistent pulmonary hypertension with mechanical ventilation, NICU stay >5 days, extracorporeal membrane oxygenation (ECMO), birthweight <1500 g, bacterial meningitis, low Apgar score of 0 to 3 at 5 minutes or 0 to 6 at 10 minutes, respiratory distress (meconium aspiration), assisted ventilation, exposure to ototoxic medication (gentamycin and tobramycin) or loop diuretics (furosemide), and physical features of a syndrome that includes hearing loss. Separate protocols exist for NICU and well infants.

- i. **Screening in the well infant nursery** includes 1 hearing screening using either OAE or ABR; if the infant does not pass, a repeat screening is done prior to discharge. If an infant passes the ABR, then no follow-up screen is required, but the pediatrician should follow-up with ongoing care which includes identifying and referring infants with risk indicators for late-onset hearing loss. If the infant fails the OAE screening but passes the ABR testing, the infant is considered a “screening pass.” Infants who fail the ABR testing should not be rescreened using the OAE but need to be reevaluated within 1 month of discharge. Infants who did not receive screening in the hospital should have an outpatient screening no later than 1 month of age.
 - ii. **Screening in the neonatal intensive care unit.** All infants need to be screened in the NICU, but infants admitted for >5 days require an ABR (not OAE) for screening to make sure neural hearing loss is not missed. If the infant does not pass, an audiologist needs to do the rescreening and, if indicated, a comprehensive evaluation with diagnostic ABR. The timing and number of hearing evaluations for infants with risk factors should be customized.
 - iii. **Infant with risk factor indicators for hearing loss.** If the infant passes the hearing screen but is at high risk for hearing loss (1 or more of the high-risk indicators listed earlier), rescreening should be done by 3 months of age, and the infant should have at least 1 diagnostic audiology assessment by 24 to 30 months of age. **Perform early and more frequent assessment** in infants with CMV, infants who have a family history of permanent hearing loss or neurodegenerative disorders or trauma, infants who have received ECMO or chemotherapy, any infant with a syndrome associated with progressive hearing loss, and infants whose caregiver is concerned about the hearing. If an infant passes the ABR, then no follow-up screen is required, but the pediatrician should follow-up per standard practice. However, if the infant passes the hearing screen but is at high risk for hearing loss, rescreening should be done within 3 months. If the infant fails the ABR, rescreening should occur within 2 weeks.
- b. **Is the newborn metabolic screen completed? If so, is it valid, or is a repeat test needed?** (See Chapter 16.) The content of the newborn metabolic screen varies among states. All initial newborn screens should be done per state protocol but essentially at 48 hours after birth and preferably after 24 hours of protein feeding. **Many screening tests are affected** by timing of the sample, diet, and whether the infant is preterm, had a transfusion, or is on total parenteral nutrition. Proper follow-up is essential for abnormal results. **Maple syrup urine disease, congenital adrenal hyperplasia, and galactosemia are 3 disorders that need to be treated since they can be fatal.** Any borderline values or abnormal initial metabolic screen results are repeated with more definitive diagnostic tests. It is important to remember that normal results do not totally rule out the presence of these diseases, because there can be false-positive results and some of these conditions have variants that present later on.

- c. **Has the mandatory pulse oximetry screening for critical congenital heart disease been done?** Routine screening is now recommended for all newborns after 24 hours of age but before discharge from the hospital to screen for low blood oxygen to detect critical cyanotic heart disease. Even though most infants will have had pulse oximetry as part of their management while in the NICU, routine care does not typically involve simultaneous measurement of both pre- and postductal saturations. For infants who have not had echocardiograms that rule out cyanotic heart lesions, critical congenital heart defect screening should be performed once they have been weaned from supplemental oxygen. If on oxygen, an echocardiogram is recommended. Some states mandate all infants have screening whether or not an echocardiogram has been performed. An infant passes the screening test if the oxygen saturation is $\geq 95\%$ in the right hand and foot and the difference is ≤ 3 percentage points between the right hand and foot. See pulse oximetry screening recommendations in Chapter 7.
- d. **Have the infant's hips been screened for developmental dysplasia?** The AAP, Pediatric Orthopaedic Society of North America, American Academy of Orthopaedic Surgeons, and Canadian Developmental Dysplasia of the Hip (DDH) Task Force recommend the following: "All newborns should have a physical examination and periodic surveillance physical examination screening for DDH." This should include looking for limb length discrepancy and asymmetric thigh or buttock (gluteal) creases, performing the Ortolani test for stability, and testing for limited/asymmetric abduction. Routine ultrasound is usually not recommended but may be recommended for certain infants (those age 6 weeks to 6 months and at high risk [breech presentation at third trimester, positive family history, parenteral concern, history of previous clinical instability, history of improper swaddling, suspicious/inconclusive physical examination] with normal positive physical findings). Surveillance and periodic physical examinations by the primary care physician on subsequent visits are recommended until walking age. See Chapters 7 and 112 for further discussion on hip testing.
- e. **Does the infant require a car seat tolerance screening evaluation?** Preterm infants are at risk of adverse cardiorespiratory effects (oxygen desaturation, apnea, and bradycardia) when placed in a semi-upright position as when using a semi-reclined car safety seat. Specific recommendations per the AAP for transport of preterm and low birthweight infants at risk of apnea and bradycardia or oxygen desaturation are as follows:
- i. **Perform a car seat tolerance screening** (car seat test/infant car seat challenge) in all preterm infants (born < 37 weeks of gestational age) to decide if physiologic maturity and stable cardiorespiratory function are present. This entails that the infant be placed in the infant's own personal car seat for a period of observation by trained hospital staff for 90 to 120 minutes or the duration of the car ride home, whichever is longer. Specific failure criteria were not provided by the AAP but include apnea (> 20 seconds), bradycardia (heart rate < 80 beats/min), and oxygen desaturation (any desaturation $< 80\%$ or ≥ 2 episodes of oxygen desaturation $< 88\%$ for > 10 seconds). If the infant fails or the events documented are significant, the following are recommended: use of car bed, supplemental oxygen, further medical assessment, or continued hospitalization. Travel in a Federal Motor Vehicle Safety Standard 213-approved car bed with the infant supine or prone is recommended for infants with documented oxygen desaturation, apnea, or bradycardia. **Other infants commonly tested using car seat tolerance screening** (AAP has no specific recommendations) include infants < 2500 g, infants with hypotonia (Down syndrome/congenital

neuromuscular disorders) or micrognathia (Pierre Robin sequence), or infants with congenital heart disease or who have undergone congenital heart surgery. **Low birthweight term infants** have a similar incidence of failure as preterm infants, with an association between maternal opiate use and increased risk of failure. It is ultimately up to each institution to decide which infants should be screened besides the AAP-recommended group.

- (a) **Teach the family how to position the infant properly** in the car safety seat and to minimize the time in the seat. Only use the car safety seat for travel.
 - (b) **The American Academy of Pediatrics recommends that all infants ride rear facing until they are at least 2 years old** or have outgrown the height or weight allowed by the manufacturer of the car seat, at which point they need to continue to ride rear facing in a convertible or 3-in-1 seat. Infants in rear-facing seats are safer because these seats support the head, neck, and spine much better due to better distribution of the force of the collision.
 - (c) **Use infant-only car safety seats with 3- or 5-point harness systems** or convertible car safety seats with 5-point harness systems. Do not use a shield, abdominal pad, or arm rest for a small infant.
 - (d) **Choose a car safety seat with the shortest distance from the crotch strap to the seat back**, with a small cloth between the crotch strap and infant and blanket rolls on both sides of the infant. The car safety seat should be reclined approximately 45 degrees and always be placed in the back seat.
 - (e) **If the infant needs a home cardiac and apnea monitor**, this needs to be used during travel and should be carefully wedged on the floor or under a seat. It is advantageous to have an adult sit in the back with the infant.
 - (f) **Parents need to bring the car seat before discharge** for training on seating the infant, proper positioning, and support.
- f. **Have all the required laboratory studies been completed and documented, if indicated?**
- i. **Hematocrit and reticulocyte count (preterm and high-risk neonates)**. Anemia of prematurity and the physiologic nadir of the red cell line may combine to cause the hematocrit to be low at the time of discharge. Other diagnoses that can lead to poor red blood cell production must also be noted and potentially treated prior to consideration for discharge. A recent complete blood count and reticulocyte count should be documented prior to discharge. Each institution should have a guideline as to what is considered safe for discharge home.
 - ii. **Serum calcium, phosphorus, and alkaline phosphatase**. Extremely premature infants and low birthweight infants are at risk for osteopenia of prematurity and must have these parameters checked during inpatient stay and prior to discharge. The AAP recommends that all breast-fed, mixed-fed, and formula-fed infants who consume <1000 mL of formula should be supplemented with oral vitamin D (minimum of 400 IU of vitamin D per day).
 - iii. **Drug levels**. Infants being discharged home on medications such as phenobarbital or theophylline should have levels tested before discharge, and the results should be recorded with dose adjustment as necessary.
- g. **Have all the required radiologic studies been completed and documented if indicated?**

- (c) **Infants with cyanotic heart disease in the first year of life.** Consultation with pediatric cardiologist is recommended.
 - (d) **Preterm infants without chronic lung disease or congenital heart disease.** Consider prophylaxis if born <29 weeks 0 days' gestation and <12 months of age. If >29 weeks 0 days' gestation, infants do not need prophylaxis unless they have congenital heart disease, CLD, or another condition.
 - (e) **Infants with neuromuscular disease/congenital anomaly** who are at risk of a lower respiratory tract infection or prolonged hospitalization because of the inability to clear secretions from the upper airway. Consider prophylaxis during the first year of life.
- i. Are there other studies that need to be completed or documented?**
- i. Electroencephalogram.** Record the results, if done more than once, in chronologic order, indicating assessment of cerebral function in infants with seizures.
 - ii. Electrocardiogram.** Documentation is useful in cases of congenital heart defect, supraventricular tachycardia, or metabolic problems.
 - iii. Echocardiogram.** Useful to note results in case of persistent murmurs or the need for follow-up.
 - iv. Other tests.** Record the findings and recommendations of any other tests.
- 6. Discharge plan special considerations**
- a. Ophthalmologic examination.** An eye examination for evaluation of retinopathy of prematurity (ROP) is recommended for all infants of gestational age <30 weeks or ≤ 1500 g and selected infants with a birthweight between 1500 and 2000 g or gestational age >30 weeks with an unstable clinical course (requiring cardiorespiratory support with high risk of ROP); these infants should have dilated eye examinations starting at 4 to 6 weeks of age or 31 to 33 weeks of PMA. Examinations should continue every 2 to 3 weeks until retinal vascular maturity is reached and no disease is present. Infants with ROP or very immature vessels should be examined every 1 to 2 weeks until vessels are mature or the risk of disease is passed. Infants with the greatest risk should be examined every week. Parents need to be told the importance of follow-up examinations and the possible consequences of serious ROP. The examination schedule is initially determined by the neonatologist based on the AAP policy statement from the Section on Ophthalmology, and then follow-up examinations are usually scheduled by the examining ophthalmologist based on retinal findings. Follow-up recommendations are:
- 1-week or less follow-up:**
 Zone 1: immature vascularization, no ROP
 Zone 1: stage 1 or stage 2 ROP;
 Immature retina extending into posterior zone II, near the boundary of zone I-zone II;
 Suspected presence of AP-ROP;
 Stage 3 ROP, zone I requires treatment, not observation.
- 1- to 2-week follow-up:**
 Posterior zone II: immature vascularization
 Zone II: stage 2 ROP
 Zone I: unequivocally regressing ROP
- 2-week follow-up:**
 Zone II: stage 1 ROP
 Zone II: no ROP, immature vascularization
 Zone II: unequivocally regressing ROP
- 2- to 3-week follow-up:**
 Zone III: stage 1 or 2 ROP
 Zone III: regressing ROP

b. Bilirubin assessment in infants >35 weeks' gestation

- i. Before discharge, every infant should be assessed for the risk of developing severe hyperbilirubinemia.** The AAP recommends doing a predischARGE bilirubin using total serum bilirubin (TSB) or transcutaneous bilirubin and/or a clinical assessment of risk factors. New studies suggest that combining a predischARGE measurement with clinical risk factors may improve the prediction of which infants will develop hyperbilirubinemia. Use the predischARGE TSB and plot the results on the nomogram (see Figure 63–2) to assess the risk of subsequent hyperbilirubinemia. Once you have the predischARGE bilirubin and assigned bilirubin risk zone, use the figure to help guide when the follow-up visit should be and when a repeat bilirubin needs to be done.
- c. Male circumcision.** The AAP states that “the health benefits of newborn male circumcision outweigh the risks, but not enough to recommend universal newborn circumcision.” The decision is up to the parents and can be performed at parental request and with their written consent before discharge. The procedure is elective, requires analgesia, and should not be done on any unstable infants or infants with serious medical conditions (ongoing apnea and bradycardia, infants with BPD/CLD on oxygen). Any infant with any penile edema or anomalies of the penis (eg, hypospadias with foreskin abnormalities, micropenis, torsion of the penis, webbed penis, chordee of the penis, any disorder of sexual development where reconstruction may be needed at a later date) should not be circumcised and be referred to a specialist. Premature infants should not have circumcision until they are healthy and being discharged. Older infants require formal anesthesia and analgesia.

III. Discharge summary information

- A. Discharge diagnoses.** A concise list of all the diagnoses for a patient, listed in chronological order of occurrence, including procedures, should be generated.
- B. Database.** Review the initial history, NICU or newborn nursery hospital course, and physical examination at discharge. Compose an organized discharge summary by systems or by problems.
 - 1. History.** Inclusive of maternal–fetal conditions (including prenatal diagnostic tests and medications), labor and delivery information, birth history (Apgar scores, head circumference, length, and weight), and neonatal history in the NICU or newborn nursery.
 - 2. Physical examination.** List any significant abnormal findings noted at birth. Perform a complete physical examination, paying careful attention to note any significant changes or findings. See Chapter 7 for details on the newborn physical examination. List infant's condition at discharge with the discharge diagnoses listed.
 - 3. Other important information.** Written feeding plan with specific breast-feeding or formula instructions, any medications at discharge, any medical equipment, follow-up appointments (eg, ophthalmology, orthopedics, audiology), car seat tolerance screening results, pulse oximetry results, newborn metabolic screening tests and dates when done, immunizations given, any pertinent lab results (hematocrit, bilirubin), any follow-up instructions for the first visit to healthcare provider.
- IV. Plan.** (Specific AAP guidelines for discharge of high-risk, late-preterm, and healthy term infants.)
 - A. American Academy of Pediatrics guidelines for high-risk infant discharge.** (Committee on Fetus and Newborn. Hospital discharge of the high-risk neonate. *Pediatrics*. 2008; 122[5]:1119–1126.) The decision to discharge a high-risk infant is dependent upon many factors: infant readiness, family and home readiness, and community and healthcare system. The AAP has also classified high-risk infants into 4 specific groups (the preterm infant, the infant with special healthcare needs or dependence on technology, the infant at risk because of family issues, and the infant with an

anticipated early death), and each group has additional minimal discharge guidelines that need to be followed.

1. Infant readiness

- a. **Demonstrate a pattern of weight gain** over a sufficient duration of time.
- b. **Make sure the infant can maintain normal body temperature** fully clothed in an open bed with normal ambient temperature (20–25°C).
- c. **Make sure the infant can feed by bottle or breast** without cardiorespiratory compromise.
- d. **Document for a sufficient duration a physiologically mature and stable cardiorespiratory function.**
- e. **Give appropriate immunizations.**
- f. **Perform metabolic screening.**
- g. **Assess hematologic status and give any appropriate therapy.**
- h. **Assess nutritional risks and institute any dietary changes.**
- i. **Perform hearing evaluation.**
- j. **Perform funduscopic examinations.**
- k. **Assess and demonstrate neurodevelopmental and neurobehavioral status.**
- l. **Perform car seat evaluation.**
- m. **Review hospital course**, identify any medical problems, and plan follow-up.
- n. **Plan an individualized home care plan**, with all necessary specialties.

2. Family and home environmental readiness

- a. **Identify at a minimum 2 caregivers** and assess their ability, commitment, and availability.
- b. **Do a psychosocial assessment of parenting strengths and risks.**
- c. **Do a home environmental assessment**, with on-site evaluation possibly included.
- d. **Review available financial resources.**
- e. **Document 24-hour telephone access, electricity, safe in-house water, and adequate heating in the home.**
- f. **Document parents'/caregivers' capability for feeding** including formula preparation.
- g. **Document basic infant care**, including comforting, bathing, skin and genital care, measuring temperature of the infant, and dressing.
- h. **Understand early signs and symptoms of illness** or any signs and symptoms that are specific to the condition of the infant.
- i. **Understand any specific precautions** for the artificial airway, feeding tube, intestinal stoma, infusion pump, or other devices needed, if indicated.
- j. **Understand giving medications**, including storing, dosage, timing, how to give medications, and recognition of signs of toxicity
- k. **Understand, if indicated, the operation, maintenance, and problem solving for any support equipment** the infant needs.
- l. **Go over the appropriate technique for any special care that the infant requires**, including maintenance of an artificial airway, physical therapy needs, oropharyngeal/tracheal suctioning, special dressing care for intestinal stoma, healing wounds, or infusion entry site.

3. Community and healthcare readiness

- a. **Identify and notify emergency medical service providers if indicated.** Make sure that an emergency intervention and transportation plan is in place.
- b. **Identify a primary care physician** who will take responsibility for the care of the infant.
- c. **Identify any surgical and/or pediatric medical specialties for follow-up care**, and make sure appointments have been made.
- d. **Identify neurodevelopmental referrals for follow-up**, and make sure appointments have been made.

- e. **Arrange home nursing visits**, and verify home care plan with the home health agency.
 - f. **Give breast-feeding mothers information on breast-feeding support**, and give a list of lactation counselors who are available for questions.
4. **Special situations (eg, preterm infant or infant with special care needs or health dependent on technology, risk of family issues, or anticipated early death)** require certain considerations beyond the normal high-risk infant discharge factors.
- a. **Preterm infants should be discharged based on physiologic criteria**, not body weight.
 - i. **Physiologic stability (most achieved at 36–37 weeks of postmenstrual age)**. Oral feedings sufficient to support appropriate growth, ability to maintain body temperature at home, and sufficient mature respiratory control (may take up to 44 weeks of PMA). A home monitor should not be used to discharge infants who are at risk of apnea and should not stop the evaluation of mature respiratory control. Supine sleeping is recommended.
 - ii. **Arrange for healthcare after discharge with a healthcare provider experienced in high-risk infant care.**
 - iii. **Develop an active program of parental involvement, preparation for care of infant at home, and an organized program to track, and monitor growth and development.**
 - b. **Infant with special care needs or whose health is dependent on technology** (most commonly nutritional or respiratory needs)
 - i. **Nutritional support.** Gavage feeding, gastrostomy tube, parenteral nutrition.
 - ii. **Respiratory support.** Home oxygen therapy, cardiorespiratory monitor/pulse oximetry, tracheostomy care, home ventilator.
 - c. **Infant at risk because of family issues.** Risk factors for subsequent child abuse and dysfunction in the family include preterm birth, prolonged hospitalization, disabling conditions, and birth defects. Maternal factors include lower education level, unstable marriage, fewer prenatal care visits, lack of social support, fewer family visits, and parenteral substance abuse/drug-seeking behaviors of parents.
 - i. **Take a multidisciplinary team approach.**
 - ii. **Identify infants who require extra support or whose home environment is at risk.**
 - iii. **Plan follow-up monitoring and home visits.**
 - d. **Infant with anticipated early death (incurable terminal disorders)**. Many of these infants will spend their last weeks of life at home cared for by the family with support of hospice care. Withdrawal of assisted ventilation can occur at home in some rare instances. The goal should be to enhance the remaining quality of life for the infant and the family. These additional aspects need to be addressed before discharge for home hospice care:
 - i. **Medical follow-up arrangements**
 - ii. **Home nursing visits**
 - iii. **Pain management and management of any distressing symptoms**
 - iv. **Arrangement of home oxygen and other equipment/supplies**
 - v. **Bereavement support information for the family/siblings/other**
 - vi. **Resources for respite care to caregivers**
 - vii. **Financial assistance**
 - viii. **If appropriate, a letter should be given to the family stating that the infant should not be resuscitated.**
- B. **American Academy of Pediatrics clinical guidelines for late preterm infant discharge.** (Engle WA, Tomashek KM, Wallman C, et al. “Late-preterm” infants: a population at risk. *Pediatrics*. 2007; 120(6):1390-1401.) Note that late preterm infants are

more physiologically immature and are at a greater risk of morbidity and mortality than term infants. They are more likely to be readmitted for feeding difficulties, jaundice, dehydration, and sepsis. Recent studies show that mothers of **late preterm and early term infants** are more likely to smoke, less likely to start and continue breast feeding, and less likely to put infants in the supine position for sleep; therefore, it is important that this group of parents have more attention and special guidance in providing appropriate home care after discharge. **Discharge criteria for the late preterm infant include criteria from both the high-risk and normal term infant.** The following are **minimum criteria for late preterm infants on discharge:**

1. **Accurately determine the gestational age.**
2. **The timing of the discharge date is individualized** and based on ability to feed, ability to maintain body temperature, health status and absence of any medical illness, and absence of social risk factors. Do not expect a late preterm infant to meet these requirements before 48 hours of age.
3. **Choose a physician for continuing care,** and make sure a follow-up appointment has been made for 24 to 48 hours after discharge. Plan additional visits until a pattern of weight gain has been established and maintained.
4. **Vital signs need to be stable and within normal reference ranges for 12 hours prior to discharge,** and these should be recorded. Record stable vital signs for 12 hours prior to discharge; respiratory rate needs to be <60 breaths/min, heart rate should be 100 to 160 beats/min, and axillary temperature should be 36.5°C to 37°C (97.7–99.3°F) in an open crib with appropriate clothing.
5. **The infant should have passed 1 stool spontaneously.**
6. **Successful feeding for 24 hours** (breast or bottle; ability to coordinate sucking, swallowing, and breathing while feeding). Assess for dehydration if weight loss >2% to 3% of birthweight per day or a maximum of 7% of birthweight during hospitalization.
7. **A formal evaluation of breastfeeding should be done.** Observation of position, latch, and milk transfer should be documented in the chart by a trained caregiver for a minimum of 2 times a day after birth. The family needs to understand the feeding plan prior to discharge.
8. **Assess the infant for risk of hyperbilirubinemia prior to discharge** using the gestational age and hours of age nomogram, assign a bilirubin risk zone, and check Figure 63–2 to see when follow-up is recommended.
9. **Do a complete physical examination,** and make sure there are no abnormalities that require further hospitalization.
10. **Make sure the circumcision site** has no active bleeding for a minimum of 2 hours.
11. **Go over maternal and infant tests,** including maternal syphilis and hepatitis B surface antigen status, cord/infant blood type, and direct Coombs result if indicated and results of stat mandated screenings including human immunodeficiency virus (HIV) testing.
12. **Perform metabolic and genetic screenings** per your state's requirements. Assess the need for a repeat newborn screening if it was done before 24 hours of milk feeding.
13. **Give the initial hepatitis B vaccine at discharge.** See page 637 for recommendations. Stress the importance of immunizations to parents.
14. **Perform a car seat safety study by a trained professional.** Make sure the seated infant was observed for apnea, bradycardia, or oxygen desaturation and passed.
15. **Perform a hearing assessment, and go over results with the family.** Document results in the medical chart, and plan follow-up if needed.
16. **Assess family, environmental, and social risk factors.** Delay discharge if a risk factor has been identified. Examples of risk factors include history of child abuse or neglect, mental illness in parent in the home, untreated substance abuse in the parent, positive toxicology test results in mom or baby, homelessness (this

pregnancy), ongoing risk of domestic violence, and adolescent mother, especially if she has other risk factors.

17. **Train mother/caregivers and ensure competency** in the following:
 - a. **Current condition of the baby and hospital course.**
 - b. **Normal pattern of urine and stool frequency** for breast-fed or formula-fed infant. Best to give written and verbal instruction.
 - c. **How to care for the umbilical cord, skin, and genital area** of a newborn.
 - d. **Proper hand hygiene.** Discuss that this decreases the risk of infection.
 - e. **How to use an axillary thermometer** in an infant.
 - f. **Appropriate layers of clothing.**
 - g. **How to identify jaundice for hyperbilirubinemia** and common signs and symptoms of sepsis and dehydration.
 - h. **How to ensure there is a safe sleeping environment.** Instruct in the practice of “back to sleep.”
 - i. **Safety issues.** Car seat, smoke/fire alarms, hazards of secondhand smoke and any environmental pollutants, and what to do in an emergency.
 - j. **Appropriate use of care by siblings and sibling’s interactions.**

- C. **American Academy of Pediatrics guidelines for healthy term infant discharge.** (Benitz WE; Committee on Fetus and Newborn, American Academy of Pediatrics. Hospital stay for healthy term newborn infants. *Pediatrics*. 2015; 135(5):948-953.) The decision to discharge a healthy term infant depends on many factors: the health and well-being of the mother and infant, the ability of the mother to care for the infant, the presence of an adequate support system at home, the access to follow-up, and the input from the mother, obstetrician, and nursing staff. Efforts should be made to discharge the mother and infant together. The following are **minimal discharge criteria for the healthy term infant** after an uncomplicated pregnancy, labor, and delivery with normal clinical course and normal physical examination:

1. **Document normal vital signs for 12 hours prior to discharge** (respiratory rate <60 breaths/min; no signs of respiratory distress; awake heart rate of 100–190 beats/min [heart rate <70 beats/min] if asleep okay if no signs of circulatory compromise), axillary temperature of 36.5–37.4°C (97.7–99.3°F) in open crib with appropriate clothing).
2. **Infant has urinated regularly and passed 1 stool.**
3. **Infant has fed twice successfully.** Document knowledge and success of breast feeding with a caregiver observing (latching on, swallowing, infant satiety) in the medical record. If bottle feeding, document that the infant can suck, swallow, and breathe successfully while feeding.
4. **Check circumcision site,** and make sure there is no significant bleeding for at least 2 hours.
5. **Assess the clinical risk of hyperbilirubinemia,** and make sure the AAP guidelines have been followed. See Chapters 63 and 99.
6. **Make sure the infant has been adequately evaluated for sepsis** based on maternal risk factors and current guidelines for infants with suspected or proven early-onset sepsis. See Chapter 146.
7. **Go over maternal blood test and screening results** (syphilis, hepatitis B antigen status, HIV test).
8. **Review infant blood tests** (eg, cord/infant blood type and direct Coombs test if indicated).
9. **Give initial hepatitis B vaccine** at discharge according to current immunization schedule and infant’s risk status. (See Appendix E)
10. **Complete newborn metabolic screening, pulse oximetry screening, and hearing screenings** per hospital protocol and state regulations. Make sure a repeat metabolic screen is done on a follow-up visit if the infant has not been fed milk for 24 hours before the test.

11. **Verify that the mother is able to:**
 - a. **State the importance of breast feeding benefits** for mother and child.
 - b. **State what is the appropriate frequency of urinating and stooling of the infant.**
 - c. **Understand umbilical cord, skin, newborn genital, and circumcision care.** Go over how to take a temperature and normal temperature assessment.
 - d. **State the signs of illness and jaundice** and has the ability to recognize them.
 - e. **Understand infant safety issues.** Car seat safety, supine positioning for sleeping, smoke-free environment, room sharing but not bed sharing.
 - f. **Recognize the importance of hand hygiene.**
12. **Car safety seat is available and appropriate for the infant,** and mother has demonstrated appropriate car seat use with infant positioning.
13. **Make sure the mother has support people** who feel comfortable with newborn care and have a working knowledge of jaundice, dehydration, and lactation and who are available for the infant and her after discharge.
14. **Identify a medical home for continuing care for the mother and infant.** Provide instructions if there is an emergency and a number for the medical home; the first follow-up visit should be scheduled at discharge.
15. **Safe home environment counseling** (if risk factors are present, delay discharge until they are resolved, and consider discussing with social services/child protective services)
 - a. **Untreated parental drug abuse** or positive urine toxicology screen in mother or infant
 - b. **Child abuse/neglect history**
 - c. **Mental illness** in parent at home
 - d. **Lack of social support** (first-time mom)
 - e. **No fixed home**
 - f. **Domestic violence history,** especially during this pregnancy
 - g. **Adolescent mother**
 - h. **Barriers to adequate follow-up** (lack of transportation to medical visits and lack of telephone access, non-English-speaking parents)
16. **Discharge <48 hours after delivery.** Follow-up appointment needs to be made, and the infant needs to be seen by a licensed healthcare professional within 48 hours of discharge. If this cannot be done, the discharge should be delayed. Follow-up visit can be done anywhere as long as the healthcare professional is competent in newborn care and the visit is reported to the infant's physician. Follow-up visit purpose:
 - a. **Establish a relationship with the medical home.**
 - b. **Weigh the infant; check general health, hydration, jaundice, and feeding patterns;** obtain adequate stooling and urination patterns. Are there any new problems? If breast feeding is not going well, make a referral for lactation support.
 - c. **Infant behavior? Mother-infant bonding/attachment?** Parental well-being? Any postpartum depression? Screen for postpartum depression.
 - d. **Reinforce infant care and feeding** and safety issues such as back to sleep, no cosleeping, and child safety seats (only for travel; not for use in home) for the mom and family or support system.
 - e. **Review any outstanding laboratory tests** performed at discharge (newborn metabolic screens).
 - f. **Perform any necessary tests** such as any that are clinically indicated (eg, bilirubin) or any newborn screening tests mandated by the state.
 - g. **Healthcare maintenance issues.** Verify the plan for healthcare maintenance, preventive care, emergency services, immunizations, periodic physical examinations, and necessary screenings.

72 No Stool in 48 Hours

- I. Problem.** The nurse reports that no stool has been passed in an infant for 36 hours. The first stool, meconium, is usually passed by 98.5% of term infants, 100% of postterm infants, and 76% of premature infants (majority are >32 weeks) in the first 24 hours of life. The majority of premature infants have delayed passage (37% in 24 hours, 32% beyond 48 hours, and 99% by 9 days in 1 study) (Table 72–1). Delayed passage of meconium was found to be in 81% of very low birthweight (VLBW) infants. Males were found to pass stool later than females. Delayed passage of meconium can be a predisposing factor for bowel perforation. The triad of failure to pass meconium, vomiting, and abdominal distention, is a sign that the infant may have intestinal obstruction.
- II. Immediate questions**
- A. What is the stooling history?** This history can give a clue to the diagnosis. An infant with a complete obstruction can pass meconium because the meconium was formed in utero distal to obstruction or a mucous stool (intestinal secretions can occur distal to the obstruction).
- 1. Has the infant passed his or her first stool?** Meconium is composed of materials ingested while the infant is in the uterus and consists of **succus entericus** (intestinal epithelial cells, lanugo, mucus, amniotic fluid, bile salts, bile acids, and debris from the intestinal mucosa). It is not sterile because it contains enteric bacteria. The time when the first meconium stool passes has been used as a **marker for normal gastrointestinal functioning** and a delay can occur because of gestational immaturity, a severe illness, a bowel obstruction or other causes.
 - 2. If meconium has been passed and normal stooling has occurred,** but not in the past couple of days, consider simple constipation.
 - 3. If delayed passage of meconium occurs,** consider prematurity, distal intestinal obstruction, or Hirschsprung disease (observed in 90% of infants).
 - 4. If meconium has never been passed,** consider imperforate anus or some degree of distal bowel obstruction.
 - 5. If meconium has been passed and stooling has occurred and then slowed down or stopped completely,** consider small bowel obstruction.

Table 72–1. TIME OF FIRST STOOL BASED ON A STUDY OF 500 TERM AND PRETERM INFANTS

Hours	Preterm Infants (%) (Majority >32 wks) ^a	Full-Term Infants (%)	Postterm Infants (%)
Delivery room (0)	5.0	16.7	32
1–8	32.5	59.5	68
9–16	63.8	91.1	88
17–24	76.3	98.5	100
24–48	98.8	100.0	—
>48	100.0	—	—

Percentages are cumulative.

^aPreterm: only 3 infants <32 weeks in the study.

Data from Clark DA: Times of first void and first stool in 500 newborns, *Pediatrics*. 1977 Oct;60(4):457–459.

B. Is there abdominal distension? Abdominal distension can be a sign of intestinal obstruction and may be present right after birth or at 24 to 48 hours, when it usually peaks. It is more common in lower obstructions, and the more distal the obstruction, the more severe is the abdominal distension. Proximal obstructions will have minimal to no abdominal distension.

If the abdominal distension is present at birth, consider antenatal intestinal obstruction/perforation from volvulus, intestinal atresia, or meconium ileus/peritonitis. Abdominal distension usually appears 24 hours or later after birth in infants with more distal or functional obstructions.

- C. Is there vomiting?** Secretions proximal to the obstruction build up and result in vomiting, which can be bilious or nonbilious. Bilious emesis is more common in proximal obstructions and suggests that the obstruction is located **distal to the ampulla of Vater** (where the fusion of the common bile duct and pancreatic duct enter the C-shaped curve of the duodenum). Bilious vomiting is seen with duodenal atresia, malrotation with midgut volvulus, jejunal ileal atresia, meconium ileus, small left colon syndrome, colorectal atresia, and Hirschsprung disease. **Nonbilious vomiting** occurs if the obstruction is proximal to the ampulla of Vater. **Sporadic bilious/nonbilious vomiting** may be seen in infants with a partial obstruction.
- D. How many hours or days old is the infant?** Infants with proximal intestinal obstructions usually present within 24 to 48 hours of birth. Infants with distal intestinal obstructions usually present a few days after birth. Infants with a functional obstruction (Hirschsprung disease) can present a few weeks after birth or later.
- E. What is the gestational age and birthweight of the infant?** An inverse relationship between gestational age, birthweight, and meconium passage exists. Studies show the older the gestational age, the shorter is the time to the first stool. Premature and VLBW infants commonly have a delayed passage of stool because of immaturity of interstitial cells of the colon, increased viscosity of meconium, and lack of triggering effect of enteral feeds on gut hormones when the patient is maintained nothing by mouth. **Failure of a full-term or postterm infant to pass meconium may signify a bowel obstruction, but in preterm infants, it may not.**
- F. Were maternal drugs used that could cause a paralytic ileus with delayed passage of stool?** Magnesium sulfate, which is used to slow the premature onset of labor, may cause a paralytic ileus. Some studies show it is associated with delayed stool passage. Narcotics for pain control or use of heroin or ganglionic blocking agents by the mother may also cause delayed passage of stool in the infant. Maternal ingestion of psychotropic drugs is associated with small left colon syndrome and delayed passage of stools.
- G. Are there any other congenital abnormalities, associated syndromes, or other diseases?** Many cases of bowel obstruction are associated with congenital anomalies, syndromes, or other diseases. **Cystic fibrosis (CF) should be considered in any infant with delayed meconium passage.**
- 1. Meconium plug syndrome:** Hirschsprung disease, neonatal hypothyroidism.
 - 2. Hirschsprung disease:** Trisomy 21, neurofibromatosis, Waardenburg syndrome, multiple endocrine neoplasia type 2, central hypoventilation syndrome, and cardiac septal defects.
 - 3. Anorectal malformation:** Genitourinary abnormalities most common; cardiovascular, spinal cord tethering, gastrointestinal (GI) complications, and VACTERL (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and radial abnormalities, and limb abnormalities) association. **Eighty percent of cases of imperforate anus have associated abnormalities:** small intestine, esophagus, genitourinary system, cardiovascular system, and sacral area.
 - 4. Small left colon syndrome:** Hypothyroidism, hypermagnesemia.
 - 5. Colonic atresia:** Gastroschisis, omphalocele, Hirschsprung disease, ophthalmic and skeletal anomalies, bladder exstrophy, exomphalos, vesicointestinal fistula, choledochal cyst. Cases of colonic atresia have been reported with congenital varicella syndrome.

6. **Meconium ileus.** Approximately 90% to 95% of babies with meconium ileus have CF; 15% of CF patients will have meconium ileus as neonates.
 7. **Duodenal atresia:** Trisomy 21 (most common in 30%), VACTERL association. Twenty to thirty percent have congenital heart disease.
 8. **Jejunal and ileal atresia.** GI anomalies occur in up to 45% of cases (malrotation, meconium peritonitis, microcolon, duplication cysts, esophageal atresia, and volvulus).
 9. **Meconium peritonitis.** CF is present in 8% to 40% of cases. Rare associations include biliary atresia, familial progressive intrahepatic cholestasis, and hemochromatosis.
 10. **Malrotation and midgut volvulus:** Gastroschisis, omphalocele, diaphragmatic hernia, bowel atresia/stenosis (duodenal or jejunal atresia), and heterotaxy.
- III. **Differential diagnosis.** The differential diagnosis of failure to pass a stool includes constipation, secondary to prematurity, and bowel obstruction, among many other causes. The main concern is being able to recognize a bowel obstruction.
- A. **Constipation.** This occurs in infants who have already passed a stool and then fail to pass one. Infants have a mean of 4 stools per day during the first week of life; this gradually decreases to a mean average of 1.7 stools per day at age 2 years. Some breast-fed infants have only 1 stool a day during the first few days of life, but as the mothers' milk comes in, the frequency increases, and they tend to have more frequent stools in the first 3 months of life than standard formula-fed infants.
 - B. **Prematurity/very low birthweight infants.** Delayed passage of meconium is common in premature and VLBW infants. Immaturity of the colon, increased viscosity of meconium, and delayed first feeding are all associated with delayed passage in these infants. These infants also have a higher risk of respiratory distress syndrome, mechanical ventilation, patent ductus arteriosus, and uteroplacental insufficiency, which also contribute to delayed passage. These infants usually do not have abdominal distension or bilious nasogastric aspirates. Delayed meconium passage in VLBW infants can be a predisposing factor for **bowel perforation** (mortality rate of 50%). Prophylactic administration of glycerin laxatives in VLBW infants resulted in improved stool passage over the first 48 hours of life but did not shorten the time to full feeding or decrease time to discharge (Cochrane review, September 2015).
 - C. **Bowel obstruction** has an incidence of 1 in 2000 live births.
 1. **Large bowel obstruction** usually presents with **abdominal distension and no stools**. This can be secondary to a meconium plug, Hirschsprung disease, anorectal malformations, small left colon syndrome, and colonic atresia.
 - a. **Meconium plug syndrome** has an incidence of 1 in 500 to 1000 births and is also known as functional immaturity of the colon, colonic immaturity, or functional colonic obstruction. This is the most common form of functional bowel obstruction in the neonate. It manifests as an obstruction in the lower left colon and rectum caused by abnormal meconium consistency creating a meconium plug. (**Note:** Consider rectal biopsy in all these patients due to the increased incidence of Hirschsprung disease.) Meconium plug syndrome is more common in infants of diabetic mothers, premature infants, and neonatal hypothyroidism.
 - b. **Hirschsprung disease (congenital aganglionic megacolon).** Accounts for approximately 15% of infants, usually male, who have delayed passage of stool. It occurs in 1 in 4000 live births. A functional obstruction is caused by congenital absence of ganglion cells in the rectum and distal colon (aganglionosis of cells in Meissner and Auerbach plexus in the rectum and variable amounts of the distal colon). The affected segment of colon and rectum fails to relax and is aperistaltic; therefore, no stool is passed. Typically, the infant is full term with delayed passage of meconium (usually after 48 hours of life) and symptoms in the first week of life (bilious vomiting, abdominal

distension). It has a sex-dependent penetrance (4 males to 1 female), and 8% of patients have Down syndrome. It is more common in white males.

- c. **Anorectal malformations** (1 in 4000–8000 infants) include imperforate anus, anal stenosis, and fistula. **The passage of meconium alone is not a sign of a correctly positioned anus.**
 - i. **Imperforate anus or anal atresia** (absent anus) can be high or low type with a fistula or anal stenosis. An infant with an imperforate anus may pass meconium if a fistula exists (meconium per urethra with rectourethral fistula in male or per vagina with rectovaginal fistula in female). There are a high percentage of associated anomalies with anal atresia (70%), such as VATER (vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia)/VACTERL association.
 - ii. **Anal stenosis is a narrowing of the anal canal and accounts for 20% of anorectal malformations.** They present with a small, tight anus, sometimes with a dot of meconium present.
 - d. **Small left colon syndrome.** This syndrome involves a reduced caliber of the colon starting at the splenic flexure causing an intestinal obstruction that is not caused by aganglionosis or meconium. It is usually seen in large but immature infants. Approximately 50% have a history of maternal gestational diabetes, and most do not pass meconium in the first 24 hours of life. The others have sepsis, hypoglycemia, hypothyroidism, or increased magnesium. **Microcolon of prematurity** is the preterm equivalent of small left colon syndrome. The colon has an abnormally small caliber. It seems to be caused by a functional obstruction with failure of the small bowel contents to pass into the colon in utero and by ganglion cell dysfunction and depressive effects of magnesium sulfate. The majority of mothers had toxemia or received magnesium sulfate. The infants present with marked distension, failure to pass meconium, and no bilious vomiting.
 - e. **Colonic atresia is a congenital defect that causes complete obstruction of the lumen of the colon.** It is felt to be secondary to a vascular or mechanical event (intestinal volvulus). It may occur with Hirschsprung disease. The infant will usually present within the first 2 to 3 days after birth with severe abdominal distension, failure to pass meconium, and bilious vomiting.
2. **Small bowel obstruction** usually presents with **bilious vomiting with or without abdominal distension**, and meconium can be passed, but it usually progresses to **decreased or no stools**. This can be secondary to meconium ileus, meconium obstruction of prematurity, small bowel atresias, meconium peritonitis secondary to perforation, or malrotation and midgut volvulus.
 - a. **Meconium ileus.** The meconium is abnormal in consistency and obstructs the distal ileum. It presents with abdominal distension and a failure to pass meconium. It occurs in 10% to 20% of newborns with CF; 80% to 90% of patients with meconium ileum have CF and thus should be tested for it. It is the most common presentation of CF in the neonatal period. Median age of infants presenting with meconium ileus is 2 weeks.
 - b. **Meconium obstruction of prematurity** is a distinct clinical entity that occurs in VLBW premature infants. Maternal history of pregnancy-induced hypertension or chronic hypertension commonly exists in these infants. Meconium is most commonly found in the distal ileum with a predisposition of intestinal perforation. These infants usually pass some meconium and then develop obstructive symptoms a few days later. Feeding intolerance is common. None of these infants have CF.
 - c. **Small bowel atresias.** Atresias are congenital defects that cause complete obstruction of the lumen of the intestine. They are thought to be secondary to a vascular/mechanical event. Atresias most commonly occur in the ileum,

followed by the duodenum and then jejunum. Bilioid emesis, abdominal distension, and failure to pass meconium are seen; jaundice is possible.

- i. **Duodenal atresia** (1 in 10,000–40,000 births). Accounts for up to 60% of intestinal atresia. Infants have gastric distension and vomiting and may pass meconium.
- ii. **Jejunal and ileal atresia.** Abdominal distension and bilioid vomiting within the first 2 days after birth. May pass meconium because it may remain in the distal bowel beyond the obstruction.
- d. **Meconium peritonitis** (1 in 30,000 births). Rare condition where the small bowel perforates proximal to the site of obstruction in utero and meconium leaks into the abdominal cavity and causes peritonitis from an inflammatory response. Most commonly caused by perforation in the small intestine (ileum most common). The obstruction can be caused by an atresia, stenosis, imperforate anus, volvulus, Meckel diverticulum, meconium ileus, intussusception, or peritoneal bands. In the majority of cases, the perforation has closed by the time of birth. Incidence of CF is 8% to 40%.
- e. **Malrotation and midgut volvulus.** Malrotation is a congenital anomaly in which there is a failure of normal rotation and fixation of the bowel. Because the intestine is not fixed in the normal position, it is prone to **volvulus**, which is a twisting of the small intestine that can cut off blood supply to the intestine. It usually presents with **bilioid emesis**; meconium is passed, but then infants progress to decreased or no stools.

3. Adhesions

- a. **Necrotizing enterocolitis.** Postoperatively, such as after surgery for necrotizing enterocolitis (NEC), there is a 30% chance of having adhesions. It usually occurs in the segment of the intestine distal to the established enterostomy, most commonly the colon.
- b. **Non-necrotizing enterocolitis patients.** Acquired intestinal atresia in non-NEC patients is very rare. It can occur from an adhesive band that can entrap a jejunal or ileal segment with its mesentery.

4. Infrequent causes

- a. **Meckel diverticulum** is a congenital diverticulum in the small intestine and is a vestigial remnant of the vitelline duct. Rarely, it can present with obstruction with bilioid vomiting, perforation, and pneumoperitoneum.
- b. **Hypoganglionosis** is a reduced number of ganglion cells; it presents with symptoms similar to Hirschsprung disease and can occur with Hirschsprung disease.
- c. **Neuronal intestinal dysplasia type A** is hypoplasia or aplasia of the sympathetic innervation of the myenteric plexus and mucosa, with inflammation of the mucosa; it presents with symptoms similar to Hirschsprung disease.
- d. **Neuronal intestinal dysplasia type B** is subtle malformation of the enteric nervous system of the submucosal plexus of the colon. It can manifest as meconium plug syndrome or small left colon syndrome.
- e. **Megacystis-microcolon intestinal hypoperistalsis syndrome (Berdon syndrome)** presents with urinary retention, dilated small bowel, microcolon, megacystis (giant bladder), and hydronephrosis. Pathology reveals that ganglion cells are present.

D. Other medical conditions/causes/associations that can cause a delay in meconium passage. Some of these conditions (eg, infection [sepsis], respiratory distress syndrome, electrolyte abnormalities) cause a functional ileus that can cause a delay in passage of stool.

- 1. **Infection.** Sepsis is the most common infection causing delayed passage of stool. Sepsis can cause a dynamic ileus and can be a mimicker of intestinal obstruction. Other infections that can result in intestinal dysfunction include pneumonia, enterovirus infection, omphalitis, and peritonitis.

2. **Respiratory distress syndrome** can cause delayed gastric emptying, which can cause dysmotility of the intestine.
3. **Electrolyte abnormalities.** Hypokalemia, hyponatremia, hypercalcemia, hypomagnesemia, and fetal hypoglycemia can also impair neonatal intestinal motility.
4. **Maternal medications.** Magnesium sulfate, narcotics, ganglionic blocking agents or illicit drugs (opiates, heroin), neuroleptics, antidepressants.
5. **Infant medications.** Theophylline, opiates, narcotic analgesics.
6. **Hypothyroidism (most common).** Other endocrinopathies—adrenal insufficiency, hyperparathyroidism, adrenal bleeding.
7. **Cystic fibrosis should be considered in any infant** with delayed meconium passage or in cholestatic infants with meconium ileus.
8. **Other less common causes.** Congestive heart failure, hyperbilirubinemia, renal vein thrombosis, hypovolemia, patent ductus arteriosus, embolism/thrombosis, uteroplacental insufficiency, mechanical ventilation.
9. **Idiopathic.** No identifiable cause.

IV. Database

- A. **Prenatal history may reveal abnormalities on the fetal ultrasound.** One of the causes of polyhydramnios is proximal GI obstruction due to secretions proximal to the obstruction, and this can occur in intestinal atresia. Fetal bowel dilatation on ultrasound (fluid-filled intestinal loops at least 15 mm in length and 7 mm in diameter) is an indirect sign of a bowel obstruction. Obstruction in a newborn on a prenatal ultrasound is usually made in the late second or third trimester. The classic “double bubble” of duodenal atresia can be seen. Moderately dilated anechoic loops showing hyperperistalsis are seen in ileal atresia. Peritoneal wall calcifications, fetal ascites, and dilated thick-walled echogenic bowel with intra-abdominal cysts are seen in meconium ileus. Prenatal ultrasound findings of meconium peritonitis, bowel dilatation, and absent gallbladder warrant screening in the parents for prenatal CF carrier.
- B. **Physical examination.** First, inspect the anus (eg, fifth digit exam, rectal thermometer, or soft feeding tube). Is the anus in the correct position? A normal anus location in a male is halfway between the base of the scrotum and the coccyx; in a female, it is halfway between the coccyx and vestibule (vaginal opening). A rectal exam will also determine if muscle tone is adequate, and it may reveal hardened stool in the rectum. If patency is in question, consult with surgery on the best way to further evaluate. **Special attention is paid to the abdomen.** Check for abdominal distention or rigidity, bowel sounds, and evidence of a mass. Erythema and tenderness are usually not seen with an obstruction unless there is perforation. Infants with Hirschsprung disease typically have a distended abdomen (63%–91% of neonates) and a tight anal canal with an empty rectum. Infants with Hirschsprung disease can also have the “squirt/blast sign” (explosive expulsion of stool after digital examination). Infants with hypothyroidism can have prolonged jaundice, lethargy, hypothermia, hoarse cry, macroglossia, umbilical hernia, large fontanel, hypotonia, and dry skin.
- C. **Laboratory findings**
 1. **Complete blood count with differential and blood culture to rule out sepsis.** A sterile urine culture should also be obtained.
 2. **Urinary drug screening** on both mother and infant to detect maternal use of narcotics.
 3. **Check newborn screening program for cystic fibrosis** because 63% of CF cases are diagnosed based on delayed stool passage issues. If screening returns positive results, newborns should have sweat chloride testing at 2 weeks of age and when the infant weighs >2 kg.
 - a. **Genetic testing and sweat tests** are recommended to rule out or in CF in every intraoperative diagnosis of meconium ileus. CF is caused by mutations in the CFTR protein. Genetic testing should be done to rule out mutations in both alleles of the *CFTR* (CF transmembrane conductance regulator) gene.

CFTR-related metabolic syndrome describes infants with an equivocal diagnosis and is found in 3% to 4% of infants with a positive screen.

D. Imaging and other studies

1. **Plain film abdominal radiographs.** A flat plate and lateral decubitus film of the abdomen should be obtained to look for ileus or bowel obstruction in any infant who has not passed a stool within 48 hours of birth. A neonate with GI obstruction will have abnormal air patterns, dilated loops of bowel, and multiple air fluid levels (fluid and gas collect in the intestine with an obstruction) at different areas depending on the obstruction. Do not order the film too early because you can miss an obstruction. Remember that at birth the GI tract is gasless and fluid filled. Air fills the stomach immediately after the first cry after birth, and within 5 minutes of life, you will see gas in the stomach; it reaches the small bowel by 3 to 4 hours, the colon by 6 to 8 hours, and the rectum by 12 hours. Important facts to remember when looking at the plain film include the following:
 - a. **Small and large bowel cannot be differentiated on plain film** because of the nondevelopment of haustra; differentiation requires a barium enema.
 - b. **The loop of bowel that is proximal to an obstruction is usually very dilated.** The loop of bowel that is distal to the obstruction will have paucity of gas in the bowel.
 - c. **Dilated intestinal loops are defined if the diameter of the loop** is more than the transverse diameter of the vertebrae or as big as the surgeon's thumb ("thumb sign").
 - d. **Intra-abdominal calcifications** can indicate antenatal perforation and can be seen in meconium ileus and meconium peritonitis.
 - e. **Perforation can occur without free air** on the radiograph.
 - f. **Absent colonic or rectal gas** indicates a complete bowel obstruction.
 - g. **With high intestinal obstruction**, <3 dilated bowel loops are seen. In low/distal intestinal obstruction, >3 dilated bowel loops are seen.
 - h. **Neuhauser sign (air mixed with meconium)** is typically seen with meconium ileus but can be seen with Hirschsprung disease, ileal atresia, and NEC.
 - i. **Other specific radiograph findings are as follows:**
 - i. **Meconium plug:** Distal obstruction with multiple dilated/distended loops of bowel with absence of rectal gas.
 - ii. **Hirschsprung disease:** Initial radiograph shows marked gaseous distension of colon with multiple dilated bowel loops with no gas in the rectum. Air fluid levels in the colon can be seen.
 - iii. **Anorectal malformation** may show multiple dilated bowel loops with no rectal gas.
 - iv. **Functional immaturity of the colon or small left colon syndrome:** Multiple dilated bowel loops with air-fluid levels.
 - v. **Colonic atresia:** Distal obstruction with frothy appearance of air mixed with meconium in right lower quadrant.
 - vi. **Meconium ileus:** Nonspecific; may show distended bowel loops proximal to the impaction. Can see Neuhauser sign (air mixed with meconium). Paucity of air-fluid levels. Calcifications, free air, and very large air fluid levels suggest complications/perforation.
 - vii. **Meconium peritonitis:** Calcifications (linear and punctate) throughout the abdomen.
 - viii. **Duodenal atresia:** Has classic "double bubble" sign: gas bubble in the stomach and the proximal duodenum and the absence of distal gas.
 - ix. **Jejunal ileal atresia:** Air fluid levels often of different size, with largest being just proximal to the site of obstruction.
 - x. **Malrotation and midgut volvulus:** Usually normal film, or gasless abdomen; intestinal dilatation suggesting small bowel obstruction or duodenal obstruction or normal. Sigmoid volvulus has a "coffee bean" sign.

2. **Ultrasound.** Targeted ultrasound of the GI tract is being used more often in the neonatal intensive care unit (NICU); it has no radiation, and infants do not need to be sedated. It can be used in infants with suspected intestinal obstructions to diagnose intestinal obstructions. Ultrasound should be done in infants with imperforate anus to also evaluate for urologic anomalies.
3. **Contrast enema.** Abdominal radiographs with contrast enema should be obtained in the majority of cases of delayed passage of stool if the patient is symptomatic. These will help define the disease process and may be therapeutic. It is contraindicated if a bowel perforation is suspected (calcifications on plain film may indicate perforation). Care must be taken because of risk of perforation in some cases (colonic atresia). Microcolon is a radiologic finding of an abnormally small caliber of colon and usually indicates distal ileal obstruction: ileal atresia, colonic atresia, colon aganglionosis, volvulus, or duplication. In some instances, such as duodenal atresia or jejunal ileal atresia, a contrast study is not necessary because the abdominal radiograph is diagnostic. Findings may include the following:
 - a. **Meconium plug syndrome.** The contrast enema is a diagnostic test for meconium plug syndrome because it shows the outline of meconium and meconium plugs. Meconium plugs are seen in a small microcolon, with distal ileum obstruction. Can see distal ileum impacted with meconium.
 - b. **Hirschsprung disease.** Contrast enema usually shows a distal, narrowed, aganglionic segment leading to a dilated proximal segment. A gradual transition zone may be seen with marked dilatation and presence of barium after 24 hours. Normal caliber left colon.
 - c. **Small left colon syndrome.** A small left colon with a change in the splenic flexure. Narrow descending and rectosigmoid colon with an abrupt transition to a huge distended colon at the splenic flexure.
 - d. **Colonic atresia.** In type 1 colonic atresia, “windsock sign” can be seen as contrast pushes against the membrane. In type 11, one can see a “hook sign” on the microcolon side of the colonic atresia.
 - e. **Meconium ileus.** Contrast enema may reveal microcolon with proximal inspissated meconium proximally. Impacted meconium pellets may be seen in the right colon or distal ileum.
 - f. **Malrotation and midgut volvulus.** The proximal duodenum is dilated and tapered to a beak shape, the distal duodenum may be spiral shaped (corkscrew appearance), and the duodenum is in a Z shape.
 - g. **Meconium obstruction of prematurity.** Meconium plugs are seen in a small microcolon, with distal ileum obstruction. The distal ileum may be impacted with meconium.
4. **Upper gastrointestinal series is indicated in evaluating high obstructions.** It can differentiate between obstruction of the duodenum and malrotation with volvulus.
5. **Anorectal manometry** should be done in all newborns with symptoms suggesting lower bowel obstruction. It records changes in anal pressure during and after rectal distension by balloon dilation. A normal rectosphincteric reflex is seen with rectal distention, and there is a drop in anal pressure. In Hirschsprung disease, there is an absent rectosphincteric reflex, which means there is no drop in anal pressure. This test is difficult to perform, but serial manometry may prevent the need for rectal biopsy. If the rectosphincteric reflex is absent, a rectal suction biopsy is needed. High-resolution anorectal manometry (HR-ARM) is an effective, safe, and minimally invasive technique that has fewer limitations than ARM.
6. **Rectosigmoid ratio/index.** The rectosigmoid ratio is the measurement of the diameter of the rectum divided by the diameter of the sigmoid colon, which is done during a contrast enema. A value <0.9 or 1 , depending on the reference, is suggestive of Hirschsprung disease.

7. **Rectal biopsy.** Biopsy either by suction anal biopsy or transanal wedge resection is the gold standard for diagnosis of Hirschsprung disease. Histology demonstrates the absence of ganglion cells and presence of acetyl cholinesterase-positive hypertrophic nerve fibers.
8. **Specific testing for Hirschsprung disease.** Three specific protein markers have been identified for Hirschsprung disease that allow for early screening and diagnosis, but they are not in widespread use. A 5-serum miRNA profile was identified and was found to be more accurate than contrast enema.

V. Plan

- A. **Rule out simple constipation and rule out or treat any underlying etiologies** such as infection (sepsis), respiratory distress syndrome, electrolyte abnormalities, hypothyroidism, or maternal/infant medications.
- B. **Premature infants.** Need to rule out pathologic cause versus normal delayed passage of stool before full workup is done. Because meconium passage can be normally delayed in infants who are premature and have a low birthweight, delayed passage of stool does not always predict GI disease. It is best to only do a diagnostic workup for intestinal obstruction in premature infants with other signs of GI disease (eg, progressive abdominal distension and vomiting).
- C. **Term infants with delayed passage need to be evaluated earlier** because failure to pass meconium in a term infant is highly suspicious for intestinal obstruction.
- D. **All infants with suspected intestinal obstruction.** Presentation can vary from asymptomatic to severe respiratory distress and cardiovascular collapse. Follow ABCs (airway, breathing, circulation) if infant is unstable and not doing well.
 1. **Oxygen and ventilation** may be necessary in infants with severe abdominal distension and respiratory distress.
 2. **Place nothing by mouth and start intravenous fluids.** If there are signs of shock, the infant may need fluid resuscitation.
 3. **Nasogastric decompression.** A no. 8 nasogastric or no. 10 orogastric tube should be placed.
 4. **Consider antibiotic therapy** if clinically indicated.
 5. **Start with plain and lateral decubitus radiographs of the abdomen first.** Do a supine, upright (if possible), or lateral decubitus film to see the bowel gas pattern and to see if there are any air fluid levels. Look for dilated loops of bowel. Are there intraperitoneal calcifications?
 6. **Perform contrast enema** if bowel gas is consistent with distal obstruction to identify lower bowel obstructions. It is the most useful test to distinguish the types of distal intestinal obstruction. A contrast enema can also be therapeutic in some cases. Consultation with pediatric radiology for the best contrast agent is recommended.
 7. **Perform an upper gastrointestinal series** if bowel gas is consistent with proximal obstruction. Upper GI may be necessary to distinguish between malrotation and volvulus and duodenal atresia.
 8. **Consider anorectal manometry and rectal biopsy** if indicated.
 9. **Pediatric surgical consultation** is recommended.
- E. **Specific treatment plans**
 1. **Constipation**
 - a. **Digital rectal stimulation is the first step.**
 - b. **Glycerin suppositories** can be used if digital rectal stimulation is unsuccessful. Saline irrigation is used in some NICUs. **Enemas are not recommended. Mineral oil or stimulant laxatives are also not recommended.**
 2. **Bowel obstruction**
 - a. **Meconium plug**
 - i. **The water soluble contrast enema to diagnose the meconium plug can also be therapeutic by clearing the meconium plug.**
 - ii. **If the obstruction is not relieved, many agents have been used** (saline enemas, glycerin suppositories, *N*-acetylcysteine, or osmotic contrast

agents such as gastrograffin). Repeated water soluble enemas are usually recommended and given every 4 to 6 hours. Rectal stimulation and enemas usually relieve the obstruction.

- iii. **If normal stooling occurs**, monitor closely.
 - iv. **If an abnormal pattern of stooling recurs**. Further workup (eg, rectal biopsy) to rule out Hirschsprung disease or blood work for hypothyroidism.
- b. **Small left colon syndrome**. Treat with contrast enema as discussed earlier. If there is an intestinal perforation or if the obstruction is not relieved with medical management (contrast enema), surgery is indicated. Rule out Hirschsprung disease and CF.
 - c. **Hirschsprung disease**
 - i. **Fluid resuscitation**, rectal irrigation, and antibiotics are important to initially treat the enterocolitis and decrease the risk of mortality.
 - ii. **Surgical repair is always needed** and can be done laparoscopically, open, or transanally. Colostomy may be indicated if early surgery is contraindicated and the colon cannot be decompressed with rectal irrigation.
 - d. **Anorectal abnormality (imperforate anus)**
 - i. **Obtain immediate pediatric surgical consultation.**
 - ii. **Evaluate for other congenital anomalies.** Genitourinary tract abnormalities (approximately 50%) are frequently seen with imperforate anus.
 - iii. **Corrective surgery is required.** Colostomy for high anomalies and perineal anoplasty or fistula dilation for low lesions.
 - e. **Functional immaturity of the colon or small left colon syndrome**. Contrast enema is usually diagnostic and therapeutic. Surgery is indicated if the obstruction is recurrent or if there is a perforation (rare).
 - f. **Colonic atresia**. Treatment is individualized for each patient based on the infant's clinical status. Some infants require a proximal colostomy with establishment of intestinal continuity done later or resection and primary anastomosis.
 - g. **Meconium ileus**
 - i. **Obstruction can be treated with a water-soluble enema.** (See page 168.) Many agents have been used (saline enemas, glycerin suppositories, *N*-acetylcysteine, or osmotic contrast agents such as gastrograffin). Low osmolality water soluble contrast agents are preferred to decrease possible fluid shifts. Adequate fluid and electrolyte replacement must be given.
 - ii. **Instillation of oral contrast agents in nasogastric tube** have been reported to decrease stool viscosity, but there is a potential for side effects and a lack of studies.
 - iii. **Operative management** may be necessary in complicated meconium ileus (obstruction is not relieved by the enema or there are calcifications in the abdominal cavity).
 - h. **Duodenal atresia**. Decompression with nasogastric suction and surgery.
 - i. **Jejunal ileal atresia**. Surgery with resection and tapering of dilated proximal bowel with enteroenterostomy.
 - j. **Malrotation and midgut volvulus**. Treat immediately with emergent laparotomy and surgery. Fluid and antibiotics are necessary.
 - k. **Meconium obstruction of prematurity**. Water-soluble contrast enemas are diagnostic and therapeutic. Surgery (diversion) may be necessary for perforation or worsening symptoms of obstruction (increasing abdominal distention).
 - l. **Adhesions**. Surgery is usually necessary to lyse the adhesions if a trial of nasogastric decompression fails.

- m. **Microcolon of prematurity.** Contrast enema examination and close observation of infants with possibility of surgical intervention if there are complications.
 - n. **Ileus caused by sepsis**
 - i. **Broad-spectrum antibiotics are initiated** after a sepsis workup is performed (see Chapter 146). Intravenous ampicillin and gentamicin are usually recommended empirically. Vancomycin may be substituted for ampicillin if staphylococcal infection is suspected (for dosages, see Chapter 155).
 - ii. **A nasogastric tube should be placed to decompress the bowel.** The infant should not be fed enterally.
 - o. **Ileus caused by necrotizing enterocolitis.** See Chapter 109.
 - p. **Ileus caused by hypokalemia**
 - i. **Treat underlying metabolic abnormalities.** Correct potassium levels if low (see Chapter 65).
 - ii. **Place a nasogastric tube to rest the bowel.**
3. **Prematurity and delayed passage of stool.** Conservative treatment is usually recommended in infants who are not vomiting but have progressive abdominal distention, even if microcolon is seen. Treatment consists of a low-osmolality, water-soluble contrast enema for passage of the stool. Consult a pediatric radiologist for appropriate contrast enema to be used. **Glycerin suppositories** are sometimes used in the NICU in infants for documented constipation and for premature infants who have not passed meconium in hope to improve feeding intolerance. They should not be used in infants who are sick or infants with congenital GI anomalies. The American Academy of Pediatrics states that the evidence for the use of glycerin suppositories or enemas in premature infants is inconclusive.
4. **Hypothyroidism.** If the serum thyroxine and thyroids-stimulating hormone levels confirm the presence of hypothyroidism, thyroid replacement therapy is indicated. Consult with an endocrinologist before starting therapy (see Chapter 129).

73 No Urine Output in 24 Hours

- I. **Problem.** The nurse alerts you that the infant has had decreased urine output for the past 24 hours. In a newborn, passage of the first urine is usually a sign of well-being, and if no urine output is seen by 24 hours of life, the infant should be evaluated. The following are common definitions relating to urine output:
- A. **Normal urine output:** $\geq 2 \text{ mL/kg/h}$ after the first 24 to 48 hours ($< 1 \text{ mL/kg/h}$ the first 12–18 hours of life).
 - B. **Oliguria** is defined as urine output < 0.5 to 1.0 mL/kg/h for 24 hours.
 - C. **Anuria** is defined as absence of urine output usually by 48 hours of age.
- Decreased urine output** can be from undocumented voiding, stressful or prolonged delivery, oliguria typically seen in the first 24 hours of life or in a premature infant, mild dehydration, syndrome of inappropriate antidiuretic hormone (SIADH), acute kidney injury (AKI), or chronic kidney disease.
- II. **Immediate questions**
- A. **Was the infant born in the past 24 hours?** At birth, a normal infant has approximately 6 to 44 mL of urine in the bladder. In 1977, Clark reported that 100% of healthy premature, full-term, and postterm infants void by 24 hours of age. Mataj

Table 73–1. TIME OF FIRST VOID BASED ON A STUDY OF 500 TERM AND PRETERM INFANTS

Hours	Full-Term Infants (%) ^a	Preterm Infants (%) ^a
Delivery room (0)	12.9	21.2
1–8	51.1	83.7
9–16	91.1	98.7
17–24	100.0	100.0

^aPercentages are cumulative.

Data from Clark DA: Times of first void and first stool in 500 newborns, *Pediatrics*. 1977 Oct;60(4):457-459.

and colleagues (2003) reported that 17% of infants void at birth, 92% by 24 hours, and 99% by 48 hours.

- B. Is the bladder palpable?** If a distended bladder is present in an infant, it is usually palpable. A palpable bladder suggests there is urine in the bladder. **Credé maneuver** (manual compression of the bladder) may initiate voiding, especially in infants receiving medications causing muscle paralysis.
- C. Has bladder catheterization been performed?** Catheterization determines whether urine is present in the bladder. It is commonly done in more mature infants.
- D. Is the infant term or premature?** Term infants are more likely to have delayed voiding than preterm infants (Table 73–1). Premature infants <32 weeks are at increased risk of AKI because of their immature kidneys and increased risk of hypovolemia.
- E. What is the blood pressure?** **Hypotension** can cause decreased renal perfusion and urine output. **Hypertension** may indicate renal/renovascular disease (if severe, suspect renal artery or venous thrombosis).
- F. Was the delivery prolonged or stressful?** Delayed voiding can be related to a prolonged and stressful birth. A study showed that infants with delayed voiding (>24 hours) were more likely to have primiparous mothers; in addition, the duration of labor was longer (first and second stage) in these infants, and they had abnormal electronic fetal monitoring. Stress increases ADH (arginine vasopressin) and aldosterone levels, which decreases urine output. Both ADH and aldosterone levels were increased in these infants with delayed voiding and stressful birth.
- G. Has the infant ever voided? Did the infant void, and was it not recorded on the bedside chart?** Table 73–1 shows the time after birth at which the first voiding occurs. **Remember:** Voiding can be missed (occurred in the delivery room or with the parents and was not recorded). Approximately 13% to 21% of infants void in the delivery room.
- H. Did the mother have oligohydramnios?** One of the etiologies of oligohydramnios (decrease in amniotic fluid) can be a decrease in fetal urine production. This can be caused by renal problems such as decreased renal perfusion, obstructive uropathy, and congenital absence of renal tissue (renal agenesis, cystic dysplasia, and ureteral atresia).
- I. Is there gross hematuria?** Gross hematuria suggests intrinsic renal disease. See Chapter 61.
- J. What medications was the mother on during her pregnancy?** Certain medications (eg, angiotensin-converting enzyme [ACE] inhibitors, nonsteroidal anti-inflammatory drugs [NSAIDs]) and high steroid level exposure if given to the mother during her pregnancy may interfere with fetal nephrogenesis, which can result in fetal renal

injury and lead to AKI and decreased urine output in the newborn. ACE inhibitors during pregnancy can cause renal tubular dysgenesis in the infant. Maternal use of indomethacin as a tocolytic agent can cause AKI in the infant. Maternal use of valsartan is associated with the development of AKI.

- K. Does the infant have a congenital renal disease? Did the prenatal ultrasound suggest kidney disease?** Prenatal ultrasound can detect congenital anomalies of the kidney and urinary tract (CAKUT). **Fetal anomaly ultrasound scan at 18 to 20 weeks** of gestation will reveal absence of amniotic fluid, bladder, and kidneys in bilateral renal agenesis. Renal agenesis, renal dysplasia, polycystic kidney disease, congenital nephrotic syndrome, and any obstruction from congenital malformations can all cause decreased urine output in the newborn.
- L. Did the mother have diabetes?** Infants of diabetic mothers have an increased risk of renal anomalies (renal agenesis, hydronephrosis, and ureteral duplication).
- M. Are there any risk factors for acute kidney injury or predisposing factors that are associated with acute kidney injury?**
- 1. High risk for acute kidney injury:** Infants on ECLS especially with a congenital diaphragmatic hernia (71%), infants post cardiac surgery (62%), infants who experienced perinatal asphyxia (38%), infants with sepsis (26%), sick near-term or term infants with low Apgar scores (18%), preterm very low birthweight (VLBW) infants (18%), and preterm extremely low birthweight (ELBW) infants (12.5%).
 - 2. Pregnancy- and delivery-related risk factors:** Pregnancy-induced hypertension, preterm premature rupture of membranes, antenatal corticosteroids, maternal NSAID use during pregnancy, low Apgar scores and lower 5-minute Apgar scores, lower cord pH, intubation at birth, and asystole at birth.
 - 3. Other risk factors:** CAKUT, clinical seizures before cooling, persistent pulmonary hypertension, transfusions, serum sodium variation, catecholamine treatment, nosocomial infections, bronchopulmonary disease, cerebral lesions, neonatal surgery, lower gestational age, patent ductus arteriosus (PDA), phototherapy, male sex, elevated gentamicin or vancomycin levels, umbilical artery catheterization, umbilical vein catheterization, mechanical ventilation (high mean airway pressures), pressor support, disseminated intravascular coagulation, shock, heart failure, left-sided congenital diaphragmatic hernia, respiratory distress syndrome, posterior urethral valves, ischemic events, renal venous thrombosis, and exposure to ampicillin, ceftazidime, ibuprofen, and catecholamine were all associated with AKI.
- N. What medications is the infant receiving?** Medications in the infant can cause pre-renal, renal, and postrenal drug-induced kidney injuries. **Contrast media** during radiology procedures can cause contrast-induced nephropathy.
- 1. Prerenal:** NSAIDs, angiotensin receptor blockers, ACE inhibitors (eg, captopril, enalapril), calcineurin inhibitors, tolazoline, and mydriatic eye drops (phenylephrine).
 - 2. Renal: Acute tubular necrosis:** aminoglycosides, amphotericin B; **papillary necrosis:** acetaminophen, NSAIDs; **glomerulonephritis:** ampicillin, rifampin, NSAIDs, foscarnet, lithium; **acute interstitial nephritis:** NSAIDs, vancomycin, β -lactam antibiotics, calcineurin inhibitors; **nephrocalcinosis:** loop diuretics; **intrinsic renal failure:** captopril, enalapril, contrast media.
 - 3. Postrenal:** Certain medications can precipitate within the tubules and cause obstruction: acyclovir (crystal-induced nephropathy), methotrexate, sulfadiazine, ciprofloxacin.
- III. Differential diagnosis.** A delay in first urination (more common in boys) can be due to failure to document or observe voiding, a prolonged or stressful delivery, physiologic oliguria seen in the first 24 hours of life or in a premature infant, or mild dehydration, SIADH, AKI, or CKD. At birth, the initial presentations of AKI and CKD are similar, and differentiating between the 2 conditions depends on the duration of the renal

dysfunction. For a complete discussion of AKI, see Chapter 86. Urine output is often difficult to accurately access in the newborn because indwelling urinary catheters are not commonly used. Note that the presence of urine does not rule out AKI because some infants with AKI will have a normal urine output.

- A. **Undocumented urine void in the delivery room** is the most common cause of a “lack of urine” in the first 24 hours of life. Remember that approximately 13% to 21% of infants void in the delivery room.
- B. **Prolonged or stressful delivery.** See Section II.F.
- C. **Oliguria in a newborn in the first 24 hours of life.** Oliguria may occur in the first day of life because of a high circulating ADH. A study showed extremely high concentrations of ADH present in the cord blood and infant at birth. Infants who were born with a difficult delivery and stressed infants also had higher plasma levels of ADH.
- D. **Oliguria in a premature infant.** Oliguria can occur in a premature infant because infants have immature kidneys because nephrogenesis is not completed until 34 to 36 weeks. An infant’s kidneys at birth also experience a decrease in cardiac output as compared to the adult kidney (at birth, 2.5%–4%; at 24 hours, 6%; at 1 week, 10%; at 6 weeks, 15%–18%).
- E. **Mild dehydration.** An infant may have decreased urine output the first few days of life, especially if the infant is breast feeding (normal is considered a minimum of 2 wet diapers on day 2 and a minimum 3–5 wet diapers on days 3–5). Inadequate breast milk production can cause dehydration. Low volume of maternal milk intake causes dehydration. Laboratory findings are usually normal or may show a minimal change. Overclothing/overheating of infants can also contribute to dehydration.
- F. **Syndrome of inappropriate antidiuretic hormone can cause oliguria.** SIADH is caused by too much ADH, which causes the infant to retain water. It consists of hyponatremia, serum hypo-osmolality, increased urine sodium, and increased urine osmolality. SIADH occurs more commonly in central nervous system disorders such as intraventricular hemorrhage, hydrocephalus, birth asphyxia, and meningitis, but may also be seen with lung disease (pneumothorax and positive-pressure ventilation). SIADH is often seen in critically ill premature and term neonates. It can also be seen in association with pain and with medications such as opiates, carbamazepine, barbiturates, theophylline, and thiazides.
- G. **Acute kidney injury.** AKI is an acute renal dysfunction and occurs when there is a decrease in glomerular filtration rate (GFR) and an increase in creatinine and nitrogenous waste products with the loss of ability to regulate fluid and electrolytes. Definitions vary and can be based on serum creatinine (SCr) (see Section IV.F and Table 86–1). AKI is defined as an increase in SCr levels associated with or without a reduction in urine output. It can range from mild injury to complete kidney failure. It has an abrupt onset and is potentially reversible. Incidence of neonatal AKI is approximately 8% to 40% with a high mortality rate (up to 60%). The most prevalent causes were sepsis and asphyxia, with infants undergoing peritoneal dialysis having a higher mortality rate.

AKI can be caused by **prerenal, renal, and postrenal** causes. Etiology of AKI is different in term versus preterm infants. **In term infants**, the cause is most commonly CAKUT, obstructive uropathy, birth asphyxia, complications from surgery, or hypothermia. **Preterm infants** develop AKI from sepsis, necrotizing enterocolitis (NEC), PDA, hypotension, and medications that are nephrotoxic. AKI can present with normal urine output. Prognosis of AKI in infants is worse than in adults, and AKI can lead to chronic kidney damage and damage of nonrenal organs; therefore, it is important to identify risk factors in neonates to prevent AKI, and in infants with the disease, early treatment is essential. **AKI is prerenal in origin until proven otherwise.**

- 1. **Prerenal acute kidney injury (most common cause of acute kidney injury in the newborn, 85%).** Normal kidneys with **inadequate or decreased renal blood flow (perfusion)**. This leads to decreased renal function. Prerenal failure

can be caused by **systemic hypovolemia** (a **true volume depletion**) or **renal hypoperfusion** (a disease process that results in decreased perfusion to the kidney). **Common causes in the NICU** are: perinatal asphyxia, hemorrhage (perinatal or postnatal), dehydration/hypovolemia, sepsis, NEC, polycythemia, hypoxemia, RDS, shock and hypotension, GI losses, third space losses, cardiac etiologies (CHF, PDA, congenital heart disease/cardiac surgery, pericarditis, cardiac tamponade), infants requiring ECLS (64% of infants on ECLS and 71% of neonates with congenital diaphragmatic hernia on ECLS have decreased renal blood flow), hypoalbuminemia, and any medication that can decrease renal blood flow (NSAIDs [indomethacin, ibuprofen {less toxic}], ACE inhibitors [captopril, enalapril], and adrenergic drugs [phenylephrine eye drops, tolazoline, angiotensin receptor blockers, calcineurin inhibitors]; aminoglycosides, amphotericin, and radiocontrast agents also cause prerenal AKI).

2. **Intrinsic/renal acute kidney injury (11%).** This occurs due to structural renal damage to the tubules, glomeruli, or interstitium. Most often, it is renal tubular dysfunction caused by an acute insult. Acute tubular necrosis (ischemic or drug or toxin induced), glomerular lesions (rare), and vascular lesions make up most of intrinsic renal failure cases. Sepsis can also cause direct tubular injury.
 - a. **Acute tubular necrosis.** Most common cause of intrinsic renal disease and can be secondary to shock, dehydration, toxins, sepsis, perinatal asphyxia, cardiac surgery, ischemic or hypoxic insults, drugs, or intravenous (IV) contrast media. **Perinatal asphyxia is the most common cause of acute tubular necrosis.** A large percentage of infants with severe perinatal asphyxia have renal failure (25% of cases are oliguric and 15% are anuric). Prolonged prerenal failure that is not treated will progress to acute tubular necrosis.
 - b. **Interstitial nephritis.** Either drug induced or idiopathic.
 - c. **Congenital renal anomalies.** Renal tubular dysgenesis, renal agenesis (Potter syndrome), renal cysts, congenital nephrotic syndrome, or hypoplastic or dysplastic kidneys. **Bilateral renal agenesis** presents with no urine since birth and is rare (1 in 4000 livebirths), autosomal dominant, probably multifactorial genetic disorder in which there is absence of both kidneys, bladder, and urine in the baby. It is more common in male infants. There is oligohydramnios in the mother and pulmonary hypoplasia in the infant. **Potter sequence** is a term used to describe the atypical physical appearance of decreased amniotic fluid secondary to multiple reasons, one being bilateral renal agenesis (pulmonary hypoplasia, low-set ears, deformity in 1 or both feet).
 - d. **Infections.** Acute pyelonephritis, sepsis, gram-negative infections, candidiasis, and intrauterine infections (toxoplasmosis, cytomegalovirus, syphilis).
 - e. **Renal vascular events.** Bilateral renal vascular thrombosis, severe renal arterial thrombosis, and bilateral renal vein thrombosis can all cause intrinsic renal failure. Ischemic or hypoxic insults (twin-to-twin transfusion, abruptio placentae, or perinatal asphyxia) can cause renal cortical necrosis. Disseminated intravascular coagulation can also cause intrinsic AKI.
 - f. **Nephrotoxic medications.** Nephrotoxic medications are commonly used in the NICU, with 1 study stating that 87% of VLBW neonates were exposed to a minimum of 1 nephrotoxic medication for an average of 14 days. Aminoglycosides, amphotericin, and radiocontrast agents cause intrinsic renal failure.
 - g. **Endogenous toxins (rare).** Uric acid (uric acid nephropathy), myoglobin, free hemoglobin.
3. **Postrenal acute kidney injury (~3%; obstructive, where urine is formed but not passed).** More common in newborn infants than in older infants and caused by a mechanical or functional obstruction to the flow of urine. The obstruction causes AKI if the urinary flow is blocked in both kidneys. The obstruction can be

in the upper tract, such as bilateral ureteropelvic junction obstruction, or lower tract, such as posterior urethral valves.

- a. **Neurogenic bladder from myelomeningocele or medications** such as pancuronium or heavy sedation.
- b. **Obstruction for any reason in a solitary kidney.**
- c. **Meatal stenosis (usually males).**
- d. **Congenital malformations:** Urethral stricture, posterior urethral valves (males only; may be complicated by bladder rupture), primary vesicoureteral reflux, imperforate prepuce, urethral diverticulum, ureteropelvic junction obstruction, uterovesical obstruction, megacystic megaureter, Eagle-Barrett syndrome (vesicoureteral reflux).
- e. **Extrinsic compression/tumors** (eg, sacrococcygeal teratoma), neonatal hematoocolpos (imperforate hymen).
- f. **Drugs.** Certain medications (eg, acyclovir, ciprofloxacin, methotrexate, sulfonamides) can precipitate within the tubules and cause obstruction. Morphine can cause functional bladder outlet obstruction.
- g. **Intrinsic obstruction:** Renal calculi, systemic candidiasis with bilateral ureteropelvic fungal bezoar formation (fungal balls causing obstruction).
- h. **Spontaneous or delivery-associated rupture of the bladder** with anuric renal insufficiency.

H. Chronic kidney disease. Chronic kidney disease is the gradual loss of kidney function (decreased renal function); it can initially present as AKI and progress to permanent renal failure. Neonatal CKD has an incidence of 1 in 10,000 live births. Causes include polycystic kidney disease (autosomal recessive and autosomal dominant), obstructive uropathy (eg, posterior urethral valves), hypoplastic or dysplastic kidney, glomerular disease, cortical necrosis, renal vascular thrombosis, genetic disorders, and unknown etiology. See Section IV.G.

IV. Database

- A. **Family history.** Any history of diabetes? Any history of urinary tract disease in other family members? History of polycystic kidney disease/congenital nephrotic syndrome may indicate chronic kidney failure rather than AKI.
- B. **Detailed clinical history (prenatal, maternal, delivery, postnatal).** Review for oligohydramnios, genetic renal disorders, and list of maternal/postnatal nephrotoxic medications. Was there any risk of infection? Did bleeding occur during the delivery? Did perinatal asphyxia occur? Was there maternal hypovolemia? Was there a prenatal ultrasound? Was it abnormal? Was the fetal heart rate monitoring normal? Is the infant premature? Did the infant require resuscitation? What were the Apgar scores?
- C. **Physical examination.** Gestational age assessment should be done. First, determine the state of hydration. It is important to evaluate the volume status to distinguish hypovolemia from hypervolemia. Tachycardia and low blood pressure may indicate hypovolemia. What is the body weight? (Weight loss indicates negative fluid balance, whereas weight gain indicates retained fluid.) Is the infant dehydrated? Is there depressed/sunken fontanelle? Is there evidence of congestive heart failure? Is the infant edematous? Does the infant have hypertension (renal disease) or hypotension (decreased renal perfusion)? Examination of the abdomen may reveal bladder distention (bladder outlet obstruction), abdominal masses, or ascites (ruptured obstructed urinary tract). Signs of renal disorders (eg, Potter facies [low-set ears, inner canthal crease]) should be noted. **Dysmorphic features suggestive of renal disease** include single umbilical artery, hypospadias, anorectal abnormalities, vertebral anomalies, abnormal ears, and esophageal atresia. Urinary ascites may be seen with posterior urethral valves. Oligohydramnios suggests possible renal problems. Does the infant have wide-set eyes; parrot beak nose; receding chin; excess dehydrated skin; large, low-set, floppy ears lacking cartilage; or deformities of the hands and feet (bilateral renal agenesis)?

1. **Prerenal acute kidney injury.** Signs of volume depletion (tachycardia and hypotension).
 2. **Intrinsic acute kidney injury.** Edema, signs of congestive heart failure, hypertension. Palpable kidneys may mean polycystic kidney, hydronephrosis, or tumors.
 3. **Postrenal acute kidney injury.** Poor urinary stream, enlarged bladder, and dribbling of urine; urinary ascites with rupture.
- D. Laboratory studies.** The following laboratory tests can help establish the diagnosis in cases of low urine output.
1. **Serum creatinine.** This is the most widely used test for AKI and to monitor renal function. Remember, creatinine at birth and the first 3 days of life reflects maternal creatinine, and it takes a couple of days to reach equilibrium. The use of creatinine in the first 48 to 72 hours to assess renal function (specifically for AKI diagnosis or GFR alteration) is not reliable. In addition, the SCr may not increase until after 25% to 50% of kidney function is lost. SCr is a marker of kidney function, not kidney damage, so it takes some time for the SCr to increase after the insult (48–72 hours). The National Kidney Disease Education Program recently created a creatinine standardization program to reduce error variation (Table 73–2).
 2. **Serum electrolytes, serum osmolality, and blood urea nitrogen also help to evaluate renal function and volume status.** Hyponatremia can be seen because of decreased excretion of water and SIADH. An increased blood urea nitrogen (BUN) and BUN-to-creatinine ratio >30 are seen in prerenal oliguria. A BUN-to-creatinine ratio of <20 can be seen in intrinsic renal damage. Electrolytes can be abnormal, especially potassium (hyperkalemia), with renal failure. Hypokalemia can be seen in the recovering stage of AKI. Dilutional hyponatremia is commonly seen in AKI. In SIADH one will see hyponatremia and hypoosmolality.
 3. **Calcium and phosphate levels.** Hypocalcemia and hyperphosphatemia can be seen.
 4. **Complete blood count and platelet count.** An abnormal complete blood count can be seen in sepsis. Thrombocytopenia or polycythemia can be seen in bilateral renal vein thrombosis.
 5. **Urinalysis and urine microscopy.** Most likely normal in prerenal disease (may see few hyaline casts) and postrenal disease. Microscopic hematuria and trace glucosuria may be normal. Protein in the urine can be normal, especially in a premature infant. The amount of protein increases in the urine with decreasing gestational age.
 - a. **White blood cells** suggest urinary tract infection
 - b. **Red blood cells, tubular cells, granular casts, renal tubular epithelial cells, and proteinuria** suggest intrinsic renal disease.

Table 73–2. PLASMA CREATININE VALUES AT BIRTH

Gestational Age (weeks)	Creatinine
23–26	0.77–1.05 mg/dL (73.1–92.8 μmol/L)
27–29	0.76–1.02 mg/dL (67.2–90.2 μmol/L)
30–32	0.70–0.80 mg/dL (61.9–70.7 μmol/L)
33–45	0.77–0.90 mg/dL (73.1–79.6 μmol/L)

Reproduced with permission from Singer SA: Acute Renal Failure in the Neonate, *NeoReviews*. 2010 May;11(5):e243-e251.

- c. **Protein in the urine** may indicate glomerular disease.
 - d. **Renal tubular epithelia cells and granular (muddy brown), cellular, and tubular casts** can be seen in acute tubular necrosis.
 - e. **Red blood cell casts** can be seen in glomerulonephritis.
 - f. **Free or form casts** can be seen with ischemia or a nephrotoxic insult.
 6. **Arterial blood pH.** A metabolic acidosis can be seen in anything that causes hypovolemia, hypoperfusion, or hypotension, such as sepsis.
 7. **Urinary indices.** See Table 86–2. BUN-to-creatinine ratio, fractional excretion of sodium (FE_{Na}), urinary sodium, urine specific gravity, urine-to-plasma creatinine ratio, urine osmolality, fractional excretion of urea, and renal failure index can help in determining whether the renal failure is **prerenal or renal (intrinsic) disease**. FE_{Na} varies inversely with gestational and postnatal age and is difficult to interpret in premature infants. In term infants, a value $<2\%$ is seen in prerenal AKI and a value $>2.5\%$ is seen in intrinsic AKI. In preterm infants, the following have been used: $<2\%$ for prerenal AKI; for intrinsic AKI, $FE_{Na} >3\%$ in infants >31 weeks' gestation and $FE_{Na} >6\%$ in infants 29 to 30 weeks' gestation. Urine sodium and osmolality can be helpful in ruling out SIADH.
 8. **Diagnostic indices related to acute kidney injury.** Besides the urinary indices discussed earlier, response to fluid challenge (increase in urine output suggests prerenal cause; no change suggests intrinsic renal disease or postrenal obstruction) and renal/abdominal ultrasonography may be helpful (normal in prerenal AKI and may be abnormal in AKI).
 9. **Biomarkers of early detection of acute kidney injury in neonates.** Biomarkers are usually abnormally expressed proteins in renal structural or tissue injury. They allow for earlier identification of neonates with AKI, before the 48 hours it takes SCr to rise. The 2 most often studied urinary biomarkers in neonates are neutrophil gelatinase-associated lipocalin and cystatin C, both which show higher sensitivity than creatinine. Many other biomarkers are under study. Some of the serum and urine levels of biomarkers are early predictive biomarkers for AKI (serum and urine neutrophil gelatinase-associated lipocalin and cystatin C, urinary interleukin-18, serum cystatin C, kidney injury molecule-1). These markers in the urine and/or serum are higher in AKI and may be predictive for AKI. Some of the biomarkers correlate with drug-induced AKI. The use of "omics" (genomics, proteomics, metabolomics) in neonatal nephrology is increasing.
- E. Imaging and other studies**
1. **Renal ultrasonography with Doppler flow studies of the bladder, kidneys, and ureters** should be done on any newborn with oliguria or anuria. It is normal in prerenal AKI and may be abnormal in renal AKI and postrenal AKI. It will rule out urinary tract obstruction and help evaluate for other CAKUTs, renal vascular abnormalities, and bladder outlet obstruction. It can help one differentiate AKI from CKD (autosomal polycystic kidney disease, renal hypodysplasia). **Doppler examination** of renal blood flow can diagnose renal vascular thrombosis.
 2. **Abdominal radiograph studies** may reveal ascites or masses. Spina bifida or an absent sacrum suggests neurogenic bladder.
 3. **Voiding cystourethrography** can help diagnose lesions of the lower tract that cause obstruction if bladder outlet obstruction is suspected. It can also rule out vesicoureteral reflux.
 4. **Radionuclide renal scanning** may be helpful in obstruction.
 5. **Cardiac echocardiogram** looking at left ventricular output may be necessary to help access intravascular fluid status.
- F. Acute kidney injury definition and staging.** There has been no standard definition of AKI in neonates. Originally, AKI was defined as a $SCr \geq 1.5$ mg/dL. There have been multiple definitions including the Acute Kidney Injury Network criteria;

the Risk, Injury, Failure, Loss, and End-Stage Kidney Disease criteria; and the Kidney Disease: Improving Global Outcomes (KDIGO) criteria. **Much work has been done to standardize the definition and criteria.** The National Institute of Diabetes and Digestive and Kidney Diseases workshop in 2013 recommended that the neonatal KDIGO criteria be used for clinical care (see Table 86–1). Further studies are needed to address gaps in this evolving definition (use of biomarkers, use of urine output change, use of accurate SCr).

- G. Kidney Disease: Improving Global Outcomes classification of chronic kidney disease in infants <2 years old.** The GFR, which is low in neonatal life, increases after birth and reaches approximately 20 mL/min/1.73 m² at 1 month of age. Calculated GFR is based on SCr and is compared to age-appropriate values to determine renal impairment in CKD. A normal GFR is one that is ≤ 1 standard deviation (SD) below the mean. Infants with a moderately reduced GFR have a GFR >1 SD to ≤ 2 SDs below the mean. Infants with severely reduced GFR have a GFR >2 SDs below the mean. The KDIGO guidelines recommend that an infant with a GFR >1 SD below the mean is a red flag and the infant should be monitored.
- V. Plan.** If sufficient time has passed and it has been determined the bladder is not palpable, the following approaches are recommended.
- A. Fluid challenge for diagnosis and initial management.** A fluid challenge can be given without evidence of heart failure or fluid overload; 10 to 20 mL/kg of crystalloid (normal saline preferred) IV over 30 to 120 minutes. Colloid is only recommended if there is an indication such as bleeding or hypoalbuminemia. If there is no response, this can be repeated once. An increase in urine output of ≥ 1 to 2 mL/kg/h indicates a **prerenal cause of AKI due to hypovolemia**. No increase in urine output suggests **intrinsic renal disease or postrenal obstruction**. If the infant shows signs of fluid overload after the fluid challenge, consider cardiac disease or third spacing (eg, sepsis, hypoalbuminemia, hydrops fetalis, or hepatic failure nephrotic syndrome).
- B. Mild dehydration.** For mild dehydration with decreased urine output (but no evidence of renal failure based on laboratory findings or clinical examination), only an increase in fluids (IV) or feedings may be necessary. For an infant only on breast feeding who is dehydrated, supplementation with formula may be considered.
- C. SIADH.** It is important to identify and treat the underlying cause of SIADH. The treatment is to gradually increase the sodium level by promoting free water excretion by fluid restriction. Treatment ultimately depends on the level of the sodium and whether seizures are present. See Chapter 69 on hyponatremia for treatment details.
- D. Initial evaluation if acute kidney injury is suspected**
- 1. Bladder catheterization** to determine if urine is being made and to rule out lower urinary tract obstruction. It will not help in renal dysfunction or upper urinary tract obstruction. It may be helpful to keep an **indwelling catheter** in the short term for accurate and strict intake and output, even though indwelling catheters are seldom used in neonates.
 - 2. Evaluation of laboratory and ultrasound results.** (See also Table 86–2.) Based on the laboratory results and ultrasound, identify whether the infant has prerenal, renal, or postrenal failure.
- E. Initial acute kidney injury management.** Nephrology consultation is recommended.
- 1. Identify high-risk infants** (any newborn with asphyxia, on ECMO, with sepsis, or requiring cardiac surgery; any sick near-term or term infant; any preterm ELBW or VLBW infant; or any infant with CAKUT) and monitor them very closely.
 - 2. Be aware of the prophylaxis for asphyxiated infants at risk for acute kidney injury per Kidney Disease: Improving Global Outcomes guidelines.** Adenosine receptor antagonists (theophylline) inhibit adenosine-induced vasoconstriction

and may help prevent AKI. Give a single dose of theophylline (5–8 mg/kg) early after birth since it is associated with better kidney function.

3. **Caffeine in preterm neonates** is associated with a decreased incidence and severity of AKI. Further studies to focus on timing and dosage are needed.
4. **Identify and mitigate any risk factors**
 - a. **Evaluate the infant's medications.** Be aware of any nephrotoxic medications. The most common medications used in the NICU that are nephrotoxic are ibuprofen, indomethacin, vancomycin, aminoglycosides, amphotericin B, and acyclovir. Adjust doses and discontinue if possible. Pharmacist support in adjusting levels can be useful.
 - b. **Be aware of and treat any reversible conditions early on** that may result in hypotension and poor renal perfusion. These may include **sepsis** (antibiotics, fluid correction, and vasopressors), **PDA** (medical or surgical closure), **NEC** (IV fluids, vasopressors), **hypovolemia** (fluid replacement), **hemorrhage** (IV fluids, packed red blood cell transfusion), and **congenital heart disease** (depends on the cause) (refer to disease- and condition-specific chapters).
5. **Fluid management.** Try to maintain fluid and electrolyte balance until renal function returns.
 - a. **Record strict intake and output.** Weigh the infant every 12 hours. Urine output can also be measured by weighing diapers every 3 hours. Remember that the measurement may be inaccurate because of evaporation by radiant warmers. Infants lose much of their body weight the first week of life. Weight gain can indicate fluid overload, whereas weight loss can indicate a need for more fluids. **Tachycardia and low blood pressure** indicate hypovolemia.
 - b. **Replace insensible fluid losses (note that these may be increased with radiant warmer):**
 - i. **Term infants:** 40 to 50 mL/kg/d.
 - ii. **Preterm infants <750 g:** 100 to 150mL/kg/d.
 - iii. **Preterm infants 750 to 1000 g:** 60 to 70 mL/kg/d.
 - iv. **Preterm infants 1000 to 1250 g:** 35 to 65 mL/kg/d.
 - c. **Avoid excessive fluid administration or dehydration.** Fluid overload with oliguria carries a poor prognosis. The majority of cases of oliguria are secondary to inadequate fluid or an increase in the loss of fluid. Diuretics, gastroschisis, and meningomyelocele (excessive insensible water loss), fluid restriction due to PDA, and pulmonary edema can all lead to fluid loss that needs to be addressed in these infants.
6. **Give a trial of diuretics (eg, furosemide) in oliguric neonates with acute kidney injury.** Loop diuretics are preferred over osmotic diuretics. It is an acceptable treatment despite lack of evidence in neonates. Diuretics are often used to maintain urine output. If the infant is unresponsive to diuretics, consideration of renal replacement therapy early on is recommended. With use, observe for electrolyte imbalances (hyponatremia, hypokalemia, and hypocalcemia) and a decrease in intravascular volume. Ototoxicity can occur with use of furosemide (especially with aminoglycosides). Furosemide can also be used if the infant has hypertension due to fluid overload.
7. **Management of hypotension.** (See also Chapter 70.) Blood pressure should be monitored closely. If hypotension is due to hypovolemia, fluid administration needs to be given. Dopamine can be used as a first-line vasopressor for treating hypotension. At lower doses, it improves renal perfusion and transiently improves SCr and urinary output. Dobutamine can be used in cases that do not respond to dopamine.
8. **Avoid any electrolyte and metabolic acidosis abnormalities.** Follow electrolytes closely for early changes and treat appropriately: dilutional hyponatremia, hyperglycemia, hyperkalemia, hyperphosphatemia, hypomagnesemia, hypocalcemia,

acidosis, and uremia. Restrict potassium unless there is hypokalemia. For metabolic acidosis, treatment with bicarbonate (*controversial*) or chronic oral replacement with acetate may be necessary.

9. **Nutritional management.** Because of an increasing BUN in AKI, protein was historically restricted to try to decrease the BUN. Fluid restriction also can contribute to lack of nutrition in these infants. It is best for the infant to receive protein early on to prevent growth failure and other poor neurodevelopmental outcomes. Maintain a minimum protein intake (1–2 g/kg/d). Human milk and formulas such as Similac PM 60/40 (low phosphate and renal solute load) are preferred for enteral nutrition. Parenteral nutrition may be necessary in critically ill infants.

F. Specific management of prerenal, intrinsic, and postrenal failure

1. **Prerenal failure.** The goal is to restore and maintain adequate renal perfusion. Because the kidneys are normal, prerenal failure is reversible once renal perfusion is restored. However, if not corrected, intrinsic renal tubular damage can occur.
 - a. **Treat the specific cause** (eg, sepsis, NEC).
 - b. **Provide volume resuscitation to restore renal perfusion.** Depending on how much fluid was given during the fluid challenge, another fluid challenge may be necessary to achieve euvolemia. Usual dose is 10 to 20 mL/kg of isotonic saline solution over 1 to 2 hours.
 - c. **Maintain adequate volume maintenance** and replacement for any losses.
 - d. **Dopamine.** Use of inotropic agents may be indicated in prerenal failure caused by hypoxia, acidosis, or indomethacin or in infants who develop hypotension. Renal dose of dopamine (1–3 mcg/kg/min) to improve renal perfusion is advocated by some, but no studies show that it improves survival. It increases urine output but does not prevent renal dysfunction or death. Cochrane review states that there is not enough evidence to give dopamine to prevent renal dysfunction specifically in indomethacin-treated preterm infants.
 - e. **Furosemide.** May be indicated if there is oliguria and volume overload. Diuretics can help in fluid management but do not change the course of AKI. Furosemide (1–2 mg/kg/dose) can increase urine flow, but limit doses due to ototoxicity, especially if there is no response noted.
2. **Intrinsic renal disease.** Supportive measures, treatment of the specific cause, and recovery and prognosis depend on the etiology.
 - a. **Discontinue any nephrotoxic medications.**
 - b. **Restrict fluid intake, and only replace insensible losses plus urine output.** Consider potassium intake restriction.
 - c. **Follow serum sodium, potassium, calcium, and phosphate, and acid-base balance.** Infants with AKI can have hyponatremia (usually dilutional), hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis.
 - d. **Consider low-dose dopamine to increase renal blood flow** (*controversial*). See Section V.F.1.d.
 - e. **Consider diuretics (eg, furosemide) if fluid overload.** Limit doses due to ototoxicity. See Section V.F.1.e.
 - f. **Follow blood pressure.** Mild hypertension can occur.
 - g. **For bilateral renal artery thrombosis:** Thrombolysis/thrombectomy is indicated in refractory hypertension.
3. **Postrenal acute kidney injury.** If an obstruction has been identified by renal ultrasound, it should immediately be treated to relieve it. The AKI can usually be reversed by relieving the obstruction.
 - a. **Pediatric urologic consultation** should be obtained.
 - b. **If obstruction is distal to the bladder.** Perform initial bladder catheterization. Surgical vesicostomy may be indicated.

- c. **If obstruction is proximal to the bladder.** Urologic surgical intervention should be considered (eg, nephrostomy tubes or cutaneous ureterostomy).
 - d. **Neurogenic bladder.** Initially managed with catheterization.
 - e. **Assessment of fluid balance** should be done.
 - f. **Medications.** Medications that cause urinary retention should be discontinued.
 - g. **Consider urinary tract infection prophylaxis** with antibiotics.
4. **Renal replacement therapy** replaces the normal blood-filtering function of kidneys. It is technically more difficult in the newborn, especially the VLBW infant, and is not routinely done. It also has a high rate of complications. There are **3 modes of therapy**: peritoneal dialysis, intermittent hemodialysis, and continuous renal replacement therapy. The most common modes of therapy in the neonate include peritoneal dialysis and continuous renal replacement therapy (CRRT). It is the **therapy of choice for severe cases of AKI**.
- a. **Indications are not absolute but include:** Refractory acidosis, uremia, electrolyte abnormalities (hyperkalemia not responding to usual medical management, high BUN and creatinine), fluid overload, metabolic disorders (hyperammonemia), congenital anomalies that result in end-stage renal disease (eg, polycystic/multicystic kidneys, oxalosis, CAKUT, inborn errors of metabolism, angiotensin receptor blockade fetopathy), and inability to provide adequate nutrition.
 - b. **Modes of renal replacement therapy**
 - i. **Peritoneal dialysis** is the **preferred method for neonates**, even in VLBW neonates. It is less difficult to do than CRRT. If peritoneal dialysis cannot be done (due to abdominal wall defect, previous abdominal surgery, hyperammonemia [ammonia best removed by ECMO or hemofiltration], anasarca, significant ascites, skin infections, or other causes), **venovenous CRRT** (hemofiltration-based dialysis modality) can be used.
 - ii. **Continuous renal replacement therapy** is challenging in neonates. Current CRRT machines approved only for patients >20 kg are being used in patients <5 kg “off label.” CRRT machines are needed with lower extracorporeal volume to provide safe renal support to small infants. There are neonatal CRRT machines (CARPEDIEM and Nidus), but they are only used outside of the United States. CRRT in neonates is still used only after medical management has failed, even though in pediatrics it is being used earlier in managing infants with AKI because it helps to maintain electrolyte homeostasis, decreases hypervolemia, and helps to provide adequate nutrition.
- G. **Acute kidney injury follow-up.** Infants with oliguric AKI have a higher mortality rate (up to 89%) than infants with nonoliguric AKI. Any infant who had AKI is at increased risk (almost 50%) for CKD. The risk factors that carry a poor prognosis in AKI are low gestational age, low birthweight, oliguria, anuria, and multiorgan involvement. Studies show that evidence of renal dysfunction can be seen in childhood in neonates who were born VLBW. In fact, renal dysfunction can occur 3 to 5 years after the episode of AKI. These infants should be followed closely after discharge, with blood pressure closely monitored. Recommendations from KDIGO practice guidelines state that all infants who had AKI should be evaluated **after 3 months** for CKD.
- H. **Chronic kidney disease.** Any infant who has a GFR value >1 SD below the mean needs to be monitored closely for CKD. Management focuses on replacing renal functions: 1, 25-hydroxylation of vitamin D, erythropoietin, fluid and electrolyte management, growth and nutrition, and renal replacement therapy for end-stage renal disease.

74 Pneumoperitoneum

- I. **Problem.** A pneumoperitoneum is seen on an abdominal radiograph. A pneumoperitoneum is an abnormal collection of free air in the peritoneal cavity. The air can be secondary to perforation of the gastrointestinal (GI) tract (most common, approximately 90% of cases) or from the respiratory tract, or it can be idiopathic with no known cause. **Necrotizing enterocolitis (NEC) with perforation** is the most common cause of a pneumoperitoneum in the neonate, and it carries a high mortality rate. Approximately 78.5% of pneumoperitoneums were secondary to NEC; therefore, a neonate with a pneumoperitoneum requires immediate evaluation and treatment because early recognition is important in successful management. **It is important to note that a diagnosis of a pneumoperitoneum does not always imply a GI perforation.** Careful assessment of each case can limit unnecessary laparotomies and their surgical complications.
- II. **Immediate questions**
 - A. **Is a tension pneumoperitoneum present?** An emergency situation, this occurs when there is a large amount of air that impairs diaphragmatic excursion. A tension pneumoperitoneum can cause significant lung compression, severe respiratory distress, compression of the vena cava, and impaired venous return with cardiovascular compromise. If present, an emergency therapeutic paracentesis should be done (see Chapter 40).
 - B. **Are signs of a pneumoperitoneum present?** These findings can include abdominal distension (most common sign), respiratory distress, deteriorating blood gas levels, and a decrease in blood pressure.
 - C. **Were signs of necrotizing enterocolitis present before?** If so, the pneumoperitoneum is most likely to be associated with GI tract perforation. Bowel perforation typically occurs at a median interval of 1 day after clinical presentation of NEC. Risk factors for NEC are gestational age <32 weeks, birth weight <1500 g, and enteral feeding.
 - D. **Does the infant have any dysmorphic features or congenital anomalies?** An infant with any dysmorphic features or congenital anomalies increases the likelihood that the perforation is GI in origin.
 - E. **Are any signs of air leak present?** If a pneumomediastinum, pulmonary interstitial emphysema, or pneumothorax is present, the peritoneal air collection may be of respiratory tract origin.
 - F. **Is mechanical ventilation being used?** High peak inspiratory pressures greater than a mean of 34 cm H₂O can be associated with a pneumoperitoneum.
 - G. **Were antenatal nonsteroidal anti-inflammatory medications used? Is the infant presently on steroids or indomethacin?** These have all been associated with GI perforation.
 - H. **Was an antenatal ultrasound done? Were any gastrointestinal anomalies detected?** If an antenatal ultrasound showed any GI anomalies, then the pneumoperitoneum is more likely to be from a GI perforation.
 - I. **Did the infant recently undergo abdominal surgery or an invasive procedure such as paracentesis?** Intra-abdominal air is normal in the immediate postoperative period following abdominal surgery and usually resolves without treatment. Paracentesis can perforate a hollow organ.
- III. **Differential diagnosis.** A pneumoperitoneum most commonly develops **secondary to perforation of the GI tract** (spontaneous, secondary from underlying GI disease, or traumatic). It can also be secondary **from the chest** (respiratory causes: air leak with or without mechanical ventilation) or **idiopathic, from no known cause** (no respiratory or GI cause found), or it can be a **normal immediate postoperative finding**. In a

neonate, unless the infant is on high ventilator settings and has an air leak, **the cause is GI perforation until proven otherwise**. Some classify pneumoperitoneum into **medical (nonsurgical)** versus **surgical**, based on the need for surgical intervention. Some classify all pneumoperitoneums that are not surgical with various terms such as nonsurgical, asymptomatic, benign, misleading, or idiopathic. Some authors have suggested these terms should be changed to **benign**, indicating that their management is not surgery.

A. Pneumoperitoneum associated with gastrointestinal perforation

1. **Spontaneous intestinal perforation.** There is no demonstrable cause (no obvious GI disease, no evidence of trauma or obstruction that causes the perforation).

Proposed etiologies include local ischemia in the perinatal period (from asphyxia or shock) or from noncommunication of the right and left gastroepiploic arteries, trauma during pregnancy or delivery, sepsis, prematurity, excessive gastric acidity, lack of intestinal Cajal cells (gastric perforation), maternal use of steroids or cocaine, or congenital defects in the muscular wall of the stomach. Spontaneous perforation occurs most commonly in the terminal ileum in premature infants (spontaneous intestinal perforation [SIP]) or in the stomach (preterm and term infants); it rarely occurs elsewhere in the GI tract.

a. **Spontaneous gastric perforation.** Occurs most commonly between the second and seventh days of life in both full-term and preterm infants. It is more common in males and African American babies. Infants present with sudden abdominal distension, respiratory distress, vomiting, lethargy, and a massive pneumoperitoneum. Perinatal stress, prematurity, and postnatal steroid use are risk factors. Many of these infants have sepsis.

b. **Spontaneous intestinal perforation.** Second most common presentation of neonatal intestinal perforation. **The single intestinal perforation** occurs primarily in the terminal ileum (rarely in the jejunum and transverse and descending colon) in infants <28 weeks' gestational age, with low birthweight <1500 g (2%–3%) or <1000 g (5%). Presentation is within the first week (hypotension and abdominal distension), it is more common in males, and is independent of feeding. There is no pneumatosis intestinalis and mortality rate is lower than with NEC. Prematurity is a major risk factor. Early exposure to postnatal steroids and postnatal exposure of indomethacin combined with steroids increases the risk of SIP. Conflicting evidence exists on whether indomethacin alone increases the risk of SIP. SIP is frequently associated with systemic candidiasis or coagulase-negative *Staphylococcus*.

c. **Spontaneous colonic perforations.** These can occur but are very rare. They are more common in preterm infants and very difficult to diagnose. Signs include significant abdominal and scrotal distension, vomiting, cyanosis, respiratory distress, and tachypnea. Most infants have a massive pneumoperitoneum.

d. **Other gastrointestinal perforations.** Isolated perforations can occur elsewhere in the intestine, including the appendix, cecum, and Meckel diverticulum.

e. **Medications associated with spontaneous perforation** include indomethacin and steroids. A meta-analysis of the effect of early treatment (<96 hours) with high doses of steroids for chronic lung disease showed an increased risk of spontaneous GI perforation. **Gastroduodenal perforation** has been associated with steroid therapy. Combined therapy (early postnatal indomethacin and glucocorticoids) increases the risk of SIP.

f. **Other causes.** Following exchange transfusion, perforation of the small and large intestine can occur. **Embolic phenomenon secondary to an umbilical artery catheter** can also contribute to perforation.

2. **Secondary perforations.** These are caused by an underlying disease: secondary to a GI disease process or an obstruction in the GI tract.

a. **Necrotizing enterocolitis.** NEC is the most common cause of gastrointestinal perforation in neonates and is the most common cause of secondary perforation. It typically presents later in premature infants (second to third week) and after

initiation of formula feeding. It carries a high mortality (up to 76% in premature infants). The perforation occurs because of local inflammation and intestinal necrosis leading to destruction of the bowel wall. The most commonly affected areas of perforation are the terminal ileum (MC ileocecal region) and proximal ascending colon, although any part of the GI tract may be involved. There is conflicting data on whether indomethacin increases the risk of NEC with intestinal perforation. **Perforation in NEC** can also be caused by a rupture of gas-filled cysts within the bowel wall (pneumatosis intestinalis). This diagnosis is a radiologic diagnosis (one sees linear or circular radiolucencies) because there are no clinical signs. It is most common in the colon but can also occur in the small bowel or stomach. It is important to note that pneumatosis intestinalis is a hallmark of NEC, but can also be seen in intestinal obstruction, vascular compromise, and milk intolerance.

- b. Gastrointestinal obstruction.** GI obstruction causes increasing intraluminal pressure, which can cause a perforation proximal to the obstruction. This can occur anywhere in the GI tract. Causes in the neonate include any GI atresia (esophageal atresia with tracheoesophageal fistula, duodenal/pylorus atresia, small/large intestine or anal atresia, and others), meconium ileus/plug, duplication cyst, small left colon syndrome, obstructive bands, Hirschsprung disease, and anorectal malformations (imperforate anus, incarcerated hernia, and others). Bowel perforation occurs in approximately 3% to 4% of infants with Hirschsprung disease.
 - c. Gastritis or peptic ulcer disease.** Perforation can be the initial presentation of ulcer disease. Perforations of the stomach (most common), duodenum, pylorus, or esophagus can occur.
 - d. Other rare causes.** Malrotation with midgut volvulus, omphalocele, ruptured appendix, gastroschisis, mesenteric thrombosis, perforated Meckel diverticulum, or idiopathic gastric necrosis.
- 3. Traumatic perforations.** An iatrogenic pneumoperitoneum can be caused by an intervention. Most gastric perforations are secondary to nasogastric (NG) or orogastric (OG) tube placement or vigorous bag-and-mask or positive-pressure ventilation.
- a. Normal transient finding following laparotomy or laparoscopy.**
 - b. Nasogastric tube trauma.** Most gastric perforations are along the greater curvature due to trauma by vigorous NG/OG tube placement. Use of a soft silastic feeding tube may reduce this risk. An NG tube in an unusual position on x-ray (eg, right upper quadrant) indicates a possible perforation.
 - c. Intubation trauma.** During an intubation, the endotracheal tube (ETT) can be inadvertently placed in the esophagus and then through the posterior wall of the stomach. If the ETT on chest x-ray is seen more distally than expected, consider intubation trauma.
 - d. Bag-and-mask/positive-pressure ventilation.** Traumatic gastric perforation can occur from vigorous bag-and-mask ventilation or be due to positive-pressure ventilation. Resuscitation with oxygen under pressure in patients with distal pyloric or duodenal obstruction can result in a perforation.
 - e. Neonatal rectal perforations of the sigmoid colon or rectum** can be caused by a rectal thermometer or rectal tubes. Because of the shape of the neonatal rectum, when a rectal thermometer is placed to a depth of 2 cm, it impinges on the anterior wall. Therefore, insert a rectal thermometer <2 cm. An attempt to push it any further may result in perforation. **Enema-induced (colonic lavage) perforations** occur in the anterior wall of the rectum or rectosigmoid. A common factor in these colonic lavages in one study was inexperienced staff performing these procedures.
 - f. Improperly performed suprapubic bladder aspiration or paracentesis** can perforate a hollow organ.

- g. **Umbilical vein catheterization** can cause perforation of Meckel diverticulum.
 - h. **Aerophagia (swallowing air) secondary to prolonged crying** may cause gastric perforation. (There is a case report on an infant who had a circumcision with prolonged crying that may have caused a gastric rupture.)
- B. Pneumoperitoneum associated with a respiratory disorder (eg, pulmonary interstitial emphysema, pneumomediastinum, or pneumothorax).** A pulmonary air leak, with or without mechanical ventilation or continuous positive airway pressure, can result in a pneumoperitoneum. It can be secondary to barotrauma in ventilated neonates with severe respiratory disease. A thoracic leak can dissect transdiaphragmatically or through the mediastinum along perivascular connective tissue to the abdominal cavity. Other pathways between the chest and abdomen include pleuroperitoneal fistula, retrograde path through pulmonary lymphatics, periaortic space, periesophageal space, or a congenital defect. **Note:** An infant can have a pneumoperitoneum from thoracic air dissection without evidence of a pulmonary air leak (pneumothorax or pneumomediastinum). In this case, an undetectable pulmonary rupture can occur with dissection into the peritoneal cavity. If there is a posterior pneumomediastinum, an air leak is probably the cause of the pneumoperitoneum.
- C. Idiopathic pneumoperitoneum.** This is a pneumoperitoneum that has no identifiable cause, and there is no evidence of GI or respiratory pathology. It may be respiratory because a pulmonary rupture with a thoracic leak may not be apparent, or it may be GI because there could be a subclinical microperforation in a hollow viscus with no leakage of bowel contents.
- D. Pseudopneumoperitoneum** occurs when there is a lucency with no free intraperitoneal air in the abdominal cavity. The lucency that mimics free air can be from a subphrenic fat pad, linear atelectasis, abnormal subphrenic anatomy, liver abscess, serosal enhancement after cardiac catheterization, transplacental transfer of non-ionic contrast, gas-forming bacterial peritonitis (*Escherichia coli* [most common] *Pseudomonas*, *Clostridium*, *Staphylococcus*, *Streptococcus*, *Klebsiella*, *Candida*), subphrenic abscess, or Chilaiditi syndrome. **Chilaiditi syndrome**, a rare condition, is the interposition of the large intestine (usually gas filled transverse colon) between the liver and right hemidiaphragm; it can present with respiratory distress and can be misinterpreted as a true pneumoperitoneum.

IV. Database

- A. Physical examination.** Although the clinical evaluation may not differentiate between respiratory or GI tract origin of the pneumoperitoneum, the examination should still focus on the pulmonary and abdominal aspects. **Abdominal distention (most common physical sign) and elevation of the diaphragm with increasing respiratory difficulty are hallmarks of a pneumoperitoneum.** Other signs and symptoms include vomiting (bilious), tachypnea, rectal bleeding, and failure or delay to pass meconium. **Is there respiratory compromise or unexplained tachypnea?** Large amounts of air in the abdominal cavity can impair diaphragmatic excursion and lung compression. Cardiovascular compromise can occur secondary to compression of the vena cava and impaired venous return. Feeding intolerance and poor activity can also be present. Is there a bluish-black discoloration of the abdominal wall (seen with SIP but not NEC)? **Scrotal swelling** may indicate gastric perforation (ie, **pneumoscotum**) and can occur without significant abdominal distension. A pneumoscotum can be secondary to a gastric perforation, perforation of Meckel diverticulum, or perforation of ileum secondary to atresia, or after aggressive resuscitation or mechanical ventilation.
- B. Laboratory studies**
1. **Complete blood count and serum electrolytes.** Elevation of the white blood cell count or a left shift may signify a GI tract perforation. Hyponatremia can be seen with NEC secondary to third spacing of fluid. Persistent or worsening thrombocytopenia can be indicative of bowel perforation.

2. **Arterial blood gas levels.** May reveal hypoxemia and increasing PCO_2 levels. Metabolic acidosis can be seen with peritonitis.
 3. **Blood culture.** Should be obtained if bowel perforation or sepsis is suspected. Infants with bowel perforation can have a positive blood culture. In one study, 18 of 30 infants had a positive blood culture (*E coli* was the most common organism).
 4. **C-reactive protein.** Correlates with the inflammatory response and may be increased in NEC.
- C. **Imaging and other studies**
1. **Transillumination of the abdomen** with a cold fiberoptic light source can be done and acts as a useful tool for diagnosis, especially if radiographs are not readily available. Place the transilluminator in the left paramedian position and direct the probe toward the midline. If the peritoneal cavity lights up, the infant probably has a pneumoperitoneum (see Chapter 44).
 2. **Radiographs.** Small amounts of air can be missed on a routine film; some infants have air, but it cannot be seen on x-ray. One study found a pneumoperitoneum in 63% of infants with GI perforation. Repeat radiographs frequently if air is suspected. Simple observation of free air is often sufficient, particularly if the air leak is large (see Figure 12–26). Supine films (some infants are too sick for an upright) are usually done. A **massive pneumoperitoneum** is suggestive of gastric or colonic perforation. Absence of pneumoperitoneum does not exclude perforation and may indicate gas reabsorption or nasogastric decompression.
 - a. **Supine anteroposterior radiograph of the chest and abdomen.** The chest may show signs of air leak syndrome (pneumomediastinum or pneumothorax) if it is suspected that the intraperitoneal air is from the respiratory tract. The abdomen may show signs of NEC (pneumatosis intestinalis or portal venous gas; see Figures 12–27 and 12–28) or ileus. Air-fluid levels in the peritoneal cavity usually indicate ileus. SIP will have a pneumoperitoneum without pneumatosis intestinalis or portal venous gas. **Classically described x-ray findings pathognomonic of a pneumoperitoneum include the following:**
 - i. **Right upper quadrant sign.** The most common finding is the presence of right upper quadrant subdiaphragmatic free air (collection of gas in the right upper quadrant adjacent to the liver, gas in the anterior subhepatic space).
 - ii. **Doge's cap sign.** Air between the right kidney and liver. It is often the first sign and appears as an oval or triangular gas shadow.
 - iii. **Cupola sign.** An inverted cup-shaped lucency (dome) of air accumulation that appears over the lower thoracic spine near the posterior part of the heart.
 - iv. **Rigler sign (double wall sign).** Gas is seen on both sides of the bowel wall (the outer and inner walls of the bowel are seen). Normally only the inner wall of the bowel is seen. If the mean wall thickness of the bowel is >1 mm, it is a positive sign. If the thickness is ≤ 1 mm, it may be a false positive.
 - v. **Falciform ligament sign.** Gas outlining the falciform ligament.
 - vi. **Football sign.** A large oval radiolucency (gas outlining the peritoneal cavity) in the shape of an American football. It can also include when the falciform ligament is seen in the center as a vertical strip surrounded by gas (the radiographic appearance of pneumoperitoneum outlining the falciform ligament was renamed falciform ligament sign; see previous text). It appears as a white streak, which is surrounded by the oval lucency of a pneumoperitoneum. The football sign is most frequently seen in infants with spontaneous or iatrogenic gastric perforation.
 - vii. **Inverted V sign.** Gas outlines the medial umbilical folds (umbilical arteries) on the supine radiograph.

- viii. **Saddle bag sign.** Spleen and liver are displaced downward toward the midline.
 - ix. **Arcade sign.** Air is seen between bowel loops and creates triangular-shaped areas of gas.
 - x. **A gasless abdomen.** May represent a perforation if there is no bowel gas to go into the peritoneal cavity (it is walled off).
 - xi. **Persistent fixed dilated bowel loops with abnormal gas shadows (localized pseudocysts) on multiple films** on an abdominal x-ray may signify intestinal perforation.
- b. **Left lateral decubitus radiographic study of the abdomen.** With the right side up, the **left lateral decubitus study** is the best examination for the detection of free abdominal air; air (seen as a homogeneous lucency or streak-like lucencies) is seen over the liver if a perforation has occurred. This is also done to show smaller leaks not appreciated on the anteroposterior abdominal film. A lateral decubitus radiograph should be serially taken when NEC is suspected. **Lateral decubitus studies** have been shown to be more sensitive in detecting a pneumoperitoneum than upright view studies.
 - c. **Upright view of the chest abdomen.** This will show air below the diaphragm but is rarely done because of the difficulty in positioning a sick infant.
3. **Ultrasound or color Doppler ultrasonography of the abdomen** can be used to detect free air, and some studies suggest it is more sensitive in the diagnosis of a pneumoperitoneum as compared to abdominal radiography. It can also diagnose free abdominal fluid, debris, and inflammatory masses. It may suggest NEC by visualizing pneumatosis intestinalis and portal venous air and can be obtained to assess ascites. The presence of intraperitoneal particulate matter strongly suggests perforation. **Complex ascites (ascites with debris) verifies bowel perforation.** Extraluminal calcifications usually indicate intrauterine intestinal perforation with intraperitoneal extravasation of meconium. It can also be used to diagnose NEC. (Central echogenic focus with hypoechoic rim can indicate necrotic bowel or presence of intermittent gas bubbles in the portal venous system and liver.) **Color Doppler studies** can detect bowel necrosis through altered blood flow.
 4. **Computed tomography scan.** This may be necessary to better identify tiny free air in the intestinal wall such as to help better diagnose pneumatosis cystoides intestinalis.
 5. **Paracentesis or diagnostic tap.** This can also help decide whether an infant needs to be surgically explored (eg, bilious or feculent fluid obtained). See Chapter 40.
 - a. **Air.** Air obtained by paracentesis may be tested for its oxygen level. If the baby is receiving oxygen supplementation and the oxygen level is high (greater than room air, $\text{FiO}_2 = 0.21$), the air is probably from a respiratory tract leak. If the oxygen is similar to room air or lower, the air is probably from the GI tract.
 - b. **Fluid (peritoneal lavage).** Fluid may be obtained by paracentesis if the diagnosis is still undetermined. If bilious or feculent (brownish) fluid is obtained, especially if bacteria are present on the Gram stain, the air is probably of GI tract origin. A positive microscopic smear of the fluid for white blood cells suggests peritonitis.
 6. **Differentiate gastrointestinal perforation from nongastrointestinal perforation to guide treatment.** If the cause of the pneumoperitoneum is in doubt, attempts to distinguish between pneumoperitoneum from GI perforation and that of idiopathic etiology can be done using the following:
 - a. **A table based on common criteria** to distinguish between a benign pneumoperitoneum (any pneumoperitoneum that is not caused by a GI perforation that requires only conservative management) and a pneumoperitoneum from a GI perforation (exploratory laparotomy) has been developed. See Table 74–1.

Table 74–1. CRITERIA TO DIFFERENTIATE BENIGN PNEUMOPERITONEUM FROM PNEUMOPERITONEUM DUE TO GASTROINTESTINAL PERFORATION IN THE NEONATES

	Benign Pneumoperitoneum	GI Perforation
Birthweight	>1500 g	<1500 g
Gestational age	>32 weeks	<32 weeks
Feed	NPO	Fed
Age at diagnosis	Early, <5 days	Late, >5 days
Antenatal ultrasound	No GI anomalies detected	GI anomalies suspected/no antenatal care
Antenatal NSAID	None	Given
Postnatal steroids	None	Given
Postnatal indomethacin	None	Given
Family history	No history of GI anomalies/ Hirschsprung disease	History of GI anomalies/ Hirschsprung disease
General exam	No dysmorphic features No other congenital anomalies	Dysmorphic features Congenital anomalies present
Peritonitis signs	Absent	Present
Clinical status	Infant's status did not deteriorate by the time pneumoperitoneum was detected	Clinical status deteriorated
Pre–x-ray diagnosis	Line placement Part of chest x-ray Mild to moderate abdominal distension	Suspected NEC
X-ray findings	Absence of pneumatosis intestinalis No evidence of intestinal obstruction Free air in the abdomen Thoracic air leak	Pneumatosis intestinalis Intestinal obstruction Free air in the abdomen

GI, gastrointestinal; NEC, necrotizing enterocolitis; NPO, nothing by mouth; NSAID, nonsteroidal anti-inflammatory drug.

Reproduced with permission from Al-Lawama M, Al-Momani HM, AboKwaik WM, et al: Benign pneumoperitoneum in newborns: which abdomen to open and which one to observe? *Clin Case Rep*. 2016 May 4;4(6):561-563.

- b. Measurement of partial pressure of oxygen in peritoneal air.** See Section IV.C.5.a.
 - c. Presence of air leak in the chest.** Increases the chance the pneumoperitoneum is from an air leak.
- 7. Contrast studies.** A low or iso-osmolar, water-soluble contrast medium can be given through an NG tube. If there is a pneumoperitoneum secondary to a GI perforation, contrast material will pass into the peritoneal cavity and confirm the diagnosis. Hyperosmolar contrasts should never be used because they can cause further damage. **Barium should never be used** because of the morbidity of barium peritonitis.

- V. **Plan.** Treatment approaches depend on the cause of the pneumoperitoneum and clinical status of the infant and includes observation only, paracentesis, (one time needle aspiration or repeated), placement of a peritoneal drain (primary peritoneal drainage), or surgical exploration. **Prompt surgical consultation is recommended for any neonate with a pneumoperitoneum, especially of GI origin.**
- A. **Emergency measures. Rule out tension pneumoperitoneum.** A tension pneumoperitoneum is the abdominal equivalent of a tension pneumothorax. Infants can present with a tense, distended abdomen with respiratory failure and cardiovascular collapse. An emergency therapeutic paracentesis must be done to reduce the pressure and allow the diaphragm to mobilize (see Chapter 40).
- B. **General measures/supportive care**
1. **Make the patient nothing by mouth.** Provide bowel rest, and stop all enteral foods and medications.
 2. **Gastric decompression** with intermittent suction. One option is to place a double-lumen tube (Replegle) on low suction. This allows 1 lumen for drainage of fluid and 1 lumen as an air vent.
 3. **Abdominal circumference is measured** and followed frequently to observe for accumulation of air. See Chapter 50.
 4. **Fluid management.** Correct electrolyte abnormalities and any third space losses.
 5. **Blood pressure support, if needed.**
 6. **Correct any coagulopathy.**
 7. **Parenteral nutrition, if indicated.**
 8. **Sepsis evaluation and prompt antibiotic therapy** may be indicated. Infants with bowel perforation are put on empiric antibiotics that cover both aerobic and anaerobic organisms.
 9. **Serial abdominal x-rays** should be done every 6 hours until stable.
- C. **Surgical intervention, which typically is an exploratory laparotomy with bowel resection,** is usually indicated for perforated or necrotic intestine, peritonitis, pain, cardiovascular instability, clinical deterioration refractory to medical management, leukocytosis, positive paracentesis (evidence of leakage from the GI tract: bilious or feculent fluid), gas in the portal vein, erythema and cellulitis of the abdominal wall, fixed dilated intestinal segment on x-ray (sentinel loop), intraperitoneal fluid increasing in amount, rapid reaccumulation of air requiring >2 peritoneal taps a day, and conservative treatment failure.
- D. **Nonsurgical intervention.** Conservative management, specifically meaning avoiding an exploratory laparotomy, is considered in some selective infants as initial management with a pneumoperitoneum secondary to GI perforation who do not have peritonitis, have a normal abdominal examination, and do not have any of the surgical indications listed earlier. A Cochrane review notes that evidence from 2 randomized trials suggests no significant benefits or harms of peritoneal drainage over laparotomy as initial surgical treatment for perforated NEC or SIP in preterm low birthweight infants. Survival rates were not statistically different between peritoneal drainage and laparotomy groups. No definitive recommendations could be made due to the very small sample size. Approximately 50% of infants who had a PPD avoided the need for laparotomy. Options include peritoneal tap or primary peritoneal drainage.
1. **Peritoneal tap/paracentesis** (see Chapter 40). Besides being diagnostic, peritoneal tapping provides peritoneal decompression and is less invasive than primary peritoneal drainage (PPD). It can aid in ventilation and also allow the bowel to heal. It is done until the abdomen is flat or the aspiration is negative. One time needle aspiration can also be effective for infants with a spontaneous intestinal pneumoperitoneum, which resulted in definitive treatment in 60% of cases. Tapping is repeated if there is reaccumulation of air as evident by an increase in abdominal circumference.
 2. **Primary peritoneal drainage.** PPD is more invasive because it involves opening the peritoneal cavity and placing a drain at the bedside. Irrigation is sometimes

done. It can be done as a stabilizing or definitive treatment. It may be the preferred surgical procedure in ELBW infants who cannot be transported to the operating room.

E. Specific measures

1. **Pneumoperitoneum of gastrointestinal tract origin.** Stop all feedings, insert NG/OG tube to decompress the abdomen, provide supportive care (respiratory and circulatory support: correct hypoxia and acidosis, correct dehydration, correct any electrolyte disturbance), correct any coagulopathy, administer intravenous (IV) antibiotics, and call for an **immediate surgical consult**. The majority of cases require an exploratory laparotomy based on indications of surgical intervention above. Other alternative options include peritoneal tapping or PPD. It is best to discuss **options with the surgeon** and make the decision based on each individual patient. **If it is decided that surgery should be performed:**

a. **Surgical management with exploratory laparotomy.** If surgery is decided upon, exploratory laparotomy is often the treatment of choice. Preoperative management includes the following:

i. **Preoperative laboratory values** should be available.

ii. **The infant should be stabilized** as much as possible before being taken to the operating room.

iii. **Intravenous antibiotics** should be started. Choice depends on the institution but should include broad-spectrum antibiotics with anaerobic coverage.

iv. **The surgical team may request a study** with a water-soluble contrast medium given through the NG tube to try to localize the perforation.

v. **Laparotomy** with primary repair or laparoscopy. **Mini-laparotomy** is a newer bedside option in infants who cannot be transferred to the operating room.

b. **Primary peritoneal drainage. This is considered conservative management, is used selectively, and is considered controversial.** Some suggest this approach for infants with the following: perforation without peritonitis, a normal abdominal examination or mild abdominal distension, normal blood gases and platelets, minimal free air, and no air-fluid levels on x-ray. **Others suggest this for isolated perforations or for infants who may be too sick for anesthesia and surgery.** Conservative management with PPD includes the following:

i. **Place NPO, give fluids and antibiotics.** Make infant NPO, start IV fluids, total parenteral nutrition, blood transfusion if indicated, and IV antibiotics.

ii. **Primary peritoneal drainage (closed abdominal drainage)** is done at the bedside. This procedure involves making a transverse incision midway between the umbilicus and anterior superior iliac crest in the right lower quadrant. A penrose drain is placed and secured after cultures are taken. The drain is removed once the drainage resolves.

iii. **Close observation and frequent physical examinations**, serial radiographs, and follow-up laboratory evaluations are required.

iv. **Delayed laparotomy** may be required in some of these infants if they fail to improve clinically (increasing need for respiratory support, ongoing sepsis, increasing inotrope requirement, increasing abdominal distension,) or have reaccumulation of free air after the drain is removed, or have persistent intestinal obstruction. Continued acidosis or free air that persists may also signify the need for laparotomy. Reviews have found that 38% to 74% infants required a delayed laparotomy.

2. **Pneumoperitoneum of respiratory tract origin.** The pulmonary air leak should be treated first if this is the cause of the pneumoperitoneum. Treatment depends upon if the infant is asymptomatic or symptomatic.

a. **Asymptomatic patients.** Observation with close monitoring is often the treatment of choice, with frequent abdominal girth measurements and follow-up

radiographic studies usually performed every 8 to 12 hours but more frequently if the patient's clinical course changes.

- b. **Symptomatic patients.** Emergency paracentesis may be necessary in some infants with compromised ventilation and can be performed with treatment of coexisting pneumothorax if present. Review the ventilator settings to avoid high pressures that will contribute to the problems. Conservative treatment can be done.
- 3. **Traumatic pneumoperitoneum.** A pneumoperitoneum caused by rectal thermometers, NG/OG placement, suprapubic bladder aspiration, umbilical venous lines, enemas, attempted intubation, or paracentesis can usually be treated conservatively. Postlaparotomy or postlaparoscopy pneumoperitoneum associated with an uncomplicated surgical procedure will resolve spontaneously over several days.
- F. **Benign neonatal pneumoperitoneum with no known cause.** Depending on the infant and his or her clinical examination, observation with conservative management is usually done. Peritoneal tapping/lavage may be necessary in some cases.

75 Pneumothorax

- I. **Problem.** An infant with respiratory distress may have a pneumothorax. A pneumothorax is the abnormal accumulation of air in the pleural space, between the visceral and parietal pleura. It can develop spontaneously (idiopathic or from underlying lung disease) or be secondary to trauma. Pathophysiology involves an increased intra-alveolar pressure, which causes alveolar rupture and results in interstitial air; this air then dissects along the perivascular spaces and ruptures into the pleural space. A pneumothorax occurs more commonly in the neonatal period than any other time in life. Incidence is approximately 1% to 2% in term newborns and approximately 6% in premature infants. A pneumothorax is generally characterized as spontaneous, traumatic, tension, or persistent.

A. Spontaneous pneumothorax

- 1. **Primary spontaneous pneumothorax.** Occurs when there is **no obvious precipitating factor and no clear cause**; it is **idiopathic**, without lung disease. **Familial spontaneous pneumothorax** (pneumothorax occurring in more than 1 neonate in the same family) is extremely rare but has been described in neonates.
- 2. **Secondary spontaneous pneumothorax.** Occurs from a complication of **underlying lung disease** (respiratory distress syndrome [RDS], meconium aspiration syndrome [MAS]), pulmonary hypoplasia (can be bilateral), transient tachypnea of the newborn, pneumonia, or congenital pulmonary cystic malformations, among other causes.

B. Traumatic pneumothorax

- 1. **Iatrogenic** occurs from an unintended insult during a procedure, such as central line placement, bronchoscopy, or thoracentesis.
- 2. **Positive-pressure ventilation (mechanical or noninvasive ventilation)** can cause barotrauma and a subsequent pneumothorax. A Cochrane review (2015) found that in preterm infants with RDS, using continuous distending pressure (eg, continuous positive airway pressure or continuous negative pressure) is associated with an increased rate of pneumothorax.
- 3. **Chest trauma** can occur when blunt or penetrating trauma occurs to the chest (rare in neonates).

- C. **Tension pneumothorax. A life-threatening condition that occurs when air is trapped in the pleural cavity under positive pressure.** Air enters the pleural cavity during inspiration, but no air is allowed to escape during expiration. It acts as a 1-way valve. Because air is trapped, intrathoracic positive pressure rises, lung volume decreases, and pressure compresses the mediastinum and causes a shift, with increased pulmonary vascular resistance. This results in an increase in central venous pressure, a decrease in venous return to the heart, and a decrease in cardiac output. In the latest stages, this causes displacement of mediastinal structures and cardiopulmonary compromise.
- D. **Persistent pneumothorax (persistent air leak).** A pneumothorax that persists >5 to 7 days in the absence of mechanical ventilatory problems. In 1 study, the major determinants of persistent pneumothorax and mortality were underlying lung pathology, need for mechanical ventilation, and bilateral pneumothorax.

II. Immediate questions

- A. **Are you sure it is a pneumothorax?** See Section IV.C.2 for classic findings of a pneumothorax on chest x-ray (CXR). Rule out artifacts and mimickers of a pneumothorax such as:
1. **Skin folds** are the most common artifact projected over the thoracic cavity. They occur as a broad curvilinear line that travels across or the chest or diaphragm into the abdomen. If the line extends beyond the lung or if there are lung markings peripheral to the line then you know it is an artifact.
 2. **Neonatal incubator access port projection**, which produces lower density round images that can look like cystic lesions or a small pneumatocele.
 3. **Scapulae margins, clothing, or inserted and overlying lines or tubes** may cause a curvilinear shadow over the lung and be misinterpreted as a pneumothorax. Look for lung markings, which will be visible in the periphery, to rule out a pneumothorax.
 4. **Companion shadows along the inferior margins of the ribs** are smooth radiopaque shadows running parallel along the bones that can mimic a pneumothorax.
 5. **Bullae or lung cysts** can mimic a pneumothorax. Bullae have a concave surface facing the chest wall. A pneumothorax typically has a convex surface facing the chest wall.
 6. **Free air in the abdomen** can extend into the mediastinum and pleural space.
 7. **Gastric dilatation or a severely distended intrathoracic stomach** can simulate a pneumothorax.
- B. **Is the infant symptomatic?** Symptoms of a pneumothorax vary depending on the size and whether the pneumothorax is under tension. Respiratory distress signs are tachypnea, chest retractions, grunting, and nasal flaring.
1. **A small pneumothorax** can be asymptomatic or can cause mild respiratory distress.
 2. **A large pneumothorax** can cause more symptoms: increasing respiratory distress, cyanosis, decreased breath sounds on the affected side, chest bulge with enlargement of the affected side, point of maximal cardiac impulse shifted away from the affected side, and an increase in heart rate and blood pressure.
 3. **A tension pneumothorax presents as a medical emergency, and the patient's status can suddenly deteriorate to a complete cardiovascular collapse.** The following signs may be seen with tension pneumothorax: severe respiratory distress, cyanosis, hypoxia, tachypnea, a sudden decrease in heart rate with bradycardia that persists, a sudden increase in systolic blood pressure followed by narrowing of pulse pressure and hypotension, an asymmetric chest (bulging on the affected side), distention of the abdomen (secondary to downward displacement of the diaphragm), decreased breath sounds on the affected side, and shift of the cardiac apical impulse (most consistent finding) away from the affected side. A cyanotic upper half of the body with a pale lower half can be seen.

- C. **Is the infant asymptomatic?** An asymptomatic pneumothorax is present in approximately 1% of neonates. It occurs more frequently in males and term and postterm infants. It is usually unilateral, with most of these discovered on CXR at admission. Up to 15% of these infants can be meconium stained at birth with a pneumothorax.
- D. **Is mechanical ventilation being used?** The incidence of pneumothorax in patients receiving positive-pressure ventilation is 15% to 30%. A life-threatening tension pneumothorax may result from mechanical ventilation.
- E. **Are there risk factors for a pneumothorax?** Neonates delivered between 30 and 36 weeks, moderately preterm, or term by cesarean section have a higher incidence of pneumothorax. The following factors are associated with an increased risk: male infant, low birthweight, prematurity, meconium-stained amniotic fluid, vacuum extraction, a low 1-minute Apgar score, ventilator treatment, perinatal asphyxia, cardiopulmonary resuscitation, transient tachypnea of the newborn, RDS, MAS (10%–30%), pneumonia, pulmonary hypoplasia (often bilateral pneumothorax), urinary tract anomalies, need for resuscitation at birth, continuous positive airway pressure, and positive-pressure ventilation. α_1 -Antitrypsin deficiency may play a role in some cases of spontaneous pneumothorax of the newborn.

III. Differential diagnosis

- A. **Clinical differential diagnosis.** Clinically, a pneumothorax can present as any process that causes respiratory distress, diminished breath sounds, or a sudden deterioration in a neonate. All of these can signify a pneumothorax or another diagnosis. It is important to recognize the differential and exclude the other causes.
 1. **Other causes of respiratory distress in a neonate:** RDS, endotracheal tube obstruction/displacement, aspiration, congenital heart disease, asphyxia, congenital diaphragmatic hernia (CDH), congenital cystic pulmonary malformation, or pleural effusions.
 2. **Other causes of diminished breath sounds:** Inadequate ventilation, malpositioned endotracheal tube, tracheal obstruction, enlarged heart, pulmonary hypoplasia, pleural effusion, CDH, or positive-pressure ventilation equipment failure.
 3. **Other causes of a sudden deterioration in a neonate:** Tension pneumothorax, pneumopericardium, massive pericardial effusion/cardiac tamponade (umbilical venous catheter, systemic air embolism), or other diseases (eg, septic shock).
- B. **Radiographic differential diagnosis** can include pneumomediastinum, congenital lobar emphysema, atelectasis with compensatory hyperinflation, CDH, congenital cystic pulmonary malformation, a large pulmonary cyst, and the artifacts noted earlier.
- C. **Pneumothorax**
 1. **Symptomatic pneumothorax (includes tension vs nontension pneumothorax)**
 - a. **Nontension pneumothorax symptoms:** Irritability, pallor, cyanosis, restlessness, apnea, mild tachypnea, respiratory distress (flaring, grunting, tachypnea, retractions).
 - b. **Tension pneumothorax symptoms** are noted in Section II.B.3.
 2. **Asymptomatic pneumothorax**
 3. **Persistent pneumothorax**
- D. **Pneumomediastinum. Air is in the mediastinal space.** Heart sounds are distant on physical examination. **Extrapleural air seen over the lung space or air in the mediastinal space may be misdiagnosed as a true pneumothorax.** On the radiograph, mediastinal air can elevate the lobes of the thymus (called “angel wing” or “spinnaker sail” sign), and the air can also track within the extrapleural space and outline the inferior aspect of the heart (“continuous diaphragm” sign). See Figure 12–23. Apical extrapleural air due to a pneumomediastinum is almost always seen bilaterally; in a pneumothorax, it is seen unilaterally.
- E. **Congenital lobar emphysema.** A rare anomaly of lung development that presents with respiratory distress and pulmonary lobar hyperinflation. Overdistention of 1 lobe secondary to air trapping occurs most commonly (47%–50%) in the left upper lobe. Other lobe involvement includes right upper lobe (20%), right middle

lobe (28%), and lower lobes (rare). The causes of congenital lobar emphysema are multifactorial.

- F. **Atelectasis with compensatory hyperinflation.** Compensatory hyperinflation may appear as a pneumothorax on a CXR.
- G. **Pneumopericardium. A pneumopericardium is air in the pericardial space.** In neonates, pneumopericardium and tension pneumothorax can both present as sudden and rapid clinical deterioration. In pneumopericardium, the blood pressure drops, heart sounds are distant or absent, and pulses are muffled or absent. Massive abdominal distention can also be seen. In tension pneumothorax, the blood pressure may initially increase, but then hypotension follows. The CXR easily differentiates the 2 conditions. A pneumopericardium has a halo of air around the heart (see Figure 12–22). Air never extends into the neck or along other mediastinal structures seen on a CXR of a pneumopericardium. The air seen on the film does not change with different positions of the infant. **The more common event is a tension pneumothorax.** If one is unsure and time does not permit radiographic verification, quick transillumination can be done. If not available or unsure of results, it is better to insert a needle in the chest on the suspected side. If no response, then a needle should be inserted on the other side. If there is still no response, then the diagnosis of pneumopericardium should be considered.
- H. **Congenital diaphragmatic hernia.** A developmental defect in the diaphragm allows the abdominal viscera to protrude into the chest, which causes pulmonary hypoplasia and decreased pulmonary vasculature and dysfunction of the surfactant system. Ninety percent of cases are on the left side. **CDH is often mistaken as a left tension pneumothorax.** CDH presents with respiratory distress, cyanosis, and circulatory insufficiency. It can be hard to differentiate a left-sided pneumothorax from a typically left-sided CDH. With CDH, the abdomen is scaphoid, and the spleen cannot be palpated. There can be a mediastinal shift on radiograph. If chest tubes are placed, there is a risk of perforating the herniated viscus. This is the most common condition associated with a gastrothorax (a distended stomach herniates through a ruptured diaphragm) and may simulate a pneumothorax.
- I. **Congenital pulmonary airway malformation (formerly known as congenital cystic adenomatoid malformation).** This rare congenital abnormality of the lung results from abnormal embryogenesis and reduced alveolar growth. Infants present with respiratory distress. Tachypnea and cyanosis can be presenting signs that are similar to a pneumothorax. Many of these are detected on ultrasound prenatally. A CXR usually identifies the mass containing air-filled cysts (see Chapter 125).

IV. Clinical findings

- A. **Physical examination.** Signs of respiratory distress classically include tachypnea, retractions, grunting, and flaring. Other signs include decreased breath sounds on the affected side, chest bulge with enlargement of the affected side, point of maximal cardiac impulse shifted away from the affected side, and increase in heart rate and blood pressure. As air increases, hypotension and decreased blood pressure can occur.
- B. **Laboratory studies.** Blood gas levels may show a decreased PaO₂, increased PCO₂, and decrease in blood pH with resultant respiratory acidosis. Metabolic acidosis due to a low cardiac output can be seen as a result of a tension pneumothorax. Both CRP and procalcitonin concentrations increase in response to a pneumothorax.
- C. **Imaging and other studies**
 - 1. **Chest transillumination** is a **rapid bedside method** to identify a pneumothorax. **Always verify the diagnosis of pneumothorax by a CXR if time permits.** (See Chapter 44 for details on transillumination techniques.) The room lights are lowered, and a fiberoptic transilluminator is placed firmly and flat against the baby's chest wall along the midaxillary area between the fourth and sixth interspaces on the side on which pneumothorax is suspected. If a pneumothorax is present, the chest "lights up" on that side. The transilluminator may be moved up and down

along the midaxillary line and may also be placed above the nipple. Transilluminate both sides of the chest and then compare the results. Premature infants will normally transilluminate more than full-term infants. Large/obese or term infants with thick chest walls do not transilluminate well. A recent study showed chest transillumination to be the **least accurate** method in the diagnosis of pneumothorax when compared to CXR and ultrasound. **Note:** Pulmonary interstitial emphysema (PIE) and pneumothorax can look the same on transillumination because they both light up.

- a. **Normal (negative transillumination results):** No pneumothorax. The only area that lights up will be a symmetric ring around the tip of the fiberoptic light and will not extend over 1 cm. Both sides will have equal translucency.
 - b. **Abnormal (positive transillumination results):** The translucency will be larger on the 1 side, and it will have an irregular pattern. If severe subcutaneous edema is present, transillumination may be falsely positive. Premature infants with PIE may also have a false-positive transillumination because diffuse PIE can give the same appearance as a large pneumothorax on transillumination.
 - c. **Suspicious:** Difficult to assess if the area of translucency is larger than the other side.
2. **Chest radiographs** are the **method of choice** for diagnosing pneumothorax. The **classic radiographic findings** include displacement of the thin white line of the visceral pleura lining the lung parenchyma from the chest wall. Lung markings are absent peripherally beyond this white line. This is not a definite sign because it can be seen in lung cysts or bullae. Early or small pneumothoraces are difficult to diagnose. Early on, there is separation of lung from the chest wall with no lung markings in that space. In infants, there is a tendency of pleural air to cloak diaphragmatic and mediastinal surfaces. A pleural line is often not seen, but a well-defined costophrenic sulcus (deep sulcus sign) can be observed. Of note, a study showed that using a personal smart phone to view a CXR image of a neonatal pneumothorax was just as accurate as viewing the image on a computer screen.
- a. **Subtle radiographic signs of a pneumothorax**
 - i. **Deep sulcus sign.** A unilateral, abnormally deepened costophrenic angle that is lower than normal. It looks like a sharp black shadow in the costophrenic angle that goes below the ribs.
 - ii. **Black stripe sign.** Medially located air in the pleural space that extends along the cardiac and mediastinal margins. It appears sharp and clear and is unilateral.
 - iii. **Black and white stripe sign.** With the black strip sign, a white stripe is seen lateral to the black stripe.
 - iv. **Inverted diaphragm sign.** The hemidiaphragm is flattened, depressed, or inverted; this sign is seen in a tension pneumothorax or basal loculated pneumothorax.
 - b. **The following radiographs can aid the diagnosis:**
 - i. **Anteroposterior view of the chest** (see Figure 12–24) will show the following:
 - (a) **A shift of the mediastinum** away from the side of pneumothorax (this is seen with tension pneumothorax).
 - (b) **Depression of the diaphragm** on the side of the pneumothorax (with tension pneumothorax).
 - (c) **Displacement of the lung** on the affected side away from the chest wall by a radiolucent band of air.
 - ii. **Cross-table lateral view** will show a rim of air around the lung (“pancaking”). It will *not* help to identify the affected side. **You must have an anteroposterior (AP) film to identify the side of the pneumothorax.** This film must be considered together with the AP view to identify the involved side. Pleural air tends to collect anteriorly and may require computed tomography or the lateral decubitus view.

deteriorating rapidly, a needle or catheter-over-needle can be placed for aspiration, followed by formal chest tube placement. There is no specific sign that distinguishes a tension from a nontension pneumothorax. The previously discussed signs of a tension pneumothorax can also occur in a nontension pneumothorax, except the signs and symptoms are more severe in a tension pneumothorax.

- i. **Needle aspiration (see Figure 75-1) can be done as an emergency or as part of planned elective aspiration.** Often this is all that is necessary if the infant is not on a ventilator. If on a ventilator, a chest tube placement may need to be followed by needle aspiration. Confirm the side that you plan to aspirate with a procedural “time-out.”

The site of puncture should be at the second intercostal space along the midclavicular line on the suspected side of pneumothorax. Cleanse this area with antibacterial solution and prepare with sterile towels. The **fourth intercostal space at the anterior axillary line** can also be used (needle would be inserted above the fifth rib). Position the infant on his or her back with the affected side on a small blanket roll so that side is elevated. This allows the air to rise to the upper part of the chest. Appropriate

FIGURE 75-1. Site of emergency needle aspiration for tension pneumothorax is puncture at the second intercostal space (ICS) along the midclavicular line.

anesthetic for pain management should be used, but in the case of a tension pneumothorax, urgency of treatment may not allow it.

- ii. **Use a 18–20-gauge percutaneous catheter over needle (recommended by *Textbook of Resuscitation*) or 19–21-gauge percutaneous catheter over needle** (per Perinatal Continuing Education Program Neonatal Care), or connect a 21- or 23-gauge butterfly needle to a 10- to 20-mL syringe with a stopcock attached.
- iii. **Palpate the third rib at the midclavicular line. Avoid insertion at or near the nipple area.** Insert needle (perpendicular to the chest surface) over the top of the third rib (to avoid the blood vessels and the nerve that run below the rib) at the second intercostal space, and **advance the catheter upward** until air is withdrawn from the syringe. Stop inserting the needle once you get air into the syringe. Have an assistant hold the syringe to withdraw the air. **If using a catheter-over-needle (Angiocath-shielded IV catheter),** the needle can be removed once the pleural space is entered (a “pop” is typically felt); a large syringe (20–60 mL) is then attached to the catheter with a 3-way stopcock. Open the stopcock between the syringe and catheter to evacuate air. When it is full, close the stopcock to the chest and empty the syringe. Continue to aspirate air until the infant improves. The needle may be removed before the chest tube is placed if the infant is relatively stable, or it may be left in place for continuous aspiration while the chest tube is being placed. Check a chest x-ray to make sure there is no residual pneumothorax.
- b. **Chest tube/pigtail catheter placement.** This may be necessary in most infants on mechanical ventilation with a tension pneumothorax, if the air leak is continuous, or if the pneumothorax does not clear after needle aspiration. See Chapter 31 for chest tube details.
- c. **If the infant does not improve with a properly functioning chest tube,** suspect extrapleural air leaks such as a pneumoretroperitoneum, pneumomediastinum, or pulmonary cyst.
- d. **If the pneumothorax is persistent after chest tube drainage,** consider the following trouble-shooting measures:
 - i. **Check to see if there is an air leak in the tubing or if it is in the lung:** Remember, bubbling in the water seal chamber is normal and indicates air is entering the system. Persistent bubbling means there is an air leak or bronchopleural fistula.
 - ii. **Check all tubing connections.** A nonfunctioning chest tube can result from disconnection of the tube from the suction mechanism, mechanical obstruction (blood clot or pleural fluid), kinked tube, or a malfunctioning suction apparatus.
 - iii. **Clamp the chest tube near the entrance of the chest cautiously.** If there is **continuous bubbling**, it means there is an air leak in the tubing. If there is **no bubbling**, it means the chest tube is outside of the chest or there is an active leak.
 - iv. **A malpositioned/incorrect tube placement** (most common cause) is a tube in the subcutaneous tissue or posterior pleural space.
 - v. **Check for possibility of a new air leak.**
 - vi. **Check for perforation of lung (most commonly injured organ) or diaphragm.**
2. **Nontension pneumothorax.** Depending on the infant’s symptoms, observation with room air only or oxygen supplementation if needed, needle aspiration, and chest tube placement are all options based on the clinical situation. In 1 study, only 7.5% of symptomatic term infants with a spontaneous pneumothorax required needle aspiration or chest tube placement.
 - a. **Mild symptoms.** Typically, observation only with serial imaging.

- b. **Symptomatic pneumothorax (not on ventilator).** Close observation, supplemental oxygen to maintain saturation and needle aspiration. In 1 study, the majority of infants could be managed with supplemental oxygen or close observation.
 - c. **Symptomatic pneumothorax (on the ventilator).** Needle aspiration and/or chest tube placement are typical options. If possible decrease the mean airway pressure (decrease PIP, PEEP, and inspiratory duration).
- C. Asymptomatic pneumothorax**
1. **If positive-pressure mechanical ventilation is being used:**
 - a. **Needle aspiration/chest tube.** A chest tube will probably need to be inserted because the ventilator pressure will prevent resolution of the pneumothorax, and a tension pneumothorax may develop. Sometimes **needle aspiration is all that is needed.** If a pneumothorax develops in a patient who is ready to be extubated, clinical judgment must be used in deciding whether a chest tube should be placed.
 - b. **Expectant management.** Recent studies are showing that some select infants on a ventilator can be managed without a chest tube. These select infants are usually more mature, on lower ventilator settings, and have better gases at the time of the pneumothorax compared to infants who require a chest tube.
 2. **If positive-pressure mechanical ventilation is not being administered** and there is no underlying lung pathology, these approaches may be considered.
 - a. **Close observation with follow-up chest radiographs every 8 to 12 hours or sooner if the infant becomes symptomatic.** The pneumothorax will likely resolve within 24 to 48 hours.
 - b. **Nitrogen washout therapy. (This method is controversial and not used widely anymore).** Older studies showed that this therapy allowed a more rapid resolution of the asymptomatic pneumothorax, but it is infrequently used due to the toxicity of 100% oxygen. The infant receives 100% oxygen for 8 to 12 hours. The theory behind this therapy is that high oxygen therapy reduces the partial pressure of nitrogen in the alveolus when compared to the pleural space. This diffusion gradient causes the nitrogen to diffuse from the pleural space into the alveoli, which results in resorption of air from the pleural space into the alveoli, resulting in faster resolution of the pneumothorax. If used, this method should be reserved for only full-term infants in whom retinopathy of prematurity will not be a problem. Some neonatal intensive care units give only enough oxygen to maintain adequate saturation and have found resolution to be similar to the hyperoxic group. **More recent studies** indicate that nitrogen washout therapy (100% oxygen) is not associated with a faster resolution of spontaneous pneumothorax in term infants compared to room air. It resulted in infants being exposed to unnecessary oxygen, longer IV therapy, and delay in reaching full feeds. **If this technique is used, it is best to use oxygen saturation targeted therapy (use only enough oxygen to maintain a normal pulse oximeter and not any more).**
- D. Persistent air leak pneumothorax** is generally defined as a pneumothorax that persists >5 to 7 days in the absence of mechanical problems. Sometimes infants who have chest tubes still have air leaks that persist for more than a week. These infants tend to have episodes of instability when air reaccumulates; some require a new or replacement chest tube and an increase in their ventilator settings. These persistent leaks are treated to decrease the complications associated with air leaks (eg, air embolus, hypotension, intracranial hemorrhage). Techniques that have been used with variable success in adults for persistent air leaks in anecdotal reports include fibrin sealants, ethanol injection, metal coils, and Watanabe spigots, and in larger studies, chemical pleurodesis, autologous blood patch pleurodesis, and endoscopically placed endobronchial valves have been used. The following treatments have been reported:
1. **Observation.** The American College of Chest Physicians states that the majority of persistent pneumothoraces, in the absence of a bronchopleural fistula, will likely

resolve spontaneously and recommends observation for spontaneous closure for 4 days.

2. **Placing the chest tube to water seal** has been successful in some cases of post-operatively persistent air leaks.
3. **Low lung volume strategy.** Reduce the inspiratory time, positive end-expiratory pressure, and peak inspiratory pressure if on conventional positive-pressure ventilation.
4. **Consider high-frequency oscillatory ventilation or high-frequency jet ventilation**, which can be used due to lower mean airway pressures.
5. **Unilateral lung intubation** has been reported as an efficient and relatively safe therapy for pneumothorax. Selective intubation of the contralateral bronchus causes the affected lung to collapse to enable the ruptured alveoli to heal. This is a very difficult procedure, especially if the left mainstem bronchus has to be intubated, with many complications. Duration of therapy should be a minimum of 48 hours.
6. **Pleurodesis with fibrin glue or povidone-iodine.** Agents are introduced into the pleural space through the chest drain that cause irritation between the parietal and visceral layers of the pleura, which closes the space between them, thus treating the pneumothorax and preventing any further air from accumulating. Fibrin glue and povidone-iodine have been used in neonates with persistent pneumothoraces.
 - a. **Fibrin glue**, such as CryoSeal C (ThermoGenesis Corp, Rancho Cordova, CA), has been injected in the chest tube with a marked reduction in the air leak. It has been used in newborns (single case reports and 1 study with 8 patients) and is an effective treatment for an intractable persistent pneumothorax but has significant risks (hypercalcemia, localized tissue necrosis, bradycardia requiring manual ventilation, diaphragmatic paralysis, and pneumothorax on the contralateral side).
 - b. **Povidone-iodine** has been used in case reports.
- E. **Pneumomediastinum.** Most do not need any treatment and usually resolve spontaneously. **Close observation is required** because it may progress to a pneumothorax or pneumopericardium. If there is a **tension pneumomediastinum**, ultrasound-guided percutaneous drainage should be urgently performed.
- F. **Congenital lobar emphysema.** If asymptomatic, conservative management with observation is recommended. If symptomatic or respiratory failure is occurring, the treatment is usually surgical excision of the affected lobe.
- G. **Atelectasis with compensatory hyperinflation**
 1. **Chest physiotherapy and postural drainage should be initiated.** Chest physiotherapy should be used with caution in premature infants. A study showed an association with intraventricular hemorrhage and porencephaly in extreme premature infants.
 2. **Treatment with bronchodilators** is indicated.
 3. **Positioning the infant with the affected (hyperinflated) side down** may speed resolution.
 4. **Bronchoscopy.** May be necessary with a mucus plug.
- H. **Pneumopericardium.** If symptomatic, the infant should be treated (urgently if experiencing cardiac tamponade) by a therapeutic pericardiocentesis (see Chapter 41). Sometimes a pericardial tube needs to be left in for continuous decompression. If asymptomatic, intervention may not be necessary, but the infant needs to be closely followed for any changes in physical examination or on CXR. Ventilator settings should be decreased if possible.
- I. **Cystic pulmonary airway malformations (formerly known as congenital cystic adenomatoid malformation).** Surgery is the treatment of choice.
- J. **Pulmonary interstitial emphysema.** Management is supportive with the goal of decreasing the mean airway pressure. For unilateral PIE, position the infant with the affected side down and decrease the inspiratory time and ventilator pressure (see Chapter 87).

76 Polycythemia: On Call

- I. Problem.** The hematocrit (Hct) is 68% in a newborn. **Polycythemia** is an increase in total erythrocyte mass empirically defined as a venous Hct >2 standard deviations above the normal value for postnatal and gestational age. **An infant who has a peripheral venous Hct $>65\%$ or a hemoglobin >22 g/dL is considered polycythemic.** Polycythemia occurs in 1% to 5% of healthy newborns (1%–2% at sea level and 5% at high altitude) and is rare in premature infants <34 weeks' gestation. The venous Hct level of 65% was chosen to define polycythemia based on an exponential increase in viscosity above this level. **Hyperviscosity** and the resultant impairment of blood flow are important in polycythemia because they cause most of the symptoms and complications. Increased blood viscosity impairs circulation of red blood cells through vessels and organs and interferes with delivery of oxygen, glucose, and amino acids to the tissues. Poor oxygen and nutrient delivery causes neurologic, gastrointestinal, metabolic, and cardiopulmonary problems. The Hct is the main determinant of blood viscosity (thickness); however, plasma proteins (especially fibrinogen), low plasma volume, and decreased erythrocyte deformability also affect blood viscosity. Blood is unable to flow freely due to increased viscosity of blood because of the increased number of erythrocytes that occurs in polycythemia. **Hyperviscosity** is defined as >14.6 centipoise (shear rate of 11.5 seconds) and is also defined as 2 standard deviations greater than the norm. Viscosity rises linearly until the Hct reaches 60% but increases exponentially when it reaches 70%.

Polycythemia hyperviscosity syndrome (PHS) is the symptom complex that involves hyperviscosity resulting from polycythemia and the symptoms that accompany it. Not all polycythemic infants will have hyperviscosity: roughly 47% of polycythemic infants will have hyperviscosity, and 24% of infants with hyperviscosity have polycythemia.

II. Immediate questions

- A. What is the central hematocrit?** If the Hct was obtained by a heel stick, it can be falsely elevated by up to 15% as compared to venous samples. Warming the heel prior to the heel stick will give a result that better correlates with the central Hct. However, treatment should **never** be initiated based on heel stick Hct values alone; **a central (peripheral venous phlebotomy) Hct is needed.** The Hct is highest in capillary samples and lowest in umbilical venous samples.
- B. What method was used to determine the hematocrit?** There are two methods of determining the Hct: **automated hematology analyzer (cell counter)**, which calculates the Hct from a measurement of the mean cell volume and hemoglobin, and the **microcentrifuge** (blood is centrifuged, plasma and packed cell volume separates, and the Hct is measured). A microcentrifuge Hct can be 2% higher than Hct by a hematology analyzer.
- C. How old is the infant?** A newborn's Hct peaks at 2 hours of age, plateaus between 2 and 4 hours of age, and then decreases back to values close to cord blood values between 12 and 24 hours of age. A value up to 71% may be normal at 2 hours of age.
- D. Does the infant have symptoms of polycythemia?** Most infants with polycythemia are **asymptomatic** (up to 90%). Symptoms of hypoperfusion correlate more with viscosity than the Hct. One study found that gastrointestinal symptoms (**poor feeding and vomiting**) were the most common symptoms. There are many signs of polycythemia, most of them nonspecific, and they include the following:
- 1. Central nervous system signs** are common in infants with polycythemia and can include lethargy, hypotonia, irritability, jitteriness, weak sucking reflex, vomiting, seizures, apnea, sleepiness, exaggerated startle, tremors, and cerebrovascular accidents.

2. **Cardiovascular.** Murmurs, congestive heart failure, cyanosis, plethora, tachycardia, cardiomegaly, and prominent vascular markings on chest radiograph. Cyanosis and tachycardia are uncommon.
 3. **Respiratory.** Respiratory distress, tachypnea, and cyanosis.
 4. **Gastrointestinal.** Poor feeding, poor sucking, vomiting, abdominal distension, and necrotizing enterocolitis (NEC).
 5. **Renal.** Proteinuria, oliguria, hematuria, renal vein thrombosis, decreased glomerular filtration rate, and transient hypertension.
 6. **Hematologic.** Thrombocytopenia, hepatosplenomegaly, thrombosis, disseminated intravascular coagulation (rare), and elevated reticulocyte count.
 7. **Metabolic.** Hypoglycemia (most common; 12%–40%), hypocalcemia (1%–11%), and increased bilirubin (33%).
 8. **Skin.** Plethora or ruddiness, jaundiced.
 9. **Genitourinary.** Testicular infarcts or priapism (majority are idiopathic).
 10. **Eyes.** Vitreous hemorrhage seen in an infant with thrombocytopenia and polycythemia.
- E. Is the mother diabetic?** Poorly controlled maternal diabetes during pregnancy leads to chronic fetal hypoxia, which may result in increased fetal erythropoiesis. Infants of diabetic mothers (IDM) have a 13% to >40% incidence of polycythemia. Good maternal glycemic control will help prevent fetal hypoxia and polycythemia.
- F. Is the infant dehydrated?** Dehydration may cause hemoconcentration, resulting in a high Hct. It usually occurs in infants >48 hours old.
- G. Does the mother live at a high altitude?** Infants born to mothers at high altitudes have a higher incidence of polycythemia.
- H. Is the infant at high risk for polycythemia?** Infants who are small for gestational age, postterm, or intrauterine growth restricted; IDMs; large for gestational age infants; infants with twin-to-twin transfusion; and infants with chromosomal abnormalities (trisomy 21, 13, or 18) have an increased risk for polycythemia.
- I. Was there delayed clamping of the umbilical cord? Were the guidelines followed? Was the cord milked?** Delayed cord clamping (DCC) is now recommended by the American College of Obstetricians and Gynecologists (ACOG), the World Health Organization (WHO), and the American Academy of Pediatrics (AAP) Neonatal Resuscitation Program for vigorous term and preterm infants. Randomized controlled trials of DCC in term and preterm infants have shown increased Hct, without increased incidence of polycythemia when following the guidelines. Umbilical cord milking (UCM), where the cord is held and blood is squeezed down the cord into the baby, is another way that newborns can receive extra blood volume at birth; however, it is not universally recommended or practiced.
- III. Differential diagnosis.** See also Chapter 116.
- A. Falsely elevated hematocrit.** Most often occurs when blood is obtained by a heel stick.
- B. Diseases that cause the same clinical signs as polycythemia that should be ruled out.**
1. **Hypoglycemia:** Intrauterine growth restriction, IDM, inborn error of metabolism, Beckwith-Wiedemann syndrome, infection, nesidioblastosis, cortisol, or insulin production abnormalities.
 2. **Respiratory disorders:** Respiratory distress syndrome, transient tachypnea of the newborn, pneumonia.
 3. **Cardiovascular abnormalities:** Persistent pulmonary hypertension of the newborn, congenital heart disease.
 4. **Neurologic abnormalities:** Intracranial hemorrhage, intracranial abnormalities, hypoglycemia, hypocalcemia, perinatal hypoxia, genetic/metabolic syndromes, venous thrombosis, infant with a high magnesium level, peripheral neuromuscular disease.

5. **Renal failure:** Acute tubular necrosis, dehydration, renal dysplasia, obstruction of the urinary tract.
 6. **Feeding intolerance.** NEC, bowel obstruction, formula intolerance, central nervous system or peripheral neuromuscular disease, genetic syndrome, IDM.
 7. **Endocrine abnormalities:** Hypothyroidism or congenital adrenal hyperplasia.
 8. **Neonatal sepsis.**
- C. **Dehydration.** Also called “relative polycythemia,” this condition is associated with weight loss and decreased urine output (sensitive indicators of dehydration). Hemocentration secondary to dehydration is suspected if $>7\%$ of the birthweight has been lost in the first 5 days of life. It usually occurs on the second or third day of life.
- D. **Primary polycythemia (very rare in newborns).** Occurs when there is a problem with the production of red blood cells (excess production) in the bone marrow and occurs from inherited and acquired mutations. Polycythemia vera, idiopathic erythrocytosis, and primary familial and congenital polycythemia are examples.
- E. **Secondary polycythemia.** Caused by an increase in the production of erythrocytes secondary to either **excess erythrocyte transfusion to the fetus or newborn** (which is considered passive) or **increased intrauterine fetal erythropoiesis** (which is considered active).
1. **Excess erythrocyte transfusion to the fetus or newborn**
 - a. **Delayed cord clamping causes placental fetal transfusion** and results in an increase in red cell mass in the neonate, but does not cause polycythemia when the ACOG/AAP guidelines are followed. Polycythemia can occur from an unattended delivery, holding the infant below the mother after birth for too long before clamping the cord, aggressive cord milking, or clamping the cord way past the recommended time. There is no set definition of the time set for DCC because it varies depending on the study. Immediate cord clamping is right after delivery (usually before 30 seconds), whereas DCC is usually >30 seconds, >1 minute, or >3 minutes after delivery depending upon the reference. The term fetus has an approximate blood volume of 70 mL/kg with immediate cord clamping and an approximate blood volume of 90 mL/kg after DCC at 3 minutes. In preterm infants, a delay in cord clamping by 30 to 45 seconds results in an 8% to 24% increase in blood volume. **AAP and ACOG recommend DCC in vigorous term and preterm neonates for 30 to 60 seconds.** WHO recommends delaying umbilical cord clamping in term infants for 1 to 3 minutes. Studies show that polycythemia does not occur with the recommended time per ACOG for delayed cord clamping.
 - b. **Type of delivery.** In a **vaginal birth**, because of contractions, there is an increased transfer of placental blood to the infant versus a caesarean delivery with absent contractions. Uterine contractions, especially strong ones, increase the blood volume in the fetus, and uterine contractions during the third stage of labor may cause most of the placental transfusion. **Use of oxytocin** in the mother can also increase contractions. An uncontrolled or precipitous delivery can lead to passive transfusion.
 - c. **Position of the infant and effect of gravity on volume of placental transfusion.** If the cord is not clamped immediately at birth, blood will flow between the placenta and the infant. If the infant is held high above the placenta, there is a decrease in placental transfusion. If the infant is held a significant distance below the placenta, transfusion of blood can occur from the placenta to the infant. Holding the infant at the level of the abdomen, chest, or the introitus will prevent the effect of gravity.
 - d. **Umbilical cord milking** is the practice of holding the infant in a neutral position while squeezing blood from the cord (either connected to the placenta or after it is cut) to the baby. **Recommendations are to milk the cord 4 times for a preterm infant and to milk the cord 5 times for a term infant.** This may

lead to a higher Hct in infants, and the main advantage of UCM over DCC is a quicker improvement in the pulmonary blood flow at birth, which will help with lung expansion at the onset of respirations. UCM is shown to have a greater placental transfusion, higher blood pressure, higher systemic blood flow, and higher urine output in infants delivered by cesarean section than infants who had DCC. UCM may be an alternative to DCC for premature infants because it is completed much faster than DCC.

- e. **Twin-to-twin transfusion** can result in increased blood in 1 twin (10%–15% of monochorionic twins). Twin-to-twin transfusion occurs with discordant amniotic fluid volumes. **Twin anemia polycythemia sequence** is an atypical form of twin-to-twin transfusion in monochorionic twin pregnancies that does not have discordant amniotic fluid volumes.
 - f. **Maternal-to-fetal transfusion (rare)**.
 - g. **Iatrogenic polycythemia** is uncommon and caused by overtransfusion of red blood cells during a transfusion.
 - h. **Acute fetal hypoxia** will result in a transfer of blood from the placenta to the fetus to maintain fetal oxygenation and cardiac output.
2. **Increased intrauterine fetal erythropoiesis.** This can occur from chronic intrauterine hypoxia or insufficiency of the placenta. In an attempt to correct the chronic intrauterine fetal hypoxia, the production of erythropoietin increases, which leads to increased red blood cell production and an increased Hct. Intra-partum asphyxia can also cause blood volume to shift from the placenta to the fetus and cause polycythemia.
 - a. **Infant.** Intrauterine hypoxia may be seen in small for gestational age infants, postmature/postterm infants, intrauterine growth restricted infants, and infants with perinatal asphyxia.
 - b. **Mother.** Maternal smoking, heavy maternal alcohol use, chronic or recurrent abruptio placentae, maternal chronic hypertension, mothers with pre-eclampsia, and severe maternal cardiac, pulmonary, or primary renovascular disease may also cause intrauterine hypoxia. Severe maternal diabetes can cause reduced placental blood flow, and pregnancy at high altitudes can cause intrauterine hypoxia.
 3. **Other causes/factors usually associated with increased erythropoiesis**
 - a. **Infant of a diabetic mother.** The incidence of polycythemia is 22% to 29%. This occurs with gestational diabetes as well as with insulin-dependent diabetes and is due to increased erythropoiesis.
 - b. **Chromosomal abnormalities:** Down syndrome (trisomy 21; 15%–33%), trisomy 13 (8%), trisomy 18 (17%), fumarate hydratase deficiency.
 - c. **Endocrine abnormalities:** Hyperthyroidism, congenital hypothyroidism, congenital adrenal hyperplasia.
 - d. **Large for gestational age infants.**
 - e. **Beckwith-Wiedemann syndrome.**
 - f. **Maternal use of β -blockers** (such as propranolol or nebivolol).
 4. **Idiopathic.** No specific cause found.

IV. Database

- A. **Physical examination.** Evaluate for dehydration; weight loss will be present and the mucous membranes will be dry, but increased skin turgor is usually not seen. True polycythemia is often associated with visible skin changes. Ruddiness or plethora is most often seen, but one can also see poor perfusion, or “pink-on-blue” or “blue-on-pink” coloration. In males, priapism may be seen secondary to sludging of red blood cells causing venous congestion. Hypothermia is also a sign of polycythemia. Assess for macrosomia. Does the infant have large fontanels (congenital hypothyroidism)? Genitourinary exam should evaluate for disorders of sex development (congenital adrenal hypoplasia). Clinical signs are listed in Section II.D.

B. Laboratory studies. The AAP does not recommend universal screening for polycythemia, but it states that selective testing should be done in high-risk infants. **Hypoglycemia, thrombocytopenia, and hyperbilirubinemia** are commonly associated with polycythemia and need to be closely followed in these infants.

- 1. Hematocrit in cord blood** >56% may predict polycythemia at 2 hours of age (controversial).
- 2. Central hematocrit (venous or arterial) is essential.** Typically recommended at 2, 12, and 24 hours of age.
- 3. Serum glucose.** Hypoglycemia is commonly seen with polycythemia. Coexisting hypoglycemia may worsen long-term outcome.
- 4. Complete blood count with differential** to evaluate for sepsis.
- 5. Platelet count.** Thrombocytopenia occurs in 51% of infants with polycythemia. Disseminated intravascular coagulation is rare.
- 6. Serum bilirubin.** Infants with polycythemia have been shown to be at increased risk of hyperbilirubinemia thought to be related to an increased turnover of red blood cells.
- 7. Metabolic panel.** Serum electrolyte, blood urea nitrogen, and creatine levels. If dehydration is being considered, these labs are important. They are usually high, or higher than baseline values, if dehydration is present. These labs are also necessary to assess renal dysfunction.
- 8. Urine specific gravity** >1.015 is usually seen with dehydration.
- 9. Arterial blood gas.** Rule out inadequate oxygenation.
- 10. Calcium.** Hypocalcemia can also be seen but is uncommon.

C. Imaging and other studies. These studies are usually not needed acutely.

- 1. Chest radiograph.** Cardiomegaly, increased pulmonary vascular markings, and pleural effusions may be seen on chest radiography.
- 2. Abdominal x-ray** if NEC is suspected.
- 3. Electrocardiogram and electroencephalogram.** Electrocardiogram (ECG) and electroencephalogram may be abnormal, but these tests are not routinely indicated. An ECG can show right ventricular hypertrophy and right and left atrial hypertrophy.
- 4. Echocardiogram.** Echocardiogram may show increased pulmonary resistance and decreased cardiac output.

V. Plan. Exclude dehydration first. Rule out other diseases that cause the same symptoms as polycythemia. The suggested treatment strategies are based on low-quality evidence and therefore should be considered weak recommendations. Routine use of partial exchange transfusion (PET) is not recommended.

A. Polycythemia preventive measures

- 1. American Academy of Pediatrics and American College of Obstetricians and Gynecologists recommend** DCC in vigorous term and preterm neonates for at least 30 to 60 seconds. **WHO recommends** delaying umbilical cord clamping in all infants for 1 to 3 minutes, while initiating early neonatal care. Early cord clamping <30 seconds is not recommended unless the infant is asphyxiated or the infant needs positive-pressure ventilation.
- 2. Do not milk or strip the umbilical cord** until further studies are done since research is still insufficient on this practice.
- 3. Do not hold the infant significantly below the placenta** with an intact cord at delivery, since this may cause passive transfusion of placental blood to the infant. Holding the infant on the mother's abdomen, chest, or introitus does not affect the volume of placental transfusion.
- 4. Routine screening.** Screening is usually not recommended but may warranted in selective infants who are symptomatic or at high risk: small for gestational age, large for gestational age, or postterm infants; infants with intrauterine growth restriction; IDMs; monochorionic twins; and infants with chromosomal abnormalities (eg, Down syndrome, trisomy 13 or 18). It is best to screen with a

capillary Hct. Some institutions do not screen healthy high-risk asymptomatic infants since asymptomatic infants with polycythemia do not benefit from treatment. Screening recommendations vary, but screening can be done at 2, 6, 12, 24, 48, and 72 hours of age.

- B. **Falsely elevated hematocrit (>65%).** If the confirmatory central Hct is normal, no further evaluation is needed. If the central Hct is high, either dehydration or polycythemia is present.
- C. **Hemoconcentration secondary to dehydration.** Check weight loss. If the infant is dehydrated (usually the infant is >48 hours of age and has lost >7%–10% of body weight) but does not have symptoms of polycythemia, a trial of rehydration over 6 to 8 hours can be attempted. Usually, a minimum of 100 mL/kg/d up to 130 to 150 mL/kg/d is given. The Hct is checked every 4 to 6 hours and usually decreases with adequate rehydration.
- D. **True polycythemia.** Treatment includes observation with or without intravenous (IV) hydration and/or PET. Treatment is usually based on whether the infant is symptomatic. Some clinicians will narrow it down further on whether the infant has **severe symptoms** (persistent hypoglycemia, severe GI symptoms, worsening apnea, worsening cyanosis) or **nonsevere symptoms**. Treatment is controversial and widely varies depending on the source of recommendations. Supportive care for hypoglycemia, thrombocytopenia, and hyperbilirubinemia should also be provided. It is best to follow your own institutional guidelines:
 1. **Asymptomatic infants** should be observed with or without IV hydration no matter what the Hct is according to some sources. A recent study did not show any evidence of clinical benefit of giving supplemental IV fluids versus routine fluids in late preterm and term neonates with asymptomatic polycythemia with an Hct of 65% to 75%. The following is a recommendation, but it is best to follow your institutional guidelines.
 - a. **Central hematocrit of 65% to 69%:** Close observation with or without IV hydration with monitoring of symptoms and follow-up Hct. The peripheral venous Hct should be reassessed every 4 to 6 hours for 12 to 24 hours. If the Hct remains stable and asymptomatic, the infant can be followed for 48 hours.
 - b. **Central hematocrit of 70% to 75%:** Consider IV hydration. Many of these patients will respond to increased fluid therapy (controversial); consider increasing fluids by 20 to 40 mL/kg/d. Some advocate feedings be withheld until Hct is <70%. Note that liberal IV fluid therapy can be associated with problems in preterm infants. Rarely, clinicians will recommend a PET for an infant with an Hct >70%.
 - c. **Central hematocrit >75%:** PET should be considered if a repeated Hct remains >75%.
 2. **Symptomatic infants with a hematocrit >65%.** Some clinicians recommend that any infant with polycythemia and symptoms be treated. The 2 options are as follows:
 - a. **Treat with observation and intravenous hydration.** IV hydration and close observation with follow-up Hct; if the infant gets worse (increasing symptoms, Hct is rising), treat with PET.
 - b. **Treat with a partial exchange transfusion.** (See also Chapter 34.) If a PET is to be done, it should be done as soon as possible because the Hct and blood viscosity peak between 2 and 4 hours. In a PET, a calculated amount of blood volume is slowly removed and replaced with fluids (normal saline) to dilute the red blood cell concentration, which decreases the Hct. The goal of PET is to decrease blood viscosity and improve end-organ perfusion. PET may be administered via an umbilical venous catheter (UVC). **Care must be taken not to place the catheter in the liver** (see Chapter 48). A high umbilical artery catheter (UAC) or a peripheral IV catheter can also be used. **Normal saline is preferred as the replacement fluid of choice** as crystalloids are as effective as colloids in PET. Crystalloids do

not carry the risk of infection or anaphylaxis and are cheaper and more readily available. Colloid products (plasmanate, 5% albumin, and FFP) have been used but are not currently recommended because of an association with NEC seen with their use. Serial Hct levels should be obtained after transfusion.

- i. Exchange formula:** Desired Hct is 55%, and blood volume is 80 mL/kg.

$$\text{Volume exchanged (mL)} = \frac{[(\text{Weight (kg)} \times \text{Blood volume (mL/kg)}) \times (\text{Actual Hct} - \text{Desired Hct})]}{(\text{Actual Hct})}$$

- ii. Use these guidelines when performing partial exchange transfusion:**
- (a) **Aliquots should not exceed 5 mL/kg** and should be removed or delivered over 2 to 3 minutes.
 - (b) **Removal of blood can be from any arterial or venous line.** Arterial lines are not recommended for infusion.
 - (c) **If there is both an umbilical artery catheter and an umbilical venous catheter,** withdraw blood from the UAC while giving the replacement fluid through the UVC.
 - (d) **If only an umbilical venous catheter is in place,** use the push-pull method: pull out the blood, and then push in the replacement fluid. **Never remove >5 mL/kg.** Isovolumetric method through 2 vessels is preferred.
 - (e) **If you have an umbilical venous catheter, umbilical artery catheter, and peripheral venous catheter in,** you can use either the UAC or UVC for blood withdrawal and then use the peripheral line for replacement fluid. Removal from the UVC and infusion in the peripheral venous catheter did not result in NEC in 1 study.
- 3. Symptomatic infant with a central hematocrit of 60% to 65%.** If all other disease entities are ruled out, these infants may indeed be polycythemic and hyperviscous. Management is *controversial*. Use clinical judgment and institutional guidelines to decide if these infants should have a PET. Some would closely observe with IV hydration.
- 4. Restrictive management protocol of neonatal polycythemia follows a more conservative approach.** Hct of 65% to 69%: no treatment. Hct of 70% to 75%: give IV fluids and no feedings until Hct is <70%. Hct ≥76% or in any symptomatic neonates: use PET. A review demonstrated that the groups did not differ in morbidities or hospital stay, nor was there an increase in risk of short-term complications.
- E. Observe for complications of polycythemia** and disorders that are more common in polycythemic infants.
1. **Apnea.**
 2. **Hypoglycemia (most common).**
 3. **Hypocalcemia.**
 4. **Thrombocytopenia.**
 5. **Hyperbilirubinemia.**
 6. **Neurologic.** Seizures, stroke, cerebral vein thrombosis.
 7. **Vascular/thromboses.** Vasospasms, peripheral gangrene. Large-vessel thrombosis and stroke.
 8. **Cardiopulmonary complications.** Cardiomegaly, tachycardia, tachypnea, arrhythmia, congestive heart failure.
 9. **Gastrointestinal complications.**
 - a. **Necrotizing enterocolitis risk** is increased in term or near-term neonates with polycythemia and hyperviscosity. Etiologies include gut mucosal injury secondary to altered splanchnic perfusion and infants who received a PET via a UVC with colloid (FFP, albumin, or Plasmanate). The development of NEC in these infants who had a partial exchange via a UVC with colloid may be related to PET with colloid, not the polycythemia.

- b. **Ileus, spontaneous intestinal perforations, intestinal atresia.**
 - c. **Treated infants had more gastrointestinal complications** (bloody stools, emesis, and abdominal distension) in 1 study, but this may have been related to PET technique.
10. **Genitourinary complications.** Decreased glomerular filtration rate, oliguria, hematuria, proteinuria, renal vein thrombosis, testicular infarcts, and priapism.
11. **Air embolism.**
- F. **Follow-up data.** PET has some benefit short term (decreases the Hct, decreases the viscosity, and reverses some physiologic abnormalities) but has not been shown to improve long-term outcome. Further research is needed to assess the impact on newborns, because there is conflicting information in the literature.
- 1. **Partial exchange transfusion benefits**
 - a. **It lowers the hematocrit and decreases the viscosity.**
 - b. **It may improve symptoms earlier on**, but this may be transient. It does not eliminate them.
 - c. **It improves microcirculation in polycythemic neonates.** Near-infrared spectroscopy showed increased cerebral oxygenation and decreased fractional tissue oxygen extraction.
 - d. **It has been shown to improve cerebral blood flow velocity and decrease pulmonary vascular resistance**, and may normalize cerebral hemodynamics (normal cerebral blood flow). Oxygen transport and systemic blood flow improve as well.
 - 2. **Controversial data on long-term outcome**
 - a. **Partial exchange transfusion does not appear to significantly improve long-term neurologic outcomes.** Newborns with hyperviscosity had significantly more neonatal problems and motor delays at 2 and 7 years of age, and they have lower IQs and achievement test results and decreased gross motor skills compared with children with a normal Hct. At 7 years of age, children who had neonatal hyperviscosity had lower IQs and decreased visual motor and neurologic function. There was no difference between those who had and had not received a PET. Children with hyperviscosity who received either PET or symptomatic care both had lower spelling and arithmetic achievement test results and gross motor skill scores. Reading, visual motor integration, and neurologic scores did not differ from normal controls. However, decreased IQ scores and lower achievement were reported in infants with hyperviscosity syndrome who were not treated with PET.
 - b. **There is no evidence of improvement** in long-term outcomes (neurologic outcome or early neurobehavioral assessment scores) following PET in symptomatic or asymptomatic infants.
 - 3. **Polycythemic infants are at risk** for speech abnormalities and for fine/gross motor delays.
 - 4. **Long-term outcome may be related** to other perinatal or clinical factors and not polycythemia or PET. Given that infants who are at higher risk for polycythemia and hyperviscosity include those undergoing chronic hypoxia in utero, the association with worse developmental outcomes may be related to the underlying cause of the polycythemia, instead of the polycythemia itself.
 - 5. **Partial exchange transfusion may lead to an increase in the risk of necrotizing enterocolitis** and gastrointestinal symptoms. **Partial exchange transfusion via umbilical vein with colloid** has been shown to increase the risk of NEC.
 - 6. **Intrauterine fetal hypoxia is related to polycythemia** and impaired long-term outcome.
 - 7. **Coexisting hypoglycemia** may worsen the long-term outcome.
 - 8. **Cochrane review** states there are no proven short- or long-term benefits to PET in infants with polycythemia who are well or who have minor symptoms. PET may increase the risk of NEC. The review notes that the risks and benefits of PET are not clear.

77 Poor Perfusion

- I. Problem.** You receive a report that an infant “doesn’t look good” or looks “mottled.” Other descriptors may include “poor perfusion” or “washed-out appearance.” This can include pallor, which can be seen in poor perfusion or may be an early sign of hypoxia or anemia. **Most of these terms refer to poor perfusion and imply there is inadequate blood flow to the tissues of the skin.** Assessing peripheral tissue perfusion is important in the clinical examination of a neonate since it can help determine who may have low systemic blood flow or cardiovascular failure. Recent studies have shown correlations between poor outcomes and peripheral hypoperfusion in preterm infants.
- II. Immediate questions**
- A. What is the age of the infant?** Hypoplastic left heart syndrome (HLHS) may cause poor perfusion and a mottled appearance. It may be seen at days 1 to 21 of life (more commonly at day 2 or 3). In an infant <3 days old (some definitions say <7 days) **early-onset sepsis** may be a cause. Associated risk factors for sepsis are premature rupture of membranes, maternal infection, and fever. **Late-onset sepsis** can occur at >3 days or after 7 days, depending upon which definition is used.
- B. What are the vital signs?** If the temperature is lower than normal, cold stress or hypothermia associated with sepsis may be present. Hypotension may cause poor perfusion (see normal blood pressure values in Table 70–1 and Appendix C). Decreased urine output (<2 mL/kg/h) may indicate depleted intravascular volume or shock.
- C. Is the liver enlarged? Are metabolic acidosis, poor peripheral pulse rate, and a gallop present?** These problems are signs of failure of the left side of the heart (eg, HLHS). Poor perfusion occurs because of reduced blood flow to the skin.
- D. If mechanical ventilation is being used, are chest movements adequate and are blood gas levels improving?** Inadequate ventilation can result in poor perfusion.
- E. Is the poor perfusion localized to only 1 area of the body?** Aortic thrombosis can present with weak femoral pulses, coldness, and **poor perfusion of the limbs.**
- F. Are congenital anomalies present?** Persistent cutis marmorata (see Section III.A.15) may be seen in Cornelia de Lange syndrome, cutis marmorata telangiectatica congenita (CMTC), Edward syndrome (trisomy 18), and Down syndrome (trisomy 21). **Chromosome 22q11 deletion syndrome** can present with abnormal vascular tone with hypotension. **Cornelia de Lange syndrome** consists of multiple congenital anomalies: a distinctive facial appearance, pre- and postnatal growth deficiency, feeding problems, psychomotor delay, behavioral problems, and malformations that mainly involve the upper extremities.
- III. Differential diagnosis**
- A. Common causes**
- 1. Sepsis.** Poor peripheral perfusion is seen as an early sign of sepsis.
 - 2. Cold stress/hypothermia.** In general, associated with a skin temperature <36.5°C (97.7°C).
 - 3. Hypotension** usually with shock.
 - 4. Hypoventilation** can cause poor perfusion.
 - 5. Respiratory distress syndrome.** Infants with respiratory distress syndrome have poor perfusion and lower perfusion index.
 - 6. Apnea/apnea of prematurity** can cause a decrease in peripheral perfusion.
 - 7. Pneumothorax.** A large pneumothorax or tension pneumothorax can cause poor perfusion.
 - 8. Hypoglycemia** can mimic hypoxemia, and poor perfusion can be seen.
 - 9. Polycythemia with hyperviscosity.** Infants have sluggish capillary refill and poor peripheral perfusion.

10. **Acute hemorrhagic anemia** due to acute blood loss can present with symptoms of hypovolemia including poor perfusion, hypotension, tachycardia, and pallor. A decrease in peripheral perfusion occurs with a 10% loss of blood volume.
 11. **Necrotizing enterocolitis.** Systemic signs are nonspecific but can include decreased peripheral perfusion.
 12. **Patent ductus arteriosus.** A hemodynamically significant patent ductus arteriosus in the first week of life can cause poor perfusion in infants <1000 g.
 13. **Left-sided obstructive heart disease.** Newborns with critical left-sided obstructive lesions (ductal-dependent systemic circulation) generally appear normal at birth, and when the ductus arteriosus begins to close, they have cardiac failure with systemic hypoperfusion (poor perfusion with cold, clammy, mottled skin), poor peripheral pulses, increasing metabolic acidosis, and shock. Cyanosis may not be seen until later. One study showed that the majority of infants presented with shock, approximately one-third presented with heart failure, and a small percentage presented with profound cyanosis. These diseases include HLHS, critical aortic stenosis (AS), coarctation of the aorta (COA) (with or without septal defect), and interrupted aortic arch (IAA). When the ductus closes, infants with COA and IAA have hypoperfusion of the lower half of the body, and infants with AS and HLHS have hypoperfusion of the entire systemic circulation.
 14. **Infant of substance-abusing mother.** Mottling can be a sign of neonatal abstinence.
 15. **Cutis marmorata** is a common vascular disorder that affects newborns and a normal physiologic response of newborns to cold. When newborns are exposed to cold, a marbling, red/blue, lacy, reticulated mottling pattern appears on the skin (usually trunk and extremities) that disappears with warming of the skin. It is due to an immature neurologic and vascular system or an exaggerated physiologic vasomotor response. It can also indicate **poor perfusion** in septic infants or in infants with shock.
 - a. **Persistent cutis marmorata** can occur in hypothyroidism, central nervous system dysfunction, cardiovascular hypertension, neonatal lupus erythematosus, Menke disease, familial dysautonomia, homocystinuria, Divry-Van Bogaert syndrome, and some congenital syndromes (Cornelia de Lange, Edward [trisomy 18], and Down [trisomy 21] syndromes).
 - b. **Cutis marmorata telangiectatica congenita, also known as Van Lohuizen syndrome.** **Cutis marmorata** needs to be distinguished from CMTC, which is a permanent rare congenial cutaneous vascular anomaly that presents as persistent cutis marmorata, telangiectasia, and phlebectasia (see Chapter 7). Vascular anomalies (Sturge-Weber syndrome and Klippel-Trenaunay-Weber syndrome) have been associated with CMTC. See Figure 7-2. CMTC does not disappear with warming of the skin.
- B. Less common causes**
1. **Enteroviral/viral or fungal infection.** Presents with poor perfusion and overwhelming sepsis.
 2. **Periventricular hemorrhage/intraventricular hemorrhage.** Presentation varies but can present with extreme signs, including sudden onset of poor perfusion, pallor, and hypotonia.
 3. **Subgaleal hemorrhage (rare).** Most commonly associated with a vacuum evacuation or forceps delivery. It progresses after birth and can have a massive amount of blood.
 4. **Inborn errors of metabolism.** Present with a history of deterioration with poor perfusion. Organic acidemia, urea cycle defects, and certain disorders of amino acid metabolism can present with poor perfusion, lethargy, and other symptoms.
 5. **Seizures.**
 6. **Hematologic.** Bleeding disorders.

7. **Adrenal problems.** Congenital adrenal hyperplasia, Addison disease, adrenal hemorrhage.
8. **Renovascular hypertension.** Presents with apnea, irritability, and mottling of the skin.
9. **Gastrointestinal problems.** Necrotizing enterocolitis (NEC), perforation, and volvulus.
10. **Systemic air embolism.** Symptoms are sudden and include mottling of the skin with pallor.
11. **Aortic thrombosis** can present with weak femoral pulses, coldness, and poor perfusion of the limbs.
12. **Chronic pain.** Infants experiencing chronic pain can exhibit decreased and poor perfusion with cool extremities.

IV. Database

A. Peripheral parameters of poor perfusion. Peripheral parameters have been used to assess peripheral circulation and cardiac output. They have not been very good indicators of low systemic blood flow; therefore, they are not great in predicting poor perfusion. Peripheral parameters include temperature, skin color, capillary refill time, acid-base balance, and urine output.

1. **Temperature (central vs peripheral temperature gradient/difference).** A central temperature (usually axillary) and a peripheral temperature (usually sole of foot) are monitored with a thermal probe. If an infant is peripherally hypoperfused, the central temperature is higher than the peripheral temperature. A gradient increase of $>2^{\circ}\text{C}$ may be an early indication of cold stress and is noted in infants with sepsis.
2. **Skin color.** Color change can be seen with poor perfusion (washed out, pallor, mottled appearance, acrocyanosis).
3. **Capillary refill time** is the time required for the normal skin color to return after a blanching pressure has been applied. It is measured by pressing on the chest, midpoint of the sternum (better intraobserver repeatability), or forehead for 5 seconds with a finger and noting the time needed for the color to return. Upper limit of normal for capillary refill is <3 seconds. **Delayed capillary refill (>3 – 4 seconds)** is a sign of tissue hypoperfusion and had a sensitivity of 55% and a specificity of 81% for predicting low superior vena cava flow in 1 study. One study found that low birthweight infants have lower capillary refilling time when compared with infants >2500 g.
4. **Acid-base balance.** Metabolic acidosis and base deficit are seen with poor perfusion.
5. **Urine output.** Oliguria (decreased urine output) can be seen with poor perfusion and can indicate reduced kidney perfusion.
6. **Other markers of poor perfusion**
 - a. **Decreased pulses** can be seen with poor perfusion.
 - b. **Warmth of extremities.** Cold extremities can indicate poor peripheral perfusion, and warm extremities can indicate normal peripheral perfusion. Warmth of extremities is not that reliable in neonatal intensive care unit infants since they are usually under the radiant warmer or in the incubator.
 - c. **Blood pressure** is used as a marker of systemic organ perfusion, but there is a poor correlation between blood pressure and cardiac output, and it may not reflect blood flow in the end organs.
 - d. **Left ventricular output** is a measurement of systemic blood flow in adults but not in infants since it not a true measure of systemic blood flow but a measure of systemic blood flow with shunt flow (through the patent ductus or foramen ovale).

B. Physical examination. Check vital signs (heart rate, core temperature, blood pressure). Examine for weak pulses and look for signs of sepsis. The cardiovascular and pulmonary examinations are important because they may suggest cardiac problems

or pneumothorax. Does the infant have an S_3 gallop with or without a cardiac murmur (left-sided, obstructive, ductal-dependent heart lesion)? Signs of trisomy 18 include micrognathia and overlapping digits. Signs of trisomy 21 include a single palmar transverse crease and epicanthal folds. Look for scalp swelling to rule out subgaleal hemorrhage. Abdominal distension can be seen with gastrointestinal problems.

C. Laboratory studies

1. **Complete blood count to evaluate for sepsis or decreased/increased hematocrit** (eg, polycythemia or blood loss).
2. **Blood gas. Metabolic acidosis and base deficit** are markers of poor perfusion. The blood gas can reveal inadequate ventilation or the presence of acidosis (seen in sepsis, shock, NEC, and other disorders). Persistent metabolic acidosis can be seen in subgaleal hemorrhage.
3. **Serum lactate level** is a marker of poor perfusion. A level >3.0 mmol/L can predict low blood flow, and a level >6.0 mmol/L is associated with morbidity and mortality.
4. **Serum creatinine** is a marker and gauge for kidney function. It is a late marker because at least 50% loss of function has to occur before the serum creatinine increases.
5. **Blood glucose levels.** To rule out hypoglycemia.
6. **Cultures.** If sepsis is suspected, a complete workup should be considered, especially if antibiotics are to be started. This workup includes cultures of blood, urine, and spinal fluid (if indicated). If enteroviral infection is suspected, send for viral cultures.
7. **Polymerase chain reaction.** Studies of stool and cerebrospinal fluid and nasopharyngeal or throat swab for *Enterovirus* and other viruses.
8. **Inborn errors of metabolism.** See Chapter 100 for appropriate tests.

D. Methods of measuring peripheral perfusion

1. **Peripheral perfusion index.** The perfusion index is an indication of the blood flow to the peripheral tissue and can correlate with the capillary refill time. **This can be derived from the pulse oximeter.** As an example, the light-emitting diode–based infrared Masimo™ pulse oximeters such as Rad-5 and Rad-5v (Masimo, Irvine, CA) display perfusion index as the pulse amplitude index, where the height of the bar represents the pulse strength (info-america@masimo.com). It continuously measures the ratio of the pulsatile blood flow (arterial) to the nonpulsatile blood (static blood in peripheral tissue). It correlates with superior vena cava flow and is useful in monitoring changes in peripheral perfusion. A low value indicates low peripheral perfusion and is associated with low superior vena cava blood flow. **Normal median perfusion index values for stable preterm infants:** on day 1 is 0.9, day 3 is 1.2, and day 7 is 1.3.
2. **Near-infrared spectroscopy** is a noninvasive continuous measure of tissue oxygenation in a specific tissue bed. A spectrophotometer is used, and a cerebral probe is placed on the left or right side of the forehead or a somatic region (renal area, abdomen, upper or lower extremities) such as the INVOS™ Cerebral/Somatic Oximeter (Covidien, Boulder, CO). It is used to measure **regional hemoglobin oxygen saturation (rSO₂)** and can measure oxygenation in the brain, renal area, abdomen (liver), skeletal muscle, and upper and lower extremities. It can be used at the bedside to identify complications of low cardiac output, renal failure, shock, seizures, and neurologic damage. A downward trend in rSO₂ may be an early sign of low cardiac output. Somatic desaturations are an early sign of shock. Cerebral desaturations are a late sign of shock. It is used in left-sided obstructive lesions to monitor for low cardiac output.
3. **Orthogonal polarization spectral imaging and sidestream darkfield imaging** are other noninvasive, noncontinuous transdermal methods to measure capillary density and visualize microcirculation. They allow measurement or assessment of peripheral tissue perfusion in term and preterm infants. They also give an indirect measure of oxygen delivery.

- 4. Laser Doppler flowmetry** has been used in evaluating peripheral perfusion in newborns. A laser beam penetrates an area of the skin and hits the red blood cells in the capillaries, venules, and arterioles; this is converted into scattered light, and a probe recognizes it and calculates a relative value of blood flow. One study found not only that blood flow in the skin correlated with systemic blood flow, but also that low skin blood flow of the feet by laser Doppler flowmetry at 18 and 24 hours after birth predicted intraventricular hemorrhage in very low birthweight infants.
- 5. Targeted Doppler echocardiography measuring superior vena cava flow.** Superior vena cava flow is a marker for systemic blood flow but is difficult to measure. Studies show that a superior vena cava flow <40 mL/kg/min in preterm infants correlates with poor neurodevelopmental outcome and late-onset intraventricular hemorrhage.
- 6. Cardiac magnetic resonance imaging measurements** of systemic blood flow are being investigated, but it is difficult to perform this procedure in infants who are extremely premature and ill.
- 7. Markers of perfusion.** The various clinical measurements over time associated with progressive poor perfusion are illustrated in Figure 77–1. The daily baseline rSO₂ numbers in preterm infants (29–34 weeks' gestation) decrease over the first few weeks of life (cerebral baseline 66%–83% rSO₂; renal 64%–87% rSO₂; abdominal 32%–66% rSO₂).

E. Imaging and other studies

- 1. Transillumination of the chest** (see Chapters 31 and 44) can be performed emergently to help determine whether or not a pneumothorax is present.
- 2. Chest radiograph** if pneumonia, pneumothorax, congenital heart lesion, or hypoventilation is suspected. In left-sided heart lesions, the radiograph shows cardiomegaly with pulmonary venous congestion (except in HLHS, in which the size of the heart may be normal). If a view taken during lung expansion shows that the lungs are down only to the sixth rib or less, hypoventilation should be considered. With hyperventilation, lung expansion is down to the ninth or tenth rib. See Figure 12–19 for a radiograph of pneumonia. See Figure 12–24 for radiograph showing a pneumothorax.
- 3. Abdominal radiograph** if NEC is suspected. See Figure 12–27 for a radiograph demonstrating pneumatosis intestinalis seen in NEC. Air can be seen with a perforation. Obstruction can be seen with malrotation with volvulus.
- 4. Echocardiography** should be performed if a congenital heart lesion is suspected. In HLHS, a large right ventricle and a small left ventricle are seen on the echocardiogram, and there is failure to visualize the mitral or aortic valve. In AS, the echocardiogram reveals a deformed aortic valve. In COA, it reveals decreased aortic diameter. In venous air embolism, one can see acute obstruction of the right ventricle outflow tract.
- 5. Head ultrasound** to rule out intraventricular bleed. Optimal imaging for subgaleal hemorrhage is by computed tomography or magnetic resonance imaging.
- 6. Computed tomography of the head** to look for intracranial air bubbles if systemic air embolism suspected. CT is also used to rule out subgaleal hemorrhage.
- 7. Karyotyping or molecular genetic testing** if trisomy 18 or 21 or a deletion is suspected. Cornelia de Lange syndrome has mutations in the *NIPBL* and *SMC3* genes.

V. Plan

- A. Immediate plan.** Infants with a low blood pressure and clinical signs of poor perfusion may be in shock and need to be urgently treated with fluids or pressors. An initial quick workup should be performed. While checking vital signs and quickly examining the patient, order a stat blood gas and a chest radiograph. Initiate oxygen supplementation and transilluminate the chest if a pneumothorax is suspected. Send a stat complete blood count and differential and blood culture.

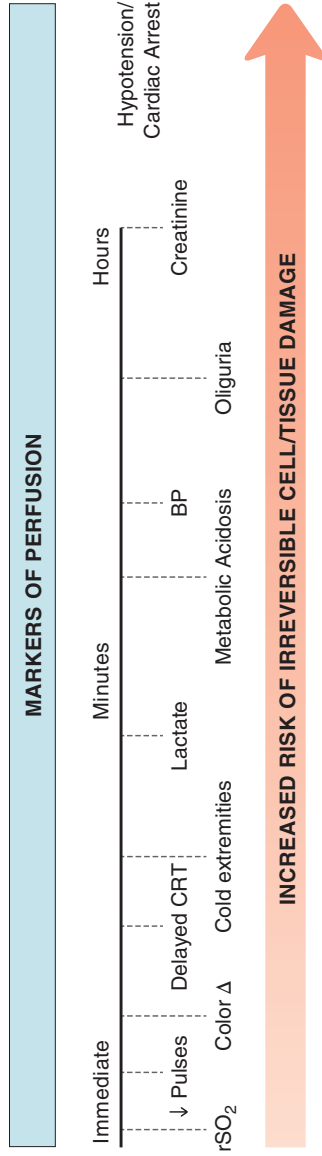

FIGURE 77-1. Time line illustrating progressive alterations in key markers of perfusion. BP, blood pressure; CRT, capillary refill time; rSO₂, regional hemoglobin oxygen saturation. (Used with permission from *William I. Douglas, M.D.*)

B. Specific plans

1. **Sepsis.** Full cultures and empirical antibiotic therapy may be started at the discretion of the physician.
2. **Cold stress.** Gradual rewarming is necessary, usually at a rate of $\leq 1^\circ\text{C}/\text{h}$. It can be accomplished by means of a radiant warmer, incubator, or heating pad. (See Chapter 8.)
3. **Hypotension or shock.** If the blood pressure is low because of depleted intravascular volume, give crystalloid (normal saline) 10 mL/kg intravenously for 5 to 10 minutes. (See Chapter 70.)
4. **Hypoventilation.** If suspected, it may be necessary to increase the pressure being given by the ventilator. The amount of pressure must be decided on an individual basis. One method is to increase the pressure by 2 to 4 cm H_2O and then obtain blood gas levels in 20 minutes. Another method is to use bag-and-mask ventilation, observing the manometer to determine the amount of pressure needed to move the chest.
5. **Pneumothorax.** See Chapter 75.
6. **Hypoglycemia.** See Chapter 67.
7. **Polycythemia.** See Chapters 76 and 116.
8. **Anemia secondary to acute blood loss.** See Chapter 88.
9. **Necrotizing enterocolitis.** See Chapter 109.
10. **Left-sided obstructive heart lesions.** Initial stabilization with respiratory support (endotracheal intubation and mechanical ventilation if poor respiratory effort and hypoxemia), volume resuscitation, inotropic support with dopamine for low cardiac output, and correction of metabolic acidosis. Immediate cardiac consultation. Prostaglandin E_1 is considered before diagnosis is confirmed if ductal-dependent systemic blood flow is suspected. The infant should be stabilized and transferred to a pediatric cardiac center. Surgery is usually indicated in all these patients. For a full discussion of cardiac abnormalities, see Chapter 94.
11. **Cutis marmorata.** If this condition is secondary to cold stress, treat the patient as described in Section V.B.2. Cutis marmorata usually resolves within weeks to months, and no formal treatment is necessary. If the condition persists, consider thyroid testing for hypothyroidism or formal genetic testing for various syndromes noted. If central nervous system dysfunction is suspected, this should be evaluated further.
12. **Periventricular hemorrhage/intraventricular hemorrhage.** Initial supportive care (eg, maintain blood pressure, stabilize blood gases, transfuse if necessary, treat for seizures). After stabilization, close follow-up is required. Serial lumbar punctures may be necessary. (See also Chapter 103.)
13. **Subgaleal hemorrhage.** Early recognition, appropriate resuscitation, supportive care as in volume replacement, blood transfusion, and coagulation factors if necessary. Pressure wrapping of the head is *controversial*.
14. **Inborn errors of metabolism.** See Chapter 100.
15. **Seizures.** See Chapters 82 and 120.
16. **Hematologic problems.** Blood transfusions and diagnosing and treating the specific bleeding disorder are necessary.
17. **Adrenal insufficiency.** Blood volume replacement and steroid therapy are usually necessary.
18. **Renovascular hypertension.** Usually treated with aggressive medical management.
19. **Intestinal problems.** See Chapters 109 and 121.
20. **Enteroviral infections.** Supportive management. See Chapter 134.
21. **Systemic air embolism.** Supportive cardiac and respiratory care. One hundred percent oxygen therapy, hyperbaric oxygen.
22. **Chronic pain.** See Chapter 15.

78 Postdelivery Antibiotics

I. Problem. Two infants were born within the past hour. One infant's mother had premature rupture of membranes (PROM) but no antibiotics. The other infant's mother was pretreated with antibiotics for a positive group B *Streptococcus* (GBS) culture taken at 36 weeks. Who should be evaluated, and who should receive empiric antibiotics? It is necessary to review some of the basic concepts of early-onset sepsis (EOS), such as definition, pathogenesis, incidence morbidity, and mortality, before treatment plans are discussed. Major organizations have varying recommendations on EOS. **This on-call problem focuses on postdelivery antibiotics for suspected EOS. Late-onset sepsis is discussed in Chapter 146,** and infections of premature infants with prolonged hospital stays may require a different workup and antibiotic choice.

A. Definition of early-onset sepsis. There are multiple definitions:

1. **The National Institute of Child Health and Human Development and Vermont Oxford Network:** The onset of sepsis at ≤ 72 hours of life. In term infants, it can be extended to < 7 days of life.
2. **The Centers for Disease Control and Prevention:** Blood culture- and/or cerebrospinal fluid (CSF) culture-proven infection occurring in the newborn at < 7 days.
3. **The American Academy of Pediatrics (2018):** Blood or CSF culture obtained within 72 hours after birth that is growing a pathogenic bacterial species.
4. **AAP definition of GBS EOS (2019).** Isolation of group B *Streptococcus* organisms from the blood, cerebrospinal fluid, or another normally sterile site from birth through 6 days of age.

B. Pathogenesis of early-onset sepsis differs in the term/late preterm infant and the preterm infant.

1. **Early-onset sepsis in the term/late term infants occurs most commonly during labor.**
 - a. **Vertically transmitted (ascending infection).** Ascending colonization with amniotic membrane rupture/leak before or during labor resulting in infection of the uterine compartment (amniotic fluid, placenta, umbilical cord, or fetus) with maternal gastrointestinal/genitourinary flora. The fetus can become infected by being colonized on the skin/mucous membranes (sepsis develops hours or days after birth), or the fetus aspirates or swallows infected amniotic fluid (sepsis begins in utero). GBS can also enter amniotic fluid through an occult tear. This is the most common cause of GBS early-onset disease (GBS EOD).
 - b. **Direct contact in the birth canal.** The neonate can acquire the pathogen as it passes through the colonized birth canal during delivery.
 - c. **Transplacentally by hematogenous spread.** Rarely, EOS develops before the onset of labor (eg, *Listeria monocytogenes* is typically transmitted from the mother to the fetus by hematogenous spread across the placenta).
2. **Early-onset sepsis in the preterm infant occurs most commonly before the onset of labor.**
 - a. **Intra-amniotic infection** from either microbial induced maternal inflammation (vaginal organisms) or the transplacental pathway (maternal oral flora or *Listeria monocytogenes*).
 - b. **Inflammation secondary to immune-mediated rejection** of the fetus or placenta from a maternal extrauterine infection or reproductive/nonreproductive microbiota.

- C. Incidence of early-onset sepsis** is highest among preterm and very low birthweight (VLBW) infants, and cases are inversely proportional to gestational age. EOS incidence is also higher among late preterm infants than term infants. The incidence of culture-proven EOS is approximately 0.8 cases per 1000 live births, 0.5 cases per 1000 live births at >37 weeks' gestation, 1 case per 1000 live births at 34 to 36 weeks' gestation, 6 cases per 1000 live births at <34 weeks' gestation, 20 cases per 1000 live births at <29 weeks' gestation, and 32 cases per 1000 live births at 22 to 24 weeks' gestation. Since the institution of the Centers for Disease Control and Prevention (CDC) guidelines (endorsed by the American Academy of Pediatrics [AAP]) for GBS prophylaxis, the incidence of early-onset GBS has decreased from an incidence of 1.8 cases per 1000 live births in 1990 to 0.23 cases per 1000 live births in 2015. Recent studies have shown that the incidence among VLBW infants (9–11 per 1000 live births in infants <1000 g) has also decreased.
- D. Organisms that cause early-onset sepsis.** Overall, GBS is most common, followed by *Escherichia coli*.
- 1. Term/late preterm infants:** GBS in 40% to 45% of cases and *E coli* in 10% to 15% of cases, with the remainder secondary to other gram-positive organisms (viridans and enterococci) and other gram-negative organisms (5%). Rare causes include *Staphylococcus aureus* (3%–4%) and *L monocytogenes* (1%–2%).
 - 2. Preterm infants:** *E coli* in 50% of cases, GBS in 25%, 10% other gram-positive organisms (viridans and enterococci), and 20% other gram negatives. Rare causes include fungal (<1%), *S aureus* (1%–2%), and *L monocytogenes* (1%). Anaerobic bacteria are present in approximately 15% of EOS cases (*Bacteroides fragilis* most common).
- E. Morbidity and mortality in early-onset sepsis.** Mortality is 2% to 3% in term infants, with 75% of deaths attributable to EOS in VLBW infants. Mortality estimates based on gestational age are as follows: 1.6% at ≥37 weeks, 2% to 3% at ≥35 weeks, 30% at 25 to 28 weeks, and 50% at 22 to 24 weeks. Mortality by birthweight is as follows: 3.5% if born weighing >1500 g and 35% if weighing <1500 g. Up to 60% of term infants and 95% of preterm infants require neonatal intensive care unit (NICU) care for respiratory distress and/or blood pressure support. Up to 50% of term infants with GBS can suffer serious morbidity (seizures, blindness, deafness, and cognitive delays). GBS EOD is also associated with stillbirth.
- F. Multiple protocols exist. Which one should be used?** There are multiple protocols for evaluation and treatment of EOS. The AAP and ACOG have published new guidelines specifically for management of GBS EOD in 2019 that officially replace prior recommendations from the CDC (last updated in 2010). AAP also recently published separate guidelines on the management of early-onset sepsis in both term/late preterm infants, and preterm infants (2018). **The AAP describes 3 primary approaches to risk assessment for term/late preterm infants that can be used, and recommend that the clinical approach for infants at risk for GBS EOD should be the same as that used for all bacterial causes of early-onset sepsis.** The AAP also states that the best approach to GBS EOD management for preterm infants involves the circumstances of preterm birth and recommends strategies based on that. In addition, a National Institute of Child Health and Human Development (NICHD) workshop (2016) published recommendations for management, and there are also various septic scoring systems available (that are referenced in the AAP guidelines). In a review of 97 nurseries located throughout the United States, 51 reported using the AAP/CDC guidelines to evaluate infants, while 11 used published sepsis risk calculators (discussed later), and 2 used clinical observation alone.

II. Immediate questions

- A. Are there any risk factors in the infant?** Risk factors vary depending upon which protocol or scoring system is used.

1. **American Academy of Pediatrics EOS Guidelines (2018) risk factors in term/late preterm or preterm infants**
 - a. **Term/late preterm infants:** Gestational age, maternal intra-amniotic infection (formerly chorioamnionitis), duration of rupture of membranes (ROM), maternal GBS colonization, appropriate intrapartum antibiotics given, and infant's clinical condition. Other risk factors that are not independent predictors include African American race, twin gestation, fetal tachycardia, and meconium-stained amniotic fluid (MSAF).
 - b. **Preterm infants:** The only risk factor that has been easy to quantify is gestational age. **Gestational age is the strongest predictor of EOS.** Infants who are born preterm because of the following are considered high risk for EOS: preterm labor, cervical incompetence, PROM, intra-amniotic infection (previously chorioamnionitis), and unexplained onset of non-reassuring fetal status.
 2. **AAP GBS EOD (2019) risk factors:** Lower gestational age, increased ROM, maternal intrapartum fever, African American race, maternal age <20 years, delivery of a previous infant with GBS, obstetric practices that may promote ascending bacterial infection (observational studies only) such as invasive fetal monitoring, membrane sweeping, frequent intrapartum vaginal examinations.
 3. **NICHD.** Based on whether there was an isolated maternal fever (maternal oral temperature $\geq 39^{\circ}\text{C}$ on any one occasion is documented fever), or suspected triple I, defined as fever without a clear source plus any of the following: fetal tachycardia (>160 bpm for 10 minutes or longer), maternal WBC >15,000 (in the absence of corticosteroids), purulent fluid from the cervical os. Confirmed triple I requires all of the above plus amniocentesis proven infection (positive gram stain), low glucose or positive amniotic fluid culture, or placental pathology revealing diagnostic features of infection.
 4. **Kaiser Permanent septic score risk factors.** Local incidence of EOS, gestational age in weeks and days, highest maternal antepartum temperature, hours of ROM, maternal GBS status, and type and timing of intrapartum antibiotics. A risk for EOS is calculated at birth based on this information. An EOS risk after clinical exam is also calculated. (See Section V.D.2 below.)
- B. Are signs of sepsis present in the infant? In all guidelines for clinical management, distinguishing between asymptomatic infants and infants with signs of illness is critical when determining the next steps.** Signs of sepsis are nonspecific (80%–100% of infected infants exhibit signs within the first 48 hours after birth) and can include apnea and bradycardia, temperature instability (more frequently hypothermia), feeding intolerance, tachypnea, jaundice, cyanosis, poor peripheral perfusion, hypoglycemia, lethargy, poor sucking reflex, increased gastric aspirates, and irritability. Other signs include tachycardia, shock, vomiting, seizures, abnormal rash, abdominal distention, and hepatomegaly. Neonatal sepsis is associated with systolic and diastolic myocardial dysfunction. Bacteremia can also occur without clinical signs. Preterm infants who are septic may have bradycardia, cyanosis, and apnea. Newborn infants with GBS EOD present clinically at or shortly after birth. Most infants become symptomatic by 12 to 24 hours of age. They can present with the following: tachypnea, tachycardia, lethargy, severe cardiorespiratory failure, persistent pulmonary hypertension, and perinatal encephalopathy.
- C. Was the mother tested for group B *Streptococcus*, and did she receive adequate intrapartum antibiotic prophylaxis if she tested positive?** The AAP and ACOG have recently published guidelines for the prevention and management of GBS EOD in newborns (2019), which replace the prior guidelines published by the CDC (and endorsed by the AAP). All pregnant women should undergo antepartum screening for GBS at 36 0/7 to 37 6/7 weeks of gestation, and receive appropriate intrapartum

antibiotic prophylaxis unless a cesarean section is performed prior to labor and with intact membranes. For the purposes of assessing risk of GBS disease in the infant, only penicillin, ampicillin, and cefazolin administered >4 hours prior to delivery are considered adequate intrapartum prophylaxis.

- D. Did the mother have a fever?** The incidence of intrapartum fever ($\geq 38.0^{\circ}\text{C}$ [$\geq 100.4^{\circ}\text{F}$]) is estimated to be present in approximately 6% to 9% of deliveries ≥ 36 weeks' gestation. In a study of >6000 deliveries, 412 mothers had intrapartum fever and only 1 developed EOS, with no significant difference in the rate of EOS among those deliveries with intrapartum fever and those without. In VLBW infants, only approximately 23% of culture-proven sepsis was associated with a maternal fever.
- E. Did the mother have signs of suspected intra-amniotic infection?** Isolated maternal fever is not synonymous with an intra-amniotic infection (formerly chorioamnionitis; see later discussion regarding terminology changes). A confirmed diagnosis of intra-amniotic infection is difficult to make prior to delivery. Maternal signs concerning for suspected intra-amniotic infection include maternal intrapartum fever (single maternal temperature $\geq 39.0^{\circ}\text{C}$ [102.2°F] or a persistent temperature of 38.0 – 38.9°C [100.4 – 102°F]) with 1 or more of the following: maternal leukocytosis, purulent cervical drainage, or fetal tachycardia.

1. Recent recommended terminology updates. In January 2015, the NICHD proposed replacing the term *CAM* (*chorioamnionitis*) with *intrauterine inflammation or infection or both* (*triple I*). Triple I is defined as maternal fever ($>39^{\circ}\text{C}$ [102.2°F] once or 38°C [100.4°F] twice) plus 1 or more of the following: fetal tachycardia (>160 beats/min for >10 minutes); maternal WBC $>15,000/\text{mm}^3$ in the absence of corticosteroids; purulent fluid from the cervical os; or biochemical or microbiologic amniotic fluid results consistent with microbial invasion. The NICHD further suggested categorizing cases as isolated maternal fever (when additional criteria are not met), suspected triple I (in the absence of objective evidence of infection in amniotic fluid), or confirmed triple I (when criteria are accompanied by objective evidence of amniotic fluid infection, which may ultimately be retrospective based on pathology). In 2017, the American College of Obstetricians and Gynecologists (ACOG) endorsed this change in terminology, suggesting that chorioamnionitis be replaced with intra-amniotic infection and adopting the distinction between confirmed and suspected cases. The AAP 2018 guidelines on EOS also reflect this change.

2. Risk factors for intra-amniotic infection include spontaneous labor, low parity, multiple digital vaginal examinations, MSAF, presence of genital tract microorganisms, prolonged active labor, prolonged ROM, and internal fetal or uterine monitoring. Studies of MSAF in isolation have not shown it to be an independent risk factor for early-onset neonatal sepsis. A recent Cochrane review identified 4 randomized controlled trials evaluating efficacy of antibiotics in preventing sepsis in infants born through MSAF and found no difference in the rate of confirmed sepsis.

III. Differential diagnosis. Helps to guide further workup and treatment.

- A. Culture-proven sepsis.** Positive cultures (eg, blood or CSF) confirm sepsis diagnosis.
- B. Suspected sepsis.** An infant has nonspecific signs of sepsis, or there is a high likelihood that the infant has sepsis based on clinical signs. Sepsis needs to be ruled out in the infant. From 18% to 33% of infants with negative blood cultures have sepsis confirmed at autopsy. Noninfectious syndromes (respiratory distress syndrome [RDS]) can mimic sepsis.
- C. Increased risk for sepsis.** The infant has risk factors based on AAP or CDC guidelines or NICHD workshop.

- D. Infant at low risk for sepsis.** Newborns without the risk factors noted previously are at low risk of sepsis.

IV. Database

- A. Complete maternal, perinatal, and birth history** should be obtained and reviewed to identify risk factors, as noted previously. **Maternal history is just as important as the birth history.** It is important to discuss the possibility of intra-amniotic infection with the obstetrician and carefully consider whether the mother has a suspected or confirmed infection.
- B. Physical examination.** Most infants with EOS exhibit abnormal signs in the first 24 hours of life. Observe for signs of sepsis (see Section II.B). Clinical observation is important, such as affect, peripheral perfusion, and respiratory status were key predictors in sepsis compared with feeding patterns, level of activity, and level of alertness in 1 study. The maternal clinical examination should be reviewed with the obstetrics and gynecology service. **Key point: EOS does occur in infants who appear healthy at birth.**

C. Laboratory studies

- 1. Definitive laboratory studies for early-onset sepsis:** Blood culture, LP.

- a. Peripheral blood cultures are the gold standard for diagnosis of sepsis and should be obtained prior to starting antibiotics.** Small specimen volumes decrease the sensitivity (a minimum of 1 mL per single bottle is recommended for optimal recovery of organisms). Using 2 separate culture bottles is advantageous to allow comparison (contamination vs true infection). Using aerobic and anaerobic systems will allow one to rule out rare strict anaerobic species. Most neonatal pathogens (GBS, *E coli*, and *S aureus*) also grow on aerobic cultures. Contemporary blood cultures can reliably detect bacteremia at 1 to 10 colony-forming units/mL. Collection systems also contain antimicrobial neutralization elements. Optimum ways to obtain blood culture in a neonate include the following (fresh vein is preferred to reduce contamination): peripheral vein, arterial puncture, newly placed intravenous (IV) catheter, and umbilical artery catheter immediately after placement. Risk of contamination is greater with umbilical vein blood culture. Umbilical venous catheter at delivery is also acceptable if the cord is adequately prepared (double clamped and adequately prepared segment of the cord).
- b. Lumbar puncture.** The use of an LP for CSF examination in EOS involves many factors. Is the infant stable enough for the procedure? Will obtaining the procedure delay starting antibiotics? **AAP guidelines for both term/late preterm and preterm infants recommend that an LP be considered in infants who are “at the highest risk of infection, especially those with critical illness.”**

- i. Term and late preterm infants:** Infants with clinical signs of illness are considered to be at the highest risk for sepsis, and in those patients it is recommended that an LP is performed prior to initiating antibiotics, **if feasible, and ensuring it does not delay the initiation of antibiotics.** If the LP cannot be done prior to antibiotic initiation, it can be reserved for cases in which the blood culture is positive. If blood cultures are negative, the incidence of culture confirmed meningitis is low (1–2 cases/100,000 live births). Culture confirmed meningitis in term infants is rare (0.01–0.02 cases/1000 live births).
- ii. Preterm infants:** The incidence of meningitis is higher among premature infants (0.7 cases per 1000 births) than among overall births. LP is recommended, as discussed earlier for term infants, prior to the start of antibiotics. If this is not possible, the physician needs to make the decision on whether to do an LP in a critically ill infant based on the

clinical status of the infant, the risk of EOS, and the risk of prolonged antibiotic therapy.

- iii. **The lumbar puncture also helps to rule out viral etiologies** such as enteroviral infection, herpes virus infection, *Parechovirus* meningitis, and meningoencephalitis.
 - iv. **Cerebrospinal fluid values in neonatal meningitis are controversial**, and meningitis can occur with normal CSF values. A study evaluating >9000 infants >34 weeks used a CSF WBC cutoff of 20 cells/mm³, which resulted in missed diagnoses in 13% of infants with confirmed meningitis. While culture remains the gold standard for evaluation of the CSF, emerging technologies such as real-time polymerase chain reaction (PCR) have an overall higher detection rate, particularly in infants who have already received antibiotics. Examples from a study on meningitis CSF lab results include the following:
 - (a) **Uninfected preterm/term infants:** Mean WBC <10 cells/mm³.
 - (b) **Infants >34 weeks' gestation with bacterial meningitis:** Median WBC >477 mm³.
 - (c) **Infants <34 weeks' gestation with meningitis:** Median WBC 110/mm³.
 - v. **Helpful facts when deciding on meningitis lab results:**
 - (a) **Infants with gram-negative meningitis** have a higher CSF WBC count than infants with gram-positive pathogens.
 - (b) **Number of bands** in the CSF does not predict meningitis.
 - (c) **If there is a >2-hour delay at the lab**, WBC and glucose decrease.
 - (d) **Cerebrospinal fluid protein concentrations in healthy term infants** are <100 mg/dL, and in preterm infants, they vary inversely with gestational age.
 - (e) **Low cerebrospinal fluid glucose** has the best specificity to diagnose meningitis.
 - (f) **In meningitis, protein concentrations are higher** and glucose concentrations are lower in term infants than preterm infants.
2. **Additional laboratory testing to be considered.** The most recent guidelines by the AAP (as well as NICHD and the Kaiser Sepsis Calculator) no longer explicitly recommend evaluating infants with additional laboratory testing other than blood culture (and lumbar puncture, if clinically indicated). There are no recommendations regarding early cessation of antibiotics based on additional laboratory testing, or continuing empiric antibiotics in the presence of a negative blood culture due to abnormal secondary laboratory testing. **Blood culture is the gold standard for identifying early onset sepsis.** The following tests can be considered in individualized cases when clinically appropriate:
- a. **Complete blood count with differential.** AAP states that using complete blood counts (CBC) alone to determine the risk of GBS EOD is not justified since it has a poor test performance in predicting disease. Immature/total neutrophil ratio (I/T) and absolute neutrophil count (ANC) are the most commonly used WBC count parameters. Many factors affect the WBC count some of which are gestational age, sex, mode of delivery, maternal preeclampsia, and placental insufficiency as well as PROM can cause bone marrow depression in the fetus and an abnormal WBC without an infection. Studies have found that the CBC lacked sensitivity for predicting EOS. A single CBC is not helpful when compared to serial tests. Timing of the CBC is important; an early CBC is not recommended, a CBC at 6 to 12 hours is optimal, after the inflammatory response has occurred. In general, **a CBC has a better negative predictive value (ability to rule out infection) than a positive**

predictive value (ability to rule in infection), especially when using serial measurements. Extreme values were associated with a higher likelihood of infection: WBC <1000 cells/uL, ANC <1000, I/T neutrophil >0.25 was associated with an infection in infants <34 weeks' gestation.

- i. **Total white blood cell count.** Abnormally low or high WBC count is worrisome. Values <6000 cells/mm³ or >30,000 cells/mm³ in the first 24 hours of life are abnormal. Only half of infants with WBC <5000 cells/mm³ or WBC >20,000 cells/mm³ have positive blood cultures. As many as 50% of infants with culture-proven sepsis have normal WBC counts. Septic infants with a WBC count <5000 cells/mm³ are more likely to have bacterial meningitis.
- ii. **Total neutrophil count.** Includes segmented (fully mature) neutrophils and bands (almost mature neutrophils). Total neutrophil count is more sensitive than the total leukocyte count but is too often normal in cases of infection. It peaks in 12 hours, and it has a poor sensitivity and poor predictive accuracy for EOS. See Table 78–1 for total neutrophil counts for variable gestational ages, Table 78–2 for neutrophil values in late preterm and term infants, and Table 78–3 for neutrophil values in VLBW infants.
- iii. **Immature neutrophil count (bands).** If >20%, it is considered abnormal. The total immature neutrophil count has poor sensitivity but better positive predictive value. See Table 78–2.
- iv. **Ratio of immature to total neutrophils.** The greatest value relies in its negative predictive value; the likelihood of infection is minimal if the I: T ratio is normal. Reference ranges for late preterm and term infants are shown in Table 78–2. In most healthy preterm infants at <32 weeks (96%), the I: T ratio is <0.22. A study of serial neutrophil values demonstrated that a combination of 3 separate neutrophil values (total neutrophils, immature neutrophils, and I: T ratio), obtained serially over the first 24 hours of life, had the greatest negative predictive value for EOS among WBC markers.
- v. **Neutropenia** is a decrease in the number of neutrophils and a good marker for sepsis because of its relatively small differential. It generally occurs only in sepsis, asphyxia, inborn errors of metabolism, hemolytic disease, and pregnancy-induced maternal hypertension. Neutropenia is more common in small for gestational age and low birthweight neonates. Early-onset neutropenia in small for gestational age infants, usually secondary to decreased production of neutrophils due to intrauterine hypoxia, can last up to 1 week, is associated with

Table 78–1. NEONATAL TOTAL NEUTROPHIL COUNT^a REFERENCE RANGES ($\times 10^3/\text{MM}^3$) (5%–95%)

Variable	Birth	12 Hours	24 Hours	48 Hours	72 Hours	>72 Hours
Term infants (>36 weeks)	3.5–18	7.5–27.5	7.0–22.5	4.2–15.8	2.8–12.9	2.7–13
28–36 weeks	1–10	3.5–25	2.8–19.2	1.7–15.8	0.5–12.5	1.0–12.5
<28 weeks	0.5–8	1.2–34	1.2–40	0.5–26	0.5–23	1.3–153

^aTotal count includes mature and immature forms.

Data from Schmutz N, Henry E, Jopling J, et al: Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited, *J Perinatol*. 2008 Apr;28(4):275-281.

Table 78–2. NEONATAL NEUTROPHIL INDICES REFERENCE RANGES FOR LATE PRETERM AND TERM INFANTS (PER MIM³)

Variable	Birth	12 Hours	24 Hours	48 Hours	72 Hours	>120 Hours
Absolute total neutrophil count ^a	1800–5400	7800–14,400	7200–12,600	4200–9000	1800–7000	1800–5400
Total immature neutrophil count ^b	≤1120	≤1440	≤1280	<800	<500	<500
I:T ratio ^c	<0.16	<0.16	<0.13	<0.13	<0.13	<0.12

^aTotal count includes mature and immature forms. Derived from the white blood cells and the percentage of neutrophils.

^bIncludes all neutrophils except segmented ones.

^cRatio of immature to total neutrophils (total immature neutrophil count divided by absolute total neutrophil count).

Table 78–3. REFERENCE RANGES FOR NEUTROPHIL COUNTS IN VERY LOW BIRTHWEIGHT INFANTS (<1500 G)

Age	Absolute Total Neutrophil Count (mm ³) (range)
Birth	500–6000
18 hours	2200–14,000
60 hours	1100–8800
120 hours	1100–5600

Data from Mouzinho A, Rosenfeld CR, Sánchez PJ, et al: Revised reference ranges for circulating neutrophils in very-low-birth-weight neonates, *Pediatrics*. 1994 Jul;94(1):76-82.

thrombocytopenia, and has an increased risk of necrotizing enterocolitis (NEC). The neutropenia ranges depend on gestational age (WBC count increases with gestational age), type of delivery (vaginal births have higher WBC counts than cesarean section without labor), type of sample (arterial samples give lower WBC counts than venous samples), and altitude (WBC counts are higher at higher altitudes). Tables 78–2 and 78–3 show historical results for late preterm/term infants and low birthweight infants, respectively.

b. Acute phase reactants (C-reactive protein and procalcitonin) have been studied to help identify infants with sepsis. Both CRP and procalcitonin concentrations can be increased in response to infections or noninfectious conditions such as asphyxia, pneumothorax, ischemic tissue injuries, hemolysis, and meconium aspiration syndrome. The AAP states that using CRP alone to determine the risk of GBS EOD is not justified since it has a poor test performance in predicting disease.

i. C-reactive protein is the acute phase reactant that has been the best studied in sepsis. An increasing CRP is worrisome and is elevated in 50% to 90% of infants with sepsis. CRP increases at 6 to 8 hours and peaks at 24 hours. If CRPs remain normal, sepsis is less likely. Early CRP should not be used to rule out sepsis because it is unreliable at the initial time of a sepsis evaluation. In a study of almost 1000 infants with culture-proven sepsis, CRP was <1 mg/dL (normal) at the onset of clinical sepsis in 25% of cases. The main interest in CRP is its negative predictive value if repeated over 1 to 3 days when the value remains normal. One study showed that 2 normal CRPs (1 acquired 8–24 hours after birth and 1 acquired 24 hours later) have a negative predictive accuracy of 99.7% and a negative likelihood ratio of 0.15 for neonatal sepsis. No recommendations exist on using an elevated CRP to help determine duration of antibiotic therapy. An estimate of normal CRP values is as follows (ranges in parentheses):

(a) C-reactive protein (term). Birth: 0.1 mg/dL (0.01–0.65 mg/dL); 21 hours: 1.5 mg/dL (0.2–10.0 mg/dL); 56 to 70 hours: 1.9 mg/dL (0.3–13 mg/dL); 96 hours: 1.4 mg/dL (0.2–9 mg/dL).

(b) C-reactive protein (preterm). Birth: 0.1 mg/dL (0.01–0.64 mg/dL); 27 to 36 hours: 1.7 mg/dL (0.3–11 mg/dL); 90 hours: 0.7 mg/dL (0.1–4.7 mg/dL).

ii. Serum procalcitonin. A prohormone of calcitonin, procalcitonin (PCT) levels are elevated in sepsis and have been used as a marker for sepsis. A single value is not helpful, whereas serial negative values are associated with absence of EOS. PCT has better sensitivity and

specificity than CRP. However, it can be increased due to asphyxia, pneumothorax, neonatal resuscitation, mothers with intra-amniotic infection (in the absence of neonatal infection), GBS colonization, and prolonged ROM (in the absence of neonatal infection). Serum PCT also increases normally in the first 24 to 36 hours of life. Normal levels over the first 48 hours are associated with no evidence of EOS. AAP does not recommend extending antibiotic therapy based on abnormal values. These factors currently limit its usefulness as a marker, and more high-quality studies are needed before it is incorporated into routine practice. Estimates of normal PCT levels are as follows (ranges in parentheses):

(a) **Procalcitonin (term)**. Birth: 0.08 mcg/L (0.01–0.55 mcg/L); 24 hours: 2.9 mcg/L (0.4–18.7 mcg/L); 80 hours: 0.3 (0.04–1.8 mcg/L).

(b) **Procalcitonin (preterm)**. Birth: 0.07 mcg/L (0.01–0.56 mcg/L); 21 to 22 hours: 6.5 mcg/L (0.9–48.4 mcg/L); 5 days: 0.10 mcg/L (0.01–0.8 mcg/L).

- c. **Baseline serum glucose.** Hypoglycemia can be an early marker for sepsis, but there is no evidence that hypoglycemia occurring in isolation in an otherwise well appearing infant is a risk factor for GBS EOD or EOS. Studies have suggested that it can be an additional sign of severe sepsis and can be used in a model to predict failure of conventional antibiotic therapy. In addition, serum glucose can be helpful when interpreting CSF glucose, as they have a linear relationship. One study suggested that for every increase in serum glucose of 1.0 mg/dL, the CSF glucose increases by 0.56 mg/dL.
- d. **Arterial blood gas.** To rule out metabolic acidosis if clinically indicated.
- e. **Platelet count/coagulation studies.** These are used to rule out thrombocytopenia and disseminated intravascular coagulation. A low platelet count is a nonspecific and insensitive test for sepsis. A decreased platelet count is usually a late sign of sepsis.
- f. **Molecular assays** include conventional and real-time PCR, PCR followed by post-PCR processing, multiplex PCR, staphylococcal PCR, and fungal PCR. They are newer methods of detecting infection based on detecting DNA from bacteria. Advantages of these tests are that they produce rapid results. Cochrane review states they may perform well as “add-on” tests. Compared to blood culture, they are more rapid, require less blood, can be more sensitive, and can be useful after the initiation of antibiotics when standard blood cultures may become sterile. They are limited in their ability to inform antibiotic choices. Blood culture remains the gold standard for antimicrobial drug susceptibility. The following is not an exhaustive list of these assays, but highlights a few that have been studied in neonates:
 - i. **16S rRNA polymerase chain reaction** uses universal primers conserved among bacterial species to detect the presence of bacteria quicker than traditional blood cultures. It has been studied in neonates and is more sensitive than blood culture in EOS. **PCR restriction fragment length polymorphism**, a related assay, can be used to identify the specific bacterial species.
 - ii. **Syndrome Evaluation System (SES).** Multiplex PCR-based diagnostic tool that has been studied in a randomized controlled trial of neonates. Detection of bacteria was 4-fold higher compared to traditional blood cultures, with 100% concordance.
 - iii. **PCR coupled with electrospray ionization mass spectrometry (PCR/ESI-MS).** Analysis of blood samples of neonates with suspected sepsis using PCR/ESI-MS had a 98% negative predictive value when compared to blood cultures. It has been proposed as a tool to allow for earlier reassessment of antibiotic administration.

3. Laboratory testing that is not routinely recommended in the evaluation of early onset sepsis:

- a. **Urine culture** is no longer recommended in infants <72 hours of age in an EOS workup. It is more appropriate for late-onset sepsis workup.
 - b. **Gastric aspirate analysis** is not recommended since it cannot be used to diagnose EOS. WBCs in the gastric aspirate at birth represent maternal response and do not correlate with sepsis in the neonate.
 - c. **Newborn surface cultures** (usually obtained from the axilla, external ear canal, groin, etc) are not recommended since they cannot be used to diagnose EOS.
 - d. **Tracheal aspirate** may be of benefit for Gram stain and culture if performed immediately after endotracheal tube placement. Some advocate this only if pneumonia is suspected or the volume of secretions increases or there is overwhelming newborn EOS. In a sample of 139 tracheal aspirate cultures taken within 12 hours of birth, 6.5% grew a pathogenic specimen. Tracheal aspirate cultures done after several days of intubation are of no value.
 - e. **Erythrocyte sedimentation rate (ESR)** is increased with infection but has limited value in diagnosing or monitoring infection. A low value does not exclude the diagnosis of sepsis.
4. **Laboratory tests in development.** The following tests are all under investigation, and the list is not exhaustive. In general, there is a lack of confirmatory studies and a wide variation in results, cost, and turnaround time, which limit their use. There are no guidelines that recommend their use at this time.
- a. **Serum amyloid A.** An apolipoprotein synthesized by the liver secreted in response to injury or infection. Serum amyloid A levels have been shown to have high sensitivity in 2 high-quality studies. Limited in use due to the cost and turnaround time.
 - b. **Cytokines.** Interleukin (IL)-6, IL-1B, soluble IL-2 receptor, IL-8, and tumor necrosis factor- α (TNF- α) all increase in response to a bacterial infection. Cytokines are also found in umbilical cord blood and can predict the risk of infection in the first few hours after birth and can predict late-onset sepsis. They are early biomarkers (2–12 hours) in sepsis and generally have very short half-lives, which creates a narrow window for detection.
 - c. **Surface antigens** found on a variety of WBCs and endothelial cells include CD11b, CD64, sCD14, and E-selectin. They require sophisticated equipment, are very expensive, and have a long turnaround time.
 - d. **Cord blood markers.** The most promising markers are IL-6, serum amyloid A, and PCT, but large studies are required.
 - e. **Other markers** being studied include lipopolysaccharide binding protein, urinary neutrophil gelatinase-associated lipocalin, calprotectin, inter- α inhibitor proteins, and other protein biomarkers (eg, fibronectin, lactoferrin).

D. Imaging and other studies

1. **Chest x-ray.** Pneumonia is a common presentation of EOS, and GBS pneumonia can mimic RDS. With signs of respiratory infection, obtain a chest radiograph to rule out pneumonia.
2. **Echocardiography and Doppler imaging.** Can be used to assess myocardial function in infants with sepsis, which can cause systolic and diastolic myocardial dysfunction.
3. **Head ultrasound or magnetic resonance imaging.** Neonatal central nervous system (CNS) infections are typically diagnosed based on clinical and laboratory findings. Imaging modalities can be useful in diagnosing complications of CNS infections, with magnetic resonance imaging (MRI) generally offering greater sensitivity and specificity. MRI can also be used to inform treatment duration.

V. Plan

A. General comments. For many cases, a decision about whether an infant requires a sepsis workup and antibiotic treatment can be straightforward. Infants who are clinically sick or have a positive history of known increased risk factors for sepsis with clinical signs should be evaluated. However, if an infant does not have a clear-cut history and clinical presentation, the decision is more difficult. Consideration must be made regarding the risks of missing early-onset sepsis in infants who are of low risk, and a need to be stewards of antibiotic use and limit overtreatment. Once the decision is made to treat the infant, treatment usually involves at least 36 to 48 hours of antibiotics after obtaining cultures. **For risk assessment and treatment it is important to remember that separate consideration of infants must be given to those born at ≥ 35 0/7 weeks' gestation and to those born ≤ 34 6/7 weeks' gestation.**

B. Historical context. The CDC guidelines for the prevention of GBS were initially published in 1996, and endorsed by AAP in 2002. The CDC published updated guidelines in 2010 which were endorsed by the AAP. While written for the evaluation and management of GBS disease in neonates, these guidelines have historically served as treatment algorithm for evaluating infants at risk for early-onset sepsis more generally. In 2017, a consensus between the CDC, AAP, ACOG, and other stakeholders determined that the AAP would revise and update neonatal care recommendations moving forward (while ACOG would update guidelines involving obstetric care). The AAP subsequently published guidelines on the management of newborns at risk for early onset sepsis in 2018, and the management of infants at risk for GBS specifically in 2019 (which officially replaces the 2010 CDC guidelines). **In the AAP GBS guidelines, they stress that "the clinical approach to risk of GBS EOD should be the same as that for all bacterial causes of early-onset sepsis", and therefore present the same options for clinical evaluation in both guidelines.** The NICHD workshop on the management of chorioamnionitis published recommendations regarding the care of neonates born to mothers with "suspected Triple I," based on their new terminology (2016). While the change in terminology has been endorsed by both ACOG and AAP, the management recommendations differ from the most recent AAP guidelines published in 2018. In these guidelines, we will primarily discuss the guidelines recommended by the AAP, but will make note of where the NICHD recommendations differ.

C. Prevention. Appropriate maternal intrapartum antibiotic prophylaxis is the only proven preventive measurement for EOS and should be given based on the newly updated AAP/ACOG Guidelines, published in 2019 and officially replacing the previous CDC guidelines. In brief, recommendations for maternal intrapartum antibiotic prophylaxis (IAP) are:

1. **Universal antepartum screening for GBS at 36 0/7 to 37 6/7 weeks of gestation** using vaginal-rectal cultures. Testing is also recommended for women who present in preterm labor and/or with PROM before 37 0/7 weeks' gestation. Women with GBS bacteriuria during pregnancy, or who had a prior child with GBS disease do not need to undergo routine screening (because IAP is already indicated).
2. **IAP is recommended in the following scenarios:**
 - a. All women who screen positive unless a cesarean birth is planned and performed prior to the onset of labor, in the setting of intact membranes.
 - b. Women with GBS bacteriuria identified during pregnancy.
 - c. Women with a history of a previous infant with GBS disease.
 - d. Women who present in preterm labor and/or with PROM at < 37 0/7 weeks' gestation.
 - e. Women who present in labor at ≥ 37 0/7 weeks' gestation with unknown GBS status if risk factors develop during labor (maternal temperature $\geq 100.4^{\circ}\text{F}$,

ROM \geq 18 hours), or if point-of-care nucleic acid amplification testing (NAAT) is positive for GBS.

3. **IAP can be considered in women with GBS colonization** in a prior pregnancy whose current status is not yet known.

D. Treatment plans for term and late preterm infants (\geq 35 weeks' gestation) can be based on three approaches (see page 1180, Figure 147–1): Categorical risk factor assessment, multivariate risk assessment, or risk assessment based on clinical condition. All these approaches are considered acceptable and each has advantages and limitations. The AAP recommend that decisions are made at the institutional level regarding which approach to use, as resources need to be allocated accordingly.

1. **Categorical risk factor assessment (see Figure 147–1A).** Classical approaches to evaluation for early onset sepsis have used categorical risk factor assessment, such as the prior CDC guidelines on management of neonates at risk for GBS. It is important to note that maternal intrapartum temperature \geq 38°C (100.4°F) is used as a surrogate for intra-amniotic infection. If categorical risk factor assessment is the chosen approach, the AAP guidelines recommend the following:

- a. **If signs of clinical illness** (abnormal vital signs such as tachycardia, tachypnea, temperature instability, supplemental oxygen requirement; requiring CPAP or mechanical ventilation or blood pressure support): Blood cultures and empiric antibiotics should be initiated. Lumbar puncture should also be considered and CSF culture before initiation of empiric antibiotics for infants who are at the highest risk of infection, especially those with critical illness. A lumbar puncture should not be performed if the infants clinical condition would be compromised. Note that antibiotics should be given promptly and not deferred because of a delay in the procedure.

- b. **If no signs of clinical illness, but maternal intrapartum temperature \geq 38°C (100.4°F).** Blood cultures and empiric antibiotics should be initiated. LP should also be considered and CSF culture before initiation of empiric antibiotics for infants who are at the highest risk of infection, especially those with critical illness. It should not be performed if the infants' clinical condition would be compromised and antibiotics should be given promptly and not deferred because of a delay in the procedure.

- c. **If neither of the above are true, is GBS IAP indicated for the mother?** (See Section V.C.)

- i. **If not indicated:** Routine newborn care

- ii. **If indicated, and adequate GBS IAP given (adequate GBS IAP is defined as the administration of penicillin G, ampicillin or cefazolin \geq 4 hours before delivery):** Routine newborn care

- iii. **If indicated, and adequate GBS IAP not given:** Clinical observation for 36 to 48 hours after birth.

- (a) This includes women who receive other antibiotics (such as clindamycin or vancomycin), or received antibiotics $<$ 4 hours prior to delivery.

- d. **Limitations.** While this is the traditional approach to management, categorical risk factor assessment means that many individual patients will have a relatively low risk of sepsis and still receive empiric treatment. This approach will therefore result in empirical treatment of many low-risk neonates.

2. **Multivariate risk assessment (Sepsis calculator).** See Figure 147–1B. The best-studied scoring system is a multivariate prediction model developed by Kaiser Permanente (<https://kp.org/eoscalc>), which they have studied in a population of $>$ 50,000 infants born at 35 weeks or later. This estimates an individual infants' risk of EOS, including GBS EOD. The scoring system led

to a reduction in the use of antibiotics and blood cultures, while maintaining the same incidence of EOS and with no change in other adverse outcomes. The tool integrates an individual infant's combination of risk factors and clinical condition to estimate an individual infant's risk of EOS. This septic scoring system is based on incidence of early onset sepsis in your unit (or using the baseline national rate of 0.5/1000 live births), gestational age in weeks and days, highest maternal antepartum temperature, hours of ROM, maternal GBS status, and type and timing of intrapartum antibiotics (only penicillin, ampicillin, or cefazolin are considered GBS specific antibiotics; if clindamycin or vancomycin are given alone one should enter no antibiotics), where all this information is put in a interactor calculator tool and the EOS risk at birth per 1000 births is calculated as a percentage. An EOS risk after the clinical exam is also calculated with a clinical and vital sign recommendation based on that risk. Clinical recommendations depending upon the percentage of risk include: no blood culture recommended, obtain a blood culture, no antibiotics recommended, empiric antibiotics recommended, or strongly consider starting antibiotics. Vital sign recommendations depending upon the percentage of risk include: routine vital signs, vital signs every 4 hours for 24 hours, or vital signs per NICU.

- a. **The classification of the infant's clinical presentation is:**
 - i. **Well appearing:** no persistent physiologic abnormalities.
 - ii. **Equivocal:** persistent physiologic abnormality ≥ 4 hours or 2 or more physiologic abnormalities lasting for ≥ 2 hours: tachycardia or HR ≥ 160 , tachypnea ≥ 60 , temperature instability $\geq 100.4^{\circ}\text{C}$ or $< 97.5^{\circ}\text{C}$, respiratory distress not requiring supplemental oxygen.
 - iii. **Clinical illness:** persistent need for NCPAP/HFNC/mechanical ventilation outside of the delivery room, hemodynamic instability requiring vasoactive drugs, neonatal encephalopathy/perinatal depression (seizure or APGAR Score at 5 minutes < 5), need for supplemental $\text{O}_2 \geq 2$ hours to maintain oxygen saturations $> 90\%$ outside the delivery room.
- b. **For the purposes of the calculator, "GBS-specific antibiotics" refers only to penicillin, ampicillin, or cefazolin.**
- c. **Limitations.** Ideally individual institutions should use local data to validate the use of the calculator at their own institution. Centers that adopt this approach need to plan ahead and provide the resources required for close clinical observation in infants who would otherwise receive empiric antibiotic prophylaxis. While expected to be rare, prompt recognition of a change in clinical condition is critical to properly reassessing those infants who receive monitoring only despite a higher than normal risk of sepsis.
3. **Risk assessment based on newborn clinical condition (enhanced observation).** See Figure 147–1C. Good clinical condition at birth is associated with a decreased risk of EOS by 60% to 70%. This approach leads to a decrease in the rate of antibiotic use. It requires significant changes to newborn care as it requires multiple physical examinations for the first 36 to 48 hours of life. Infants who appear ill at birth or those that develop signs of illness over the first 48 hours after birth are treated with antibiotics.
 - a. **Who and when to examine?**
 - i. **Conduct serial examinations on all newborn infants without regard to risk of EOS.** Physical examinations to detect the presence of clinical signs of illness would be performed serially (eg, every 4–6 hours) for the first 48 hours of life. This scenario would identify those low risk infants that develop EOS (1/10,000 live birth of term/late preterm infants).
 - ii. **Decide a categorical or multivariate approach for those infants at risk.** Conduct serial physical examinations to detect the presence of

clinical signs of illness for the first 48 hours of life in those infants at risk. Physical examinations and vital signs ideally would be performed every 4 to 6 hours for the first 36 to 48 hours of life.

iii. Infants whose mothers had an intrapartum temperature $\geq 38^{\circ}\text{C}$ (100.4°F) or inadequate indicated GBS IAP. Serial physical examinations and vital signs for 36 to 48 hours.

b. Who to treat?

i. Any infant who has signs of clinical illness at birth, or normal at birth but develops signs of clinical illness in the first 48 hours after birth.

(a) Treat empirically with antibiotic agents.

(b) Further evaluate with laboratory screening (blood culture and consider LP and CSF culture prior to initiation of empiric antibiotics for infants; LP should not be performed if the infant's clinical condition would be compromised and antibiotics should not be deferred because of a delay in the procedure).

c. Who not to treat? An infant with no signs of clinical illness, whose maternal intrapartum temperature was $<38^{\circ}\text{C}$ (100.4°F), or adequate indicated GBS IAP does not need treatment and should receive routine newborn care.

d. Limitations. This approach places the largest proportion of infants into the category of "close observation," which requires formal processes to ensure that serial, well-documented physical examinations occur. Individual centers would also need clear criteria based on physical examination for additional evaluation and empiric antibiotic administration.

4. NICHD proposed algorithm. The NICHD Workshop (2015) recommended a categorical approach which separates isolated maternal fever from suspected intra-amniotic infection (fever plus fetal tachycardia >160 bpm for 10 minutes or longer, maternal leukocytosis $>15,000$ per mm^3 , or purulent fluid from the cervical os), while all three approaches described and endorsed by the AAP above use maternal fever as a surrogate for intra-amniotic infection (Kaiser calculate factors highest maternal temperature). In infants ≥ 34 weeks who are well appearing with either isolated maternal fever or suspected intra-amniotic infection, the NICHD risk assessment recommends clinical observation only with "frequent close observations" (but not specific recommendations regarding serial examination). They also endorse the use of the Kaiser Sepsis Calculator for patients who fall in the "suspected intra-amniotic infection" category.

E. Treatment approach for infants ≤ 34 6/7 weeks' gestational age. These infants are at the highest risk for early onset infection from all causes. **Preterm infants can be categorized by level of risk for EOS based on their circumstances of birth** (see page 1183 or Figure 146–2). Clear communication and documentation between OB and neonatology are critical in these cases to insure an accurate risk assessment. Clinicians can adopt one of the following strategies:

1. Preterm infants at highest risk for EOS. Any infant born preterm because of cervical insufficiency, preterm labor, PROM, intra-amniotic infection (consider when a pregnant woman presents with unexplained decreased fetal movement and/or there is sudden and unexplained poor fetal testing), and/or acute and otherwise unexplained onset of nonreassuring fetal status are at the highest risk of EOS and GBS EOD.

a. Obtain a blood culture and start empirical antibiotic treatment.

b. Consider an LP for culture and analysis of CSF in clinically ill infants with a high risk of infection, unless the procedure will compromise the infant's clinical condition.

c. Give antibiotics promptly, do not defer because of a delay in a procedure.

2. Preterm infants at lowest risk for EOS. Are born under circumstances that include **all of these criteria:** maternal and/or fetal indications for preterm

birth (eg, maternal eclampsia or other noninfectious medical illness, placental insufficiency, fetal growth restriction), birth by cesarean delivery, absence of labor, attempts to induce labor, or any ROM before delivery. AAP guidelines state that acceptable initial approaches to management for these patients include:

- a. **No laboratory evaluation and no empiric antibiotic therapy.**
 - b. **Blood culture and clinical monitoring.**
 - c. **Infants who do not improve after initial stabilization** and/or those infants who have severe systemic instability, giving empirical antibiotics may be reasonable but is not mandatory.
3. **Preterm infants at unclear risk for EOS.** Infants delivered for maternal and/or fetal indications but who are born by vaginal or cesarean section after attempted induction of labor and/or with ROM before delivery. These infants are at a potentially higher risk of GBS EOD.
- a. **If the mother has an indication for GBS IAP and adequate IAP (penicillin, ampicillin, or cefazolin ≥ 4 hours before delivery) is not given or if there is concern for intra-amniotic infection** (consider when a pregnant woman presents with unexplained decreased fetal movement and/or there is sudden and unexplained poor fetal testing), **or the infant has respiratory or cardiovascular instability.**
 - i. **Obtain a blood culture and start empirical antibiotic treatment.**
 - ii. **Consider an LP for culture and analysis of CSF** in clinically ill infants with a high suspicion for GBS EOD, unless the procedure will compromise the infant's clinical condition.
 - b. **Infants that are well at birth:** close observation.
 - c. **Infants with respiratory and/or cardiovascular instability after birth:** obtain a blood culture and initiate antibiotic therapy.
4. **NICHD proposed algorithm.** For infants ≤ 34 weeks' gestation, the NICHD proposed algorithm is in line with the AAP guidelines. They recommend blood culture and empiric antibiotics in the setting of suspected/confirmed Triple I, or isolated maternal fever. The algorithm does not address other risk factors for EOS aside from intra-amniotic infection.
- F. **Antibiotic therapy.** Consider the risk/benefit balance before starting antibiotic therapy for the risk of EOS as well as continuing antibiotics if there is no documented infection. **If the decision is to treat** (empirical treatment based on risk factors, positive cultures, term infants who are critically ill with negative cultures):
1. **Obtain blood cultures prior to initiating antibiotic therapy,** and consider CSF analysis if clinically indicated at the initiation of therapy (infant is unwell but stable enough to undergo the procedure). LP is also indicated after initiating empiric antibiotic therapy if there is a positive blood culture, the infant develops clinical signs or lab values highly suspicious for sepsis or meningitis, or the infant does not respond to treatment. Any other cultures that seem appropriate should be sent to the laboratory (eg, if there is eye discharge, send a Gram stain and culture).
 2. **Ampicillin and gentamicin, in combination are the first choice** for antibiotics as empirical initial therapy in newborn EOS. It will cover GBS, most other streptococcal and enterococcal species, and *L monocytogenes*. The majority of gram-negative isolates that cause EOS are sensitive to gentamicin. Once a pathogen is identified, narrow therapy if possible unless synergism is necessary. If GBS is identified in the culture, penicillin G is the drug of choice, with ampicillin as an acceptable alternative.
 - a. **Antibiotic resistance:** Extended-spectrum β -lactamase producers are bacteria that contain enzymes that confer resistance to β -lactam antibiotics, as

duration of hospitalization. The studies have been small, and larger trials are needed.

8. **Selenium/melatonin supplementation.** Melatonin has been studied as an adjuvant therapy in the treatment of neonatal sepsis in a few small studies and showed improvement in clinical and laboratory parameters. Selenium supplementation has been shown to reduce the incidence of sepsis in very preterm infants, but the studies were small and in countries with low selenium concentrations. More studies are needed.
9. **Zinc** is a cofactor for many enzymes and is needed for the immune system to work properly. There are limited data available on its use in sepsis. Two randomized controlled trials done in India compared antibiotic treatment with zinc as adjuvant to antibiotic treatment alone. One study showed a reduction in mortality and improved developmental scores at 12 months. The other study showed no improvement in mortality but improvement in neurologic outcome at 1 month.
10. **Lactoferrin** is a normal component of human colostrum and milk thought to enhance the host immune system. The most recent Cochrane systematic review found 6 randomized controlled trials evaluating its use. They found that lactoferrin added to enteral feeds decreased the incidence of late-onset sepsis and NEC stage 2 or 3, but the evidence was low quality. Ongoing trials will hopefully enhance the quality of evidence.
11. **Recombinant human activated protein.** There were no trials identified in the most recent Cochrane systematic review on its use. There are significant side effects noted in adult studies. It is not recommended for use in neonates at this time.

79 Pulmonary Hemorrhage

- I. **Problem.** A nurse informs you that an infant has bloody secretions from the endotracheal tube (ETT). **Pulmonary hemorrhage is bleeding into the lungs.** It is typically an acute, catastrophic, often life-threatening event **that causes a sudden deterioration in the infant's clinical condition** and is characterized by fresh continuous bloody fluid from the ETT or lower respiratory tract. **Histologically**, it is defined as fresh hemorrhage in the alveolar spaces or interstitium of the lung. The incidence of pulmonary hemorrhage varies from 1 to 12 per 1000 live births. It can be as high as 50 per 1000 live births if high risk (eg, premature, intrauterine growth restriction [IUGR]). The mortality rate can be up to 50% in premature infants. Survivors of pulmonary hemorrhage require longer ventilator support, and many will develop bronchopulmonary dysplasia/chronic lung disease (60% of premature infants). Studies show an increased risk of death and survival with neurosensory impairment, increased incidence of cerebral palsy and cognitive delay, and an increased risk of seizures and periventricular leukomalacia at 18 months of age.
- II. **Immediate questions**
 - A. **Are any other signs abnormal?** Typically, an infant with a pulmonary hemorrhage is a ventilated low birthweight infant, often from a multiple birth, and 2 to 4 days old (usually in the first week of life). Late-gestation infants with pulmonary hemorrhage usually have low 1- and 5-minute Apgar scores. The infant with a pulmonary

hemorrhage can have a sudden deterioration: hypoxic, severe retractions, associated pallor, shock, apnea, bradycardia, and cyanosis.

- B. Is the infant hypoxic? Has a blood transfusion recently been given?** Hypoxia or hypervolemia (usually caused by overtransfusion) may cause an acute rise in the pulmonary capillary pressure and lead to pulmonary hemorrhage.
- C. Is there bleeding from other sites?** If so, coagulopathy may be present, and coagulation studies should be obtained. Volume replacement with colloid or blood products may be needed.
- D. What is the hematocrit of the endotracheal blood?** If the hematocrit (Hct) is close to the venous Hct, it represents a true hemorrhage, and the blood is usually from trauma or a bleeding diathesis. Aspiration of maternal blood will result in an Hct close to the venous Hct. If the Hct is 15 to 20 percentage points lower than the venous Hct, the bleeding is likely hemorrhagic edema fluid. This is seen with the majority of cases of pulmonary hemorrhage (such as those secondary to PDA, surfactant therapy, and left-sided heart failure; others discussed later).
- E. Has there been a recent procedure, or has suctioning just taken place? Was surfactant recently given?** Vigorous suctioning, traumatic intubation, or chest tube insertion may be a cause. Surfactant can also be associated.
- F. Did the mother or infant have any risk factors for pulmonary hemorrhage?** Major risk factors include IUGR, surfactant therapy, PDA, sepsis, and coagulopathy.

- 1. Maternal risk factors.** Breech delivery, maternal cocaine use, maternal hypertension during pregnancy, abruptio placentae, maternal antibiotic therapy, pre-eclampsia, possible previous pregnancy losses. Note that antenatal steroids may be protective.

- 2. Infant risk factors. Prematurity is the most common risk factor.** Others include IUGR, respiratory problems (hypoxia, asphyxia, RDS, meconium aspiration, pneumothorax, surfactant treatment, or any need for ventilator support), mechanical ventilation, PDA with left-to-right shunting, disseminated intravascular coagulation (DIC), cold injury, oxygen toxicity, urea cycle defects, multiple births, male sex, overwhelming sepsis, infections/sepsis, coagulopathy, hypothermia, polycythemia, IUGR, erythroblastosis fetalis, extracorporeal membrane oxygenation/extracorporeal life support, toxemia of pregnancy, heart failure, oxygenation index ≤ 100 , previous use of blood products, weight < 1000 g at birth, and intubation in the delivery room. Presence of PDA or early-onset sepsis increases the risk in ELBW infants. **Significant risk factors for infants near term or term** are hypotension, requirement of positive-pressure ventilation in the delivery room, and meconium aspiration. **Significant risk factors for preterm infants** are thrombocytopenia and requirement for positive pressure ventilation in the delivery room.

- G. Did the infant receive prophylactic indomethacin?** Prophylactic indomethacin reduces the rate of early serious pulmonary hemorrhage by 35%, but only in the first few days after birth. It did not decrease the rate after the first week.

III. Differential diagnosis. Most cases of pulmonary hemorrhage are secondary to hemorrhagic pulmonary edema and not a true bleed. The differential diagnosis includes the following:

- A. Direct trauma to the airway** due to nasotracheal or endotracheal intubation, vigorous suctioning, bag-and-mask ventilation, mechanical ventilation, or lung trauma during chest tube insertion. Local trauma usually has a smaller amount of bleeding with no clinical deterioration.
 - 1. Bleeding from the upper respiratory tract (nasal cavity, pharynx, larynx) or upper gastrointestinal tract,** which can mimic a pulmonary hemorrhage.
 - 2. Aspiration of maternal blood after cesarean or vaginal delivery.** The majority of blood is usually obtained from the nasogastric tube, but blood may be seen in the ETT. An Apt test can be done on the blood to determine if it is maternal blood (see Chapter 60).

- B. Hemorrhagic pulmonary edema.** The fluid is not whole blood but a mixture of plasma and blood with a low Hct, usually 15% to 20% below the expected venous Hct. Its cause is not known and may be multifactorial: stress, injury to fragile pulmonary capillaries, inadequate surface tension, acute left ventricular failure caused by asphyxia, and severe acidosis or other conditions that lead to capillary endothelium injury. The most accepted theory is that a decrease in pulmonary vascular resistance causes an increase in left-to-right shunting through a patent ductus arteriosus (PDA), which increases the pulmonary blood flow. This causes an increase in capillary filtrate and red blood cells, which leak into the alveoli. It is essentially an extreme form of pulmonary edema. Other theories include surfactant dysfunction, role of surfactant in platelet function, or intrauterine neutrophil activation in premature infants with RDS causing pulmonary hemorrhage.
- C. Massive pulmonary hemorrhage** is a pulmonary hemorrhage that involves at least 2 lobes of the lungs. The presence of a PDA or early-onset sepsis is associated with an increased risk of massive pulmonary hemorrhage (MPH) in ELBW infants. A higher 5-minute Apgar score is associated with a decreased risk of MPH.
- D. Other disorders associated with pulmonary hemorrhage**
- 1. Hypoxia/asphyxia.** Acute left ventricular failure due to asphyxia is a factor in pulmonary hemorrhage. Intrauterine and intrapartum asphyxia can be related to pulmonary hemorrhage. Resuscitation may exacerbate pulmonary hemorrhage.
 - 2. Hypervolemia.** Overtransfusion or fluid overload.
 - 3. Congenital heart disease or congestive heart failure (especially in pulmonary edema caused by patent ductus arteriosus).** A PDA can cause a rapid increase in pulmonary blood flow. In 1 series, 60% of infants with pulmonary hemorrhage had a clinical PDA, with >90% of those with a pulmonary hemorrhage having a PDA of >1.6 mm in size. Pulmonary hemorrhage occurred after corrective surgery in a neonate with transposition of the great arteries and intact ventricular septum with a postoperative computed tomography scan showing an aortopulmonary collateral artery arising from the descending aorta.
 - 4. Pulmonary related.** RDS, pulmonary interstitial emphysema, pneumothorax, meconium aspiration, and pneumonia (usually caused by gram-negative organisms). Pulmonary congestion (severely reduced left ventricular function in an asphyxiated or septic infant) can also be a factor. Diffuse pulmonary emboli can be a predisposing factor. Extralobar pulmonary sequestration can cause recurrent pulmonary hemorrhage.
 - 5. Surfactant administration.** Pulmonary hemorrhage within hours of surfactant therapy may be related to a rapid increase in pulmonary blood flow due to improved lung function. There is a significant relationship between pulmonary hemorrhage and a clinical PDA in surfactant-treated infants. Rescue surfactant therapy did not increase the risk of pulmonary hemorrhage, but prophylactic surfactant did. Studies show that pulmonary hemorrhage inactivates surfactant due to contamination with red blood cell lipids and hemoglobin.
 - 6. Hematologic disorders.** Severe Rh incompatibility, thrombocytopenia, vitamin K deficiency bleeding (from failure to administer vitamin K), and coagulation protein disorders or congenital factors (von Willebrand disease). Coagulation abnormalities may not be the direct cause of pulmonary hemorrhage (as believed earlier) but have been found to exacerbate the degree of hemorrhage. DIC is not seen often in infants with pulmonary hemorrhage but can be seen after an MPH.
 - 7. Hypoplastic lung disease.** Because of the reduced size of the vascular bed in pulmonary hypoplasia, there is a higher chance of an increase in lung microvascular pressure that can cause a pulmonary hemorrhage.
 - 8. Prematurity, intrauterine growth restriction, and/or multiple births.**

9. **Cold injury syndrome.** Cold injury causes platelet aggregation, which causes thrombocytopenia, which is a major risk factor for pulmonary hemorrhage. In 1 study of hypothermic infants and newborns, pulmonary hemorrhage was a primary cause of death.
10. **Infection/sepsis.** Overwhelming sepsis is seen in many cases of pulmonary hemorrhage and may be associated with the DIC that accompanies sepsis and the increased microvascular permeability. Pulmonary hemorrhage can occur from coxsackievirus B infection and multiple infections with septicemia (eg, congenital cytomegalovirus, *Haemophilus influenzae*, *Escherichia coli*, *Candida*, *Staphylococcus epidermis*).
11. **Urea cycle defects with hyperammonemia.** These infants typically have hepatomegaly, coagulopathy, and usually normal liver function tests except for hyperammonemia. Pulmonary bleeding is usually a terminal event in these infants.
12. **High concentrations of oxygen or oxygen toxicity.** Histologic evidence of oxygen toxicity has been associated with MPH. It causes increased microvascular permeability.
13. **Airway hemangioma (rare).**
14. **Neonatal pulmonary hemosiderosis.** Idiopathic pulmonary hemosiderosis is a very rare disease that causes acute recurrent episodes of hemoptysis as a result of a pulmonary hemorrhage, iron deficiency anemia, abnormal amount of hemosiderin in the alveolar macrophages, and diffuse alveolar infiltrates.

IV. Database

- A. **Physical examination.** Typically, the infant is premature and, on the second to fourth day of life, has a sudden cardiorespiratory deterioration and bloody secretions from the airway. Clinical signs may vary from the infant being pale, limp, and unresponsive, to fighting the ventilator (usually term infants), to looking well. The infant can be cyanotic, bradycardic, apneic, gasping, hypotensive, agitated, hypoxic, or hypercapnic or have an increased work of breathing and require more ventilatory support. Note the presence of other bleeding sites and signs of pneumonia, infection, or congestive heart failure. Look for peripheral edema, hepatosplenomegaly, and murmur of a PDA. Listen to the chest for decreased breath sounds and crepitations. There can be a **prodrome of frothy, reddish, blood-tinged tracheal secretions** before the pulmonary hemorrhage.
- B. **Laboratory studies**
 1. **Complete blood count with differential and platelet count.** With pneumonia, sepsis, or other infection, results of these studies may be abnormal. Thrombocytopenia may be seen. The Hct should be checked to determine whether excessive blood loss has occurred.
 2. **Coagulation profile (prothrombin time, activated partial thromboplastin time, thrombin time, D-dimers, fibrinogen level)** may reveal coagulation disorders. Coagulation studies are not abnormal prior to the bleed but are usually abnormal after the bleed. Secondary DIC frequently occurs with a pulmonary hemorrhage.
 3. **Arterial blood gas levels** detect a severe hypoxia, hypercarbia, and a metabolic acidosis. The oxygenation index can increase significantly after the hemorrhage.
 4. **Sepsis evaluation.** Blood cultures should be drawn because many infants with a pulmonary hemorrhage have bacterial sepsis. Any other cultures that are appropriate should be done depending on the infant.
 5. **Serum electrolytes** should be checked for hypoglycemia and hypocalcemia. Check blood urea nitrogen and creatinine for renal function because these infants can have renal failure.
 6. **Apt test** if aspiration of maternal blood is suspected. (See Chapter 60.)
 7. **Hematocrit of the aspirate** may differentiate between hemorrhagic pulmonary edema and a true bleed (see Section II.D).

8. **Ammonia level** to evaluate for urea cycle defects that can be associated with pulmonary hemorrhage.
9. **Metabolic workup.** Complete any of the state-mandated newborn screens before any blood is given, if possible.

C. Imaging and other studies

1. **Chest radiograph** can be variable and nonspecific. Pulmonary hemorrhage often looks like pneumonia on radiographs, and it is difficult to distinguish between the 2 conditions. With pulmonary hemorrhage, radiographic findings depend on whether the hemorrhage is focal (patchy, linear, ground-glass opacities; nodular densities; or fluffy opacities), lobar (hemorrhage in 1 lobe of the lung causing consolidation), or massive (the film shows a complete whiteout with just an air bronchogram visible or diffuse ground-glass opacities). The chest radiograph can also be clear in an early pulmonary hemorrhage.
2. **Lung ultrasonography** can be used to diagnose pulmonary hemorrhage. The main findings associated with pulmonary hemorrhage on ultrasound are lung consolidation with air bronchograms (83%), shred sign (92%), pleural effusion (84%), and pleural line abnormalities and disappearing A lines (100%). The shred sign demonstrated a sensitivity of 91% and a specificity of 100% for diagnosing pulmonary hemorrhage.
 - a. **The shred sign was the most common and specific ultrasound finding of pulmonary hemorrhage.** It is a static sonographic sign observed in lung consolidation. The sign represents where the deeper border of the consolidated lung tissue that makes contact with the aerated lung is shredded and irregular.
 - b. **Pleural line** is the parallel echogenic line under the superficial layers of the thorax that move during respiration.
 - c. **A lines** are a series of horizontal, echogenic parallel lines below the pleural line that are equidistant from one another.
3. **Echocardiogram** to rule out left-to-right shunting through a PDA, assess ventricular function, identify intravascular fluid overload (dilatation of the left atrium, sometimes dilatation of the left ventricle), and evaluate the need for vasoactive medications.

V. Plan

A. Emergency measures

1. **Suction the airway initially (sometimes as often as every 15 minutes) until bleeding subsides.** This is critical to reduce the risk of secretions blocking the airway. Use a 6.5-F suction catheter for a 2.5-mm ETT and an 8.0-F suction catheter for a 3.0- or 3.5-mm ETT. **Percussion should be used with caution and has no primary role in pulmonary hemorrhage.**
2. **Oxygen therapy should be given.** If already given, increase the inspired oxygen concentration to maintain a normal saturation.
3. **If mechanical ventilation is not being used,** consider using it. Infants with a massive pulmonary hemorrhage should be intubated and ventilated.
4. **If already on a ventilator,** increase the mean airway pressure to reverse or slow down the hemorrhagic pulmonary edema.
 - a. **Increase the positive end-expiratory pressure to 6 to 8 cm H₂O (or higher if needed).** This may cause tamponade of the capillaries, forces edema back into the pulmonary vascular bed, and improves ventilation and oxygenation. Risks of increasing positive end-expiratory pressure include hypercapnia and hyperventilation.
 - b. **Consider increasing the inspiratory time.** Some will also use a long inspiratory time (0.4–0.5 seconds).
 - c. **Consider increasing the peak inspiratory pressure.** Consider if bleeding does not subside to improve ventilation and raise the mean airway pressure.

B. Other measures

1. **Support and correct the blood pressure with volume expansion (colloids) and inotropes.** (See Chapter 70.) Vasoactive medications may be necessary.
2. **Blood volume and hematocrit** should be restored with slow administration of packed red blood cell transfusions after the infant has been stabilized. The majority of these infants are not volume depleted, and thus administering excessive fluid volume may only worsen the situation (increasing the left arterial pressure may increase the pulmonary edema).
3. **Correct acidosis** by correcting hypovolemia, hypoxia, and low cardiac output. Bicarbonate infusion in certain select cases may be considered **if metabolic acidosis persists** after ventilation is adequate and volume is restored but is not routinely recommended (*controversial*).
4. **Treat any underlying disorder.**
 - a. **Early recognition and treatment of patent ductus arteriosus** is essential, especially in extremely premature infants. Pharmacologic or surgical treatment of the PDA should be considered. Surgical treatment is preferred because indomethacin can exacerbate the bleeding.
 - b. **Treat sepsis/infection** with antibiotics if indicated. Get blood cultures and start antibiotics. The chest x-ray often looks like pneumonia, so antibiotics are usually started.
 - c. **Correct any underlying disorders of coagulation** if present. Platelets and vitamin K may need to be given.

C. Other measures to consider if the preceding methods are not effective (*controversial*)

1. **Endotracheal tube administration of epinephrine or nebulized epinephrine (0.1 mL/kg of 1:10,000 dilution) (*controversial*).** This is used because of its vasoconstrictive effects (may cause constriction of the pulmonary capillaries which decreases bleeding) and inotropic effects (increases mean airway pressure). Epinephrine or 4% cocaine (4 mg/kg) may be a useful adjunct in the management of pulmonary hemorrhage. Epinephrine is more often used clinically, even though the efficacy has not been proven in clinical trials.
2. **Consider high-frequency ventilation.** It is not known whether high-frequency ventilation has any benefits over conventional ventilation, but some studies suggest that high-frequency ventilation may improve survival. One review showed a 71% survival with the use of high-frequency ventilation (high-frequency jet ventilation, high-frequency oscillatory ventilation [HFOV], and high-frequency flow interrupter were used in the review) after conventional ventilation failed. HFOV has been used as rescue therapy in some infants with MPH; it decreased the oxygenation index in these infants and the infants showed dramatic improvement.
3. **Rescue surfactant.** Consider using a single dose of surfactant after the infant is stabilized on the ventilator. Although surfactant may be a contributing factor of pulmonary hemorrhage, a **single dose** has been reported to improve respiratory status based on the oxygenation index after the infant has been stabilized on the ventilator.
 - a. **American Academy of Pediatrics Committee on Fetus and Newborn** states that surfactant treatment is plausible because blood inhibits surfactant function, but because of the lack of studies, the benefit has not been established. **The committee recommends that rescue surfactant may be considered in infants with hypoxic respiratory failure** caused by secondary surfactant deficiency in pulmonary hemorrhage.
 - b. **Cochrane review (2012)** could not give a recommendation because there were no randomized trials done to evaluate the effect of surfactant in pulmonary hemorrhage. They feel more trials are needed.
4. **High-frequency oscillatory ventilation combined with pulmonary surfactant.** This combination was found to improve the oxygenation function and

shorten the duration of pulmonary hemorrhage and ventilation time in 1 study.

5. **Diuretics.** Some advocate diuretic therapy (furosemide 1 mg/kg) if there is evidence of significant fluid overload. Furosemide does have a beneficial effect on respiratory function in pulmonary edema (it decreases lung lymph flow and improves ventilation/perfusion mismatch), but there is no direct evidence that it is effective in pulmonary hemorrhage.
6. **Steroids.** Because chronic inflammation was found on lung biopsies of infants with pulmonary hemorrhage and more infants survived with pulmonary hemorrhage who had been on steroids, steroid use can be considered. Methylprednisolone (1 mg/kg every 6 hours during hospital stay and 1 mg/kg daily thereafter and discontinued after a 4-week period) has been reported to be beneficial.
7. **Recombinant factor VIIa.** Recombinant activated human factor VIIa (rFVIIa) is a vitamin K–dependent glycoprotein which is a low-volume alternative to blood products and is effective as a panhemostatic agent. It activates platelets, thereby causing thrombin formation and fibrin clotting. If platelets are given at the same time, the effect is enhanced. It is approved for use in life-threatening hemorrhages and perioperative prevention in patients with certain types of inherited or acquired hemophilia (A and B). It has been used in very low birthweight infants with a pulmonary hemorrhage when conventional ventilator management failed. There are a few positive studies, but the optimal dose has not been established. One dose of 50 mcg/kg twice per day 3 hours apart for 2 to 3 days was used successfully. A recent study on infants <30 weeks' gestation or with a birthweight of <1250 g with pulmonary hemorrhage who either did or did not get a dose of rFVIIa showed that rFVIIa administration was 67% effective in stopping pulmonary hemorrhage (single dose of 50 mcg was given), decreasing the blood product requirement, and improving coagulation test parameters with no increase in short-term complications. It did not decrease the intraventricular hemorrhage rate or mortality.
8. **Hemocoagulase** is a purified enzyme mixture from the venom of the Brazilian snake *Bothrops atrox*. It decreases bleeding time and helps with coagulation. A study of preterm infants treated with hemocoagulase (0.5 KU [Klobusitzky units]) through the ETT every 4 to 6 hours until the hemorrhage stopped plus mechanical ventilation for pulmonary hemorrhage showed promising results; the duration of ventilation, pulmonary hemorrhage, and mortality were all decreased compared with controls. Another study used it prophylactically, and it was associated with a decrease in incidence and duration of the hemorrhage, but had no effect on mortality. Due to potential risks of use and lack of quality studies, routine use is not recommended yet. **Use as a last resort.**

D. Specific targeted therapy

1. **Direct nasotracheal or endotracheal trauma.** If there is significant bleeding immediately after an endotracheal or nasotracheal intubation, trauma is the most likely cause; surgical consultation is indicated.
2. **Aspiration of maternal blood.** If the infant is stable, no treatment is needed because the condition is typically self-limited.
3. **Coagulopathy.** See Chapter 92.
 - a. **Vitamin K deficiency bleeding.** Vitamin K, 1 mg, administered intravenously with fresh-frozen plasma with active bleeding.
 - b. **Other coagulopathies.** Transfusion of blood products and correction of coagulopathies is necessary. Fresh-frozen plasma, 10 mL/kg every 12 to 24 hours, may be given. If the platelet count is low, transfuse 1 unit and monitor closely. Monitor prothrombin time/partial thromboplastin time, platelet count, and fibrinogen level. DIC is managed as noted in Chapter 92.
4. **Sepsis.** Appropriate antibiotics should be started immediately.

80 Rash and Dermatologic Problems

- I. **Problem.** A nurse calls you to tell you that an infant has a rash. A rash is any change of skin that affects its color, appearance, or texture. **Although the majority of rashes in newborns are benign and require no treatment, certain rashes require a workup and intervention.**
- II. **Immediate questions**
- A. **What are the characteristics of the rash?** Morphology of the lesion aids differential diagnosis. Is it **macular** (flat lesion <1 cm), **papular** (raised up to 1 cm), **nodular** (raised up to 2 cm), **vesicular** (raised, <1 cm, filled with clear fluid), **bullous** (raised, >1 cm, with clear fluid), or **pustular** (raised with purulent fluid)?
- B. **Are there petechiae (tiny pinpoint red dots from broken blood vessels), purpura (large, flat area of blood under tissue), or ecchymosis (very large bruised area)?** All can result from intradermal bleeding and need to be differentiated from **erythema** (redness of the skin). With erythema, the redness is cleared when pressed and returns when you release. With pressure, petechiae, purpura, and ecchymosis do not blanch. Petechiae on the lower body after a breech delivery or upper body with a vertex presentation can be normal. If widespread, petechiae are considered abnormal. **Petechiae and purpura can signify thrombocytopenia and require a workup.**
- C. **Is there a history of a congenital infection?** Obtain a thorough maternal history. TORCH (toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus) infections are known to cause rashes. The “**blueberry muffin baby**” has widespread purpura and papules and can be seen in rubella (the term was first used to describe infants infected with rubella in the epidemic of 1960), cytomegalovirus (most common viral infection), and syphilis. Cutaneous extramedullary hematopoiesis causes the “blueberry muffin” rash. The “blueberry muffin” rash has historically been associated with congenital viral infections but can also be seen in blood disorders (hemolytic disease of the newborn, twin-to-twin transfusion, hereditary spherocytosis), vascular disorders (multiple hemangiomas), and malignancies (neuroblastoma, congenital leukemia cutis, Langerhans cell histiocytosis, and congenital rhabdomyosarcoma). See Chapter 148 and disease-specific chapters.
- D. **Is the infant ill appearing?** A well infant with a rash suggests a benign rash. A febrile or ill-appearing infant with a rash requires a thorough workup to search specifically for an infectious cause.
- E. **What medications did the mother receive during pregnancy and delivery? Is the mother breast feeding and taking any medications?** Medications are a rare cause of rash in infants. Methimazole, an antithyroid medication, and also valproic acid during pregnancy have been associated with aplasia cutis, a localized absence of skin on the scalp (see Figure 80–1).
- F. **Does the skin lesion make you think of a genetic disorder?** Skin lesions can be associated with genetic syndromes. **Blisters:** epidermolysis bullosa. **Brown, flat patches:** Neurofibromatosis. **Cutis marmorata:** Cornelia de Lange syndrome and in trisomies 18 (Edward syndrome) and 21 (Down syndrome). **Deficient hair and nails:** ectodermal dysplasias. **Scaly, thick skin:** ichthyoses. **Thin, fragile skin:** collagen disorders and hypoplasia of the dermis. **Unformed skin:** aplasia cutis congenita, Adams-Oliver syndrome, and epidermolysis bullosa. **White skin and hair:** piebaldism and tuberous sclerosis.
- III. **Differential diagnosis**
- A. **Absence of part of the skin. Aplasia cutis congenita** consists of 9 groups of disorders based on the location and presence of other malformations that involve absence of

FIGURE 80–1. Aplasia cutis congenita on scalp. (Used with permission from Andrew Bowe, DO, *Pediatrics Medical Group*.)

part of the skin. It can be localized (most commonly on the scalp) or involve a large portion of the body (Figure 80–1).

- B. Skin and soft tissue infections in the neonatal intensive care unit.** These are common because preterm infants have fragile skin. Types of infections seen are **cellulitis, abrasions, and abscesses** and usually occur where the skin has been traumatized (diaper areas, surgical incision sites, fetal scalp electrodes, venipuncture sites, heel stick sites). The most common organism is *Staphylococcus aureus*. Methicillin-resistant strains are becoming more frequent. Skin and soft tissue infections involving surgical procedures (gastrointestinal [GI] tract) are caused more commonly by gram-negative rods and yeasts. **Omphalitis**, an infection of the umbilical stump and the area around it, can also occur and is usually caused by bacteria (gram negative or gram positive).
- C. Benign skin disorders/rashes that usually require no workup or intervention.** These rashes are very common.
- 1. Erythema toxicum.** The most common newborn rash, it consists of erythematous macules with a central papule or pustule. It can be present at birth, typically appears within the first 48 hours, and resolves by 2 weeks of age. It is more common in full-term infants and more common on the trunk, extremities, and perineum. New lesions can appear after the initial onset and usually disappear after a week (Figure 80–2).
 - 2. Transient neonatal pustular melanosis.** These 2- to 5-mm pustules are usually present at birth on various sites, typically the face and sacrum of full-term infants. Pustules evolve and disappear within 48 hours, but can leave hyperpigmented macules that spontaneously resolve after a few months (Figure 80–3).
 - 3. Sebaceous gland hyperplasia.** Tiny yellow papules usually occurring on the cheeks and nose. Smaller and more yellow than milia.
 - 4. Milia.** Tiny (1-mm) white-yellow papules frequently present on the face, chin, forehead, and scalp. Caused by sebaceous retention cysts (Figure 80–4).
 - 5. Miliaria crystallina.** Obstruction of eccrine/sweat ducts. May appear on the scalp or face as vesicular or papular lesions with or without erythema. Exacerbated by heat and humidity, they resolve quickly when the infant is cooled.
 - 6. Miliaria rubra (“prickly heat”).** One- to two-mm papules or papulopustules surrounded by small red areas. Miliaria pustulosis is a variant with more pustules and less erythema.
 - 7. Miliaria profunda.** Deep obstruction of the sweat ducts. White papules and edema that can prevent sweating, leading to hyperthermia.

FIGURE 80-2. Erythema toxicum. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

8. **Acropustulosis of infancy.** Recurrent areas of pruritic vesicopustules develop on the palmar surface of the hand and plantar surface of the feet. Usually last 7 to 14 days (Figure 80-5).
9. **Seborrheic dermatitis.** Patchy redness and scales on the scalp (“**cradle cap**”), face, skin folds, and behind the ears.
10. **Neonatal acne.** Erythematous comedones, papules, and pustules. May be present at birth or develop during early infancy; may take several weeks or months for complete resolution (Figure 80-6).
11. **Sucking blister.** Vesicular or bullous lesions present at birth on fingers, lips, or hands; no associated erythema (distinguishes these from herpetic lesions).
12. **Subcutaneous fat necrosis.** Erythematous nodules and plaques occurring during the first few weeks of life and resolving by 2 months of age. Usually on areas

FIGURE 80-7. Subcutaneous fat necrosis. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

of trauma (face, back, arms, legs, and buttocks). Hypercalcemia can occur if these lesions calcify (Figure 80-7).

13. **Nevus simplex** (“stork bite,” “salmon patch,” “angel’s kiss”). Pink macules that are dilated superficial capillaries, seen commonly at the nape of the neck, midforehead, and upper eyelids, but also on nose and upper lip, that usually fade within a year. The most common vascular malformation.
 14. **Mongolian spot (congenital dermal melanocytosis)**. A blue-black macular discoloration at the base of the spine and on the buttocks but can occur elsewhere. More common in blacks (>90%) and Asians (81%); usually fades over several years. Extensive spots have been described in infants with GM1 gangliosidosis (Figure 80-8).
 15. **Harlequin sign (color change, not Harlequin fetus)**. Secondary to vasomotor instability, there is a sharp demarcation of blanching (one side of the body is red and the other is pale) that usually only lasts a few minutes.
 16. **Infantile hemangioma**. A common vascular tumor (3%–5% of all infants). More common in girls and preterm infants.
 17. **Benign petechiae**. Nonblanching erythematous macules present on the lower body after a breech delivery or upper body with a vertex presentation.
- D. Rashes caused by infections.** These typically require intervention. The most common pathogens are *S aureus*, *Streptococcus* species, *Candida albicans*, and herpes simplex.
1. **Bacterial infections causing rashes**
 - a. *Staphylococcus aureus*

FIGURE 80-8. Mongolian spots (congenital dermal melanocytosis is preferred term). (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

FIGURE 80–9. Staphylococcal scalded skin syndrome. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children’s Hospital of Philadelphia Division of Dermatology.)

- i. **Impetigo (nonbullous and bullous).** Usually presents with intact vesicles, and then intact pustules rupture, erode, and dry out to form crusts often secondary to an infected umbilical wound.
 - ii. **Staphylococcal scalded skin syndrome.** Toxin-mediated disease (exfoliative toxins A and B) with age-related presentations. In the first week of life, staphylococcal scalded skin syndrome (SSSS) presents as a tender scarlatiniform rash, with flaking and desquamation presenting in older infants and children (Figure 80–9). Bacteremia is rare; however, superinfection and significant dehydration can occur with severe presentations.
- b. **Cutaneous streptococcal infections.** Uncommon, group A streptococcal infections can have an erysipelas-like eruption. Skin infections caused by group B streptococci are very rare. Vesiculopustular lesions, abscesses, and cellulitis (most common) have been reported.
 - c. **Syphilis.** This rash consists of small reddish-copper maculopapular eruptions that, like nasal secretions, are highly infectious. Hemorrhagic bullae on the palms and soles are characteristic of syphilis.
 - d. **Listeria monocytogenes.** Small (2- to 3-mm) cutaneous pinkish-gray granulomas, termed *granulomatosis infantisepticum*, are characteristic of severe newborn infection.
2. **Viral infections causing rashes**
 - a. **Herpes simplex virus** (Figure 80–10). See also Chapter 137.
 - i. **Congenital herpes simplex virus.** Transmitted perinatally and occurs in 3 forms (disseminated disease, localized central nervous system [CNS] disease, and skin, eyes, and/or mouth [SEM] disease). Infants with SEM disease present with erythematous papules or vesicles that progress to pustular clusters with intense erythema in 80% of cases. Typically associated with low birthweight, chorioretinitis, and microcephaly.
 - ii. **Neonatal herpes simplex virus.** This type of herpes infection is often severe with high morbidity and mortality and can occur anytime between birth and 6 weeks of age.
 - b. **Varicella-zoster virus.** See also Chapter 153.

FIGURE 80–10. Herpes simplex virus. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

- i. **Congenital/fetal varicella syndrome.** Acquired in utero in the first or second trimester (before 20 weeks' gestation). Infant is born with cicatricial scars.
- ii. **Congenital/perinatal/early neonatal varicella.** Acquired in utero late in third trimester (greater than 20 weeks' gestation) or in the first few days postpartum. Infant presents with centripetal rash similar to postnatal rash in the first 10 to 12 days of life.
- iii. **Postnatally acquired chickenpox.** No transplacental infection. Infant presents with symptoms on days 12 to 28 of life. Typical chickenpox rash with centripetal spreading first on trunk and then face and scalp. All stages appear (red macules, clear vesicles, crusting) (Figure 80–11).

FIGURE 80–11. Varicella zoster on the abdomen. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

- c. **Cytomegalovirus.** Most common congenital infection. The majority of cases are asymptomatic. If symptomatic, they can have multiorgan disease with petechiae (from thrombocytopenia), purpura, and jaundice.
 - d. **Rubella.** Can have petechiae, but if severe, may have bluish red maculopapular rash (“blueberry muffin”) that appears on the head and face and then becomes generalized in 1 to 3 days.
 - e. **Zika.** Single-stranded RNA virus in the same family as dengue, yellow fever, and West Nile, among others, that was originally identified in Africa in 1947. Zika came to prominence recently following a large outbreak in 2015 in Brazil, the first known emergence in the Western Hemisphere. Approximately 50% of exposed adults and older children present with fever and maculopapular rash within 1 week of exposure to a mosquito bite within an endemic area. Further information regarding high-risk areas can be found at www.cdc.gov/zika/geo/index.html and wwwnc.cdc.gov/travel/page/zika-travel-information.
 - i. **Congenital Zika.** Can cause fetal loss and severe brain abnormalities, such as microcephaly, subcortical calcifications, ventriculomegaly, abnormal gyral patterns, agenesis of the corpus callosum, and cerebellar hypoplasia.
 - ii. **Perinatal transmission of Zika.** Occurs when the mother is infected with Zika virus within 2 weeks of delivery and the infant gets the virus at or around the time of delivery. Symptoms include maculopapular rash, conjunctivitis, arthralgia, and fever.
3. **Fungal infections causing rashes**
- a. **Candida albicans.** The most common fungal infection in neonates is discussed here. Other species (eg, *Candida parapsilosis*, *Candida lusitanae*, *Candida glabrata*) are less common.
 - i. **Candida diaper dermatitis/oral candidiasis (thrush).** Most common presentation of *Candida* infections in a normal infant. The diaper rash is usually erythematous with satellite pustules. Oral candidiasis can present with fussiness and refusal to take oral feedings and is characterized by white patches in the oral cavity that cannot be easily scraped away.
 - ii. **Congenital candidiasis.** Acquired in utero, infants can either have cutaneous or systemic disease (especially extremely preterm infants). **Congenital cutaneous candidiasis** presents with an extensive rash within 12 hours of birth. The rash consists of erythematous macules, diffuse papules, and pustules. Unlike erythema toxicum, this rash frequently involves the palms and soles. In term infants, there is desquamation of these lesions, which may mimic SSSS. Premature infants may present with a rash with variable presentation (pustules, vesicles, or a burn-like dermatitis with peeling) (Figure 80–12). In **congenital systemic candidiasis**, the majority of infants do not have a rash but can present with pneumonia, meningitis, or other presentations. This is a very invasive infection with a high mortality rate, especially in very low birthweight infants.
 - b. **Aspergillus.** This has been reported to cause cutaneous fungal infections but is rare.
 - i. **Primary cutaneous aspergillosis.** Characterized by lack of involvement of organs except the skin at the time of diagnosis. Preterm infants are at risk for primary cutaneous aspergillosis (PCA) because of vulnerability of their skin and immature host defenses. Risk factors include prematurity, neutropenia, prior use of antibiotics, and glucocorticoid administration. A plaque with an eschar is characteristic of PCA. Disruption of the skin occurs due to contaminated hand splints, skin maceration caused by oximeter sensor, or adhesive tape.
 - ii. **Secondary aspergillosis.** Characterized by involvement of organs and a maculopapular eruption caused by thrombosis of small vessels.

FIGURE 80–12. Congenital cutaneous candidiasis. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children’s Hospital of Philadelphia Division of Dermatology.)

4. **Parasitic infections that can cause a rash**
 - a. **Scabies.** An infestation with the mite *Sarcoptes scabiei* has been reported in infants as young as 2 weeks. Infants tend to have widespread lesions often on the face and scalp (usually not seen in older patients who present with intertriginous locations). They can have papules, nodules, vesicles, and pustules caused by burrowing of the adult female mites. Itching is intense, especially at night.
 - b. ***Toxoplasma gondii* infections.** The classic triad for infection by *Toxoplasma gondii* is chorioretinitis, intracranial calcifications, and hydrocephalus. The infant may also present with a maculopapular rash and petechiae similar to other TORCH infections.
- E. **Rashes that cause scaling.** Usually benign and self-limited. Infectious and dietary etiologies need to be ruled out because they need immediate treatment. Genetic and immune etiologies can be considered later in the differential.
 1. **Postmaturity.** The majority of term and postmature infants normally shed their skin. The skin appears similar to parchment paper and peels off. This is a normal physiologic finding that requires no medical treatment.
 2. **Seborrheic dermatitis.** Usually seen on the scalp and flexure areas. It is a red erythematous rash with yellow scaling. Can be seen in the diaper area and is self-limiting.
 3. **Fatty acid deficiency.** Superficial scaling and desquamation can occur. Can be seen in fatty acid deficiency syndrome (where infants have decreased fat stores) or in fat malabsorption. Fatty acid replacement is necessary.
 4. **Ichthyoses.** May present as “harlequin fetus” or “collodion baby.” Many types of ichthyoses are present. These are genetic disorders that cause severe thick, scaly skin, sometimes with restricted movement. The infant can have a shiny, tight membrane covering at birth that can peel off. The skin is prone to cracking and secondary infection. Some of the ichthyoses are associated with sensorineural hearing defects; others are associated with neurologic problems including seizures (Figure 80–13).
 5. **Infantile eczema.** Scaling is present. Eczema is rarely seen in the newborn but is often seen in infants.
 6. **Atopic dermatitis.** Red scaly and itchy rash; rarely seen in the newborn.
 7. **Staphylococcal scalded skin syndrome.** See page 731 and Figure 80–9.

FIGURE 80-13. Lamellar ichthyosis. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

8. **Psoriasis.** Seen as a diaper rash with dissemination (scaly patches beyond the diaper rash) or can present as erythroderma progressing to pustular psoriasis.
 9. **Candida infections.** These can also cause redness and scaling (see earlier).
 10. **Syphilis infections.** See page 731.
 11. **Ectodermal dysplasias.** There are >150 subtypes, but the most common form is X-linked recessive hypohidrotic ectodermal dysplasia.
 12. **Immunodeficiencies.** Infants with immunodeficiencies (acquired immunodeficiency syndrome [AIDS], severe combined immunodeficiency, diffuse cutaneous mastocytosis, Wiskott-Aldrich syndrome, Langerhans cell histiocytosis) can have a red scaly rash.
 13. **Neonatal lupus.** An immune-mediated disorder that is caused by maternally transferred autoantibodies (SSA/Ro, SSB/La, and/or U1RNP). Major manifestations are skin and cardiac (primary cause of congenital heart block). Skin findings are transient and usually start at a few weeks of age but can be present at birth. Two variants are papulosquamous and annular. Fifteen to twenty-five percent of cases have cutaneous manifestations. Typical rash involves 0.5- to 3-cm annular erythematous papules with a central scale. Liver and hematologic involvement occurs in about 10% of cases (Figure 80-14).
- F. Rashes that cause blisters and bullae.** Infectious and dietary causes need to be ruled out because they require immediate treatment. Then less common causes can be evaluated.
1. **Epidermolysis bullosa.** A group of inherited diseases that cause blistering. Trauma induces the blisters. Congenital localized absence of skin is often noted at birth (Figure 80-15).
 2. **Zinc deficiency dermatosis.** Presents as a blistering rash or more commonly an eczematous rash on the angle of the mouth, chin, or cheeks in a U-shaped distribution and on the diaper area. It can be red and scaly and can have a dark color at the periphery.
 3. **Congenital herpes infection.** See Section III.D.2.a.i.
 4. **Staphylococcal scalded skin syndrome.** See Section III.D.1.a.ii.
 5. **Incontinentia pigmenti.** A rare X-linked dominant genetic disorder that is more common in females. It has 4 stages: stage 1 occurs at birth to 2 weeks—vesiculobullous (erythematous vesicles/bullae that occur linearly on the trunk, extremities, and scalp); stage 2 occurs 2 to 3 weeks after birth—verrucous; stages 3 and 4 occur later. Infants can also have neurologic, dental, and ophthalmologic abnormalities. **Note:** Stage 1 lesions can be confused with herpes simplex infection (Figure 80-16).

FIGURE 80-14. Neonatal lupus. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

6. **Less common causes.** Genetic disorders, epidermolytic hyperkeratosis, toxic epidermal necrolysis, and bullous mastocytosis.
- G. **Birthmarks.** The majority of birthmarks are benign and require no treatment. However, if there are many lesions present, this may signify an associated syndrome, or if very large, patients can be at risk for melanoma and have to be closely followed. Vascular lesions need to be evaluated because they may interfere with vital organs.
 1. **Pigmented lesions**
 - a. **Café-au-lait spots (macules).** Benign lesions that are oval or irregular with a light brown color. If they are >5 mm in diameter and there are >6, suspect an associated syndrome (think neurofibromatosis, Albright syndrome, Turner or Noonan syndrome, tuberous sclerosis, ataxia-telangiectasia).
 - b. **Mongolian blue spot.** See page 730.
 - c. **Nevus of Ota/Ito.** A blue or grayish area involving the orbital and zygomatic area common in Asians that carries the risk of glaucoma. Unlike Mongolian spots, these do not fade.
 2. **Diffuse hyperpigmentation.** Not normal and can be secondary to Addison disease, biliary atresia, hepatic atresia, sprue, melanism, lentiginosis, porphyria, or Hartnup disease or idiopathic.
 3. **Hypopigmentation/hypopigmented lesions**
 - a. **Diffuse or localized loss of pigment.** This can be secondary to phenylketonuria, Addison disease, trauma, postinflammation, or genetic.
 - b. **Ash-leaf macules.** Small area of hypopigmentation, oval shaped, and similar to the leaf of an ash tree; a marker for tuberous sclerosis.

FIGURE 80-15. Congenital absence of skin in epidermolysis bullosa, dominant dystrophic. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

FIGURE 80-16. Incontinentia pigmenti. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

- c. **Hypomelanosis of Ito.** Syndrome (primarily neurologic) with hypopigmented macule or linear/whorled pattern of hypopigmentation.
 - d. **Partial albinism (piebaldism).** An autosomal dominant disorder of off-white macules on forehead, scalp, trunk, and extremities. This type of depigmentation can also be seen secondary to Addison disease, tuberous sclerosis, vitiligo, and Klein-Waardenburg syndrome.
 - e. **Albinism.** Genetic disorders that cause abnormal melanin synthesis.
- 4. Vascular lesions**
- a. **Port wine stain (nevus flammeus).** This usually presents at birth on the face or extremities. It is a permanent capillary angioma. Rarely it is associated with Sturge-Weber syndrome, Klippel-Trenaunay syndrome, Parkes-Weber syndrome, or *RASA-1* mutations (Figure 80-17).
 - b. **Nevus simplex/salmon patch.** See page 730.
 - c. **Hemangiomas.** Most common benign tumors of vascular endothelium of infancy and are more frequent in premature infants. Females are more likely to be affected, and they occur most commonly on the head and neck, followed by the trunk and limb.
 - i. **Superficial (“strawberry”) hemangioma.** A bright red tumor (of dilated mass of capillaries) that protrudes above the skin and can appear anywhere on the body. Usually does not require treatment unless it interferes with vital functions.
 - ii. **Deep (cavernous) hemangioma.** More deep into the skin and bluish red; usually benign unless it interferes with vital organs.
 - iii. **Mixed hemangioma.** This has both deep and superficial components.

FIGURE 80-17. Port wine stain. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

- iv. **Benign neonatal hemangiomatosis.** Multiple congenital cutaneous hemangiomas that appear at birth or shortly after with spontaneous regression of lesions within the first 2 years of life.
 - v. **Diffuse neonatal hemangiomatosis.** Multiple cutaneous hemangiomas plus hemangiomas of at least 3 separate organ systems. This disorder has a grave prognosis if not recognized and treated.
- H. Rashes that cause petechiae/purpura.** These may relate to birth trauma (considered “normal”) or, if generalized and recurring, can signify a serious infection or hematologic etiology that needs immediate evaluation and treatment.
1. **Birth trauma.** Petechiae on the lower body after a breech delivery or on the upper body with a vertex presentation can be normal. They do not recur.
 2. **Autoimmune disorders.** Neonatal lupus with maternal transmission of autoantibodies.
 3. **Thrombocytopenia.** Usually generalized scattered petechiae, particularly in response to minor trauma.
 4. **Neonatal alloimmune thrombocytopenia.** An isoimmune reaction that can cause thrombocytopenia and severe bleeding, including intracranial bleeding.
 5. **Maternal idiopathic thrombocytopenic purpura.** Approximately 80% of cases of thrombocytopenia are caused by autoimmune form.
 6. **Coagulation factor deficiencies.** Petechiae and purpura are more common in thrombocytopenia, with large ecchymoses, muscle hemorrhages, and bleeding from heel sticks, venipuncture, and other sites more common with coagulation defects.
 7. **Sepsis/infection related.** Usually caused by gram-negative bacterial sepsis (*Escherichia coli*, *Pseudomonas*). Listeriosis and aspergillosis are also involved. Coxsackievirus can cause “blueberry muffin” lesions.
 8. **Disseminated intravascular coagulation.** Main causes are sepsis, birth asphyxia, necrotizing enterocolitis, and respiratory distress syndrome. One can see petechiae on the skin, and bleeding can occur from venipuncture sites and the GI tract.
 9. **Purpura fulminans.** Symmetrical and well-defined lakes of confluent ecchymosis without petechiae, with sudden onset and development of hemorrhagic bullae and sudden death. Characteristic of meningococcal sepsis or other life-threatening infection.
 10. **TORCH infections.** Toxoplasmosis, other infections (syphilis), rubella, cytomegalovirus, and herpes can all cause “blueberry muffin” lesions (widespread papules and purpura) (Figure 80–18).

FIGURE 80–18. “Blueberry muffin” lesion of congenital leukemia. Can also be seen in congenital viral infections (TORCH [toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus]), blood and vascular disorders, and other malignancies. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children’s Hospital of Philadelphia Division of Dermatology.)

FIGURE 80-19. Congenital melanocytic nevus of the scalp. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

11. **Maternal drugs.** Salicylates (especially during last 2 weeks of pregnancy).
 12. **Congenital leukemia cutis.** A rare disorder. Cutaneous leukemic infiltrates occur in 25% to 30% of infants with congenital leukemia. Infants can present with petechiae, purpura, firm blue violaceous lesions, purple nodules, hepatosplenomegaly, lethargy, pallor, and fever. Chloromas (nodular infiltrations of the skin that are solid collections of myeloblasts) look like red-purple papules and nodules (“blueberry muffin” rash) (see Figure 80-18). Congenital leukemia can be associated with Down, Edward, and Patau syndromes. Can be confused with benign hemangiomas.
- I. Rashes that lead to malignant transformation**
1. **Congenital melanocytic nevus.** Nevi that are small (<1.5 cm) and intermediate (<20 cm) in size are common with a small risk of malignant melanoma (Figure 80-19). Large congenital nevi (>20 cm) and giant congenital nevi (>40 cm) have a higher risk of malignant transformation (5%–15% risk). Giant congenital nevi also have a risk of neurocutaneous melanosis (Figure 80-20).

FIGURE 80-20. Congenital giant melanocytic nevus. (Used with permission from Andrew Bowe, DO, Pediatrix Medical Group.)

FIGURE 80–21. Sebaceous nevus of Jadassohn. (Used with permission from Andrew Bowe, DO, *Pediatrix Medical Group*.)

2. **Sebaceous nevus of Jadassohn.** Congenital hamartomatous lesion located on the scalp. It grows with age and most commonly transforms into malignant basal cell carcinoma or a benign trichoblastoma. Found in approximately 0.3% of newborns. (Figure 80–21).

IV. Database

- A. **History.** Obtain thorough history from the mother and family and a detailed history from the obstetric department. Is there a family history of skin disorders? Many skin disorders are genetic (ichthyoses, immunodeficiency, albinism). Asking about recent infections (varicella), early infections during the pregnancy (congenital infections), sexual history (syphilis), unusual travel destinations, and pet history (*T gondii*) may provide some clues to the diagnosis. Does the mother have herpes? Did she have any unusual food products or undercooked food (*Listeria*)? What medications did the mother take?
- B. **Physical examination.** Check vital signs. Is the infant febrile, or does the infant appear sick, suggesting an infection? Do not just examine the presenting rash, but check the entire body to see if there are signs of the rash anywhere else. The distribution of the rash may be characteristic. Frequent follow-up examinations may document any progression or resolution of the lesions. Examine the eye to check for chorioretinitis (TORCH infections). Hepatosplenomegaly may be seen in congenital TORCH infections.
- C. **Laboratory studies**
 1. **Sepsis evaluation** if systemic infection suspected. **Aspirate appropriate lesions** that contain fluid for bacterial culture, viral culture, polymerase chain reaction, and fungal culture.
 2. **If active bleeding suspected**, send complete blood count (CBC) with differential, platelet and reticulocyte count, TORCH titers, and sepsis workup.
 3. **Potassium hydroxide prep** if *Candida*/fungal infection suspected (reveals pseudohyphae).
 4. **Wright stain** of lesion fluid can show polymorphonuclear neutrophils with bulloous impetigo and transient neonatal pustulosis and eosinophils with erythema toxicum. Wright stain of milia shows keratinocytes.
 5. **Mineral oil prep** can show mites and ova with scabies.

6. **Polymerase chain reaction or direct fluorescent antibody of cutaneous lesion** if herpes suspected.
 7. **Skin biopsy** is sometimes indicated, especially if the lesion is atypical.
 8. **Gram stain, culture** of the purulent material of cellulitis/abscess. Gram stain of staphylococcal pustulosis will show gram-positive cocci and neutrophils.
 9. **Maternal and neonatal autoantibodies** for lupus.
 10. **Coagulation studies.** Platelet count, fibrinogen, prothrombin time, and partial thromboplastin time.
 11. **Molecular cytogenetic analysis of DNA of skin biopsy** if congenital leukemia suspected.
- D. Imaging and other studies (rarely needed)**
1. **Computed tomography scan or contrast-enhanced magnetic resonance image of the head** to rule out calcifications if Sturge-Weber syndrome is suspected.
 2. **Ultrasound, echocardiography, and/or computed tomography scans** may be needed to manage hemangiomas.
 3. **Imaging studies** may be necessary for larger defects of aplasia cutis congenita to rule out underlying bone or soft tissue defects.
- V. Plan.** As noted previously, the majority of rashes that occur in the neonate do not require treatment. **Pediatric dermatology consultation** is recommended for any unusual lesions. It is important to note that acyclovir is recommended early in cases of infants with a vesicular skin rash, even if the diagnosis of herpes is not confirmed.
- A. Aplasia cutis congenita.** Depending on the size and involvement, treatment includes medical (local includes cleaning, ointment, possible antibiotics), surgical (none if small; larger may require excision with closure, skin grafting, and other treatment), or both.
- B. Skin and soft tissue infections (abscesses and/or cellulitis, omphalitis).** Incision and drainage of **abscess** (if indicated) with local wound care. Send fluid for culture and sensitivity. An incision and drainage of the abscess may be adequate if the infant is not clinically ill. If the infant is clinically ill, a CBC with differential and blood culture are usually done. Antibiotics (usually nafcillin) are started to cover for skin flora, unless methicillin-resistant *S aureus* is suspected (use vancomycin). Lumbar puncture is done if the infant has any signs suspicious for meningitis. Infants with **cellulitis**, especially at intravenous (IV) sites, are usually treated with antibiotics based on culture or empirically with oxacillin or nafcillin and gentamicin. **Omphalitis** is treated with a full sepsis workup (including a lumbar puncture), and antibiotics (ampicillin and gentamicin) are started to cover both gram-positive and gram-negative organisms until the results of culture and sensitivities are available.
- C. Benign skin disorders.** No treatment is necessary.
- D. Rashes that are caused by infections.** See specific infectious disease chapters for more details where appropriate.
1. **Staphylococcus aureus.** Systemic antibiotics.
 2. **Streptococcus.** Cutaneous infection is usually group A, which is treated by penicillin.
 3. **Syphilis.** See Chapter 147.
 4. **Listeria monocytogenes.** Ampicillin and an aminoglycoside such as gentamicin (cephalosporins are not active).
 5. **Herpes simplex.** Acyclovir 60 mg/kg/d IV divided every 8 hours for 14 days for SEM disease only if there is no CNS involvement or disseminated disease.
 6. **Varicella.** Acyclovir and VariZIG (varicella-zoster immune globulin; see doses in Chapter 155) may decrease the severity of the course and improve outcome. Treatment must begin early in the course of the illness.
 7. **Cytomegalovirus.** Ganciclovir (Cytovene) in adults; limited data in pediatrics. Parenteral ganciclovir and oral valganciclovir are being used but are limited to use in those with symptomatic congenital cytomegalovirus disease with CNS disease. See Chapter 132.

8. **Rubella.** Supportive management. See Chapter 145.
 9. **Candida albicans.** Systemic antifungal medications such as amphotericin B to treat disseminated infection. Topical antifungals are used to treat isolated skin lesions. Thrush is treated by oral nystatin, 0.5 mL inside each cheek twice daily, for 10 days.
 10. **Aspergillus.** Voriconazole is the drug of choice. (In children age 2–12 years, load with 9 mg/kg IV every 12 hours for 2 doses, and then continue IV dosing of 8 mg/kg/dose every 12 hours.) Maintain drug levels between 2 and 6 mcg/mL.
 11. **Scabies.** Apply 5% permethrin cream topically. (**Note:** Permethrin is off label in neonates and may not be safe in very low birthweight infants.)
 12. **Toxoplasmosis.** See Chapter 149.
- E. Rashes that cause scaling**
1. **Postmaturity.** No treatment is necessary.
 2. **Seborrheic dermatitis.** Usually resolves by 1 year; supportive care.
 3. **Fatty acid deficiency.** Replacement of fatty acids through IV lipid solutions or diet is necessary.
 4. **Ichthyoses.** Aggressive supportive care, close monitoring of fluid and electrolytes, and meticulous skin care with the goal of preventing infections. Collodion babies frequently have temperature instability and excessive fluid loss.
 5. **Infantile eczema.** Avoid any irritants; use protective creams such as zinc oxide in the diaper area. Short-term topical steroids may be needed.
 6. **Atopic dermatitis.** Emollients and mild topical steroids are used.
 7. **Staphylococcal scalded skin syndrome.** Antibiotics (IV penicillinase resistant, antistaphylococcal [eg, Cloxacillin]), supportive care, and attention to fluid and electrolyte management.
 8. **Psoriasis.** Topical steroids and sometimes wet dressings are used.
 9. **Candida.** See Section V.D.9.
 10. **Syphilis.** See Chapter 147.
 11. **Ectodermal dysplasias.** Supportive care with artificial tears.
 12. **Immunodeficiencies.** See specific entity.
 13. **Neonatal lupus erythematosus.** Thorough cardiac examination, liver function tests, and CBC. Apply protective sunscreen and avoid direct sunlight for 4 to 6 months. Topical steroids may be necessary.
- F. Rashes that cause blisters and bullae**
1. **Epidermolysis bullosa.** Meticulous skin care, infection prevention, and special attention to nutrition and feedings because of the problems with dysphagia from scarring.
 2. **Zinc deficiency dermatosis.** Zinc supplementation.
 3. **Congenital herpes.** See Chapter 137.
 4. **Staphylococcal scalded skin syndrome.** See Section V.D.1.
 5. **Incontinentia pigmenti.** No specific treatment for the cutaneous lesions.
- G. Birthmarks**
1. **Hyperpigmented lesions.** Most of these lesions require no treatment. If the lesions are large (>3 cm), removal is recommended. Giant hairy nevi are removed to prevent cancer development.
 2. **Hypopigmented lesions.** Piebaldism is treated with cosmetic camouflage. Those with albinism should follow sun restriction guidelines and use sunblock.
 3. **Vascular lesions.** Many hemangiomas can be closely watched and left to regress. If treatment is necessary, steroid therapy, embolization, excision, occlusion, laser therapy, α -interferon, and radiotherapy are options. Port wine stains can be treated with laser therapy. Need to differentiate benign neonatal hemangiomatosis from diffuse neonatal hemangiomatosis because treatment is different.

- H. Rashes that cause petechiae and purpura.** These rashes usually require a thorough workup and treatment if there is a bleeding disorder. Infections are treated with antibiotics or antiviral agents. Platelet transfusion and replacement of coagulation factors may be necessary.
- 1. Birth trauma.** No treatment is necessary.
 - 2. Autoimmune disorders such as maternal or neonatal lupus.** Cardiology examination to look for heart block is indicated.
 - 3. Thrombocytopenia, neonatal isoimmune thrombocytopenia/maternal idiopathic thrombocytopenic purpura.** See Chapter 128.
 - 4. Coagulation factor deficiencies.** See Chapter 92.
 - 5. Sepsis/TORCH infections.** See Chapters 146 and 148.
 - 6. Disseminated intravascular coagulation.** See Chapter 92.
 - 7. Purpura fulminans.** Treat the underlying infection.
 - 8. Congenital leukemia.** The optimum treatment plan is unclear. Treatment consists of intensive combination therapy plus supportive care.

81 Sedation and Analgesia

- I. Problem.** An infant with pulmonary hypertension with extreme lability needs sedation. Should this infant be sedated, and which agent is available to use? An infant is having a bedside procedure, should I use a local anesthetic? (See Chapter 15.)
- II. Immediate questions**
- A. What is the indication for the sedation?** Agitation and movement by the infant during procedures such as extracorporeal life support (ECLS) can risk injury. Certain procedures (eg, magnetic resonance imaging [MRI]) mandate that the infant be immobilized, so sedation may be required. Infants with extreme lability on mechanical ventilation may benefit from sedation.
 - B. Why does the infant need analgesia?** If the newborn is to undergo minor procedures such as elective circumcision, local anesthesia is usually administered. For emergency procedures such as chest tube placement, the need for analgesia must be weighed against the delay of administering the analgesic agent.
 - C. If treating for agitation while an infant is on mechanical ventilation, is the infant adequately ventilated?** Hypoxia and inadequate ventilation can result in agitation, and sedation is dangerous in these situations.
 - D. Is sedation needed for a short period (eg, for a diagnostic procedure) or long term?** Certain medications are indicated for short-term sedation and should not be used long term.
- III. Differential diagnosis and indications**
- A. Indications for analgesia.** Whether newborns can experience pain remains in the philosophical realm, but they undeniably react to painful stimuli (nociception). Such stimuli elicit both clinical symptoms (eg, tachycardia, hypertension, and decreased oxygenation) and complex behavioral responses in term and preterm infants. By 23 weeks' gestation, the nervous system has developed sufficiently to enable the conduction of nociceptive stimuli from peripheral skin receptors to the brain. The development of the descending inhibiting pathways occurs at a later stage; therefore, the more immature infant may have an even lower threshold for noxious stimulus than at a later age. Neonates possibly have an increased sensitivity to pain compared with

older age groups. During surgical interventions, the neonate, like the adult, mounts a hormonal response that consists of the release of catecholamines, β -endorphins, corticotropin, growth hormone, and glucagon as well as the suppression of insulin secretion. This response is reduced by prior administration of analgesia or anesthesia. Although we do not know whether the neonate experiences psychological distress and lasting psychological sequelae, it has been estimated that during their stay in the neonatal intensive care unit (NICU) infants experience an average of 14 painful procedures a day during the first 2 weeks of life. Thus, there are enough reasons to attempt to control exposure to pain as well as other unpleasant experiences.

1. **Major surgical procedures such as ligation of the ductus arteriosus or laparotomy require major anesthesia.** General anesthesia should be provided by inhalation of anesthetic gases or intravenous (IV) administration of narcotic agents. In all these conditions, **the use of paralytic agents without analgesia is absolutely contraindicated.**
2. **Postoperative management**
 - a. **Narcotic agents should always be included in the immediate postoperative period.** Supplementary sedation is often provided by benzodiazepines, which are useful to combat agitation and potentiate the effect of opiates. It is important to remember that these sedative agents do not have any analgesic effect and, therefore, cannot be given alone to relieve pain.
 - b. **Other pain-relieving agents.** IV paracetamol (acetaminophen) has been used in Europe for neonatal analgesia and is now available in the United States (Ofirmev). Its use may be helpful to reduce the dosage and frequency of opiate administration.
3. **Minor surgical procedures.** Analgesia for so-called “minor procedures” is mostly provided by local anesthesia, at times supplemented by small doses of opiates or sedative agents.
 - a. **Unless the infant’s condition requires extreme urgent action, provide analgesia for procedures** such as chest tube insertion and vascular cutdown.
 - b. **The need for local analgesia for circumcision** is becoming less controversial and is now widely accepted.
 - c. **The effectiveness of and need for analgesia for more minor procedures** such as lumbar puncture have not been demonstrated.
4. **“Stressful” conditions.** There is wide controversy with regard to providing analgesia or sedation in “stressful” conditions, akin to “anxiolysis” in the adult and pediatric populations. The period during which mechanical ventilation and its related routine procedures are provided has been identified as the most frequent time when infants are being “stressed.”
5. **“Painful” conditions.** Pain scores and scales have been proposed to provide a rational approach for assessing the need for and monitoring the efficacy of pain management. Those scores are usually composites of measured behavioral, physiologic, and stress responses. Several pain scoring tools have found widespread use. Those used most commonly are the Neonatal Infant Pain Scale (NIPS); the Children’s Revised Impact of Event Scale (CRIES); the Premature Infant Pain Profile (PIPP); the Neonatal Facial Coding System (NFCS); the Neonatal Pain, Agitation, and Sedation Scale (N-PASS); the Distress Scale for Ventilated Newborn Infants (DVSNI); the Pain Assessment Tool (PAT); the COMFORT scale; and the Échelle de Douleur et d’Inconfort du Nouveau-né Scale (EDIN). The wide variety of these scores exemplifies the lack of a gold standard.
 - a. **The arguments in favor of analgesia or sedation for these situations are as follows:**
 - i. **It reduces the level of various biochemical markers** of stress, such as blood levels of catecholamines, cortisol, and β -endorphin.
 - ii. **It lessens the duration of hypoxemia** associated with endotracheal intubation and/or suctioning.

iii. **Additional argument for its use** involves the difficulty in diagnosing discomfort and pain when the infant is under muscle paralysis.

b. **The arguments against such routine use of analgesia or sedation are as follows:**

i. **The pharmacokinetic characteristics of narcotic agents** in the preterm infant are variable and not always predictable.

ii. **The same assumed “safe” dose** for some infants can, for others, result in severe toxicity (eg, hemodynamic and respiratory depression or toxic accumulation, leading to a transient comatose state).

iii. **The prolonged use** (sometimes as little as 4 days) of narcotic and sedative agents is associated with the rapid development of tolerance, withdrawal, and encephalopathy and the requirement for higher ventilatory support in the early phase of respiratory distress syndrome. Furthermore, it often delays weaning from mechanical ventilation.

iv. **Treating for “agitation” by sedation** can be dangerous when the former is the result of inadequate ventilation or hypoxemia. Therefore, before treating agitation, one must always ensure, by careful examination, that the endotracheal tube is not obstructed or misplaced and that adequate ventilating pressures are being used.

B. Indications for sedation

1. **Extreme respiratory lability.** Infants who have demonstrated extreme respiratory lability develop hypoxemia rapidly with minimal handling. Infants with severe pulmonary hypertension and pulmonary vascular hyperreactivity are often candidates for sedation.

2. **Therapeutic procedures.** When it is necessary to prevent the child from moving vigorously (eg, during ECMO/ECLS), sedation may be needed to prevent accidental dislodgment of the vascular cannulas.

3. **Diagnostic procedures.** Procedures that require the child to be immobilized include imaging procedures such as MRI, cardiac catheterization, and occasionally computed tomography (CT).

4. **Elective endotracheal intubation and rapid sequence intubation.** The question of premedicating neonates before nonemergent intubation has been debated in the past, and its use is on the rise. Various combinations of drugs have been proposed, including anticholinergic agents (to prevent reflex bradycardia), short-acting analgesics and/or hypnotic/sedatives (to prevent pain and hypertension), and muscle relaxants (to decrease the time and number of attempts for successful intubation). See Table 33–2.

IV. Database

A. **Physical examination.** Before instituting any type of sedation or analgesia, there must be a clear diagnosis. The physical examination is directed at the underlying condition.

B. **Laboratory studies.** These are usually not needed, except in the context of the underlying disease.

C. **Imaging and other studies.** Such studies are usually not needed, except in the context of the underlying disease.

V. Plan

A. **General management.** Prevention of distress and pain should be a priority in the neonatal unit and in newborn nurseries. Measures to prevent or minimize stress in the neonate should include the following:

1. **Reduce noise** (eg, close the incubator door gently).

2. **Protect the infant from intense light.**

3. **Cluster blood drawings as much as possible.**

4. **Use spring-loaded lancets for heel sticks.**

5. **Replace tape with a self-adhesive bandage.**

6. **Perform intratracheal suctioning only if indicated.**

7. **Use adequate medication before invasive procedures.**

B. Specific agents

1. Pharmacologic management provided by systemic analgesia

- a. Opiates.** All opiates may lead to respiratory depression and hypotension. Muscular rigidity is seen mostly with the synthetic opiates with rapid IV administration, such as fentanyl (>2 mcg/kg), sufentanil, and especially alfentanil. The risk of chest wall rigidity can be attenuated by slow administration (preferably over 3–5 minutes or at least 1–2 minutes). It can be treated with a muscle-relaxing agent (eg, rocuronium) and acutely reversed by naloxone (0.1 mg/kg).
- i. Morphine sulfate.** The most commonly used opioid for sedation during mechanical ventilation. A loading IV dose of 50 to 200 mcg/kg is followed by IV infusion of 10 to 40 mcg/kg/h. The peak action occurs in 20 minutes and lasts for 2 to 4 hours in full-term infants and 6 to 8 hours in preterm infants. The use of morphine infusions reduces pain and stress in mechanically ventilated preterm infants at the expense of increasing the duration of mechanical ventilation. For shorter duration of sedation, only 50 to 100 mcg/kg (0.05 to 0.1 mg/kg) can be administered IV or intramuscularly (IM). The onset of action will occur only 5 to 10 minutes after IV administration of the drug and after 10 to 30 minutes when given IM.
 - ii. Fentanyl (Sublimaze).** Frequently used in neonates for its ability to provide rapid analgesia. It has a faster onset (3–4 minutes) and shorter duration of action (30 minutes) and is 13 to 20 times more potent than morphine. Fentanyl blocks endocrine stress responses and prevents pain-induced increases in pulmonary vascular resistance, while hemodynamic stability is better preserved than with morphine because it causes less histamine release. For anesthesia, use IV bolus 10 to 50 mcg/kg, and for analgesia, use 1 to 4 mcg/kg. In case of no IV access, it can be given IM, resulting in a slower onset of action (7–15 minutes). A continuous IV infusion of 1 to 3 mcg/kg/h may be used for ongoing sedation. Tolerance to opioid-induced analgesia and sedation occurs more rapidly than with morphine. A cumulative fentanyl dose of >2.5 mg/kg or a duration of infusion >9 days is predictive of opioid withdrawal syndrome.
 - iii. Remifentanyl.** Has a chemical structure identical to that of fentanyl but has twice its analgesic potency. An IV administration of 1 to 3 mcg/kg gives nearly immediate analgesia that lasts only 3 to 15 minutes.
 - iv. Sufentanil.** Give 0.2 mcg/kg over 20 minutes, then continuous IV, 0.05 mcg/kg/h.
- b. Ketamine.** It is an *N*-methyl-*D*-aspartate receptor antagonist with analgesic and amnesic effects. In addition to its analgesic efficacy, ketamine has the advantage of maintaining stable cardiovascular and respiratory function. Ketamine also exerts a bronchodilator effect and improves lung compliance. Infrequent transient laryngospasm and excessive salivation have been reported. At a dosage of 0.5 to 2 mg/kg IV, its onset of action is between 0.5 and 2 minutes, and the duration of action is 5 to 60 minutes. It can also be given IM or enterally. It does not affect cerebral blood flow and might be a good choice for unstable hypotensive neonates requiring procedures such as intubation or ECMO cannulation. Primate studies have shown apoptotic and necrotic cell death after prolonged ketamine exposure in early postnatal life (day 5 of life), whereas this is not seen at a later age (day 35 of life) and with shorter duration of exposure (3 hours). Use in the NICU has been limited. It may be of value, possibly in combination with atropine sulfate, for sedation before endotracheal intubation. Infants with severe bronchopulmonary dysplasia and refractory bronchospasm may also benefit from the use of ketamine for its additional bronchodilatory effect.

c. **Propofol.** A nonbarbiturate anesthetic used for induction of anesthesia. It is lipophilic and rapidly equilibrates between plasma and brain with quick loss of consciousness (within 30 seconds) and short duration of action after a single bolus dose (3–10 minutes). Possible adverse effects are histamine release, apnea, hypotension, bradycardia, and bronchospasm. It often causes pain at injection site. Neonatal dosing has not yet been well established.

2. Pharmacologic management provided by sedative-hypnotics

a. **Benzodiazepines.** Activate γ -aminobutyric acid (GABA) receptors and produce sedation, anxiolysis, muscle relaxation, amnesia, and anticonvulsant effects. They may improve synchrony with assisted ventilation but offer little pain relief. Side effects include respiratory depression, hypotension, dependence, and occasional neuroexcitability or clonic activity resembling seizures.

i. **Midazolam (Versed)** has a rapid onset of action (1–2 minutes) and can produce apnea if given too rapidly. Its very short half-life (30–60 minutes) makes it a good choice for brief rapid sedation. Midazolam is given as a single dose, 50 to 100 mcg/kg, or by continuous infusion at a rate of 0.4 to 0.6 mcg/kg/min. Withdrawal may occur when given continuously for >48 hours. Combining midazolam with opioids increases the incidence of adverse effects of both agents. Although it is the most commonly used benzodiazepine in the NICU, concern about its efficacy and safety has been raised recently. The lower number of GABA_A receptors in neonates may contribute to neuroexcitability and myoclonic activity that resembles or progresses to convulsions.

ii. **Lorazepam (Ativan)** has a longer duration of action (8–12 hours) and may require less frequent dosing (50–100 mcg/kg every 8 hours).

b. **Chloral hydrate.** A sedative-hypnotic used primarily for short-term sedation but is not available in the United States. It is especially useful during diagnostic procedures such as CT and MRI. The onset of action is usually within 10 to 15 minutes. Administer 20 to 50 mg/kg every 6 to 8 hours rectally or orally for sedation. It should not be used long term.

c. **Acetaminophen (Paracetamol)** inhibits the cyclooxygenase-2 enzymes in the brain. It is frequently used in conjunction with other pain relief to decrease opioid use, especially for postsurgical pain. IV acetaminophen decreases the amount of opioids needed after surgery and is particularly useful for routine postsurgical care with opioid-sparing effects. In contrast to its use in older children or adults, acetaminophen rarely causes hepatic or renal toxicity in newborns. In both preterm and term infants, the clearance of acetaminophen is slower than in older children, so oral or rectal dosing is required less frequently. Single oral doses of 10 to 15 mg/kg may be given every 6 to 8 hours; 20 to 25 mg/kg can be given rectally at the same time intervals. For IV acetaminophen in neonates, pharmacokinetic analysis suggests a loading dose of 20 mg/kg and maintenance dose of 7.5 mg/kg every 6 to 8 hours for neonates between 23 and 32 weeks of postmenstrual age (PMA). Total recommended daily dose is 20 to 30 mg/kg at 24 to 30 weeks PMA, 35 to 50 mg/kg at 31 to 36 weeks PMA, and 50 to 60 mg/kg at 37 to 42 weeks PMA. The administration of the repeated dose should not exceed 48 to 96 hours. The new IV formulation (Ofirmev) requires extreme caution because a 10-fold dosing error is facilitated by the preparation's concentration being formatted for adult use.

d. **Dexmedetomidine (Precedex)** is a selective α_2 -adrenoceptor agonist that, unlike traditional sedative agents, is reported to produce its sedative effect, at least in part, through an endogenous sleep-promoting pathway that does not produce clinically significant respiratory depression. Although not approved for use in children by the US Food and Drug Administration, it has gained popularity in pediatric critical care. The use of dexmedetomidine as a primary agent in low-criticality patients offers the benefit of rapid achievement of targeted sedation levels. The use of dexmedetomidine to facilitate extubation

in children intolerant of an awake, intubated state may abbreviate ventilator weaning. For clinicians using this medication, initial loading doses in the range of 0.35 to 1 mcg/kg over 10 minutes and continuous infusion of 0.25 to 0.75 mcg/kg/h are used. The most common side effects of dexmedetomidine are hypotension and bradycardia, which generally resolve by decreasing the dose.

3. **Additional medications for premedication for nonemergency intubation (rapid sequence intubation)**

a. **Muscle relaxants.** Given to facilitate intubation and minimize the increase in intracranial pressure that occurs during awake intubation. The adverse effects of muscle relaxants may include histamine release, tachycardia, hypertension/hypotension, and bronchospasm. Their effects can be reversed by atropine and neostigmine. **The use of a muscle relaxant for intubation should never be attempted without the presence of individuals well experienced with the bag-and-mask ventilation technique.** As an alternative to bag-and-mask ventilation, an appropriate-size laryngeal mask airway has been used successfully in late preterm and term newborns.

i. **Vecuronium.** Vecuronium 0.1 mg/kg IV has a duration of action of 30 to 40 minutes.

ii. **Rocuronium.** Rocuronium 0.6 to 1.2 mg/kg IV, a metabolite derivative of vecuronium, has a quicker onset to paralysis (1–2 minutes) and shorter duration of action (20–30 minutes).

iii. **Succinylcholine.** Succinylcholine (1–2 mg/kg IV) is a neuromuscular depolarizing agent with the most rapid onset of action (20–30 seconds) and the shortest duration (4–6 minutes) of all muscle relaxants. If no IV access is available, it can be administered IM (2 mg/kg); this results in a longer onset of action (2–3 minutes) and duration of action (10–30 minutes) than when administered IV. **Succinylcholine is contraindicated in the presence of hyperkalemia or a family history of malignant hyperthermia.**

b. **Vagolytic agents.** Prevent bradycardia during intubation and decrease bronchial and salivary secretions.

i. **Atropine.** Dose is 0.02 mg/kg IV or IM. Its onset of action is 1 to 2 minutes, and the duration of action is 0.5 to 2 hours. Tachycardia occurs frequently.

ii. **Glycopyrrolate.** Dose is 4 to 10 mcg/kg IV. Tachycardia occurs less frequently than with atropine.

4. **Pharmacologic management provided by local analgesia**

a. **Subcutaneous infiltration with lidocaine, 0.5% to 1% concentration.** Always use solution without epinephrine. Maximum dose (subcutaneous infiltration): 5 mg/kg or 1 mL/kg of 0.5% concentration or 0.5 mL/kg of 1% concentration.

b. **Buffered lidocaine.** One part sodium bicarbonate with 10 parts 1% lidocaine; typically prepared in the hospital pharmacy. The pain associated with anesthetic infiltration is reduced by buffering the pH from 7.0 to 7.4.

c. **Topical local anesthetics**

i. **Lidocaine 2.5% and prilocaine 2.5% (EMLA cream).** This is a eutectic anesthetic mixture (ie, liquid at room temperature). A single dose of 0.5 to 1.25 g of EMLA cream applied under an occlusive dressing provides adequate local anesthesia 60 to 80 minutes later. In the term infant, it is an alternative to penile dorsal block for anesthesia during circumcision. The risk of methemoglobinemia (from prilocaine) may restrict its use to the full-term infant, and repeated doses should be avoided.

ii. **Tetracaine 4% gel (Ametop).** Apply 1.5 g 30 to 60 minutes before the procedure. It has no risk of methemoglobinemia, but its repeated use may lead to contact dermatitis.

iii. **4% Liposomal lidocaine cream (L.M.X.4 or Ela-Max).** Increasingly used in pediatrics for its rapid onset of action (20–30 minutes) and can be applied with (preferred) or without an occlusive dressing.

5. **Oral sucrose.** A disaccharide composed of fructose and glucose shown to promote calming behaviors and reduce distress associated with acute painful events. Gustatory inputs from the taste buds lead to cholecystokinin release in the brainstem, which activates descending inhibitory opioid. It is effective for the management of procedural pain in the neonate. Analgesic effects are present with doses as low as 0.1 mL of 24% sucrose. The usual dose is 0.5 to 1.5 mL of a 24% sucrose solution given by syringe or pacifier 2 minutes before procedures such as heel stick or venipuncture. The potential risk for fluid overload, hyperglycemia, and necrotizing enterocolitis should limit this method to infants >34 weeks' gestation. Other sweet-tasting liquids such as glucose, mother's milk, and saccharin are reported to be equally effective.
6. **Nonpharmacologic management.** Physical measures such as the use of swaddling, containment, or facilitated tucking as well as skin-to-skin contact with the mother ("kangaroo care") are likely to be efficacious in decreasing the noxious effects of the routine procedures (eg, heel stick) needed for the management of the sick infant. Nonnutritive sucking may be helpful.

82 Seizure Activity: On Call

- I. **Problem.** The nurse reports that an infant is having abnormal movements of the extremities consistent with seizure activity. A **seizure is an event** defined as "a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain." Further categories of a neonatal seizures include:
 - A. **Clinical-only seizure:** "A sudden paroxysm of abnormal clinical changes that occur without a definite EEG [electroencephalogram] seizure."
 - B. **Electroclinical seizure:** "Clinical signs that occur simultaneously with an electrographic seizure."
 - C. **Electrographic-only (subclinical) seizure:** "Presence of a definite EEG seizure that is not associated with any clinical signs of a seizure."
 - D. **Epilepsy:** Involves recurrent unprovoked seizures and is defined as "a disease of the brain defined by any one of the following conditions: at least two unprovoked seizures or reflex seizure occurring more than 24 hours apart, one unprovoked or reflex seizure and a probability of having another seizure similar to the general recurrence risk after two unprovoked seizures occurring over the next 10 years, or diagnosis of an epilepsy syndrome."
 - E. **Status epilepticus:** Seizures appear in close succession or do not stop. Status epilepticus is a serious condition that requires prompt medical attention. There is no real definition of status epilepticus in neonates. Three definitions that have been used in the literature are as follows: (1) continuous seizures for a minimum of 30 minutes or seizures that recur over at least 30 minutes that do not return to a baseline neurologic activity; (2) at least 30 minutes of seizure activity over a 1-hour defined period; and (3) EEG seizure activity of >50% of the recording time of approximately 30 minutes.

The incidence of seizures in the neonatal age group is higher than at any other time in life, about 2 to 3 per 100 live births (up to 13 per 100 live births in preterm infants and up to 58 per 100 live births in very low birthweight infants). Studies have reported there is a higher incidence in preterm infants (vs term), low birthweight infants (vs normal weight), male infants (vs females), and African American infants (vs white or other races or ethnicities).

The etiology and semiology of seizures are quite different in neonates compared to older age groups. Most seizures in neonates are symptomatic of an acute illness and caused by an underlying condition. Most neonatal seizures occur during the first 24 hours of life. Developmental immaturity of the neonatal brain (immature inhibitory systems and the predominance of excitatory neurotransmitters) leads to unique seizure tendency and seizure patterns, altered drug pharmacodynamics, and increased susceptibility to developmental effects of anticonvulsants. This makes it imperative that we are able to recognize seizures and differentiate seizures from the movements that mimic seizures. It is now known that neonates with seizures are not only at a higher risk of death, but also at an increased risk of developmental delay, cerebral palsy, and epilepsy. Additional information on seizures can be found in Chapter 120.

II. Immediate questions

A. Is the infant really seizing? Is this a nonepileptic motor phenomenon seen in neonates? Is this a seizure mimic? It has been recognized that seizures are only correctly identified by clinical observation in 50% of cases. Infants can have many unusual movements that may look like seizures but are not. It is important to distinguish between the 2 conditions because nonepileptic events do not require treatment with anticonvulsants. Seizure mimics might occur in healthy or sick neonates. Some seizure mimics are benign events, whereas others indicate an underlying brain dysfunction. It is sometimes difficult to distinguish these, and an EEG is often necessary to distinguish between seizures and seizure mimics. Seizures have associated autonomic changes, have abnormal ocular movements, and are sometimes associated with ictal EEG discharges that seizure mimics do not have. The ability to stop the movements by restraining the body part or changing the position of the infant and movements that are elicited by tactile stimulation are characteristic of nonseizure movements. The following are nonepileptic events that occur in neonates that may be confused with seizures.

1. **Jitteriness/tremors.** The most common abnormal movement in a neonate is a tremor; up to 44% of infants will be jittery. A **tremor** is “an involuntary rhythmical oscillatory movement of equal amplitude.” **Jitteriness** is recurrent tremors. Etiology includes elevated levels of circulating catecholamines and immaturity of spinal inhibitory interneurons and can be benign or pathologic. In a jittery infant, eye movements are normal (no ocular deviation), limb movements are bilateral with both phases of movement having equal speed, movements can be stimulus sensitive and can be suppressed by holding the limb, and there are no associated autonomic changes. In an infant who is seizing, eye movements are usually abnormal (eg, staring, blinking, nystagmoid jerks, or tonic horizontal eye deviation); movements are not stimulus sensitive, are asymmetric with a faster contraction and slower relaxation phase, and cannot be suppressed by holding the limbs; and autonomic changes occur. **Transient neonatal jitteriness** can occur with maternal use of opiates, marijuana, inhaled volatile substances, and selective serotonin reuptake inhibitors (sertraline [Zoloft]). **Familial tremor of the chin** is an autosomal dominant condition that can be seen in an infant who is crying. **Neonatal hyperexcitability syndrome** is a coarse tremor that is seen in mildly asphyxiated neonates with increased tendon reflexes and excessive Moro response. **Persistent or worsening tremors** need to be evaluated, and the following need to be ruled out: seizures, hypoglycemia, hypocalcemia, hypomagnesemia, hypothermia, hyperthyroidism, intracranial hemorrhage (ICH), drug withdrawal, sepsis, and vitamin D deficiency.
2. **Nonepileptic myoclonus** is an irregular shock-like movement of a limb that is caused by the muscle contracting. It can be benign or pathologic. Note that during sleep an infant can have fragmentary myoclonic jerks or an isolated myoclonic jerk as the infant wakes up, which is considered normal.
 - a. **Benign neonatal myoclonus or benign neonatal sleep myoclonus.** This presents with rhythmic movements (myoclonic jerks of the extremities, whole body [usually not the face], or trunk) only during sleep. They occur from

birth to 6 months, can last up to 1 hour (mistaken for status epilepticus), can be provoked, and stop when the infant is awakened.

- b. Pathologic nonepileptic myoclonus.** Infants present with focal/multifocal or generalized myoclonic jerks secondary to a pathologic cause (hypoxic ischemic encephalopathy [HIE], infection, medications, cerebral vascular events, severe intraventricular hemorrhage [IVH], drug withdrawal, toxic metabolic disturbances [glycine encephalopathy, drugs], and others).
- 3. Apnea.** Apnea as a seizure manifestation is not very common in infants. If it occurs, it happens more often in term infants than in premature infants. Apneic episodes in an infant are associated with bradycardia, whereas apnea with a seizure is usually associated with tachycardia and other manifestations such as eye opening, hypertension, stiffening, clonus, or mouth movements.
- 4. Hyperekplexia (congenital stiff-person syndrome, familial startle disease).** Hyperekplexia is a rare, nonepileptic disorder. It may be caused by glycine receptor gene mutations, and in some infants, it is inherited as an autosomal dominant disorder. It has a minor and a major form. Often confused with a seizure, it can present only as the exaggerated startle (minor form), or it can present with a triad of symptoms: an exaggerated startle (tonic flexion of limbs and trunk, clenching of fists, and anxious stare) to external stimuli, nocturnal myoclonus, and a generalized stiffness with an increased risk of sudden infant death syndrome. Hallmark of this disease: Tap the nasal bridge, and the infant will elicit an exaggerated startle.
- 5. Neonatal opsoclonus (“dancing eyes”).** This is characterized by rapid, random, to-and-fro oscillations of the eyes. It can be continuous and occur during sleep. Note that nystagmus is rhythmic horizontal oscillations of both eyes, whereas opsoclonus is irregular and chaotic. It can be seen as a transient phenomenon in a healthy infant, in neonates with major neurologic or visual disabilities, or as an early sign of herpes simplex encephalitis or in HIE.
- 6. Rapid eye movement–associated movements.** During rapid eye movement sleep, infants can have rapid vertical and horizontal eye movements, grimacing, sucking episodes, twitching of a limb, or movements of the entire body that look similar to a seizure.
- 7. Excessive hiccups.** Hiccups are normal in neonates except in the case of glycine encephalopathy, where excessive hiccups can occur with apnea and seizures.
- 8. Motor automatism.** These are movements that include pedaling, swimming, and bicycling. They are not associated with EEG abnormalities and may be secondary to brainstem release.
- 9. Oral-buccal-lingual movements.** These movements consist of tongue thrusting or lip smacking and can be normal or associated with seizure activity. If normal, usually no other manifestation of seizures occurs. Sucking and puckering movements are considered normal if no other signs are seen. **Tongue fasciculations in the neonate** are seen with lower motor neuron disease. Assess movements when the tongue is at rest.
- 10. Sandifer syndrome.** Infants with gastroesophageal reflux can have spells of opisthotonic posturing and stiffening with staring, apnea, and jerking of extremities after feeding. This can be secondary to pain from acidic material refluxing into the esophagus or an effort to decrease reflux by increasing lower esophageal sphincter tone.
- 11. Paroxysmal extreme pain disorder.** Presents at birth, this is an autosomal dominant condition that is caused by a sodium channelopathy involving SCN9A that can occur in the neonatal period. It features nonepileptic tonic attacks of excruciating pain that affect different parts of the body (eg, rectum, genitalia, face, limbs); skin flushing, infants who are red and stiff, harlequin color changes, and abnormalities in the pupil can be triggered by defecation. Often misdiagnosed as hyperekplexia/epilepsy.

12. **Neonatal dystonia/dyskinesia.** These abnormal movements (arching, fisting) can be associated with HIE, metabolic diseases, or maternal drug toxicity.
 13. **Parexysmal tonic downgaze or upgaze** can be seen rarely in neonates and is more common in infants. It is a sustained upward or downward deviation of the eyes that lasts for several hours or all day.
 14. **Congenital nystagmus.** Congenital nystagmus presents at birth or few days after and is a rhythmic, horizontal oscillations of the eyes. A full ophthalmologic evaluation is needed because visual sensory abnormalities may occur with rare tumors or visual pathway defects.
 15. **Bronchopulmonary dysplasia-associated extrapyramidal movement disorder.** Preterm infants with severe bronchopulmonary dysplasia can exhibit oral-buccal-lingual movements (darting tongue), restlessness, and chorea-like movements of the limbs, neck, trunk, and face. The presumed cause is chronic hypoxemia, most likely caused by injury to the basal ganglia.
- B. Are there vital sign changes?** The majority of vital sign changes are not manifestations of seizures, and those that are include oxygen desaturation and apnea, especially when accompanied by other signs of a seizure.
- C. How old is the infant?** The age of the infant is often the best clue to the cause of the seizures. Common causes of seizures for specific ages are as follows:
1. **At birth.** Maternal anesthetic agents injected into the neonate accidentally during delivery can cause severe tonic seizures typically in the first few hours of life. The neonate presents with apnea, flaccidity, asphyxia, and seizures.
 2. **Within 30 minutes to 3 days after birth.** Pyridoxine deficiency (B6-dependent seizures). These infants can also have seizures in utero.
 3. **Day 1 (first 24 hours).** Metabolic abnormalities such as hypoglycemia, hypocalcemia, or HIE (presenting at 6–18 hours after birth and becoming more severe in the next 24–48 hours); birth trauma (presents at ≥ 12 hours: primary subarachnoid hemorrhage, laceration of falx or tentorium with subdural hematoma); central nervous system (CNS) intrauterine infections and sepsis; drug withdrawal; inadvertent local anesthetic toxicity; and pyridoxine dependency.
 4. **At 24 to 72 hours.** Cerebral dysgenesis, neonatal stroke (cerebral infarct, intracerebral hemorrhage, cortical vein/sinus thrombosis), IVH, subarachnoid hemorrhage with cerebral contusion from birth trauma, metabolic disorders (hypocalcemia, hypoglycemia, hyponatremia, hypernatremia), glycine encephalopathy, urea cycle disorders, aminoacidurias, organic aciduria, drug withdrawal, pyridoxine dependency, meningitis.
 5. **At 72 hours to 1 week.** Familial neonatal seizures, cerebral malformations, cerebral infarction, hypoparathyroidism, vascular events, kernicterus, glycine encephalopathy, urea cycle disorders, aminoacidurias and organic aciduria, hypocalcemia, and TORCHZ (toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus, and Zika virus) infections.
 6. **At >1 week.** Late-onset hypocalcemia, peroxisomal disorders, cerebral dysgenesis, fructose dysmetabolism, Gaucher disease type 2, GM1 gangliosidosis, herpes simplex virus type 2 encephalitis, ketotic hyperglycinemia, maple syrup urine disease, tuberous sclerosis, urea cycle disorders, methadone withdrawal, and De Vivo syndrome (earliest seizures at 2 weeks of age, but typically in this range).
 7. **Variable onset.** Stroke, sinus thrombosis, other developmental defects, epilepsy syndromes, ICH, intracranial infection, and hypocalcemia.
- D. Is the infant full term or preterm?** HIE is the most common cause of seizures in **full-term and premature infants**. In **term babies**, the second most common cause is a perinatal ischemic stroke. With ICH, term infants are more likely to have a subarachnoid hemorrhage or a subdural hemorrhage; **preterm babies** are more likely to have a germinal matrix hemorrhage–IVH. The prevalence of **hypoglycemia**,

hypocalcemia, and CNS infections is the same as for term and preterm infants. The following can cause seizures at any gestational age: meningitis, metabolic disorder, focal cerebral infarction, and congenital anomalies. Preterm infants with seizures are at higher risk for long-term adverse outcomes than term infants with neonatal seizures.

- E. What is the blood glucose level? Is the infant at risk for hypoglycemia?** Hypoglycemia is the **most common metabolic problem in neonates** and is an easily treatable cause of seizures in the neonatal period. The incidence is 1 to 5 per 1000 live births but is higher in at-risk populations (late preterm infants, term small for gestational age [SGA] infants, infants of diabetic mothers [IDM]/large for gestational age [LGA] infants). A blood glucose should be obtained immediately to rule out low blood sugar.
- F. Is there a history of a sentinel hypoxic event occurring immediately before or during labor and delivery? Does the neonate have 1 of the 4 signs consistent with an acute peripartum or intrapartum event?** Because HIE is the most common cause of neonatal seizures in term and preterm infants, it is important to obtain a thorough prenatal and delivery history. Sentinel events include ruptured uterus, umbilical cord prolapse, maternal cardiovascular collapse, amniotic fluid embolus with maternal hypotension and hypoxemia that is severe and prolonged, and fetal exsanguination (fetomaternal hemorrhage/vasa previa). The American Academy of Pediatrics (AAP) list of neonatal signs consistent with an acute peripartum or intrapartum event include the following: fetal umbilical artery acidemia with pH <7 or base deficit >12 or both, Apgar score <5 at 5 and 10 minutes, presence of multiple-organ failure consistent with HIE, and evidence of acute brain injury on brain magnetic resonance imaging (MRI) or spectroscopy consistent with hypoxia-ischemia. Other factors include fetal heart rate monitor and MRI patterns that are consistent with an event.
- G. Is there a family history of seizures?** If so, a genetic or inherited syndrome may be present. There are many syndromes and causes of epilepsy that are genetic, with more genes discovered nearly every week. Examples include all the early infantile epileptic encephalopathies (Ohtahara syndrome), self-limited familial neonatal epilepsy, Zellweger syndrome, Smith-Lemli-Opitz syndrome, and others.
- H. Are there any risk factors for neonatal seizures?** Risk factors described vary by study and region.
- 1. Maternal risk factors:** Primiparity, grand multiparity, obesity, intrauterine growth restriction (IUGR), heavy cigarette smoking, maternal diabetes, pre-eclampsia, gestational diabetes, thyroid dysfunction, abnormal amniotic fluid volume, asthma, advanced maternal age, maternal age of 18 to 24 years, and suspicious or ominous fetal heart rate (FHR) tracing before labor.
 - 2. Intrapartum risk factors:** Prolonged second stage of labor, fetal distress, cesarean or operative vaginal delivery, maternal fever, TORCHZ infections, history of rubella, ruptured uterus, umbilical cord prolapse, maternal cardiovascular collapse, amniotic fluid embolus with maternal hypotension and hypoxemia that is severe and prolonged, fetal exsanguination (fetomaternal hemorrhage/vasa previa), and suspicious or ominous FHR tracing before labor.
 - 3. Infant risk factors:** Prematurity, postmaturity, low birthweight, high birthweight, male sex, birth in a private or university hospital, birth by cesarean section, SGA, infants of African American mothers, CNS and major systemic anomalies, cardiorespiratory failure, and congenital heart disease (CHD).
- III. Differential diagnosis** (see also Chapter 120 and Table 120-1). The majority of newborns (75%–90%) with seizures have an **underlying pathologic cause**, and few cases are idiopathic or part of an epileptic syndrome. Note that although the causes of neonatal seizures are extensive, **3 etiologies** account for almost 75% of all neonatal seizures: **HIE (40%–50%), perinatal arterial ischemic stroke (10%–15%), and ICH (10%–20%)**. Other causes are noted later in this chapter. **Neonatal epilepsy genetics** is a

rapidly expanding field involving many genetic disorders associated with neonatal-onset epilepsy. Seizure activity may be secondary to the following:

A. Central nervous system abnormalities

1. **Hypoxic etiologies. Hypoxic ischemic encephalopathy (HIE)** is the **most common cause** of neonatal seizures in both **full-term and preterm infants** and causes up to 50% of seizures in the first 48 hours of life (more common first 24 hours of life). The majority of cases occur because of an acute peripartum or intrapartum event. MRI studies suggest the period around birth accounts for >75% of the causative period. It can be secondary to prenatal, perinatal, and postnatal causes. Other hypoxic events can occur in the neonatal period that may cause seizures.
2. **Infarction/stroke.** A **perinatal arterial stroke** is the **second most common cause** of seizures in full-term infants, and up to 97% of infants diagnosed with a neonatal stroke present with seizures. These infants usually present with focal seizures in the first 18 to 36 hours of life and can be active and alert between seizures, unlike infants with HIE. **Cerebral sinus venous thrombosis** is less common than an arterial stroke and has an incidence of 1 in 8 to 38,000 children per year. It presents with seizures and diffuse and focal neurologic deficits. There are genetic risk factors and disorders predisposing to an ischemic stroke.
3. **Central nervous system hemorrhage.** ICH, including subarachnoid and subdural hemorrhage (more common in term infants), germinal matrix hemorrhage, periventricular-intraventricular hemorrhage, parenchymal hemorrhage (mainly in preterm), and intracerebral hemorrhage (traumatic or spontaneous), can cause seizures in the neonate. **Subarachnoid hemorrhage** in term infants can cause seizures on the second postnatal day, and infants may appear well during the interictal period. **Subdural hemorrhage** is usually associated with trauma (cerebral contusion) and can be asymptomatic in a less severe hemorrhage; in the most common type, the infant will present with focal seizures in the first 48 hours of life. **Germinal matrix hemorrhage-IVH** occurs in premature infants from hemorrhage in the small blood vessels in the subependymal germinal matrix and can be associated with parenchymal injury; infants present with seizures in the first 3 days of life. There are genetic risk factors and disorders that predispose an infant to fetal or neonatal IVH or intraparenchymal hemorrhage; one example is related to *COL4A1*, which encodes type IV collagen.
4. **Brain malformations.** Brain malformations cause seizures in 5% to 10% of neonates. The majority of these do not present with seizures in the neonatal period. For example, only 5% of infants with tuberous sclerosis present with seizures. Often the infant has obvious anomalies of the face or head if developmental abnormalities are present. Common malformations include lissencephaly, focal cortical dysplasia, subcortical band heterotopia, periventricular nodular heterotopia, schizencephaly, hemimegalencephaly, polymicrogyria, and hydranencephaly, and many have a genetic basis. **Neurocutaneous syndromes** (tuberous sclerosis complex, association with hemimegalencephaly, and incontinentia pigmenti) are also included and all have a genetic cause.
5. **Hypertensive encephalopathy** (very rare) can be secondary to neonatal thyrotoxicosis or renovascular disease.

B. Transient metabolic disturbances

1. **Hypoglycemia** is responsible for 3% to 7.5% of neonatal seizures, with the onset of seizures typically occurring on the second day. Hypoglycemia occurs more commonly in high risk infants who are term or late preterm SGA, LGA, and IDM infants. Seizures from hypoglycemia occur more commonly in SGA infants than in IDMs. A blood glucose should be obtained immediately to rule it out.
2. **Hypocalcemia** is responsible for approximately 2.3% to 9% of neonatal seizures. Most infants with hypocalcemia are asymptomatic. **Early hypocalcemia** (first 2–3 days of life) usually occurs in infants with prematurity, birth asphyxia, IUGR,

and low birth weight and in IDM infants. Early hypocalcemia is often associated with seizures and not the primary cause of seizures. **Late hypocalcemia** (5–14 days of life) usually occurs in full-term infants, and if moderate to severe, it is more common in male and Hispanic infants. It can occur from nutritional causes (unusual in the United States), genetic causes, maternal hyperparathyroidism or neonatal hypoparathyroidism, or vitamin D deficiency or with CHD (DiGeorge syndrome may or may not be present). Approximately 50% of infants with hypocalcemic seizures have hypomagnesemia.

3. **Hypomagnesemia** is a rare cause of seizures and often occurs along with hypocalcemia. It is frequently seen in premature infants or infants with respiratory distress syndrome, diarrhea, or neonatal hepatitis. Consider this if a neonate with hypocalcemia continues to seize after adequate calcium therapy. **Primary hypomagnesemia** (presents alone) is very rare and is caused by a defect of magnesium absorption or handling (**inherited hypomagnesemia** examples: congenital magnesium malabsorption, neonatal severe primary hyperparathyroidism, hypomagnesemia with secondary hypocalcemia) and presents with seizures at 2 to 6 weeks of age.
 4. **Hypонатremia** is an uncommon cause of neonatal seizures. Causes include oxytocin administration, excessive fluid intake, syndrome of inappropriate antidiuretic hormone (ICH, HIE, bacterial meningitis), congenital adrenal hypoplasia, congenital hypothyroidism, and maternal water intoxication.
 5. **Hypernatremia is also an uncommon cause** of neonatal seizures and can be caused by breast milk hypernatremia (more common in term infants), inadequate fluid replacement, excessive sodium bicarbonate administration, and rarely diabetes insipidus. Rapid correction of hypernatremia with fluid resuscitation can cause cerebral edema and seizures.
- C. **Infectious etiology.** The incidence of infection causing seizures in newborns is equal in preterm and term infants and is the etiology in 5% to 20% of newborns with seizures. It is important to note that **early seizures** usually occur with nonbacterial infections (cytomegalovirus or toxoplasmosis) and that **late-onset seizures** occur with bacterial meningitis or herpes simplex encephalitis.
1. **Meningitis, encephalitis, or brain abscess.** Bacterial meningitis (most common pathogens are *Escherichia coli* and group B *Streptococcus*) usually presents with seizures at the end of the first week or later. Herpes simplex is the most common cause of nonbacterial encephalitis. **Brain abscesses** occur as a complication of bacterial meningitis and are very rare, and most cases are secondary to gram-negative organisms (*Pseudomonas*, *Serratia*, and *Proteus* species). **Encephalitis** is most commonly caused by viral infections but can be caused by bacteria.
 2. **Sepsis.** Often due to gram-negative bacilli and group B *Streptococcus*. Sepsis without meningitis can present with seizures.
 3. **Congenital infections.** Toxoplasmosis, cytomegalovirus, herpes simplex, rubella, and coxsackie B virus can all present with seizures in the neonate. Intrauterine toxoplasmosis or cytomegalovirus can present with seizures in the first 3 days of life. Seizures with herpes present after 7 days of life and are usually focal. Zika virus can cause seizures and trigger epilepsy in infants.
- D. **Inborn errors of metabolism presenting as neonatal seizures (genetic metabolic causes)** (see also Chapter 100). Seizures are a common presenting symptom in metabolic disorders and present as medically intractable seizures. Seizure type or EEG findings are rarely specific for a particular metabolic disorder. Seizures caused by inborn errors of metabolism (IEM) usually start in the antepartum period and do not respond to anticonvulsants. Clinically, these infants get progressively worse and have worsening EEG abnormalities. EEG may show burst suppression or unexplained slowing of the background activity. MRI shows brain atrophy. Infants have clinical findings of HIE with no history of HIE. Other signs that an infant may have an IEM include family history, progressive myoclonic epilepsy, seizures related to eating,

seizures get worse with some antiepileptic medications, and unexplained status epilepticus. IEMs presenting with seizures almost always have other extraneurologic signs and symptoms. They can also be seen in infants after feeding who are >72 hours of age. The IEMs presenting with seizures include aminoacidopathies, urea cycle disorders, and organic acidurias. The most common of these, which present with hyperammonemia or acidosis or both, include nonketotic hyperglycinemia, sulfite oxidase deficiency, multiple carboxylase deficiency, glutaric aciduria type II, and urea cycle defect. Other less common causes of neonatal seizures include mitochondrial (pyruvate dehydrogenase deficiency and cytochrome c oxidase deficiency) or peroxisomal disturbances (Zellweger syndrome or neonatal adrenoleukodystrophy). Other IEMs presenting with intractable seizures in the neonatal period include glycine encephalopathy, D-2-hydroxyglutaric aciduria, pyruvate carboxylase deficiency, γ -aminobutyric acid transaminase deficiency, dihydropyridine dehydrogenase deficiency, congenital disorders of glycosylation, mitochondrial glutamate transporter defect, Menkes disease, peroxisomal biogenesis defects, and mitochondrial encephalopathy. **Vitamin-responsive IEMs** include pyridoxine dependency, pyridoxal phosphate-dependent seizures, folinic acid-responsive seizures, and multiple carboxylase deficiency (biotin dependent). **Pyridoxine dependency**, a rare disease, is a pyridoxine metabolism disturbance whereby the infant can present with intrauterine seizures or seizures within the first few hours of life. The seizures are multifocal and clonic and do not respond to any medication. If they are not treated, the infant will progress to a progressive encephalopathy and death. Antiquitin deficiency is the main cause of pyridoxine-dependent epilepsy. **Pyridoxamine phosphate oxidase deficiency** is a disorder that involves a molecular defect involving pyridoxamine phosphate oxidase. The infant presents with fetal seizures and encephalopathy. In **folinic acid-responsive seizures**, infants present with seizures in the first few hours of life and an EEG with multifocal sharp waves. **It is important to note treatable causes of IEMs because it is vital to recognize these early on so they can be treated** (pyridoxine-responsive seizures, pyridoxine 5'-phosphate oxidase deficiency, folinic acid-responsive seizures, multiple carboxylase deficiency, GLUT-1 deficiency [De Vivo syndrome], 3-phosphoglycerate dehydrogenase deficiency, primary hyperinsulinemic hypoglycemia, congenital magnesium malabsorption, cerebral creatine disorders, and congenital disorders of glycosylation).

E. Congenital hypothyroidism can present with neonatal seizures.

F. Genetic epileptic syndromes

- 1. Inherited metabolic syndromes.** Those that can present with seizures include Zellweger syndrome spectrum, Smith-Lemli-Opitz syndrome, DEND syndrome, and microcephaly capillary malformation syndrome. **DEND syndrome** encompasses developmental delay, epilepsy, and neonatal diabetes. Hyperinsulinism/hyperammonemia syndrome is associated with hypoglycemia and neonatal seizures (20% present within the first 72 hours of life).
- 2. Syndromic genetic etiologies** that are associated with neonatal seizures include early-onset Aicardi-Goutieres syndrome (pseudo-TORCHZ syndrome), Charge syndrome, DiGeorge syndrome, Wolf-Hirschhorn syndrome, and trisomies 13, 18, and 21.

G. Neonatal epileptic syndromes. The following are early epileptic syndromes that can present in the newborn period (**rare cause of neonatal seizures**). These infants can have a normal examination and appear well with recurrent seizures. It is important to identify these infants because the treatment and long-term management are different.

- 1. Self-limited (benign) familial neonatal epilepsy.** Autosomal dominant inheritance and family history are required. Seizures start between days 4 and 7 of life, can occur over hours to days, and include initially unilateral clonic events involving the face and limbs and then tonic events with autonomic features, apnea, and cyanosis in up to 33% of infants. The most common genetic etiology is mutation in *KCNQ2*; mutations in *KCNQ3* have also been noted.

2. **Early myoclonic encephalopathy is a rare epileptic encephalopathy.** It can present within hours of birth or up to 10 days of life with frequent (almost continuous) seizures and early encephalopathy. Seizures begin as myoclonus, either localized or involving the face and limb. Focal seizures can then occur, followed by tonic seizures. EEG is characteristic (bursts of paroxysmal activity with lack of activity). There is usually no family history because this condition is usually sporadic, but genetic etiology (*ErbB4*) or underlying metabolic defect (eg, glycine encephalopathy) or cerebral malformation may exist. Infants have reduced life expectancy.
 3. **Early infantile epileptic encephalopathies.** There are 3 of these, but only 1, Ohtahara syndrome, presents in the neonatal period. Ohtahara syndrome is a severe epileptic syndrome with frequent intractable seizures and severe early encephalopathy. All infants have frequent early-onset tonic seizures, and some have focal clonic or hemiclonic seizures. Etiologies include the following: structural brain malformation (most common), sporadic, metabolic (nonketotic hyperglycinemia, carnitine palmitoyl transferase deficiency, mitochondrial disorders, pyridoxine/pyridoxal 5'-phosphate disorders, and others), and genetic causes (most common associated genes are *STXBP1* and *KCNQ2*).
- H. Unknown and other causes.** In approximately 10% of seizures, the cause is either unknown or secondary to other causes.
1. **Unknown.** No identifiable etiology.
 2. **Other causes**
 - a. **Infant of mother with substance use disorder** (see Chapter 102). Seizures are an uncommon manifestation of withdrawal, especially opiate withdrawal. Infants usually present with seizures in the first several days. Infants can also have an abnormal EEG without seizures (30% in opiate withdrawal). Seizures can also occur in nonnarcotic withdrawal (alcohol, antidepressants, tricyclic antidepressants, diazepam, propoxyphene, selective serotonin reuptake inhibitors, barbiturates, sedative-hypnotics, cocaine). Neonatal jitteriness can occur from maternal use of sertraline (Zoloft). Infants exposed to heroin present with signs of neonatal abstinence syndrome within 24 hours of birth; with methadone or buprenorphine exposure, they present with neonatal abstinence syndrome 2 to 6 days after delivery.
 - b. **Local anesthetic intoxication (rare cause).** If a local anesthetic (eg, mepivacaine) is accidentally injected into the infant's scalp during a pudendal or paracervical block (most common) or epidural block or during local anesthesia for an episiotomy, seizures can occur within the first 6 hours of birth. Transplacental transmission has also been reported. This occurrence is often mistaken for HIE, since both present with early occurrence of seizures. Seizures are most commonly tonic. Three diagnostic features of local anesthetic intoxication include the following: the infant has pupils fixed to light that are commonly dilated, the infant will exhibit the "doll's eye" reflex (oculocephalic reflex; when head is turned to the right side, the eyes turn to the left; when the head is turned to the left, the eyes move to the right), and the infant will improve over the first 24 to 48 hours with proper support. Look for needle marks on the scalp and confirm by sending the level of suspected agent in the blood, urine, or cerebrospinal fluid (CSF).
 - c. **Drug toxicity.** Toxic doses of theophylline or caffeine can cause jitteriness and seizures. Early high-dose caffeine therapy has been associated with an increase in seizures and total seizure burden in extremely premature infants.
 - d. **Polycythemia with hyperviscosity** rarely causes seizures.
 - e. **Acute bilirubin encephalopathy.** These infants can have mental status changes, hypertonia, retrocollis and opisthotonos, and rarely seizures.
 - f. **Extracorporeal life support-related seizures** occurred in 5% to 30% of neonates and children who underwent ECLS. One risk factor was low cardiac output syndrome.

g. Congenital heart disease may result in seizures and epilepsy. Congenital heart disease (CHD) with cyanotic right-to-left shunts (transposition of the great arteries and tetralogy of Fallot) accounts for the majority, but CHD with left-to-right shunts also causes seizures. Seizures also occur after hypothermic cardiopulmonary bypass surgery and repair of cyanotic CHD. CHD is also part of syndromes that predispose infants to seizures.

IV. Database

A. History. A detailed history (prenatal, natal, and postnatal history) may help diagnose seizure activity. Does the mother have gestational diabetes, maternal hyperparathyroidism, prolonged rupture of membranes, peripartum fever, or any sexually transmitted diseases/sexually transmitted infections? Does the mother use any medications or drugs? Is there maternal narcotic abuse? Does the mother have a bleeding disorder or any history of epilepsy in the family? Did the mother experience excessive fetal movements (intrauterine seizures)? A history of consanguinity and previous neonatal deaths in the family might suggest IEMs. The provider observing the activity should record a complete description of the event on the chart. Did the mother note hiccups in utero (nonketotic hyperglycemia)? Is there any history of birth trauma, difficult delivery, or perinatal asphyxia?

B. Physical examination. Pay close attention to the neurologic status. Look at the scalp for evidence of injection during delivery. Is there macro-/microcephaly? Does the cutaneous examination reveal a vesicular rash (herpes, incontinentia pigmenti)? Look for dysmorphic features seen in Zellweger syndrome or Smith-Lemli-Opitz syndrome. Is there hepatosplenomegaly, hypotonia, or dysmorphic features (suggests peroxisomal or lysosomal disorders)? Are there inverted nipples and abnormal fat pads (consider congenital disorders of glycosylation)? An ophthalmology examination is recommended because there are various abnormalities on the exam (retinitis pigmentosa, cataracts) that can be seen in metabolic diseases.

C. Clinical classification of seizures. In the evaluation of an infant, it is useful to use a defined classification system to clearly identify the clinical characteristics of the seizure. The clinical classification of neonatal seizures has historically been based on Volpe or Mizrahi and Kellaway. A new classification is being developed by the ILAE but has not been published yet. Note that >50% of neonatal seizures are seen only on EEG and are not clinically apparent.

1. Volpe classification is based on clinical observations

a. Subtle: Most common type of seizure in preterm and term infants. Involves any alterations in neonatal behavior, motor functions, and autonomic function that are usually difficult to recognize and are overlooked. Examples include **ocular movements** (blinking, staring, eye deviation), **oral movements** (chewing, sucking, smiling, mouthing), **body movements** (pedaling, swimming, limb posturing), and **autonomic phenomena** (central apnea [more common presentation of a subtle seizure in term infant], changes in blood pressure or heart rate, pallor, increased secretions). Many of these alterations may not represent seizure activity but brainstem release (automatic reflex behaviors released when the cerebral cortex is not functioning normally). If found in preterm infants, it is more common and more likely to be seizure activity than if found in term infants.

b. Clonic: Can be unifocal/multifocal; repetitive jerking typically seen in 1 extremity or only 1 side of body.

c. Myoclonic: Can be focal, multifocal, or generalized; rapid flexion/extension movements of extremities, twitching or jerking movements. Typically involves 1 extremity or several body parts.

d. Tonic: Focal (less common) or generalized (more common). Typically involves 1 extremity or whole body with extension of arms and legs or stiffening of body with decerebrate posturing. Eyes deviate upward, and infant may be apneic.

2. **Mizrahi and Kellaway classification is based more on pathophysiology**
 - a. **Focal clonic:** Muscle contractions that are rhythmic.
 - b. **Focal tonic:** Sustained limb/trunk posturing.
 - c. **Myoclonic:** Single contractions that are random.
 - d. **Spasms:** Flexor/extensor spasms; may occur in clusters.
 - e. **Electrographic:** The majority of neonatal seizures are EEG-only seizures (no clinical correlate, subclinical, or nonconvulsive), would not be identified unless continuous EEG monitoring occurred, and are common in high-risk neonates. Only one-third of seizures are accompanied by clinical signs on a video EEG.
 - f. **Generalized tonic:** Sustained symmetric posturing.
 - g. **Motor automatism:** Oral-buccal-lingual, ocular, and limb movements.
3. **The International League Against Epilepsy is revising its classification, and it will be published shortly. This represents work available for public comment prior to publication.**
 - a. **With clinical signs**
 - i. **Motor**
 - (a) **Automatisms:** Coordinated motor activity that occurs when cognition is impaired. In the neonate, these seizures are very common and are seen in HIE and preterm infants. It is usually oral and is associated with other features. Can be unilateral, bilateral asymmetric, or bilateral symmetric.
 - (b) **Clonic:** Either symmetric or asymmetric jerking of the same muscle groups, usually repetitive. Most common seizure type recognized in the neonate. It is typically seen in vascular etiologies in term infants (neonatal stroke, cerebral hemorrhage) and in HIE. Can be focal, multifocal, or bilateral.
 - (c) **Epileptic spasms:** Sudden extension, flexion, or mixed extension-flexion of mainly truncal and proximal muscles. May occur in clusters (eg, head nodding, subtle eye movements, grimacing). Can be unilateral, bilateral asymmetric, or bilateral symmetric. Seen most commonly in IEMs or Ohtahara syndrome.
 - (d) **Myoclonic:** Brief (<100 millisecond), involuntary, multiple or single contractions of muscles/muscle groups of variable parts of the body. In the neonate, it is similar to nonepileptic myoclonus. Can be focal, multifocal, bilateral asymmetric, or bilateral symmetric. Typically seen in IEM, myoclonic encephalopathy, genetic epilepsy syndromes, preterm infants, and HIE.
 - (e) **Sequential:** A type of seizure characterized by a sequence of signs, symptoms, and EEG changes at different times. In the neonate, it presents with a variety of clinical signs. Seen typically in genetic etiologies; often seen in channelopathies (benign familial neonatal epilepsy or *KCNQ2* encephalopathy)
 - (f) **Tonic:** An increase in muscle contraction that is sustained and can last a few seconds to minutes. In the neonate, it is most commonly focal, unilateral, or bilateral asymmetric. Can be focal, bilateral asymmetric, or bilateral symmetric. Can be seen in HIE but is typically seen in genetic etiologies (early infantile epileptic encephalopathy, *KCNQ2* and *KCNQ3* mutations, other epileptic encephalopathies).
 - ii. **Nonmotor**
 - (a) **Autonomic:** Alteration of the autonomic nervous system including cardiovascular, gastrointestinal, vasomotor, thermoregulatory, and pupillary functions. Seen in IVH, temporal and occipital lobe lesions, and Ohtahara syndrome.

(b) **Behavior arrest:** Arrest of all activities. Rarely occurs in isolation and can include focal and motor seizures. Can include apnea and other autonomic manifestations.

iii. **Unclassified.** Unable to classify in a category.

b. **Without clinical signs (electrographic only).** Most common seizure type in preterm and term infants. Occurs in infectious causes and in HIE (thalamus/basal ganglia injury); also seen in neonates undergoing cardiac surgery.

D. Laboratory studies. It is important to rule out the most common etiologies that require immediate treatment. Blood glucose to rule out hypoglycemia and lumbar puncture once the seizures stabilize to rule out bacterial meningitis are important to do as early as possible since treatment is essential. Other laboratory tests should include arterial blood gas, serum electrolytes (sodium, potassium, calcium, magnesium, and phosphorus), and complete blood count with differential. Check the newborn screening results for hypothyroidism and some IEMs.

1. Metabolic workup

a. **Serum glucose.** If bedside testing is <40 mg/dL, obtain a central value.

b. **Serum sodium.** To evaluate for hyponatremia or hypernatremia.

c. **Serum ionized and total calcium levels.** Only an ionized calcium (most accurate) is necessary, but if this cannot be done stat, a total calcium should be ordered.

d. **Serum magnesium.**

2. Infection workup

a. **Complete blood count with differential.** A hematocrit also rules out polycythemia.

b. **Inflammatory markers** such as C-reactive protein or procalcitonin.

c. **Blood, urine, and cerebrospinal fluid cultures (for bacteria and viruses).** CSF polymerase chain reaction for herpes simplex virus if suspected.

d. **Serum immunoglobulin M and immunoglobulin M-specific TORCHZ titers.** The serum immunoglobulin M titer may be elevated in TORCHZ infections.

3. **Urine drug screening.** If neonatal abstinence is suspected.

4. **Theophylline or caffeine level** if toxicity is suspected.

5. **Blood gas levels.** To rule out hypoxia or metabolic acidosis.

6. **Serum bilirubin** if indicated.

7. **Additional studies for inborn errors of metabolism.** Check newborn screening for any positive results. Include serum ammonia (increased in urea cycle and organic acid metabolism defects), lactic acid (elevated in organic acid metabolic disorders), pyruvate, CSF lactate, urine organic acids/serum amino acid assays, carnitine levels, and an acylcarnitine profile. Test serum and CSF for glycine (nonketotic hyperglycinemia) and serine (serine deficiency). Test plasma and urine α -aminoadipic semialdehyde and pipercolic acid levels (elevated in pyridoxine dependency). Test CSF for pyridoxal phosphate and biogenic amines, elevated CSF glycine (transient or true nonketotic hyperglycinemia), low CSF glucose with normal blood glucose (glucose transporter deficiency), elevated CSF lactate (mitochondrial disorder), and low CSF biogenic amine metabolites (neurotransmitter deficiency).

8. **Lumbar puncture.** To rule out bacterial or viral meningitis and encephalitis. If blood is in the CSF, it may suggest an IVH. Cultures and rapid testing of the fluid should be done to diagnose infection (see Chapters 38 and 140). Check CSF as noted earlier in Section IV.D.7. Additional analysis of CSF includes CSF neurotransmitters for folinic acid-responsive seizures, glycine for nonketotic hyperglycinemia, lactic acid for mitochondrial disorders, and neurotransmitters for 5-hydroxyindoleacetic acid and homovanillic acid. Elevated ammonia level may indicate a urea cycle or organic acid metabolism defect.

9. **Genetic testing.** Genetic testing is now recommended for neonates with epilepsy in order to diagnose the cause, which can guide management and targeted treatment plans as well as help in determining the prognosis and recurrence risk for families. Newborn epilepsy is often due to identifiable genetic causes. In 1 study of 29 infants with epilepsy not linked to another cause, 83% had a genetic cause. In another study, >75% had identifiable genetic etiologies. **Neonatal epilepsy genetics** is a rapidly expanding field. The genetic causes of seizures can be grouped into genetic vascular, genetic metabolic, genetic syndromic, genetic cellular, and malformations of cortical development. Genetic testing is now recommended as early as possible in neonates who have no identifiable cause for epilepsy based on initial and secondary testing. **Epilepsy gene panels (next-generation sequencing–based tests)** are recommended as the first-line genetic test for genetic epilepsies over chromosomal microarray tests because the diagnostic yield is better. One example is the epilepsy gene panel. The most common gene identified by a gene panel analysis is *SCN2A*. A genetic etiology may help in developing a treatment plan and in determining prognosis and recurrence risk for families. See genetic testing information at <https://www.ncbi.nlm.nih.gov/gtr>. **Pharmacogenomics of epilepsy** is of interest since it will focus on detecting genetic markers that identify infants who are refractory to medications, which will allow better medication selection. For example, **genetic testing for hyperekplexia** includes mutations in the *GLRA1* and *SLC6A5* genes, sequence analysis of the *ARHGEF9* gene, or mutations in the *GLRB* and *GPHN* genes. Do a single-gene test or multiple-gene panel that includes *ALDH7A1* for a mutation analysis (to rule out possible antiquitin deficiency in pyridoxine dependency).
- E. **Imaging and other studies.** An ultrasound, computed tomography, or magnetic resonance imaging test may be performed as part of an evaluation to help determine the etiology of neonatal seizures. Each test has its strengths and weaknesses in diagnosing intracranial lesions. These tests should not be done to determine the presence or absence of clinical seizures.
1. **Ultrasound examination of the head.** First-line imaging test to rule out CNS malformations, confirm periventricular hemorrhage–IVH, intracerebral bleeds. Studies report an abnormal finding was found on head US in 10% to 43% of infants.
 2. **Cranial magnetic resonance imaging.** A very sensitive test (seizure etiology detected in 88%–95% of cases) that is used to help determine the etiology of the seizures. It actually has greater sensitivity in identifying ischemic damage, ICH, and brain malformations than CT or ultrasound. Its disadvantage is that it is difficult to obtain in an unstable infant. MRI of an infant with an IEM will show prominent brain atrophy. **Magnetic resonance angiography and venography** is helpful in making the diagnosis of cerebral infarction. **Diffusion-weighted imaging** is helpful in early hypoxic injury. **Brain magnetic resonance spectroscopy** should be considered because it can help in the diagnosis of IEMs.
 3. **Computed tomography scan of the head.** To diagnose subarachnoid or subdural hemorrhage. It may also reveal calcifications in a congenital malformation or cerebral infarction if suspected.
 4. **Electroencephalography.** (See also Chapter 18.) The EEG gives important diagnostic and prognostic information and can also aid in the management of seizures in newborns. **The American Clinical Neurophysiology Society Guideline on continuous EEG monitoring in neonates recommends EEG testing** to clarify if a clinical event is a seizure, to detect seizures in high-risk neonates, to monitor for seizure recurrence during weaning of medications, to monitor burst suppression, and for other long-term monitoring indications. The World Health Organization (WHO), International League Against Epilepsy (ILAE), and the International Bureau of Epilepsy (IBE) recommend that all clinical seizures should be confirmed by an EEG if available. It should not be performed

for the purpose of determining the etiology of the seizures. AAP recommends that all newborns with HIE who receive therapeutic hypothermia need either an amplitude-integrated EEG (aEEG) or conventional EEG for identification of seizures. **Certain EEG patterns can suggest etiology** (eg, IEM: usually nonspecific, but burst suppression is seen in nonketotic hyperglycemia, generalized bursts of bilaterally synchronous 1- to 4-Hz activity with spikes or sharp waves are seen in pyridoxine dependency, and high-voltage and rhythmic delta slow waves with myoclonus and paroxysmal responses during photic intermittent stimulation are seen in progressive myoclonic epilepsy). **The EEG also predicts neurologic sequelae in infants.** With a normal EEG, <10% of infants will have neurologic sequelae; with moderate abnormalities on EEG, approximately 50% of infants will have neurologic sequelae; with severe abnormalities on EEG, ≥90% of infants will have neurologic sequelae. There are several types of EEG used in the neonatal intensive care unit:

- a. **Basic conventional electroencephalography** is done on infants at low risk for seizure activity. It is limited for capturing seizures because the usual duration is 60 minutes, but can be up to 8 hours. Most infants will have seizures if the recording is for a minimum of 24 hours.
- b. **Continuous electroencephalography (cEEG).** The cEEG captures the electrical activity over a prolonged period of time (≥24 hours) Most infants will have seizures if the recording is for a minimum of 24 hours.

It is also used to aid in management of seizures. The American Clinical Neurophysiological Society states that the continuous EEG is superior to the aEEG (see Section IV.E.4.d) for monitoring and classifying neonatal seizures.

- c. **Multichannel video EEG recording** is considered the **gold standard for diagnosis of seizures in neonates.** It is recommended to characterize clinical events and to assess for artifacts that may mimic electrographic seizures. It is recommended for 24 hours as most infants will have a seizure within the first day.
- d. **Amplitude-integrated electroencephalography (aEEG).** Smaller portable units are used at the bedside with only 2 to 4 scalp electrodes, instead of the usual 12 to 16. These units also provide shorter, simpler readouts than the conventional EEG. These units detect most seizures in at-risk infants. aEEG has a high sensitivity and specificity when performed by experienced users. Use of aEEG is associated with a shorter time to diagnosis of seizures in encephalopathic infants. It has been stated it is a “**useful initial complementary tool**” because there are concerns of underdiagnosing seizures and neonatologists are not confident in their aEEG interpretations.

- V. **Plan** Treatment consists of stabilizing the infant, ensuring adequate ventilation and circulation first, and then quickly sending stat labs for any underlying disorders that may be causing the seizures (eg, hypoglycemia, hypocalcemia, sepsis evaluation). Treat any acute transient metabolic conditions before starting an antiepileptic medication. **Neonatal seizures are considered the most common neurologic emergency. The workup should be begun as soon as possible.**

- A. **General measures.** If an infant is actively seizing or is having repeated seizure activity, it is considered an emergency and the infant should be treated as soon as possible. If the infant is not actively seizing and is stable, one can attempt to confirm and verify the seizure with an EEG if possible. WHO, ILAE, and IBE guidelines strongly recommend that all clinical seizures be confirmed by an EEG. They also recommend that “any electrical seizure, even in the absence of a clinically apparent seizure, should be treated.”

1. **Airway, breathing, circulation.** Assess the infant’s airway, breathing, and circulation. Intubation and mechanical ventilation may be necessary to maintain oxygenation. Correct hypoxia and metabolic acidosis.

2. **Check laboratory studies for metabolic causes.** There is no evidence to support or reject giving empirical treatment prior to obtaining laboratory studies. Remember that treating infants empirically with glucose before lab results can cause worsening of hyperglycemia in HIE and that giving intravenous (IV) calcium can cause asystole or skin necrosis.
 - a. **Check glucose level.** Hypoglycemia needs to be ruled out and treated before an antiepileptic drug is considered. A bedside glucose test should be done immediately to rule out hypoglycemia while a stat sample is sent to the laboratory for confirmation. If the paper-strip test shows low blood glucose, it is acceptable to give 10% glucose, 2 mL/kg IV push, before obtaining results from the laboratory. If one is unable to measure a serum glucose, consider empirical treatment with glucose. Unexplained or persistent hypoglycemia should be thoroughly evaluated (see Chapter 67).
 - b. **Obtain stat serum calcium, magnesium, and sodium levels.** If these levels were low on earlier values and a metabolic disorder is strongly suspected as the cause of the seizures, it is acceptable to treat the infant before new laboratory values are available.
 3. **Rule out sepsis/meningitis.** Sepsis evaluation is recommended and possible treatment with antibiotics. Some sources recommend all infants who have had a seizure be evaluated for sepsis/meningitis, others recommend to only do a work up if there are clinical signs or if they are considered a high risk for an infection. If the decision is made to begin antibiotics, preferably do it after obtaining a sepsis evaluation, including a blood culture and lumbar puncture. If this is not possible, empirical treatment with antibiotics if clinical signs are present can be considered. Do a lumbar puncture once the infant is stable enough to perform it. **Treat herpes encephalitis** with acyclovir or treat if there is a high index of suspicion of herpes infection.
 4. **Some institutions will treat the infant with pyridoxine** before an antiepileptic drug is given (weak WHO recommendation), whereas others will give it after antiepileptic medications have been given. Follow your institution guidelines. **Only consider this** if all other obvious etiologies are ruled out.
 5. **Pediatric neurology consultation is recommended**, especially if seizures persist, are prolonged, or are recurrent.
- B. Anticonvulsant therapy (Table 82–1).** The decision to treat with antiepileptic medication is very difficult because there are no clearly defined, evidence-based guidelines, the recommendations vary, and there is very little scientific evidence to support the best management of seizures in the neonate. In fact, Cochrane review states there is little evidence from randomized controlled trials to support the use of any of the anticonvulsants currently used in the neonatal period. **WHO, ILAE, and IBE guidelines recommend treatment** of any clinically apparent seizure in a neonate if it lasts >3 minutes or if the infant has brief serial seizures. They also recommend that all electrical seizures should be treated, even if there are no apparent clinical signs of a seizure. There is extensive experimental data on neonatal seizures in animal models but very little data on human newborns. The majority of evidence suggests that a single neonatal seizure does not cause any serious defects, but prolonged or brief recurrent seizures may be associated with worse outcomes since they can be damaging to the developing brain. Seizures can cause immediate and long-term adverse consequences, including developmental delay, cerebral palsy, cognitive impairment, epilepsy, and even death. Therefore, treatment of seizures is recommended. However, treatment of seizures with antiepileptic medications is not benign because of the associated risks of the medications (respiratory depression and others) and the effects on the immature brain, which are not well defined. **Seizure medications** are often referred to as **first-line, second-line, and third-line/emerging medications**. It is very difficult to categorize medications into these groups because it depends on the reference or study that is quoted. Follow your institutional guidelines on

Table 82-1. MEDICATIONS USED FOR NEONATAL SEIZURES

Drug	Drug Class	Dosing Regimens	Comments and Side effects
Phenobarbital	Barbiturate	LD: 15–20 mg/kg/dose IV; may repeat 5–10 mg/kg/dose every 15–20 minutes to a maximum total dose of 40 mg/kg MD: 3–5 mg/kg/d IV/PO in 1–2 divided doses	<ul style="list-style-type: none"> • Additional respiratory support may be required. • Therapeutic drug monitoring recommended with trough between 15 and 40 mcg/mL.
Phenytoin/ fosphenytoin	Hydantoin anticonvulsant	LD: 15–20 mg/kg/dose IV MD: 4–8 mg/kg/d IV/PO in 2–3 divided doses	<ul style="list-style-type: none"> • Fosphenytoin is a prodrug of phenytoin; dosing is per phenytoin equivalent (PE) and fosphenytoin is preferred over phenytoin due to better cardiac adverse effect profile and lower risk of extravasation (vesicant). • May cause blood dyscrasias, severe dermatologic reactions, and hepatotoxicity. • Hypotension and cardiac arrhythmias may occur with rapid infusion. • Therapeutic monitoring is recommended with troughs of 8–20 mcg/mL for total phenytoin and 1–2.5 mcg/mL for free phenytoin. • Hazardous agent; exercise appropriate handling precautions.
Levetiracetam	Miscellaneous anticonvulsant	LD: 10–50 mg/kg/dose IV MD: 10–80 mg/kg/d IV/PO in 2 divided doses	<ul style="list-style-type: none"> • May cause CNS depression, agranulocytosis, pancytopenia, thrombocytopenia, severe dermatologic reactions, and isolated elevation in diastolic blood pressure in young patients. • Abrupt discontinuation may increase seizure frequency. • Dosing adjustment may be required in renal impairment.
Lidocaine	Antiarrhythmic	LD: 2 mg/kg/dose IV over 10 minutes MD: 5–7 mg/kg/h × 4 hours, then 2.5–3.5 mg/kg/h × 6–12 hours, then 1.25–1.75 mg/kg/h × 12 hours	<ul style="list-style-type: none"> • Caution use in renal and/or hepatic impairment. • Contraindicated in severe heart block. • Therapeutic goal is 6–7 mcg/mL after continuous infusion for 4–6 hours.

Diazepam	Benzodiazepine	0.1–0.3 mg/kg/dose IV; may repeat every 15–30 minutes to a maximum total dose of 2 mg	<ul style="list-style-type: none"> ● Not recommended as first-line agent; use only after multiple agents have failed. ● Vesicant; injection contains benzoic acid, sodium benzoate, and benzyl alcohol. ● Caution use in renal and/or hepatic impairment.
Lorazepam	Benzodiazepine	0.05–0.1 mg/kg/dose IV; may repeat in 5–15 minutes as needed	<ul style="list-style-type: none"> ● May cause CNS and respiratory depression and myoclonus (especially in premature neonates). ● Injection formulation may contain polyethylene glycol and/or propylene glycol. Avoid high-dose and/or long-term use to prevent toxicity. ● Caution use in renal and/or hepatic impairment.
Midazolam	Benzodiazepine	LD: 0.05–0.15 mg/kg/dose IV MD: 0.06–0.4 mg/kg/h continuous infusion	<ul style="list-style-type: none"> ● May cause hypotension, respiratory depression, CNS depression, and myoclonus (especially in premature neonates). ● Caution use in renal impairment.
Topiramate	Miscellaneous anticonvulsant	5–10 mg/kg/d PO once daily	<ul style="list-style-type: none"> ● May cause hyperammonemia, encephalopathy, metabolic acidosis, hyperthermia, and nephrolithiasis. ● Dosing adjustment may be required in renal and hepatic impairment. ● Abrupt discontinuation may increase seizure frequency. ● Hazardous agent; exercise appropriate handling precautions.

CNS, central nervous system; IV, intravenous; LD, loading dose; MD, maintenance dose; PO, oral.

Data from Vanden Hoek TL, Morrison LJ, Shuster M, et al. Part 12: Cardiac arrest in special situations: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2010; 122(18 Suppl 3):829–861; and Lexi-Comp Online™, Pediatric & Neonatal Lexi-Drugs Online™, Hudson, Ohio: Lexi-Comp, Inc.; 2017; November 13, 2017.

which medications to use and when to use them. **First-line agents typically include** phenobarbital (most common), phenytoin, and benzodiazepines (lorazepam and midazolam); some units are now using levetiracetam. **Second-line agents typically include** phenytoin/fosphenytoin, levetiracetam, benzodiazepines, and lidocaine. **Third-line or emerging agents may include** clonazepam, lidocaine, topiramate, bumetanide, vigabatrin, and lamotrigine. **Medications reported but rarely used for neonatal seizures include** primidone, carbamazepine, lignocaine, valproic acid, pentobarbital, and thiopental. Phenobarbital and phenytoin are the most common antiseizure drugs used in the neonatal period even though their efficacy is poor (phenobarbital has approximately 43% seizure control, phenobarbital with phenytoin together has approximately 60% seizure control).

1. **Phenobarbital is the preferred first-line drug**, despite suboptimal efficacy. WHO, ILAE, and IBE strongly recommends this as the first-line agent because it is easier to administer, low cost, and readily available. Initially, 20 mg/kg IV is given as the loading dose, and if the seizures resolve, begin a maintenance dose of 3 to 4 mg/kg/d PO/IV divided twice a day. If seizures continue after 15 to 20 minutes, give an additional dose of 10 to 20 mg/kg IV, up to 40 to 50 mg/kg in 24 hours.
2. **If seizures persist after a maximum dose of phenobarbital, there is no real consensus on the second drug of choice.** Second-line drugs include phenytoin/fosphenytoin, levetiracetam, lidocaine, and benzodiazepines. Most often, phenytoin is given as the second-line drug. **Give phenytoin (Dilantin)** 20 mg/kg/dose at a rate of ≤ 1 mg/kg/min. **Fosphenytoin may be preferred** at some centers (see dosage in Chapter 155) because it has been associated with fewer side effects than phenytoin (less hypotension, fewer cardiac abnormalities, and less soft tissue injury). **As a second-line antiepileptic drug, WHO, ILAE, and IBE guidelines (2012) recommend either a benzodiazepine or phenytoin or lidocaine for control of seizures. WHO (2017) recommends either midazolam or lidocaine in any neonate who is continuing to have seizures.** Some clinicians will choose the second medication based on whether the infant has any cardiac abnormalities or cardiac instability. **With cardiac issues**, it may be better to choose midazolam or levetiracetam. **For infants without cardiac issues**, choose fosphenytoin or lidocaine. Remember if using phenytoin or lidocaine, cardiac monitoring is recommended.
3. **Levetiracetam used as second-line medication.** Over the past decade, there has been an increasing interest in using levetiracetam in neonatal seizures. Recently there are a few studies confirming its effectiveness as a first-line treatment with less side effects than phenobarbital (lethargy, feeding difficulty). It has been used off-label by pediatric neurologists for treating neonatal seizures for many years. According to the current research, it has a good safety profile, good efficacy, and favorable pharmacokinetics and seems to be a promising agent for seizure control in neonates. Loading dose is 20 mg/kg, and maintenance dose is 10 to 80 mg/kg/d in 2 divided doses.
4. **Lidocaine.** Used as a second- or third-line drug. Mechanism of action is uncertain as an anticonvulsant. Used more commonly in Europe. Full-term infants respond better than preterm infants. Avoid in infants with CHD. Reduce dose in premature infants and those undergoing therapeutic hypothermia. Stop after 36 hours because there is a risk of toxicity.
5. **Benzodiazepines.** Respiratory depression can occur with these medications but is usually not a problem because most infants are already on mechanical ventilation. Most institutions use lorazepam.
 - a. **Lorazepam.** Used as second- or third-line drug. Given IV, dose can be repeated 4 to 6 times in a 24-hour period. It is advantageous to use over diazepam because its duration of action is longer and it causes less sedation, hypotension, and respiratory depression. Dose is 0.05 to 0.1 mg/kg every 8 to 12 hours.

- b. **Midazolam.** Useful in refractory neonatal seizures. A short-acting benzodiazepine that can be given by continuous infusion. Less respiratory depression and sedation than with diazepam and lorazepam. See dose in Chapter 155.
 - c. **Diazepam.** Effective anticonvulsant but used less often because of multiple issues (short duration of action, risk of circulatory collapse with respiratory failure, contains sodium benzoate, which can increase kernicterus risk).
6. **If seizures persist and other causes have been ruled out:** Three disorders need to be considered because they are treatable. First treat with pyridoxine. If that does not work, try pyridoxal 5'-phosphate. If that does not work, try folinic acid.
- a. **Pyridoxine (B6)-dependent seizures.** A trial dose of pyridoxine (vitamin B6), 50 to 100 mg, is given IV (with EEG monitoring) followed by a 30-minute observation period. If a response is seen, a maintenance dose of 50 to 100 mg/d orally is given. With pyridoxine dependency, the seizures stop quickly after the medication is given and the EEG normalizes. See dosing in Chapter 155.
 - b. **Pyridoxine 5'-phosphate oxidase deficiency.** A trial of pyridoxal 5'-phosphate needs to be given. Dose is 30 mg/kg/d in 3 doses.
 - c. **Folinic acid-responsive seizures (rare).** Obtain CSF neurotransmitter studies. Then folinic acid is given at 2.5 to 5 mg orally twice a day; dose may be increased to up to 8 mg/kg/d.
7. **If seizures still persist.** The following adjunctive agents may be used depending on institutional preference:
- a. **Bumetanide** is another novel neuroprotective agent. It was shown to be safe and had promising antiseizure activity in an early-phase trial. Can be given IV or intramuscularly.
 - b. **Valproic acid.** Effective for recurrent seizures and status epilepticus, but because of the high risk of fatal hepatotoxicity in neonates, it is of limited value. Can be given orally, rectally, and IV.
 - c. **Oral agents used in neonatal seizures** (however, because they are administered orally only, they are difficult to use because of dosing issues and variable blood levels)
 - i. **Topiramate.** Although the research is limited, topiramate has been used as an add-on agent for refractory neonatal seizures and has been found to be effective. Furthermore, the benefit of topiramate lies in the fact that it is neuroprotective in hypoxic injury.
 - ii. **Carbamazepine.** Has been used as an initial agent with success in a small study and as maintenance therapy as an alternative to phenobarbital or phenytoin.
 - iii. **Primidone.** Another oral agent that has been used in small studies with success but had variable blood levels in another study. It can only be given orally.
 - iv. **Clonazepam, felbamate, lamotrigine, and vigabatrin** are others reported.
8. **Medications used for refractory status epilepticus or seizures resistant to other medications.** **Pentobarbital anesthesia** has been used for refractory status epilepticus but has the potential for serious complications, and intense monitoring is required. **Thiopental** has been used in ventilated patients but is no longer available in the United States.
- C. **Specific measures based on etiology of the seizure**
1. **Hypoxic ischemic injury.** Therapeutic hypothermia is now the standard of care for hypoxic ischemic injury. Therapeutic hypothermia may decrease electrographic seizures in neonates. WHO, ILAE, and IBE do not recommend prophylactic treatment with phenobarbital in the absence of clinical seizures. Cochrane review states that prophylactic barbiturate therapy to infants following perinatal asphyxia did decrease the risk of seizures, but there was no decrease seen in mortality. See Chapter 43.

2. **Hypoglycemia.** Give 2 mL/kg IV of dextrose 10%; give a second dose if necessary. Make sure the infant is on maintenance glucose. Treat and determine the cause, as outlined in Chapter 67.
3. **Hypocalcemia.** Give 100 to 200 mg/kg of calcium gluconate slowly IV under cardiac monitoring. Make certain that the infant is receiving maintenance calcium therapy (usually 50 mg/kg every 6 hours). Confirm correct IV position. (See also Chapter 91.)
4. **Hypomagnesemia.** Give 0.2 mEq/kg of magnesium sulfate IV every 6 hours until magnesium levels are normal or symptoms resolve. (See Chapter 105.)
5. **Hyponatremia.** See Chapter 69.
6. **Hypernatremia.** If hypernatremia is secondary to decreased fluid intake, increase the rate of free water administration. The amount of sodium needs to be decreased; it should be reduced over 48 hours to decrease the possibility of cerebral edema.
7. **Infection.** If sepsis is suspected, a complete workup should be performed and empirical broad-spectrum antibiotic therapy initiated. Remember aminoglycosides have poor CSF penetration. Antiviral therapy (acyclovir) should be considered in infants >1 week of age or sooner if there was premature rupture of membranes for treatment of herpes simplex virus. Some institutions treat all infants with seizures empirically with acyclovir when there is a high index of suspicion for herpes infection.
8. **Local anesthetic intoxication.** Infants improve over 48 hours with prompt recognition, because the half-life of the medication is 8 to 10 hours. Vigorous support including ventilation and removal of the drug by diuresis, with acidification of the urine, is recommended and more effective than removal by exchange transfusion. Seizure medications are usually not needed. Outcome is favorable.
9. **Drug withdrawal syndrome.** Supportive therapy and anticonvulsants are used. (See Chapter 102.)
10. **Subarachnoid hemorrhage.** Only supportive therapy is necessary. (See Chapter 103.)
11. **Subdural hemorrhage.** Only supportive therapy is necessary, unless the infant has lacerations of the falx and tentorium, for which rapid surgical correction is necessary. Hemorrhage over cerebral convexities is treated by subdural taps. (See Chapter 103.)
12. **Polycythemia with hyperviscosity.** IV hydration and/or partial plasma exchange are often used. (See Chapters 34 and 116.)
13. **KCNQ2- and SCN2A-related neonatal epilepsy.** Use sodium channel blockers such as oral carbamazepine (drug of choice) or phenytoin.
14. **DEND syndrome.** Treat with oral hypoglycemic agents (sulfonylurea) because insulin does not work.
15. **Hyperinsulinism/hyperammonemia syndrome.** Treat with diazoxide.
16. **Treatable inborn errors of metabolism**
 - a. **Pyridoxine-responsive seizures.** Treat with pyridoxine.
 - b. **Pyridoxine 5'-phosphate oxidase deficiency.** Treat with pyridoxyl phosphate.
 - c. **Folinic acid-responsive seizures.** Treat with folinic acid and pyridoxine.
 - d. **Multiple carboxylase deficiency.** Treat with biotin.
 - e. **GLUT-1 and pyruvate dehydrogenase deficiency.** Treat with ketogenic diet.
 - f. **3-Phosphoglycerate dehydrogenase deficiency.** Treat with serine.
 - g. **Primary hyperinsulinemic hypoglycemia.** Treat with glucose.
 - h. **Congenital magnesium malabsorption.** Treat with magnesium.
 - i. **Cerebral creatine disorders** (guanidinoacetate methyltransferase and arginine: glycine amidinotransferase deficiency). Treat with oral creatine

monohydrate. Guanidinoacetate methyltransferase deficiency also requires supplementation with ornithine and a restriction of arginine/protein.

j. **Congenital disorders of glycosylation type Ib.** Treat with mannose.

- D. **Maintenance anticonvulsant therapy** is not needed if 1 or 2 loading doses stop the seizures and it does not recur (controversial). If repeated doses are needed and seizures continue, a maintenance dose should be started 12 hours after the loading dose.
- E. **Duration of therapy.** From 10% to 30% of neonates who have seizures will have subsequent epilepsy. Three factors should be considered in determining the duration of therapy: neonatal examination (if abnormal, the risk of having recurrent seizures is higher), cause of the neonatal seizure (risk after cortical dysgenesis is approximately 100%; after HIE, 30%–50%; after late-onset hypocalcemia, 0%), and the EEG results (normal or minimal depression showed no risk; marked depression showed a risk of 41%).
- F. **When to stop the antiepileptic medication.** WHO, ILAE, and IBE guidelines state that if the infant has a normal neurologic examination and/or a normal EEG, one can consider stopping the medication if the infant is seizure free for 72 hours. For an infant on 1 medication, one can just discontinue the medication. For an infant on >1 medication, stop the medications 1 at a time, and stop phenobarbital last.

83 Traumatic Delivery

- I. **Problem.** An infant is noted to have severe bruises after birth, and a nurse observes that the infant is not using his right arm. The birth was noted to be traumatic, and the nurse calls you to evaluate the infant. The terms **birth injuries** and **birth trauma** are used interchangeably. According to the National Vital Statistics Reports, **birth injury** is “the impairment of the infant’s body function or structure due to adverse influences that occurred at birth.” **Birth trauma** is defined as “a physical injury sustained by an infant in the process of birth.” The rate of birth trauma has declined over the past 20 years, and the incidence is unclear, with study estimates ranging from approximately 6 to 8 per 1000 live births. The highest percentage of birth injuries occurs in mothers who were subjected to birthing instruments (eg, vacuum extraction, forceps). African Americans and Hispanics experience lower rates of birth injuries than whites and Asians/Pacific Islanders. Birth injuries occur from both vaginal and cesarean deliveries. Infants delivered by cesarean section are at risk for different types of birth trauma than infants delivered vaginally. Infants delivered by cesarean have a decreased risk of all birth trauma due to the decreased risk of clavicle fractures and injuries to the brachial plexus and scalp. Birth injuries can range from minor (petechiae) to severe (spinal cord injury resulting in death). The **most common birth injuries** are brachial plexus palsy (Erb palsy), bone fractures (fracture of the clavicle most common), cephalohematoma, caput succedaneum, intracranial hemorrhage, subconjunctival hemorrhage, facial paralysis, spinal cord injuries, and cerebral palsy. **Documentation of injuries** (Mongolian spot [now called congenital dermal melanocytosis], rib fractures, clavicle fractures, retinal hemorrhages) is very important at the first physical examination because some of these injuries can be confused with nonaccidental trauma after discharge.

II. Immediate questions

A. Are there any risk factors for a birth injury? Certain factors predispose the infant to birth injuries. **Macrosomia and instrumental deliveries** are major risk factors.

1. Risk factors

- a. Maternal:** Small maternal stature, primigravida, maternal pelvic abnormalities, maternal obesity, cephalopelvic disproportion, increased maternal age (clavicle fracture), maternal trauma 1 to 2 weeks before delivery (intra-abdominal injuries in infant), twin pregnancy (femur fracture).
- b. Delivery:** Prolonged or very rapid labor, precipitous delivery, difficult fetal extraction, abnormal presentation (especially breech by vaginal delivery; 30 per 1000 live births), cephalopelvic disproportion, nuchal cord, oligohydramnios, instrumental deliveries (use of mid-forceps [4-fold increase] or vacuum extraction [3-fold increase]), excessive traction during delivery.
- c. Infant:** Macrosomia irrespective of route of delivery The higher the degree of macrosomia the higher is the risk of birth injury (risk is increased by 2-fold with BW of 4000–4500 g, 3-fold with BW of 4500–4900 g, and 4.5-fold with BW >5000 g), very large fetal head, very low BW infant, fetal anomalies (osteogenesis imperfecta), prematurity, male gender (head and neck trauma), shoulder dystocia (brachial plexus injury, clavicular fracture, humerus fracture).

2. Injuries associated with risk factors

- a. Vacuum extraction:** Subgaleal hemorrhage, depressed skull fracture, iatrogenic encephalocele, cephalic hematoma, cephalohematoma, intracranial hematoma, subdural hemorrhage, retinal hemorrhage.
 - b. Forceps delivery:** Most common cause of injury to the facial nerve, cephalohematoma.
 - c. Forceps and vacuum extraction:** Shoulder dystocia, retinal hemorrhages, intracranial hemorrhage, cephalohematoma, subdural hemorrhage.
 - d. Breech presentation:** Long bone fractures, intracranial hemorrhage, brachial plexus palsy, lacerations of the buttocks.
 - e. Macrosomia:** Clavicle and rib fractures, shoulder dystocia, cephalohematoma, caput succedaneum.
 - f. Premature birth:** Intracranial and extracranial hemorrhage, bruising.
 - g. Precipitous delivery:** Retinal hemorrhage, bruising, intracranial or extracranial hemorrhage.
 - h. Abnormal presentation:** Lacerations, retinal hemorrhage, bruising.
 - i. Shoulder dystocia:** Brachial risk injury.
- B. Is the injury so serious that it requires immediate attention?** The majority of birth injuries are not serious and do not require urgent treatment. Significant injuries are an emergency and require immediate intervention and close monitoring; significant injuries include subgaleal hemorrhage (can be fatal), posterior fossa subdural hematoma (can cause brainstem compression resulting in respiratory compromise), spinal cord injuries (can be fatal), and abdominal organ injuries (present as shock secondary to bleeding and require immediate diagnosis).

III. Differential diagnosis (based on site of injury)

A. Skin trauma

- 1. Petechiae.** Petechiae are small (<3 mm) bruises that do not blanch on pressure. They usually **occur with a precipitous delivery, breech presentation, or tight nuchal cord.** In birth trauma, petechiae are usually localized (eg, on the head, neck, upper chest area, and lower back). There is no associated bleeding, and no new lesions appear. If petechiae are diffuse and continue to progress, suspect coagulopathy, disseminated intravascular coagulation (with abnormal coagulation profiles, thrombocytopenia, oozing from bleeding sites such as venipuncture), infection (other signs such as temperature irregularity and cardiopulmonary distress are present), or other systemic disease.

2. **Ecchymosis/bruising.** A bruise is a superficial injury produced by trauma with extravasation of blood into the skin. Ecchymosis is a nonraised skin discoloration >1 cm caused by blood vessel rupture with blood leaking into the layer of skin tissues. Ecchymosis can be from a medical condition (thrombocytopenia), internal bleeding, or trauma. Bruising can occur after a traumatic delivery, especially when labor is rapid or the infant is premature or in a breech delivery. Extensive ecchymoses may indicate occult blood loss. The risk of hyperbilirubinemia (usually at 3–5 days) is increased in these injuries (increased bilirubin due to blood breakdown).
 3. **Abrasions or lacerations** are more frequent in emergency cesarean deliveries for fetal distress. These can occur due to a scalpel or other instrument during delivery and are usually located on the scalp, buttocks, or thigh. Sometimes suturing is necessary for deep lacerations. Fetal scalp blood sampling can cause a scalp abrasion.
 4. **Forceps injury/marks.** Frequently, reddish linear marks are seen across both sides of the face from the pressure of the blades.
 5. **Scalp electrode injury.** The site of insertion of the scalp electrode can sometimes become infected (1% of cases), and in premature infants, it can rarely cause severe bleeding.
 6. **Subcutaneous fat necrosis** is caused by localized pressure and ischemia to the fatty tissue in the subcutaneous space during the birth process and usually occurs in term or postterm infants. Typically involves the trunk, shoulders, arms, thighs, cheeks, and buttocks with a well-circumscribed firm lesion of the skin and underlying tissue. It usually appears between 6 and 10 days of age. Lesion size is 1 to 10 cm, lesions can be irregular and hard, the overlying skin can be deep red/purple or colorless, and the condition can cause hypercalcemia. (See Chapter 80 and Figure 80–7.)
 7. **Neonatal alopecia** (hair loss) can occur associated with birth trauma. Neonatal alopecia needs to be differentiated from aplasia cutis congenital, which is localized congenital absence of the skin with loss of subcutaneous tissue, bone, or dura not usually related to birth trauma.
- B. Head trauma**
1. **Traumatic cyanosis.** Cyanosis of the head and face can occur from venous congestion, from a face presentation, or a tight umbilical cord around the neck.
 2. **Soft tissue injury.** Bruising and petechiae.
 3. **Latrogenic encephalocele with enlarging subcutaneous cerebrospinal fluid collection** is a herniation of brain tissue (not involving the meninges) and is a rare complication of a vacuum extraction delivery. It presents similar to a caput succedaneum.
 4. **Extracranial injury.** See also Chapter 7, Figure 7–3.
 - a. **Caput succedaneum.** Relatively common, this accumulation of blood and serum (from increased pressure of the uterine and vaginal walls during labor on the fetal head) causes an edematous swelling at birth over the presenting part of the scalp during a vertex delivery. Associated with overlying erythema, bruising, and petechiae. This swelling is subcutaneous but exterior to the periosteum. **It crosses the midline of the skull and suture lines.** It is usually associated with molding. Hyperbilirubinemia rarely develops. A **vacuum caput** is a caput succedaneum that occurs during a delivery using a vacuum device. It typically has well-defined margins of the vacuum cup.
 - b. **Cephalohematoma.** This is subperiosteal accumulation of blood that is caused by rupture of superficial veins between the skull and periosteum. Incidence is up to 2% of all live births. It is more common in males and in instrumental deliveries (4–5 times higher in forceps deliveries, 8–9 times higher in vacuum deliveries, and 11–12 times higher in forceps plus vacuum deliveries). The bleed is below the periosteum overlying 1 cranial bone, usually

the parietal bone. **There is no crossing of the suture lines**, the scalp is not discolored, and the swelling sometimes takes ≥ 24 hours to become apparent because the bleeding is slow. The affected area is largest on postnatal day 3. An associated skull fracture is present in up to 25% of affected infants (often a linear fracture). Hyperbilirubinemia (sometimes significant if the lesion is extensive) may develop. The cephalohematoma can become infected with complications such as skull osteomyelitis (*Escherichia coli* most common), and sepsis or meningitis can occur. Two conditions that are similar and might be confused with cephalohematoma are cranial meningocele (associated with pulsations, increased pressure with crying) and caput succedaneum (crosses the midline, with discoloration of the skin).

- c. **Subgaleal hemorrhage** (also called subaponeurotic hemorrhage) is the least common extracranial injury but the most serious and is caused by rupture of the emissary veins that connect the scalp veins to the dural sinuses. It occurs in approximately 64 in 10,000 vacuum extraction deliveries and 4 in 10,000 noninstrumented deliveries. Blood collects in the soft tissue space between the epicranial aponeurosis and the periosteum of the skull. Diffuse swelling of the soft tissue, often spreading toward the neck and behind the ears, and periorbital swelling are also evident. **The “classic triad” is tachycardia, decreased hematocrit, and an increasing occipital frontal circumference (OFC). The OFC can increase 1 cm for every 30 to 40 mL of blood.** Associated signs include hemorrhagic shock, severe blood loss (potential to hold $>40\%$ of the total blood volume), shock, anemia, hypotonia, seizures, and pallor. This can be a fatal complication (mortality rate up to 14 %) of a traumatic birth.
5. **Intracranial injury.** Most common is subdural hemorrhage (73%), then subarachnoid (20%), intracerebral (20%), intraventricular, and epidural hemorrhage. (See also Chapter 103.)
- a. **Subdural hemorrhage** is the **most common intracranial hemorrhage** in a term newborn (2.9 per 100,000 spontaneous deliveries; if vacuum or forceps are used, incidence is 5.8 per 100,000; if both vacuum and forceps are used, incidence is 29 per 100,000). It is caused by rupture of the bridging veins and causes blood between the arachnoid layer of the brain and dura mater. Infants usually present in the first 24 to 48 hours after birth with stupor, altered level of consciousness, seizures, respiratory depression, apnea, irritability, full fontanelle, unresponsive pupils, and coma. Posterior fossa subdural hemorrhage is rare (suspected if excessive fetal molding) but may result in death from compression of the respiratory center in the brainstem.
 - b. **Subarachnoid hemorrhage** is the **second most common intracranial hemorrhage**. It is caused by rupture of the bridging veins in the subarachnoid space. Blood is located between the arachnoid membrane and pia mater. Usually asymptomatic, but signs can occur at 24 to 48 hours after birth: seizures, apnea, and other complications such as high bilirubin. Typical scenario is a well term baby with new-onset seizures; apnea is common in premature infants.
 - c. **Intraparenchymal hemorrhage**
 - i. **Intracerebellar hematoma/cerebellar hemorrhage.** Associated with traumatic delivery and can present with apnea, unexplained motor agitation in preterm infants, bulging fontanel, and decreased hematocrit.
 - ii. **Intracerebral hemorrhage.** This can occur from cranial birth trauma but is more commonly associated with other causes.
 - d. **Intraventricular hemorrhage (IVH)** is usually associated with preterm deliveries and not associated with birth trauma. IVH in term infants can occur secondary to birth trauma or asphyxia. Incidence is 4% in term infants and is highest in vacuum- and forceps-assisted delivery. IVH presents with apnea, lethargy, cyanosis, seizures, weak suck, and high-pitched cry.

- e. **Epidural hematoma (rare).** This is injury to the middle meningeal artery. Blood is between the skull and outside of the dura. One cause is the infant being dropped during delivery. Signs are similar to those of subdural hemorrhage (hypotonia, seizures, bulging fontanelles, change in level of consciousness), and it is diagnosed by head computed tomography (CT) or magnetic resonance imaging (MRI). Clinical manifestations are usually delayed, and it is often associated with linear skull fracture and cephalohematoma.
 - f. **Contusion bruise (cerebral and cerebellum) of the brain.** Presents with nonspecific neurologic dysfunction. CT demonstrates punctate hemorrhages.
6. **Skull fracture** injuries are uncommon in neonates; most are linear and are associated with a cephalohematoma. Fractures at the base of the skull may result in shock. Occipital fractures are most commonly associated with breech deliveries. Evaluate for any **neurologic deficit** because this changes management.
- a. **Linear (nondepressed) fracture (most common).** A break that traverses the full thickness of the skull, is straight, and has no displacement. The parietal bone is usually involved. Usually without any signs, but bleeding can occur, most commonly extracranially. Rarely, intracranial bleeding can occur.
 - b. **Depressed fracture** (also called “ping-pong fracture”) of the skull is caused by the bone (most commonly the parietal or the frontal) being displaced inward. There is an increased incidence of an intracranial process in depressed fractures, especially those >1 cm. Depressed fractures are often visible and can result in seizures. They occur from birth trauma, but a congenital depressed fracture of the skull can also occur prenatally or in the absence of trauma. **Subdural hematoma** is the most common intracranial injury associated with a depressed skull fracture.
 - c. **Occipital osteodiastasis.** This is usually a complication of breech deliveries but is rare now because the American Congress of Obstetricians and Gynecologists recommends cesarean delivery for term breech singletons. It is a traumatic separation of the cartilaginous joint between the squamous and lateral portions of the occipital bone that results in a posterior fossa subdural hemorrhage associated with laceration of the cerebellum. There are 3 types: a classic form, a fatal form, and a less severe variant compatible with survival.

C. Facial trauma

1. **Fractures of the nose, mandible, maxilla, lacrimal bones, and septal cartilage.** These can often present as respiratory distress or feeding problems and require treatment. Urgent plastic surgery/otorhinolaryngology consultation is recommended.
2. **Dislocations of the facial bones.** Nasal septal dislocation (the most common facial injury) can occur and presents as stridor and cyanosis. Facial bone and mandibular fractures can occur.
3. **Facial nerve injury.** This is the most common peripheral nerve (cranial nerve VII) injury secondary to birth trauma and is seen in up to 1% of live births. Most cases implicate forceps use, but approximately 33% occur in deliveries without instruments. The injury is secondary to the pressure of the forceps or the face lying on the maternal sacral promontory. The nerve is injured at the point where it emerges from the stylomastoid foramen. Rule out other causes of asymmetric crying face (congenital deficiency or absence of the depressor anguli oris muscle, which controls the downward motion of the lip) by observing that the eye and forehead muscles are unaffected in asymmetric crying face.
 - a. **Peripheral facial nerve injury (more common)** involves the entire side of the face. At rest, the infant has an open eye on the affected side. The nasolabial fold is flattened, and the mouth droops. When the infant cries, the findings are similar to those with central paralysis.
 - b. **Central facial nerve injury.** Involves the lower half or two-thirds of the contralateral side of the face. On the paralyzed side, the nasolabial fold is

obliterated, the corner of the mouth droops, and the skin is smooth and full. When the infant cries, the wrinkles are deeper on the normal side, and the mouth is drawn to the normal side.

- c. **Peripheral nerve branch injury.** Only 1 group of facial muscles is involved (mouth, eyelid, or forehead), and injury results in paralysis of only that area.

D. Ocular trauma

1. **Eyelids.** Edema and bruising can occur. Swollen eyelids should be forced open to examine the eyeball. Laceration of the eyelid can also occur.
 2. **Orbit fracture.** Rarely occurs. Immediate ophthalmologic evaluation is necessary if disturbances of the extraocular muscle movements and exophthalmos are evident. Severe injuries may result in death.
 3. **Horner syndrome.** Due to impaired sympathetic outflow with signs such as miosis, partial ptosis, enophthalmos, and anhidrosis of the ipsilateral side of the face. Delayed pigmentation of the ipsilateral iris can be seen as the child grows.
 4. **Subconjunctival hemorrhage.** A common finding that resolves without treatment.
 5. **Cornea.** Haziness can be secondary to edema or use of eye prophylaxis. With persistent cornea opacity (haziness/clouding) and prolonged corneal edema, suspect detachment of the Descemet membrane. A forceps injury can induce a tear in the Descemet membrane; it is usually unilateral with a vertical break.
 6. **External ocular muscle injuries** involving the third, fourth, and sixth cranial nerves.
 7. **Optic nerve injury.** Vision may be affected.
 8. **Intraocular hemorrhage**
 - a. **Retinal hemorrhage.** It occurs most commonly in vacuum deliveries (75%) but can occur in spontaneous vaginal deliveries and cesarean deliveries. Cause is unknown, but it is believed to be due to the pressure exerted on the head through the birth canal. Most commonly, a flame-shaped or streak hemorrhage is found near the optic disk. It can be seen 3 to 4 weeks after birth. A subdural hemorrhage can cause preretinal and intraretinal hemorrhages.
 - b. **Subconjunctival hemorrhage (under the conjunctiva)** is a common finding that resolves without treatment.
 - c. **Hyphema** is gross blood in the anterior chamber and should be evaluated by ophthalmology.
 - d. **Vitreous hemorrhage** is indicated by floaters, absent red reflex, and blood pigment seen on slit-lamp examination by ophthalmology.
- E. Ear injuries** (abrasions, bruising, hematomas, avulsion, or laceration of the auricle) can occur, often due to forceps. Fetal malposition also contributes to injuries to the ear. Hematomas of the pinna can lead to a “cauliflower ear” (an irreversible condition that occurs when the external portion of the ear is injured; a collection of fluid develops under the perichondrium, cartilage dies, fibrous tissue is formed, and the outer ear becomes deformed and swollen).
- F. Nose injuries.** Nasal fracture and dislocation of the nasal cartilage can occur. The most common is nasal dislocation; incidence is <1%. Nasal deformity without dislocation can also occur. Nasal fracture and dislocation are increased in prolonged delivery, with increased head circumference, and in vaginal delivery.
- G. Vocal cord injuries/recurrent laryngeal nerve injury.** Although rare, these injuries can occur as a result of excessive traction on the head during delivery and are caused by an injury to the recurrent laryngeal branch of the vagus nerve. Often associated with forceps in a difficult delivery, they can result in bilateral or unilateral vocal cord paralysis and may cause acute respiratory compromise.
1. **Unilateral paralysis** involves the recurrent laryngeal branch of 1 of the vagus nerves in the neck. Asymptomatic at rest, but hoarse cry, weak cry, abnormal voicing, and mild to moderate stridor with inspiration are seen. Unilateral vocal cord paralysis is usually left sided because of the nerve’s longer course and position for injury.

2. **Bilateral paralysis.** Caused by trauma to both recurrent laryngeal nerves. Signs include respiratory distress, stridor, and cyanosis.

H. Neck, shoulder, and chest injuries

1. **Shoulder dystocia.** Occurs when the head is delivered and the shoulder gets stuck during delivery. Trauma to the neck can occur when the baby is delivered. The most common injury is brachial plexus injury, but the clavicle can be broken or cord compression can occur.
2. **Clavicular fracture.** The **most common bone fracture during delivery** (~1%–1.5% from birth trauma). Risk factors include macrosomia, increased maternal age, shoulder dystocia, and use of instruments at delivery (forceps and vacuum). Most fractures are greenstick/incomplete type. If the fracture is complete, symptoms involve decreased or absent movement of the arm, gross deformity of the clavicle, pain response on palpation, localized crepitus and petechiae over affected side, and an absent or asymmetric Moro reflex. Nondisplaced fracture usually presents with no symptoms, and the diagnosis is made because of callus formation at 7 to 10 days. Bilateral clavicle fractures can occur but are rare. Brachial plexus injury or phrenic nerve palsy can be associated.
3. **Rib fractures.** Very rare.
4. **Brachial plexus injury.** Incidence is 0.5 to 2.5 per 1000 live births. Involves paralysis of upper arm muscles following trauma to spinal roots C5 to T1. Usually secondary to a prolonged delivery of a macrosomic infant with excessive strain on the head, neck, and arm. The spinal roots of the fifth cervical through the first thoracic spinal nerves (brachial plexus) are injured during birth. This is usually unilateral and occurs twice as often on the right as the left. Brachial plexus injury is diagnosed by **unilateral arm weakness**. Obstetrical shoulder dystocia training was associated with a lower incidence of brachial plexus injury. There are 4 forms of brachial plexus injury:
 - a. **Erb palsy (Erb-Duchenne palsy)** caused by injury to nerve roots C5 and C6. Erb palsy is the most common form of brachial plexus injury and involves the upper arm (~90% of cases). The fifth and sixth cervical roots are affected, and the arm is adducted and internally rotated and fully extended at the elbow with pronation of the forearm and flexion of the wrist. (“waiter’s tip” position). The deltoid muscle is paralyzed, which prevents the arm from being raised. The paralysis of the biceps brachii and brachialis muscle causes the arm to be limp and the forearm pronated. The Moro reflex is absent or weakened. The grasp reflex is intact, which rules out total arm paralysis. In some infants, a complete ossified cervical rib is found, and some feel that this anatomic variation (also including fibrous bands) is thought to cause narrowing of the supra-costoclavicular space, allowing the nerves to be more susceptible to trauma. If the infant with brachial palsy has tachypnea and needs oxygen, rule out phrenic nerve involvement because brachial palsy can be associated with phrenic nerve palsy.
 - b. **Total brachial plexus injury** is present in almost 10% of cases, and all nerve roots are involved. Entire arm (global or total brachial plexus) paralysis is present. Because the entire brachial plexus is damaged, the patient has a flaccid arm that hangs limply with no reflexes. Horner syndrome can accompany this injury if the sympathetic fibers of T1 are damaged.
 - c. **Klumpke palsy.** Occurs when there is damage to the C8 to T1 nerve roots and is isolated to the lower arm because the seventh and eighth cervical and first thoracic roots are injured; it is rare (<1% of cases). The hand is paralyzed, the wrist does not move, and the grasp reflex is absent (ie, “dropped hand”). Cyanosis and edema of the hand can also occur. An ipsilateral Horner syndrome (ptosis, miosis, and enophthalmos) can be seen because of injury involving the cervical sympathetic fibers of the first thoracic root.
 - d. **Horner syndrome** is a preganglionic injury with damage to the sympathetic outflow via nerve root T1. The classic triad is miosis (a constricted pupil),

(partial) ptosis (upper eyelid droops over the eye), and anhidrosis (loss of hemifacial sweating). Enophthalmos (posterior retrodisplacement of the eyeball in the orbit) can also be associated.

5. **Phrenic nerve paralysis** involves the C3, C4, and C5 nerve roots. Difficult breech delivery with lateral extension of the neck, with avulsion of C3 through C5 nerve roots, can cause **diaphragmatic paralysis** (75% of cases). It can be associated with brachial plexus injury. Signs include recurrent episodes of cyanosis, tachypnea, irregular respirations, and thoracic breathing with no bulging of the abdomen. It causes ineffective respirations and presents with difficulty breathing in the first few hours of life, with elevation of the diaphragm on x-ray.
 6. **Sternocleidomastoid muscle injury** is also called congenital muscular torticollis and involves a well-circumscribed, immobile mass (1–2 cm) in the midportion of the sternocleidomastoid muscle (SCM) that enlarges, regresses, and disappears. This results in a transient torticollis after birth. The head tilts toward the involved side, the chin is elevated and rotated, and the infant cannot move the head into normal position. Usually occurs on the right side of the neck and is most apparent at 1 to 4 weeks of age. Facial asymmetry can be seen.
- I. Spinal cord injuries.** Rare (<0.2 per 10000 births) and are caused by lateral or longitudinal stretching force of the neck or hyperextension or torsion of the fetal neck. Signs vary depending on the location of the injury, and these injuries usually occur with breech deliveries or use of forceps. They can involve meningeal damage with epidural hemorrhage, spinal artery occlusion, vertebral artery injuries and occlusion, laceration of the spinal nerve roots and bruising, and laceration or complete transection of the cord. The higher the injury, the greater is the risk of respiratory problems. Suspect this in a neonate with severe respiratory compromise and profound hypotonia. Spinal shock can occur, which presents with paralyzed abdominal movements, diaphragmatic breathing, distended bladder, and extremities that are flaccid.
1. **Infants with a high cervical lesion or brainstem injury.** Usually born stillborn or with severe respiratory depression, shock, or hypothermia with paralysis at birth. Mortality is high. Death usually occurs within a few hours after birth.
 2. **Upper or midcervical lesions.** Present with lower extremity paralysis, absent deep tendon reflexes, absent sensation in the lower half of the body, constipation, urinary retention, and respiratory depression.
 3. **Lesions in the seventh cervical to first thoracic roots.** Injury may be reversible. Muscle atrophy, contractures, bony deformities, constant urinary leakage.
 4. **Partial spinal cord injuries.** On neurologic examination, these infants have signs of spasticity.
- J. Abdominal organ injuries (uncommon and infrequent)** are associated with maternal trauma 1 to 2 weeks before delivery or trauma during the delivery process. **Most common is liver injury.** These injuries should be suspected with shock, increasing abdominal circumference, anemia, pallor, and irritability. These infants can be asymptomatic for hours and then deteriorate acutely. Risk factors for these injuries include macrosomia and breech presentation. **Intraperitoneal bleed needs to be ruled out in every infant who presents with shock and abdominal distension,** and paracentesis is essential for diagnosis.
1. **Liver hematoma/rupture/fracture.** The liver is the most commonly injured solid organ by direct pressure from birth trauma. **Subcapsular hematomas** are the most common lesion, are usually not easily diagnosed, and are usually asymptomatic at birth (subtle signs of blood loss include poor feeding, tachypnea, pallor, and onset of jaundice). **Rupture of the hematoma** presents with

sudden circulatory collapse and discoloration of the abdominal wall. Liver fracture can present with shock, anemia, pallor, and abdominal distension.

2. **Splenic hematoma/rupture.** Signs are similar to rupture of the liver; blood loss and hemoperitoneum may be seen. Less frequent than hepatic injury.
 3. **Adrenal hemorrhage.** Usually right sided (70 %) and unilateral (90%). Presents with an abdominal mass. Symptoms vary depending on degree and rate of hemorrhage and include fever, tachypnea, flank mass, pallor, purpura, hypotension, cyanosis, poor feeding, shock, irritability, vomiting, and diarrhea. Hypoglycemia, early-onset hyperkalemia, and prolonged hyperbilirubinemia can be seen.
 4. **Renal hemorrhage.** Suspect in a newborn with a flank mass and hematuria with a history of birth trauma.
- K. Extremity injuries.** See also Chapter 112. Besides the clavicle, the humerus and femur are the most common fractures during the birth process.
1. **Fractured humerus** is seen in 0.2 per 1000 deliveries and is the second most common fracture during birth trauma. The arm is immobile, and there can be swelling and localized crepitus, with pain on movement and palpation. Moro reflex is absent on the affected side.
 2. **Fractured femur** occurs in 0.13 per 1000 deliveries and is the third most common fracture during birth trauma. Usually occurs secondary to breech delivery with a pop or snap sometimes heard at delivery. Infants with congenital hypotonia are at risk. Deformity is usually obvious; the affected leg does not move, there is swelling, and there is pain with assisted movement.
 3. **Fractured radius.** Rare.
 4. **Epiphyseal separation.** Rarely seen, this usually involves the radial head but can also involve the humeral or femoral epiphysis. Examination reveals adduction, internal rotation of the affected arm, and poor Moro reflex. Femoral separation exhibits more pain and tenderness with palpation.
 5. **Sciatic nerve palsy.** Rare and can occur in breech deliveries. Prolonged labor and a forceful extraction of the leg are usually obtained from the history. Complete or partial paralysis can occur.
 6. **Radial nerve palsy (rare).** Infants present with absent wrist and digital extension but good shoulder and elbow function. Ecchymosis and fat necrosis may support a compression injury during labor.
 7. **Growth plate injuries** can occur in the long bones in the newborn. They are often misdiagnosed as joint fractures with dislocation. Birth injuries to the growth plates can occur and have been reported in the proximal humerus (shoulder) and the distal humerus (elbow).
- L. Genital injuries.** Neonatal genital trauma can occur in both males and females. It is a rare and uncommon complication of breech presentation. Males can have edema, bruising, and diffuse hematoma of the scrotum. Females may present with swollen and tender masses with diffuse hematoma of the labia majora and discoloration of both the labia majora and minora. Injury usually does not affect micturition.
1. **Testicular and epididymal injury.** Findings are scrotal swelling, with the infant experiencing vomiting and irritability. A **hematocele** can form if the tunica vaginalis testis is injured; the scrotum will not transilluminate and needs to be differentiated from a congenital hernia/hydrocele usually by ultrasound. **Scrotal rupture** has only been reported in case reports. Scrotal hematoma may be a sign of adrenal hemorrhage.
 2. **Perineal/rectovaginal injury/tear.** Rare birth injury that has been reported usually with breech presentation delivered vaginally.
- M. Umbilical cord rupture.** This can occur from trauma from an operative vaginal delivery (forceps or vacuum device used). Hemorrhage with bradycardia and respiratory distress can occur.

IV. Database

A. Physical examination. Details on the initial physical examination of the newborn are found in Chapter 7.

1. **Skin.** Look for petechiae, bruising, and any lacerations. Check the side of the face for forceps marks. Look for and palpate any area that looks like fat necrosis.
2. **Head.** Carefully examine the head for any evidence of a caput succedaneum, cephalhematoma, subgaleal hemorrhage, or fracture. Check to see whether the suture lines are crossed (differentiates between the caput succedaneum and cephalhematoma). Depressed skull fractures are obvious; others may require radiologic studies.
3. **Face.** Examine the face at rest and during crying to look for any facial asymmetry (nerve palsy or facial fractures). Facial fractures can present with asymmetry of the face, ecchymoses, edema, poor feeding, or respiratory distress. Check for any signs of respiratory distress (stridor or cyanosis).
4. **Eyes.** Examine the eyeball and the eyelid. Make sure that extraocular muscle movements are normal. Check for the red reflex. Check for corneal clouding and edema. Funduscopic examination within the first 24 hours of birth will increase the chance of finding a retinal hemorrhage.
5. **Ears.** Examine the front and back of the ear, looking for lacerations, swelling, and hematomas.
6. **Nose.** Check for dislocation versus deformation. Flatten the tip of the nose; with a deformation, no nasal deviation occurs, whereas with a dislocation, one can see the deviated septum and the nares collapse.
7. **Vocal cords.** Signs may include high-pitched cry or stridor. If injury is suspected, examine the vocal cords by direct laryngoscopy or use a flexible fiberoptic laryngoscope.
8. **Neck and shoulder injuries.** Carefully examine the neck and the shoulder. Check Moro and grasp reflexes. Examine the arm to see whether movement is normal. Check respirations, and note any thoracic breathing. Make sure the head rests in a normal position and is not tilted. Examine the hips in an infant with congenital torticollis, since 10% will have congenital hip dysplasia.
9. **Spinal cord.** A careful and thorough neurologic examination should be done.
10. **Abdomen.** Examine the abdomen, and check for ascites, masses, and increase in size.
11. **Extremities.** Observe for movement and deformity. Check for pain with passive movement and palpation.
12. **Genitalia.** Examine the testes and the penis in males; transilluminate the scrotum. Carefully look at labia for bruising or hematoma.

B. Laboratory studies based on site of trauma

1. **Skin**
 - a. **Platelet count.** A normal platelet count excludes neonatal thrombocytopenia.
 - b. **Serum bilirubin test.** Hyperbilirubinemia may result from reabsorption of blood from extensive ecchymoses.
 - c. **Serum hematocrit.** Anemia may result from severe ecchymoses.
 - d. **Calcium levels** should be followed with fat necrosis due to hypercalcemia risk.
2. **Head**
 - a. **Hematocrit.** Blood loss can occur, sometimes requiring transfusions, especially in subgaleal hemorrhage.
 - b. **Serum bilirubin.** Significant hyperbilirubinemia may result from cephalohematoma or other traumatic bleeding event.
 - c. **Coagulation studies** are required to detect the consumption coagulopathy associated with subgaleal hemorrhage.
3. **Face.** Arterial blood gas may be indicated in infants with grunting. Nerve excitability or conduction tests are recommended if there is no improvement in the facial nerve palsy after 3 to 4 days.

4. **Eyes, ears, or vocal cords.** No laboratory tests are usually required.
5. **Neck and shoulder.** Arterial blood gas helps diagnose hypoxia associated with phrenic nerve paralysis.
6. **Spinal cord.** The usual laboratory tests required for respiratory depression and shock, if indicated.
7. **Abdomen.** Obtain hematocrit to rule out anemia and blood loss and urine dipstick to check for hematuria. Consider abdominal paracentesis with fluid sent to the laboratory for cell count with differential.
8. **Extremities and genitalia.** No laboratory tests are usually needed.

C. Imaging and other studies

1. **Head.** Skull radiographs should be obtained to rule out the possibility of skull fractures. Head ultrasonography can be performed at the bedside and can detect an intracranial hemorrhage if the image is high quality and the sonographer is experienced. It is used to detect IVH. A CT scan can also be obtained and can be useful in the diagnosis of an intracranial hemorrhage (epidural, subarachnoid). MRI should be obtained if neurologic symptoms occur or if an intracranial injury occurs with a cephalhematoma or a skull fracture. Imaging should be considered in any infant with a large caput succedaneum that does not decrease in 72 hours, if the swelling increases >24 hours after delivery, or if there are neurologic deficits.
2. **Face.** Radiographs should be considered if a significant injury is suspected. A cranial CT scan or MRI may be necessary to further delineate the fracture.
3. **Eyes.** Radiographs, to rule out orbit fracture, may be indicated. Ultrasound and handheld optical coherence tomography may be necessary to rule out Descemet membrane detachment.
4. **Neck and shoulder**
 - a. **Ultrasound or radiograph of the clavicle** is necessary for confirmation of the diagnosis of fracture. Ultrasound is a satisfactory alternative to a radiograph for the diagnosis of fractures of the clavicle.
 - b. **Radiograph of the chest for phrenic nerve paralysis** will show an elevated diaphragm. **Fluoroscopy** reveals elevation of the affected side and descent of the normal side on inspiration with phrenic nerve impairment. Opposite movements occur with expiration. **Dynamic ultrasound of the diaphragm for phrenic nerve evaluation** shows abnormal motion on the affected side.
 - c. **Magnetic resonance imaging of the neck and spine** for nerve root avulsion.
 - d. **Electroencephalogram.** Reveals the extent of the denervation weeks after the injury.
5. **Spinal cord**
 - a. **Cervical and thoracic spine radiographs.**
 - b. **Magnetic resonance imaging.** Most reliable method for diagnosing spinal cord injuries.
6. **Abdomen.** Abdominal ultrasound usually diagnoses liver rupture or subcapsular hematoma, splenic rupture, adrenal hemorrhage, and kidney damage. An abdominal radiograph may reveal a stomach bubble displaced medially in splenic rupture. CT scan and ultrasonography are the preferred modalities to diagnose an abdominal injury.
7. **Extremities.** A radiograph/ultrasound of the extremities usually confirms the diagnosis of bone injury. An **ultrasound** is diagnostic for epiphyseal separation because it can diagnose a growth plate injury since it can visualize the nonossified epiphysis.
8. **Genitalia.** Ultrasonography is usually diagnostic.

V. Plan

A. Skin

1. **Petechiae.** No specific treatment is necessary because traumatic petechiae usually fade in 2 to 3 days.

2. **Subcutaneous fat necrosis.** The lesions require observation only because they usually disappear within weeks to a few months without any cutaneous sequelae. Extensive calcification can occur within the lesions, and pain can occur, requiring analgesics. Hypercalcemia is a life-threatening complication of subcutaneous fat necrosis and can occur in approximately 35% to 56% of infants. Its exact cause is unknown. Closely monitor blood levels for up to 6 months after the onset of the fat necrosis for symptomatic hypercalcemia (vomiting, fever, and weight loss with high serum calcium), which can occur up to 6 months. This can usually be treated with restricting supplemental calcium and vitamin D, intravenous hydration, and furosemide. In severe cases, hydrocortisone therapy and bisphosphonates have been used.
3. **Ecchymoses.** No specific treatment is necessary because they usually resolve within 1 week. Monitor for hyperbilirubinemia (reabsorption of blood from a bruised area), anemia (blood loss from bruising), and hyperkalemia if extensive.
4. **Lacerations and abrasions.** For abrasions, cleaning the wound and observation are all that is needed. For lacerations, if superficial, the edges may be held together with butterfly adhesive or Steri-Strips. If deeper, they should be sutured with 7–0 nylon. Healing is usually rapid. Observe for infections, especially a scalp lesion and caput succedaneum.

B. Head

1. **Caput succedaneum.** No specific treatment is necessary because it resolves within the first several days after birth but can be present for up to 4 to 6 days. It rarely causes jaundice or significant blood loss. Rarely, scalp necrosis can occur. Consider imaging if there is a large caput succedaneum that does not go away in 48 to 72 hours after birth or if there is an increase in swelling 24 hours after birth, presence of neurologic deficits, or hemodynamic instability.
2. **Cephalhematoma.** Observation is usually all that is needed. Incision and aspiration are **not recommended**. The cephalohematoma usually resolves in 3 to 4 weeks, leaving a palpable subcutaneous nodule that is reabsorbed after 3 to 4 months. CT or skull radiography may be necessary if neurologic symptoms occur or underlying skull fracture needs to be ruled out. In some cases, blood loss and hyperbilirubinemia can occur and should be treated.
3. **Subgaleal hemorrhage.** Recommended treatment is close observation and aggressive management of hypovolemia and severe blood loss with shock.
 - a. **Place an umbilical venous line for access;** place an arterial line for blood pressure management and labs.
 - b. **Measure serial hematocrit and occipital frontal circumference.** Volume loss needs to be treated aggressively (10–20 mL/kg bolus infusions) with normal saline, whole blood, fresh-frozen plasma, or packed red blood cells. Assume a 40-mL amount of blood loss for every 1-cm increase in occipital frontal circumference.
 - c. **Consider treating metabolic acidosis,** provide adequate oxygenation and assisted ventilation, monitor serial hematocrits, and evaluate for coagulopathy.
 - d. **Monitor fluid intake and urinary output.**
 - e. **If hypovolemic shock develops,** treat immediately with volume resuscitation, and correct any coagulopathy.
 - f. **Phototherapy** may be needed for indirect hyperbilirubinemia (see Chapters 63 and 99).
 - g. **Observe any skin lesions** for infection and treat appropriately.
 - h. **Surgical evacuation of the hematoma** may be required if there are signs of brain compression, if there is increased intracranial pressure, if bleeding does not subside, or if there is severe clinical deterioration.

4. **Intracranial hemorrhage.** Circulatory and ventilatory support is indicated in deteriorating conditions. Consultation with neurosurgery is recommended. (See also Chapter 103.)
 - a. **Subarachnoid hemorrhage.** Resolution usually occurs without treatment. Observe for signs of herniation; if present, surgical evacuation is needed.
 - b. **Epidural hemorrhage.** Close observation is usually all that is needed. Monitor for signs of herniation; if present, surgical evacuation may be necessary. Prompt surgical evacuation for large bleeds has good prognosis with early treatment.
 - c. **Subdural hemorrhage.** Treatment depends on the location and how much bleeding has occurred. Most infants can be closely observed without surgical intervention. Surgical evacuation is necessary for infants who have signs of increased intracranial pressure. Posterior fossa subdural hemorrhage treatment is supportive with correction of coagulopathy. Consultation with neurosurgery is recommended if there is hydrocephalus, severe hemorrhage, or dysfunction of the brainstem.
 5. **Skull fracture.** The majority of skull fractures are asymptomatic. If there is any evidence of any neurologic deficit or if the depression is >1 cm, further imaging is necessary.
 - a. **Linear skull fractures.** Uncomplicated linear skull fractures usually require only close follow-up evaluation and monitoring.
 - b. **Depressed skull fractures. Check for neurologic deficits.**
 - i. **If the fracture is <1 cm with no neurologic deficit,** manage by close monitoring.
 - ii. **If the fracture is >1 cm.** Imaging with CT is recommended to rule out other intracranial lesions. Neurosurgical consultation is recommended as soon as possible if there is evidence of an intracranial lesion. A vacuum extractor or breast pump (*controversial*) has been used to elevate the fracture but is not routinely recommended because not enough studies have been done to prove that it is safe and effective.
 - iii. **If cerebrospinal fluid leakage is seen** (usually from the nose or ears), start antibiotic therapy and consult neurosurgery immediately.
 - iv. **Follow-up imaging is recommended** to rule out leptomeningeal cyst formation.
- C. **Face**
1. **Facial nerve injury.** No specific therapy is necessary. Full resolution usually occurs by 2 to 3 weeks. Neurology consult should be obtained if no improvement after 3 weeks.
 - a. **Complete peripheral paralysis.** Cover the exposed eye with an eye patch and instill synthetic tears (1% methylcellulose drops) every 4 hours. This will prevent irritation from the dryness.
 - b. **Electrodiagnostic testing.** May be beneficial in predicting recovery.
 - c. **Surgery.** May be necessary in severe cases.
 2. **Fractures.** Maxilla, lacrimal, mandible, and nasal fractures require immediate evaluation because healing begins as early as 7 to 10 days and untreated fractures can result in subsequent eating issues and malocclusion. An oral airway is required, and surgical consultation is needed. The fractures must be reduced and fixated immediately. Otorhinolaryngology and plastic surgery consultations are recommended. If the fracture involves the sinus or middle ear, antibiotics are recommended. Treated fractures usually heal with no evidence of complications.
- D. **Eyes.** Hemorrhages (subconjunctival or retinal) can occur after a vaginal delivery because of increased pressure and venous congestion. Ocular and periorbital injury can occur from malpositioned forceps. Ophthalmology consultation is recommended.
1. **Eyelids.** Edema and bruising usually resolve within 1 week. **Laceration of the eyelid** may require microsurgery.
 2. **Orbit fracture.** Immediate ophthalmologic consultation is required.

3. **Horner syndrome.** No treatment is necessary, and resolution usually occurs.
4. **Subconjunctival hemorrhage.** No treatment is necessary because the blood is usually absorbed within 1 to 2 weeks. No long-term complications occur.
5. **Cornea.** Haziness disappears usually within 2 weeks. If persistent and if rupture of Descemet membrane has occurred, then a white opacity of the cornea will occur. This is usually permanent, and ophthalmologic input is essential.
6. **Intraocular hemorrhage**
 - a. **Subconjunctival hemorrhages** usually resorb and resolve within 1 to 2 weeks. No long-term complications occur.
 - b. **Retinal hemorrhage.** Usually disappears within 1 to 7 days. No treatment is necessary. If there is an associated optic nerve injury, there is increased risk of visual impairment.
 - c. **Hyphema (in anterior chamber).** Usually resolves without treatment within 1 week.
 - d. **Vitreous hemorrhage.** If resolution does not occur within 1 year, surgery must be considered.
- E. **Ears.** Consult an otolaryngologist if the temporal bone or cartilage is involved.
 1. **Abrasions and ecchymoses.** These injuries are usually mild and require no treatment, except for keeping the area clean, because they resolve spontaneously.
 2. **Hematomas.** Incision and evacuation may be indicated. Hematomas of the pinna should be drained to prevent the development of “cauliflower ear.”
 3. **Avulsion of the auricle.** Surgical consultation is required if cartilage is involved.
 4. **Laceration of the ear.** Most of these can be sutured with 7–0 nylon sutures.
- F. **Nose**
 1. **Protection of airway** is essential and consult with otorhinolaryngology.
 2. **Treat fractures promptly** because deformities can occur if fractures are not fixed. Nose fractures start to heal as early as 7 days.
 3. **Treatment of nasal dislocation is important** to make sure there is no long-term septal deformity.
- G. **Vocal cords**
 1. **Unilateral paralysis.** Observe these infants closely. Keeping them quiet and giving small, frequent feedings decrease the risk of aspiration. This condition usually resolves within 4 to 6 weeks.
 2. **Bilateral paralysis.** Intubation is required if there is airway obstruction. Otorhinolaryngology consultation and tracheostomy are usually required. The prognosis is variable.
- H. **Neck and shoulder**
 1. **Clavicular fracture.** No specific treatment is necessary. Immobilization (pinning the infant's sleeve to the shirt) is sometimes done to help decrease pain, and the prognosis is excellent. Pain medication (acetaminophen) can be given. Once a callus is formed, the pain subsides.
 2. **Brachial plexus injury/palsy.** Once the diagnosis is made, physical therapy is started and continued weekly for at least 3 months. Immobilization and physical therapy help prevent contractures until the brachial plexus recovers. Recovery depends on the extent of the lesions and is usually good but may take many months. In Erb-Duchenne paralysis, one can see improvement in 2 weeks, and recovery is usually complete by 3 to 4 months. Orthopedic consultation is recommended early on, especially if no improvement of range of motion is seen; brachial plexus nerve root avulsion needs to be ruled out. Nerve reconstruction is *controversial*; infants with brachial plexus nerve root avulsion are eligible, and if done, it is performed around age 6 months or older. Botulinum toxin has been used in older infants with contractures. Pain management is important, and infants tend to self-splint. Prognosis varies from 0% to 90% recovery. In Klumpke paralysis, the prognosis is poorer, and sometimes recovery is never complete. Muscle atrophy and contractures can occur.

3. **Phrenic nerve paralysis.** Treatment is close observation, usually supportive and nonspecific, and the prognosis is usually good, with recovery usually by 1 month. Some infants may require continuous positive airway pressure or mechanical ventilation. Surgical plication or diaphragmatic pacing may be pursued if recovery is not made.
 4. **Sternocleidomastoid muscle injury.** Most recover spontaneously. Passive exercise (stretching of the muscle) should be started and done several times a day. It usually resolves by 3 to 4 months of age. Approximately 20% of cases do not resolve, and if it is not resolved within 6 months after physical therapy, surgery should be considered. Rule out hip dysplasia because 10% of SCM injuries will have it as well.
- I. **Spinal cord.** Prognosis depends on the level and severity of the injury. Most infants with a severe spinal cord injury do not survive. Treatment is supportive, and some require intubation for respiratory problems. Specific therapy needs to be directed at the bladder, bowel, and skin because these present as ongoing problems. Neurology and neurosurgical consultations are recommended.
- J. **Abdomen.** Surgical consultation is needed, and the prognosis for all of these injuries depends on early recognition and treatment. Early management strategies that increase survival include volume replacement and identifying and correcting coagulation disorders.
1. **Liver rupture.** Fluid resuscitation, transfusion to replace blood loss and clotting factors, possible surgery (laparotomy) with evacuation of hematomas, and repair of any laceration.
 2. **Splenic rupture.** Volume replacement with transfusion of whole blood and correction of coagulation disorders. Exploratory laparotomy with preservation of the spleen, if possible.
 3. **Adrenal hemorrhage.** Management is supportive, with blood transfusion and intravenous steroids for adrenal insufficiency. Surgery is rarely needed.
- K. **Extremities**
1. **Fractured humerus.** Obtain an orthopedic consultation. Immobilize the arm with the elbow in 90 degrees for usually 2 weeks. Displaced fractures may require closed reduction and casting; the prognosis is excellent.
 2. **Fractured femur.** Obtain an orthopedic consultation. Splinting and strict immobilization are necessary. For a stable undisplaced fracture, a splint is used. Unstable fractures require Pavlik harness or a spica cast. Overall, the prognosis is excellent.
 3. **Epiphyseal separation.** Treatment is immobilization of the extremity for 10 to 14 days.
- L. **Genitalia**
1. **Edema and bruising.** These usually resolve within 4 to 5 days, and no treatment is necessary.
 2. **Testicular injury.** Urgent urologic or pediatric surgical consultation is necessary because rupture may require surgical repair.
 3. **Hematocoele.** Elevate the scrotum with cold packs. Resolution occurs without other treatment, unless there is a severe underlying testicular injury.
 4. **Perineal lesions.** Pressure with a moist saline pack can control vulvar hematomas. A more serious injury (eg, perineal or rectovaginal injury or tear) may require multilayer primary repair.

84 Vasospasms and Thromboembolism

I. Problem. An infant with an indwelling umbilical artery catheter develops a vasospasm in 1 leg. The nurse notifies you that another infant with an indwelling umbilical line has no pulses in the lower legs with severely decreased perfusion. Infants during the first month of life are at much higher risk of thrombosis and its complications when compared to any other pediatric age. This is due to many factors: an immature coagulation and fibrinolytic system (hypofibrinolytic state, decreased synthesis and altered function of some coagulation proteins, accelerated clearance of factors, platelet function differences, more active coagulation mechanism), smaller vessel size, and frequent indwelling catheter use (thrombogenic material in catheter, catheter slows blood flow and may damage the vascular endothelium, frequent medications may damage vessel wall). Other risks include maternal, delivery, neonatal, acquired, and inherited prothrombotic abnormalities. Incidences vary depending on the source, type of thrombosis, and screening methods used, but overall incidence of a symptomatic thromboembolic event is 5.1 per 100,000 live births and 2.4 to 6.8 per 1000 neonatal intensive care unit (NICU) admissions, affecting term and preterm male and females equally.

II. Immediate questions

- A. Is there a catheter in place? Can the catheter be removed?** Catheters involved include central venous catheters, arterial and venous umbilical catheters, and other arterial catheters. The **most prevalent risk factor for an arterial or venous thrombosis is an indwelling vascular catheter.** It has been stated that “90% of thromboembolic events are catheter related.” Evaluate the need for the catheter. If the catheter can be removed, this is the treatment of choice. **Vasospasm** is most commonly related to the use of umbilical artery catheters (UACs), but it can also occur in other catheters such as radial artery catheters. Over 90% of **venous thromboembolisms** in newborns are secondary to central venous lines. **Portal venous thrombosis** is often associated with the placement of an umbilical venous catheter (UVC). **Arterial thromboses** are almost always secondary to arterial vascular catheterization of central or peripheral arteries (UAC: renal artery thrombosis, aortic thrombosis). In some cases of thrombosis, **the catheter should not be removed so thrombolytic medication can be given** into the line. **Note: Renal vein thrombosis** is the most common type of venous thrombosis **not related to a central venous catheter.**
- B. Was a medication given recently through the catheter?** Most medications, if given too rapidly, can cause a vasospasm.
- C. How severe is the vasospasm?** Deciding on the severity of the vasospasm may dictate treatment choices (see Sections IV.B.1 and IV.B.2).
- D. Is there a pulse in the affected extremity?** A loss of pulse with a thrombus is a medical emergency.
- E. Does the infant have any risk factors for thromboembolism?**
- 1. Maternal.** Advanced maternal age, hypertension, autoimmune disorders, premature rupture of membranes, maternal diabetes, maternal obesity, maternal lupus, preeclampsia, infertility, oligohydramnios, prothrombotic disorder, intrauterine growth restriction (IUGR), chorioamnionitis, family history of thrombosis, antiphospholipid or anticardiolipin antibodies.
 - 2. Delivery.** Instrumentation, fetal heart rate abnormalities, emergency delivery/cesarean section, traumatic delivery, induction with prolonged labor.
 - 3. Neonate.** Central arterial catheters (most common risk factor for arterial thromboembolism), central venous catheters (one of the most common risk factors for venous thromboembolism), cyanotic congenital heart disease, birth asphyxia,

sepsis, small for gestational age, IUGR, patent ductus arteriosus, respiratory distress syndrome, polycythemia, necrotizing enterocolitis (NEC), meconium staining, pulmonary hypertension, dehydration, major surgery, extracorporeal life support (ECLS), congenital renal vein defects, congenital nephrotic syndrome (increased venous thromboembolism risk) or nephritic syndrome, prematurity, hypotension, disseminated intravascular coagulation (DIC), impaired liver function, fluctuations in cardiac output, low cardiac output, prothrombotic disorders and elevated hematocrit (increases risk of UVC-associated thrombosis), postnatal steroid use in premature infants.

4. **Inherited factors.** Protein C (most common thrombophilic risk factor) or protein S deficiency, plasminogen deficiency, factor V Leiden mutation, antithrombin deficiency, elevated fasting homocysteine, prothrombin gene G20210A mutation, elevated lipoprotein(a) levels, and others.

III. Differential diagnosis

A. **Vasospasm is a muscular contraction (spasm) of an arterial vessel**, manifested by an acute color change (white or blue) in the perfused extremity (upper or lower extremity, sometimes only on the toes or fingers). Occasionally, the color change extends to the buttocks and the abdomen. The change in color is usually transient (usually <4 hours). It may be caused by prior injection of medication, intravascular arterial catheterization, or arterial blood sampling. A vasospasm can be a manifestation of a thromboembolism, but a thromboembolism will have discoloration of the skin that will not recover in 4 hours with other signs unique to the thromboembolism.

B. **Thromboembolism.** A **thrombosis** is the condition where a blood clot forms (a **thrombus**) in an artery or vein and can cause partial or complete obstruction. An **embolism** is the condition where part of the blood clot detaches, becomes mobile, and moves and lodges in a blood vessel and may cause obstruction or vasospasm. **Thromboembolism** is “blocking of a blood vessel by a particle that has broken away from a blood clot at its site of formation.” A **thrombosis can be iatrogenic (catheter related) or spontaneous (non-catheter related) and can be arterial or venous.**

1. **Arterial thrombosis includes:** Aortic thrombosis, peripheral arterial thrombosis, mesenteric artery thrombosis, renal artery thrombosis, pulmonary embolism, neonatal arterial perinatal stroke.
2. **Venous thrombosis includes:** Limb thrombosis, renal vein thrombosis, inferior vena cava thrombosis, superior vena cava thrombosis, right atrial thrombosis, cerebral sinovenous thrombosis (CSVT), neonatal portal vein thrombosis, mesenteric venous thrombosis, umbilical vein thrombosis.
3. **Venous and arterial:** A **systemic air embolism** or **stroke** can occur from a venous or arterial embolism.

C. **Inherited/congenital thrombophilias.** Less commonly, thromboembolic phenomena are due to inherited or acquired thrombophilias. **Thrombophilia describes inherited or congenital blood coagulation disorders that predispose the infant to thrombosis.** Positive family history, early onset of disease, and >1 thromboembolism are clues to an inherited thrombophilia. **Prothrombotic genetic mutations** do not appear to increase the risk of umbilical catheter-associated thrombosis. The presence of inherited thrombophilias is increased in neonates with renal, portal, or hepatic venous thrombosis and stroke.

1. **Inherited/congenital.** Established genetic factors are factor V Leiden mutation, prothrombin G20210A mutation, protein C deficiency, protein S deficiency, and antithrombin deficiency. Rare genetic factors are hyperhomocystinemia (MTHR enzyme gene mutation) and dysfibrinogenemias. Other **indeterminate factors** include elevated factor VIII or IX or XI, tissue plasminogen activator, plasminogen deficiency, elevated lipoprotein (a), factor VII or XII, and others.

- 2. Acquired.** Severe illness, sepsis, asphyxia, maternal lupus, maternal diabetes, and poor cardiac output are some of the risk factors of acquired thromboembolism. **All of these conditions can cause** deficiencies of protein C, protein S, or antithrombin III which can cause acquired thrombophilia. Elevated factor VIII activity, antiphospholipid antibodies, and lupus anticoagulant and anticardiolipin antibody can also cause it. Placental transfer of antibodies can cause an acquired thrombophilia in the newborn. Newborns with sepsis have an increased and ongoing consumption of coagulation factors and platelets, with reduced levels of protein C.
- 3. Neonatal purpura fulminans is a rare but very severe condition that should be treated as a medical emergency** as it can cause loss of limbs from necrotic/gangrenous affected areas or be fatal. It can be inherited or acquired. If inherited, it is caused by a deficiency in protein C (more common) or a deficiency in protein S (less common) and presents after birth (2–12 hours) with ecchymosis, venous and arterial thromboses, and DIC. Severe protein C deficiency can cause severe complications (sometimes antenatally) such as thrombosis of cerebral vasculature and retinal detachment resulting in blindness. The **acquired form** is more common and usually occurs in older infants but has been described in neonates. It is secondary to a consumptive coagulopathy (infection such as eg group B *Streptococcus*, DIC, antiphospholipid antibodies, acute venous thrombosis, or cardiac bypass) or decreased synthesis (galactosemia, warfarin therapy, severe hepatic dysfunction, or severe congenital heart disease).

IV. Database

A. History

- 1. For vasospasm:** Ask about what happened prior to the vasospasm. Was a medication given? Was an umbilical or percutaneous arterial line placed?
- 2. For thrombosis:** Ask about risk factors (see earlier) and what signs the infant is showing. Obtain a detailed family history of any inherited clotting or other hematologic disorder.

B. Physical examination. The severity of the vasospasm and thrombosis must be assessed because it dictates treatment. Early clinical signs are similar in both vasospasm and thrombosis (pallor, cyanosis, weak peripheral pulses), and it may be difficult to differentiate a vasospasm from early signs of a thrombosis. The areas of involvement, appearance of the skin over the involved areas, and pulses of the affected extremity are measures of severity. Compare the affected extremity with the other extremity. A handheld Doppler is useful to assess peripheral arterial flow. Determine if the thrombosis is arterial or venous.

- 1. Severe vasospasm.** Involves a large area of 1 or both legs, the abdomen, or the buttocks. In the upper extremity, a severe vasospasm includes most of the arm and all of the fingers. The skin may be completely white. Decreased perfusion is present, and pulses of the affected extremity are weak but detectable.
- 2. Less severe vasospasm.** Involves a small area of 1 or both legs (usually some of the toes and part of the foot). In the arm, it can involve part of the extremity and some fingers. The skin has a mottled appearance, and pulses are present but can be diminished.
- 3. Thrombosis.** A thrombosis can be arterial or venous. If pulses are completely absent, an arterial thrombosis, which is a medical emergency, is likely. Venous thrombosis is more common. Iatrogenic venous thrombosis in the newborn occurs most commonly from an indwelling venous catheter (90% central venous pressure or UVC) or from a non-catheter-related reason (most commonly renal vein thrombosis). **If catheter related**, presentation may include difficulty infusing and withdrawing from the line. Other signs are persistent thrombocytopenia and persistent infection. See Table 84–1 for clinical signs and symptoms of thromboembolism in critically ill neonates.

Table 84–1. CLINICAL SIGNS AND SYMPTOMS OF THROMBOEMBOLISM IN CRITICALLY ILL NEONATES

	Extremities	Intestine	Kidney	Aorta/Inferior Vena Cava	Central Nervous System	Lung
Arterial early signs	Extremities pale and/or cold Pulse weak or absent Blood pressure reduced	Mesenteric artery infarction: Feeding intolerance Gastric aspirates: bilious Stools: bloody Bowel wall pneumatosis	Renal artery thrombosis: Blood pressure elevated	Aorta: Blood pressure higher in arms than in legs	Arterial ischemic stroke: Lethargy Seizures (<i>no</i> hemiplegia)	Pulmonary embolism: Right heart failure Oxygen saturation low Ventilation/perfusion mismatch
Venous early signs	Venous thrombosis: Limb swelling Pain Cyanosis Hyperemic color	Portal vein: Impaired liver function Splenomegaly Hepatomegaly	Renal vein thrombosis: Hematuria Proteinuria Abdominal mass	Inferior vena cava: Hematuria Lower limb edema Both kidneys palpable Respiratory distress	Lethargy Seizures	
Late signs	Venous collaterals Reduced limb growth Postthrombotic syndrome (edema, pruritus, cellulitis, purpura, eczematous dermatitis)	Portal vein: Portal hypertension Gastrointestinal hemorrhage Hepatic atrophy Splenomegaly	Blood pressure abnormalities Renal insufficiency	Inferior vena cava: Leg and abdominal pain Varicose veins Postthrombotic syndrome	Neurodevelopmental delay Cognitive impairment Cerebral palsy	Right heart hypertrophy

Reproduced with permission from Veldman A, Nold MF, Michel-Behnke I: Thrombosis in the critically ill neonate: incidence, diagnosis, and management. *Vasc Health Risk Manag.* 2008;4(6):1337–1348.

4. Specific thromboses

- a. **Venous thrombosis.** Premature infants are more likely to have a venous thromboembolism than term infants. Most venous thromboses occur secondary to a central venous line. Sites in which a venous thrombosis can occur are limb (peripheral veins in limb), renal vein, inferior vena cava, superior vena cava, right atrium, cerebral sinovenous system, portal vein, mesenteric vein, umbilical vein, and less commonly adrenal and hepatic veins. Catheter-associated venous thrombosis in an infant usually presents with difficulty using the central venous line. Infants can have pulmonary embolism, organ impairment, or superior vena cava syndrome.
- i. **Central venous line–associated venous thrombosis (peripheral/limb thrombosis).** Malfunction of the central venous line. Symptoms include swollen and edematous extremities, pain, elevated temperature, cyanosis, hyperemia, and discoloration with distended superficial veins. Superior vena cava syndrome can develop in upper limb involvement.
 - ii. **Renal vein thrombosis** is the most common type of spontaneous venous thrombosis (not related to a central venous catheter). Classic triad (seen in ~13%) includes gross hematuria, thrombocytopenia, and a palpable flank mass (unilateral or bilateral enlargement of the kidneys). Acute hypertension, proteinuria, and renal dysfunction can also occur. There is a higher male prevalence, it is usually unilateral (75%) or involves the left kidney (64%), and it is increased in premature infants, with a high level of thrombophilia. The majority of cases present in the first 3 days of life, but it can also develop in utero. In 50% of cases, the thrombosis reaches the vena cava (with lower limb cyanosis, edema, hypothermia); 25% of cases are bilateral. An acute scrotum (discoloration and pain upon palpation) can be caused by renal vein thrombosis.
 - iii. **Inferior vena cava thrombosis.** Edematous, cool, cyanotic lower limbs, respiratory distress, and hypertension can also be seen. If renal vein is involved, obstruction of the renal vein (palpable kidneys and hematuria) can be seen.
 - iv. **Superior vena caval thrombosis.** Common after repair of complex congenital heart disease. It can be asymptomatic or symptomatic (edema/swelling in upper limbs and head, chylothorax, heart failure).
 - v. **Right atrial thrombosis** is a thrombosis of the superior vena cava with extension into the right atrium. The majority of patients have had a central venous catheter (most important risk factor), with an increased association of the catheter tip in the right atrium. Also occurs in infants with complex congenital heart disease undergoing repair. It can be asymptomatic (detected on echocardiography), or symptoms may include signs of congestive heart failure or right-sided heart failure (new murmur, bradycardia, tachyarrhythmia, respiratory distress, persistent sepsis, pericardial tamponade). Right atrial thrombi can be life threatening and disseminate into lungs or obstruct the right pulmonary artery (infant has acute onset of respiratory distress and stroke).
 - vi. **Cerebral sinovenous thrombosis** is a multifactorial rare disease (2.6 per 100,000 newborns per year) and usually presents with generalized (most common) or focal seizures. Clinical symptoms include apnea, agitation, sepsis-like depressed consciousness, poor tone, respiratory distress, fetal distress, lethargy, and poor feeding. Most common sites are sinuses (multiple), superior sagittal sinus, straight sinus, and transverse sinus. **Thalamic hemorrhage suggests CSVT.**

- vii. **Portal vein thrombosis** is uncommon but is increasing in incidence. Risk is higher in neonates than in children. Clinical presentation is nonspecific or asymptomatic in 90%. Impaired liver function with elevations of liver enzymes, portal hypertension, hepatomegaly, and splenomegaly can be seen. UVC, exchange transfusion, omphalitis, sepsis, and thrombophilia are all risk factors. **UVC position** (unless placed in the portal vein) is not significantly associated with portal vein thrombosis.
 - viii. **Mesenteric venous thrombosis** is very rare and presents with gradual onset of abdominal pain with vomiting, diarrhea, and hematochezia and with later signs once necrosis develops. Heme-positive stool is seen.
 - ix. **Umbilical vein thrombosis.** Very rare but life threatening. The majority of cases have umbilical cord abnormalities (knot in cord, stretching of cord, obstetrical complications due to a systemic fetal condition such as maternal diabetes, hemolytic disease, fetomaternal transfusion). Portal vein thrombosis should be ruled out.
- b. Arterial thrombosis.** Less common than venous thrombosis, this occurs more commonly in the iliac, femoral, or cerebral arteries. Almost always related to arterial vascular catheterization of UAC (descending tract and renal arteries), peripheral arterial line, or femoral artery catheters. Symptoms depend on the location and size of the thrombus (line dysfunction, blanching, ischemia and cyanosis of the extremity, arterial hypertension, NEC, sepsis, persistent thrombocytopenia, and stroke). Incidence varies; one report indicated 1% to 3% based on clinical signs, 14% to 35% based on ultrasonogram findings, and 64% based on angiography. **Spontaneous (not catheter related)** arterial thromboses are rare but usually involve the iliac artery, left pulmonary artery, aortic arch, and descending aorta, and symptoms depend on the location. Neonatal arterial thrombosis can occur in the aorta and present as cyanotic heart disease such as coarctation of the aorta. Sites in which arterial thrombosis can occur include aorta, peripheral arteries, mesenteric arteries, renal arteries, and pulmonary arteries. Infants can have renal failure, hypertension, organ failure, peripheral gangrene, intestinal necrosis, and death.
- i. **Aortic thrombosis.** Rare in newborns. UAC will stop working, and blood pressure will be higher in the arms than in the legs. Decreased or no pulses in the lower extremities with color change and a decrease in perfusion. Oliguria, microscopic or gross hematuria, signs of NEC, systemic hypertension, or congestive heart failure can be seen. Congenital cytomegalovirus infection has been implicated as a cause of **aortic arch thrombosis** since it can infect and damage vascular endothelium. **Note:** Aortic thrombosis can mimic NEC (bowel ischemia) and coarctation of the aorta (blood pressure differences in the upper and lower body).
 - ii. **Peripheral arterial thrombosis.** Radial, posterior tibial, and dorsalis pedis arterial lines are rarely associated with thrombosis. Signs include weak or absent peripheral pulse, pallor of the extremities, coldness, and decreased perfusion of the extremity. Acute arterial occlusion in a limb in a newborn is rare.
 - iii. **Mesenteric artery thrombosis.** Similar to signs of NEC. (Bloody stools, bilious aspirates, abdominal pain, feeding intolerance, pneumatosis).
 - iv. **Renal artery thrombosis.** Causes elevated blood pressure, with or without renal failure.

- v. **Umbilical artery catheter–associated thromboses.** Asymptomatic or presents with poor perfusion and blanching of ≥ 1 toe, 1 or both limbs, or buttocks. Occlusion of the renal arteries (hypertension, renal failure), occlusion of the mesenteric arteries (NEC), or occlusion of the spinal arteries (spinal cord infarction) can occur.
 - vi. **Pulmonary embolism.** Very rare with only a few cases reported in neonates. Clinical signs include respiratory failure. It can be seen in infants with congenital heart disease with right heart failure, poor oxygenation, and ventilation/perfusion mismatch.
 - vii. **Spontaneous arterial thromboembolism.** Very rare in infancy. Most common thrombotic sites include, in descending frequency: umbilical, aorta, extremities, cerebral, subclavian, pulmonary, and placental. Risk factors include congenital, acquired, inherited prothrombotic risk, and maternal. Evaluate for prothrombotic disorder.
- c. **Venous or arterial embolism/occlusion.** These include systemic air embolism or a stroke.
- i. **Systemic air embolism.** In neonates, it is devastating and usually fatal. Most iatrogenic air emboli are venous and occur from central venous catheters (UVC, peripherally inserted central catheter [PICC]), but rarely can also occur from peripheral venous or arterial lines. A disconnected line is a common cause. Air embolism secondary to mechanical ventilation (barotrauma leads to systemic gas embolism) is rare but can occur in premature infants. Suspect embolism if air bubbles are in the infusion line. Clinical signs of systemic air embolism are usually sudden and dramatic and can include pallor, cyanosis, hypoxemia, seizures, shock, bradycardia, respiratory distress, mottling of the skin, or neurologic deficits (if central nervous system [CNS] emboli) such as paraplegia. Infants with cyanotic congenital heart disease are at a risk for **cerebral arterial gas embolism** from infusion lines.
 - ii. **Neonatal and perinatal stroke.** This is classified as a cerebrovascular accident that occurs from 20 weeks' gestation up to 28 days of life after birth and includes ischemic (blockage of vessel) and hemorrhagic (blood vessel ruptures and bleeds) event. These include perinatal arterial ischemic stroke, hemorrhagic stroke, and CSVT. Incidence is 1 in 1600 to 4000 live births. Ischemic stroke accounts for 80%, and 20% are CSVT or hemorrhage. **Ischemic strokes are either arterial (thromboembolism/thrombosis) or venous. Neonates present with seizures (focal or generalized)** 12 to 72 hours after birth with nonspecific neurologic signs including lethargy, temperature instability, feeding difficulties, respiratory failure, and encephalopathy (hypertonic/irritable or hypotonic/lethargic). With CSVTs, a tense anterior fontanel, engorged scalp veins, and diastasis of the cranial sutures may be seen. They rarely present with a unilateral motor deficit (hemiparesis), as seen in older children.
 - (a) **Perinatal arterial ischemic stroke** is occlusion of the cerebral arterial flow entering the brain that most commonly occurs from arterial infarction in the left hemisphere. Most (89%) present with an isolated lesion in anterior circulation (internal carotid artery, anterior cerebral artery, and middle cerebral artery), most often left sided. Usually secondary to embolism (indwelling intravascular catheters) but can also be secondary to lupus anticoagulant. Placental pathology may play a role in the etiology. Most infants present within the first 3 days of life with seizures (95%), abnormal tone, or altered mental status. Other symptoms are nonspecific (feeding difficulties, respiratory problems, hemiparesis).

- (b) **Hemorrhagic stroke (includes parenchymal, subarachnoid, or intraventricular hemorrhage).** Secondary from intracranial hemorrhage from ischemic infarction of arterial/venous or primary intraparenchymal hemorrhage. Causes include idiopathic, bleeding diatheses or vascular anomalies, ECMO, vitamin K deficiency, coarctation of the aorta, and venous thrombosis. Presents with seizures, apnea, poor feeding, hypotonia, encephalopathy, and focal weakness.
- (c) **Cerebral sinovenous thrombosis is very rare and occurs when there is occlusion of the venous blood flow in a major sinus.** It can cause hemorrhagic infarction and bleeding and usually involves the superior sagittal and lateral sinuses. Majority of cases are secondary to preeclampsia, diabetes, and chorioamnionitis in the mother or systemic illness and inherited thrombophilia in the neonate. Presents with focal/generalized seizures, lethargy, irritability, poor feeding, jitteriness, cranial nerve palsies, hemiparesis, and decreased level of consciousness.
- (d) **Inherited thrombophilias.** See Chapter 92.
- C. Laboratory studies.** Not usually needed for vasospasm. Infants with non-catheter-related thromboses or severe, recurrent, or spontaneous thromboses should undergo further laboratory testing. A baseline coagulation profile should be obtained if a thrombosis is suspected and clot-dissolving medication is to be used.
1. **Baseline coagulation profile.** Prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, international normalized ratio (INR), plasma fibrinogen concentration.
 2. **Complete blood count with peripheral blood smears.**
 3. **Platelet count.** Thrombocytopenia usually accompanies thrombosis in neonates and is one of the most sensitive indicators of thrombosis. The thrombus itself and the use of heparin can cause thrombocytopenia.
 4. **D-dimer measurement.** Negative D-dimers can rule out thrombosis.
 5. **Genetic tests.** May be done at some point to evaluate congenital thrombophilia.
 6. **Cytomegalovirus workup if suspected.** See Chapter 132.
 7. **Workup for a suspected prothrombotic disorder.** Includes antithrombin, protein S, and protein C concentrations; activated protein C resistance; factor V Leiden mutation; prothrombin gene 20210A mutation; lipoprotein levels; and plasma homocysteine values. Maternal testing for lupus anticoagulant and anti-cardiolipin antibody. See Chapter 92 for more details.
- D. Imaging and other studies.** Imaging confirms the diagnosis of a vascular thrombosis, but the best imaging modality is *controversial*. Catheter angiography is the most accurate imaging technique but is invasive and has high radiation exposure; therefore, it is used selectively and usually as a last test. Common approach is to start with a Doppler ultrasound and, if negative, go on to magnetic resonance imaging (MRI) or computed tomography (CT) or a more invasive test. **Cranial ultrasound prior to starting any antithrombotic therapy is essential.**
1. **Doppler ultrasound (real-time ultrasonography with color Doppler flow imaging).** Commonly the first imaging test used, it can evaluate blood flow through arteries and veins. It is readily available and noninvasive with no exposure to radiation. It can also be used to monitor progress over time. In renal vein thrombosis, ultrasound shows enlarged echogenic kidneys with a loss of renal corticomedullary differentiation, and in color Doppler ultrasound studies, there is absence of flow in the involved veins. Transfontanelar Doppler ultrasound can help diagnose an ischemic stroke.
 2. **Magnetic resonance angiography.** Usually performed under sedation or general anesthesia (to limit motion artifact). Recommended to diagnose perinatal ischemic stroke in term infants.

3. **Computed tomography angiography.** Injection of contrast material with CT scanning to diagnose arterial and venous vessel disease. Quicker test than MRI, and sedation not always required.
 4. **Ultrasound of the head.** To evaluate for intraventricular hemorrhage (IVH) before initiating thrombolytic therapy.
 5. **Computed tomography of the head.** To evaluate for CSVT or to identify intracranial air bubbles in air embolism.
 6. **“Linograms.”** Injecting radiopaque dye directly into the catheter to detect an intraluminal clot.
 7. **Contrast venography/magnetic resonance venography** is considered the gold standard for diagnosing neonatal catheter-induced thromboembolism. Done by injection of contrast through peripheral vessels.
 8. **Catheter angiography uses magnetic resonance imaging, computed tomography, or plain x-ray.** Contrast is injected in a catheter to produce images of a major blood vessel. Can be performed through the UAC and can be used to diagnose aortoiliac thrombosis. In several studies, this procedure was found to be the most effective diagnostic technique. It can be used to diagnose an ischemic neonatal stroke. A contrast study should be considered before administering a fibrinolytic agent. Remember, this test is difficult to perform in sick neonates. MRI angiography can also be used to diagnose pulmonary embolism.
 9. **Magnetic resonance imaging/diffusion magnetic resonance imaging** to diagnose a stroke from a venous sinus thrombosis.
 10. **Echocardiography (transthoracic)** is used to diagnose right atrial thrombosis. An echocardiogram of venous air embolism shows an acute obstruction of the right ventricular outflow tract secondary to air embolism (known as an “air lock”).
 11. **Ventilation/perfusion scan** to diagnose rare pulmonary embolism.
- V. **Plan.** Management of vasospasms is *controversial*, whereas the management of thrombosis is largely based on treatment plans for older children and adults. Current management protocols for thrombophilia can be obtained from the International Children’s Thrombophilia Network (phone: 1-800-NO-CLOTS). The network was established as a free consultative service and to develop collaborative research studies.

A. Key management points

1. **Monitor for potential signs of vasospasm or thromboembolic complications** in all infants with any intravascular catheter.
2. **Thromboembolism can occur in newborns** and produce little or no clinical symptoms.
3. **Heparin is often added to neonatal infusions** because it prolongs patency, extends catheter life (UACs, UVCs, PICCs, peripheral arterial catheters), and may also decrease the incidence of thromboembolic occlusions. For extremely low birthweight infants, use the lowest dose. There are no randomized trials of heparin use in PICCs, but its use is common in NICUs. Heparin use in UVCs is *controversial*, but the majority of NICUs use heparin in UVCs. Heparin is not used in peripheral intravenous (IV) lines. **Common recommendations include the following:**
 - a. **Central venous lines** (UVC, PICC, percutaneous central venous catheter). The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines study recommends heparin in central venous access devices (CVADs) to maintain patency. They recommend unfractionated heparin (UFH) continuous infusion at 0.5 U/kg/h or intermittent local thrombolysis to maintain CVAD patency. Cochrane review supports the prophylactic use of heparin in peripherally placed percutaneous central venous catheters in neonates and recommends monitoring for side effects. For a blocked CVAD, local thrombolysis after clinical assessment is recommended.

- b. **Peripheral arterial catheters.** The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines study recommends UFH continuous infusion at 05 U/mL at 1 mL/h.
 - c. **Umbilical artery catheters.** Heparin (0.25–1 U/mL) for a total heparin dose of 25 to 200 U/kg/d to maintain patency. Per the Perinatal Continuing Education Program, 12 U/kg body weight/h is recommended for continuous infusion. Cochrane review notes the use of heparin (as low as 0.25 U/mL) is recommended to prolong the life of the catheter by decreasing the incidence of catheter occlusion. It does not decrease the incidence of UAC-related aortic thrombosis. Heparinization of intermittent flushes alone is ineffective in preventing catheter occlusion. The **American Academy of Pediatrics** recommends low doses of heparin (0.25–1.0 U/L) through the UAC. The **American College of Chest Physicians Evidence-Based Clinical Practice Guidelines** (2012) recommend prophylaxis with a low-dose UFH infusion via the UAC (heparin concentration of 0.25–1 U/mL; total heparin dose of 25–200 U/kg/d to maintain patency).
 - d. **Congenital nephrotic syndrome.** Because infants with congenital nephrotic syndrome are at risk of venous thromboembolism, some advocate giving prophylactic anticoagulant therapy depending on the severity. Infants who develop venous thromboembolism should be treated with anticoagulant therapy for the duration of the nephrotic syndrome.
4. **Umbilical lines should be removed as soon as possible when they are no longer needed** because duration of both UACs and UVCs is a significant risk factor for thrombosis. The Centers for Disease Control and Prevention recommends that UACs should not be left in place >5 days after insertion and that UVCs should be removed as soon as possible but can be used for up to 14 days.
 5. **High umbilical artery catheters** have a lower incidence of thrombotic complications and a longer catheter life. Low UACs are associated with an increased incidence of vasospasms and cyanosis of the extremities. Cochrane review and the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend **high position** for UACs. Some advocate abandoning low UACs due to the risks involved (see Chapter 28).
 6. **Use a peripheral arterial line over a UAC.** Choose a safer site for a peripheral arterial line that has collateral circulation (radial, dorsalis pedis, posterior tibial arteries, ulnar arteries).
 7. **If there is difficulty infusing into the line,** consider a thrombotic event.
 8. **Heparinization of flush solution** without heparinization of the infusate is inadequate. Use of intermittent heparin flushes has no benefit over normal saline (NS) flushes.
 9. **Always use umbilical artery catheters** with a hole at the end and not the side, as the side hole may increase aortic thrombosis risk. Single-lumen construction is associated with a decrease in thrombosis. Cochrane review states that side hole catheters should be avoided for UACs in neonates.
 10. **The use of multiple-lumen umbilical venous catheters** is associated with a decrease in the need for peripheral IV lines in the first week of life but with an increase in catheter malfunctions.
 11. **Heparin-bonded catheters versus polyvinyl chloride catheters** showed no difference in the incidence of aortic thrombosis or duration of patency.
 12. **A peripherally inserted central catheter line** has a lower incidence of thrombosis when compared to a central line. The highest incidence is in femoral lines.
 13. **Papaverine, an opium alkaloid with vasodilatory and spasmolytic action,** was found to prolong the patency of peripheral arterial catheters in a study of neonates, with no difference in the incidence of IVH (*controversial*).

14. **Peripheral nerve block (case reports only)** has successfully been used as an effective treatment for neonatal vascular spasm and/or thrombosis causing limb ischemia. The mechanism is induction of vasodilatation of the peripheral vessels (sympathetic blockade) and inhibition of peripheral vasoconstriction (decreased pain release of antidiuretic hormone, cortisol, and catecholamines).
 15. **Hyperbaric oxygen therapy (experimental and controversial)**. Anecdotal evidence in a case report of **hyperbaric oxygen therapy combined with anti-coagulant therapy** demonstrated improved outcome of neonatal arterial thromboembolism of lower extremities.
- B. Vasospasm.** This can be secondary to a **peripheral arterial line or UAC**. Treatment is **controversial**, and guidelines vary extensively. Check your institution's guidelines before initiating treatment. Rapid intervention is recommended. Noninvasive treatments include removal of the catheter and warming the contralateral extremity. Secondary treatments include topical vasodilators and other medications (papaverine, lidocaine). Use of heparin and thrombolytics is not recommended. If the vasospasm does not resolve with treatment and the tissue ischemia persists, this could represent the primary event leading to thrombosis and a change in management.
1. **Severe vasospasm of the leg or arm**
 - a. **If possible, remove the catheter.** Spontaneous resolution is likely with some success in warming the contralateral extremity before removing the catheter. If warming does not resolve the vasospasm, remove the catheter. If warming does resolve the vasospasm, closely follow the infant, and if the vasospasm returns, remove the catheter.
 - b. **Warming the contralateral leg/arm.** Wrap the entire *unaffected* leg in a warm (not hot) washcloth. This measure dilates the blood vessels in the unaffected arm and causes a sympathetic **reflex vasodilatation** response in the affected arm. Treatment should continue for 15 minutes before a beneficial effect is seen. Do not wrap the affected arm or leg, as this will increase the metabolic demand and blood flow to an area that is already compromised.
 - c. **If symptoms persist after warming contralateral extremity and removing the catheter:**
 - i. **Topical nitroglycerin therapy (controversial)** (2% ointment, 4 mm/kg, applied as a thin film over the area). Nitroglycerin has a direct vasodilating effect on vascular smooth muscle, is readily absorbed through the skin, and improves circulation. Reports note 1 application, but some repeat it every 8 hours for 2 to 27 days. Improvement was usually seen within 15 to 45 minutes. Observe for hypotension.
 - ii. **Papaverine (controversial)**. A spasmolytic and mild vasodilator with direct action on vascular smooth muscle. Dosing is 1 mg intramuscularly in the unaffected leg; the effect is apparent within 30 minutes.
 - iii. **Lidocaine** has been used intra-arterially for vasospasm. It has a vasodilating effect with questionable results (*controversial*).
 - iv. **Intra-arterial lidocaine and papaverine** have been used successfully to treat a catheter-induced vasospasm during arterial catheterization (*controversial*, case reports only).
 - d. **If it is not possible to remove the catheter (as in a tiny infant) and this is the only catheter.** Consider a papaverine-containing solution (60 mg/500 mL in 1/2 NS with 1.0 U/mL heparin) through the catheter as a continuous infusion for 24 to 48 hours (*controversial*). If the vasospasm resolves, the infusion may be stopped. If the vasospasm does not resolve, remove the catheter. **Exercise caution using this technique** in premature infants in the first few days of life where the incidence of developing an intracranial hemorrhage is high.
 2. **Less severe vasospasm of the leg/arm.** Follow recommendations in Sections V.B.1.a and V.B.1.b for severe spasm.

- C. **Problems with vasospasm and peripheral tissue ischemia.** Ischemia can sometimes occur after a vasospasm. Even after a catheter has been removed, a persistent vasospasm or small emboli in distal end arteries can cause poor perfusion of an extremity. **Topical 2% nitroglycerin ointment** (4 mm/kg of body weight) can be applied to the ischemic area with no adverse effects except mild episodes of decreased blood pressure (*controversial*). One small study found that **intra-arterial papaverine** before removal of the patent arterial line was effective in preventing residual damage in arterial catheterization–induced ischemia in extremely low birthweight neonates.
- D. **Thromboembolism.** If suspected and there is loss of pulses in the affected extremity, it is a **medical emergency**. Symptomatic thrombosis can lead to irreversible organ damage or loss of limbs or digits. The most common treatments are observation with supportive care, anticoagulation therapy with heparin or low molecular weight heparin (LMWH), thrombolytic agents (clot-dissolving drugs, streptokinase, and tissue plasminogen activator), or surgery. Clot-dissolving drugs can cause severe bleeding, and there are no current randomized trials comparing these treatments. Management is *controversial*. Treatment depends on the extent and severity of the thrombus (occlusive or nonocclusive thrombosis, life-threatening thrombosis, thrombosis that can lead to loss of limb or organ). Management is similar for peripheral arterial thrombosis, venous thrombosis, and aortic thrombosis.
1. **Asymptomatic thrombosis.** Supportive care and monitoring of the size of the thrombus. If the thrombus advances, therapy with an anticoagulant may be necessary.
 2. **Mild or minor thrombosis.** This can present with decreased limb perfusion, hypertension, and hematuria and can usually be treated with removal of the catheter, supportive care, and close ultrasonographic follow-up. Many of these resolve spontaneously.
 3. **Moderate thrombosis.** This has all the findings of mild/minor thrombosis plus oliguria and congestive heart failure. Can be treated with systemic heparin therapy and with management of systemic hypertension.
 4. **Major thrombosis.** Presents with all of the above plus major multiorgan failure. Should be treated aggressively with systemic heparin therapy, antithrombotic agents, and supportive care. May require further evaluation for underlying hypercoagulable disorder.
- E. **General guidelines for thrombosis treatment.** Treatment involves supportive care, observation only, thrombolytic and/or anticoagulant therapy, and surgery. (See also Chapter 92.) It is best to consult a pediatric hematologist experienced in treating thrombosis prior to starting therapy and have the hematologist manage the patient.
1. **Supportive care**
 - a. **Prompt removal of the catheter is indicated** unless it is needed to facilitate arteriography or thrombolytic drug infusion. A CVAD or UVC should be removed after 3 to 5 days of thrombolytic therapy. Peripheral arterial catheters should be removed immediately; this is mandatory in their management except in rare isolated cases.
 - b. **Prior to starting antithrombotic therapy**, obtain PT, aPTT, and platelet and fibrinogen levels.
 - c. **Treatment of volume depletion, electrolyte abnormalities, sepsis, thrombocytopenia, and anemia is essential.** Control hypertension and any coagulation deficiency or hypofibrinogenemia before initiation of treatment.
 - d. **Emergency consultation** with vascular surgery and pediatric hematology is recommended.
 - e. **Evaluate patients for intraventricular hemorrhage** before initiating thrombolytic therapy. A cranial ultrasound is a must. During treatment, ultrasounds of the head should be obtained at regular intervals.

- f. Absolute contraindications for thrombolytic therapy.** Contraindications include the following: CNS surgery in the previous 3 weeks, major surgery or bleeding in the past 10 days or birth asphyxia in the past 7 days, evidence of active bleeding, invasive procedures within previous 3 days, seizures within the past 48 hours, gestational age <32 weeks, and thrombolytic therapy.
- g. Relative contraindications** for anticoagulant and thrombolytic therapy are hypertension, severe coagulation deficiency, platelet count $<50 \times 10^4/\text{mm}^3$ ($<100 \times 10^4/\text{mm}^3$ for ill neonates), fibrinogen concentration $<100 \text{ mg/dL}$, and INR >2 .
- h. The Neonatal Central Venous Line Observational Study on Thrombosis (NEOCLOT)** is being conducted in the Netherlands to address catheter-related thrombosis (central venous catheter thrombosis) management in a clinical trial (*BMC Pediatrics*, February 23, 2018).
- 2. Heparin therapy is recommended** for clinically significant thrombosis with the purpose of preventing embolism or expansion of the clot. **LMWHs** are best because of the following advantages: reduced need for laboratory monitoring, subcutaneous dosing, longer half-life (dose every 12–24 hours), more predictable response, decreased risk of osteopenia and heparin-induced thrombocytopenia, and decreased risk of bleeding. **Advantages of UFH** are the fast reversibility and low cost. Cochrane review found no evidence to recommend or refute the use of heparin for the treatment of neonates with thrombosis. Monitor platelet counts if heparin is used. Obtain daily complete blood count with platelets and aPTT. **General recommendations are as follows:**
- a. Low molecular weight heparin therapy using enoxaparin (Lovenox)** is the treatment of choice in neonates with symptomatic thrombosis. Other LMWH preparations include dalteparin and rivarparin. For therapeutic treatment in infants <2 months of age, use enoxaparin 1.5 mg/kg/dose every 12 hours subcutaneously; if >2 months, use 1.0 mg/kg/dose subcutaneously. Recent studies reinforce the necessity and safety of higher doses to achieve target anti-factor Xa levels (1.7 mg/kg in term infants, 2 mg/kg in preterm infants every 12 hours subcutaneously). Follow anti-factor Xa activity levels 4 to 6 hours after subcutaneous dose (target anti-factor Xa range of 0.5–1 U/mL; or target anti-factor Xa range of 0.5–0.8 U/mL in a sample taken 2–6 hours after subcutaneous injection). Adjust as needed.
- b. Unfractionated (standard) heparin is preferred over low molecular weight heparin in patients with renal insufficiency.** Load 75 U/kg IV over 10 minutes, then 28 U/kg/h maintenance through a dedicated IV line. (Premature infants: 25–50 U/kg/h over 10 minutes, then 15–20 U/kg/h.) **Adjust based on aPTT 4 hours after initiation of each dosing change** (target aPTT 60–85 seconds). Duration of therapy is generally 5 to 14 days. Always increase or decrease the infusion amount by 10%, depending on the aPTT. If the aPTT is >96 seconds, hold the heparin for 30 to 60 minutes and start at a lower infusion rate. Avoid long-term use of therapeutic UFH in children.
- c. If urgent reversal of unfractionated heparin effect is needed due to bleeding or heparin-induced thrombocytopenia,** IV protamine can be given based on the total amount of heparin administered in the previous 2 hours. Stopping the infusion is usually sufficient for LMWH, and protamine is only partially effective. Dosing is 1 mg of protamine per 100 U of heparin via IV infusion over 10 minutes.
- d. Duration of thrombosis treatment.** This has not been established; guidelines include between 6 weeks and 3 months.
- e. During anticoagulant therapy,** maintain the platelet count $>50 \times 10^9/\text{L}$ and the fibrinogen $>100 \text{ mg/dL}$.

3. **Oral anticoagulants.** Not recommended in neonates (bleeding risk, difficulty in maintaining therapeutic doses, drug interactions including vitamin K content of the diet, tablet formulation). May be indicated for some cases of long-term management. Two therapies are used: warfarin or acenocoumarol. Initial dose is 0.2 mg/kg/d to achieve an INR between 2 and 3. Other dose reported is 0.33 mg/kg/d. If bleeding occurs from an excessive dose, give vitamin K.
4. **Thrombolytic drugs.** These medications break down fibrin by converting plasminogen to plasmin. Do not use in milder cases, and few studies have been done in very preterm infants. With life-threatening thrombosis or the possibility of limb loss or organ damage, 1 of these drugs may be used. Treatment with thrombolytics is *controversial*, and it is best to follow institutional guidelines. When using thrombolytic therapy, maintain a platelet count $>50 \times 10^4/\text{mm}^3$ ($50 \times 10^9/\text{L}$) and fibrinogen >100 mg/dL using selected platelet transfusion and cryoprecipitate. Monitor PT/INR, partial thromboplastin time (PTT), and fibrinogen every 4 hours. If the catheter is still patent, the medications can be given through it. If the catheter is obstructed and needs to be removed, systemic therapy is used. Recombinant tissue plasminogen activator (tPA) is more effective near the thrombus than streptokinase or urokinase.
 - a. **Recombinant tissue plasminogen activator (alteplase)** has become the **drug of choice** over the older agents streptokinase or urokinase (lower risk of allergies, the shortest half-life, fewer manufacturing concerns). It has an increased affinity for fibrin-bound plasminogen, making it more effective near the thrombus. See Chapter 155 for dosage.
 - b. **Infusion of intra-arterial streptokinase** has been successful in some infants. One study found the efficacy and safety were similar to tPA. Dosing is 2000 U/kg IV over 30 to 60 minutes or 1000 to 2000 U/kg/h as continuous infusion for 6 to 12 hours. Lower doses (500 U/kg/h) have been effective. In 1 study of aortoiliac thrombosis, a dose of 50 U/kg/h given directly into the clot was effective. Because of systemic side effects (allergic and toxic reactions and bleeding), its use has declined.
 - c. **Urokinase** is no longer available in the United States but may be used in other countries; it is not formally approved for use in children. Dose reported has been 4400 U/kg initial bolus dose IV over 10 minutes, then 4400 U/kg/h for 6 to 12 hours.
 - d. **The newer thrombolytic agents argatroban, bivalirudin, and fondaparinux have limited data in pediatrics.** Argatroban (direct thrombin inhibitor) has been used for heparin-induced thrombocytopenia in adults. There is not enough evidence to warrant its use. Bivalirudin (direct thrombin inhibitor) has had 1 study in pediatric patients and 1 in infants. Fondaparinux is a selective antithrombin-dependent factor Xa inhibitor with no studies in patients <1 year of age. The **target-specific oral anticoagulants**/direct oral anticoagulants (direct factor Xa inhibitors and direct factor IIa inhibitors) dabigatran, rivaroxaban, and apixaban may be promising because they have high bioavailability and rapid onset of action, limit the need for monitoring, have minimal interactions and foreseeable anticoagulant effects, and are under study in children.
5. **Catheter-directed thrombolysis.** A method in which the thrombolytic agent is injected directly into the thrombus. In some reports, it is superior to systemic thrombolytic therapy with fewer side effects. It has also been used if neonates fail to respond to UFH therapy. **For a blocked CVAD**, local thrombolysis is recommended after clinical assessment. **For neonates with limb-threatening or organ-threatening femoral artery thrombosis** who fail initial UFH therapy, thrombolysis is recommended. Drug of choice is tPA with a dose of 0.01 to 0.05 mg/kg/h.

6. **Surgery.** Microsurgery has been successfully performed in a small subset of neonates and may be indicated in the presence of an occluding embolism if thrombolysis is contraindicated for peripheral arterial occlusion, but it is rarely recommended because of the small caliber of their blood vessels, frequent reocclusion, and the poor clinical status of the infant with the thrombosis. Guidelines are not well established. Surgical options include thrombectomy, microvascular reconstruction, vascular decompression through the use of a fasciotomy, mechanical disruption of the thrombus (medical thrombectomy), and amputation. If antithrombotic therapy is contraindicated, arteriotomy, embolectomy, and microvascular reconstruction are options.
7. **Specific treatments**
- a. **Peripheral arterial catheter–related thromboembolism.** Remove the catheter immediately. In symptomatic peripheral arterial catheter–related thromboembolism, UFH anticoagulation with or without thrombolysis or surgical thrombectomy with microvascular repair with heparin therapy is recommended. Surgical consult is recommended. Thrombolytic therapy is recommended if viability of the limb or organ is compromised.
 - b. **Central venous access devices or umbilical venous catheters with confirmed thrombosis.** Remove CVAD or UVC after 3 to 5 days of therapeutic anticoagulation. Recommendation: initial anticoagulation or supportive care with radiologic monitoring for extension of the thrombosis. In infants who have not been treated, start anticoagulation if extension occurs. Start with either LMWH or UFH, and then administer LMWH for a total duration of 6 weeks to 3 months. Give a prophylactic dose of anticoagulation if either the CVAD or UVC is still in after completion of therapeutic anticoagulation until it is removed. If the VTE is causing major occlusion, resulting in critical compromise of limbs or organ, use tPA and fresh-frozen plasma (FFP) prior to finishing treatment.
 - c. **Acute femoral artery thrombosis.** Therapeutic doses of IV UFH as initial therapy or LMWH for a total of 5 to 7 days of anticoagulation. For infants with limb-threatening or organ-threatening femoral artery thrombosis who fail to respond to UFH therapy and in whom there are no contraindications: thrombolysis. With contraindications and when organ or limb death is imminent: surgical intervention.
 - d. **Renal vein thrombosis.** Treatment is *controversial*. Outcomes are similar between supportive care and anticoagulation. Anticoagulant therapy with heparin has improved survival and prevents renal atrophy. Remove the central catheter in the inferior vena cava if present.
 - i. **Supportive care.** Correction of fluid and electrolyte disturbances and treatment of infection. If DIC, consider UFH/LMWH.
 - ii. **Unilateral (no renal impairment, no inferior vena cava extension).** Either supportive care with close observation and follow-up by radiology for extension of thrombosis or start on anticoagulation therapy with UFH/LMWH or LMWH in therapeutic doses for total duration between 6 weeks and 3 months. **Unilateral (with extension into inferior vena cava):** anticoagulation for 6 weeks to 3 months. Possible surgery.
 - iii. **Bilateral renal vein thrombosis with evidence of renal impairment:** Anticoagulation with UFH/LMWH or initial thrombolytic therapy with tPA, followed by anticoagulation with UFH/LMWH.
 - iv. **Patients with renal insufficiency:** UFH is preferred over LMWH. If using LMWH, use a lower dose.

- e. **Stroke.** Anticoagulant therapy is usually not recommended; the exception is a cardioembolic stroke where anticoagulant therapy is used. Treatment should consist of avoiding or managing seizures.
 - i. **Venous sinus thrombosis (without significant intracerebral hemorrhage).** Heparinization is recommended for 6 weeks to 3 months. **With significant intracerebral hemorrhage:** anticoagulation or supportive care with radiologic monitoring, and anticoagulation if extension of the thrombus occurs.
 - ii. **First arterial ischemic stroke with no documented ongoing cardioembolic source.** Supportive care is recommended over anticoagulation. **With documented cardioembolic source,** anticoagulation recommended with UFH or LMWH.
 - iii. **Recurrent arterial ischemic stroke.** Anticoagulant or aspirin therapy.
 - iv. **Cerebral sinovenous thrombosis without significant intracranial hemorrhage.** Anticoagulation, initially with UFH or LMWH and then LMWH for 6 weeks to 3 months.
- f. **Cerebral sinovenous thrombosis with significant hemorrhage.** Either anticoagulation or supportive care with monitoring by radiology of the thrombosis at 5 to 7 days and anticoagulation if the thrombus extends.
- g. **Right atrial thrombosis.** Remove central venous catheter. Small thrombi possibly can be treated conservatively (*controversial*). Start anticoagulation therapy with UFH or LMWH. If compromised cardiac function, start tPA.
- h. **Systemic air embolism.** Use caution in setting up infusion lines with complex parts; use of IV fluid filters may decrease air embolism. Treatment is supportive cardiac care and supportive respiratory care, with 100% oxygen therapy. Hyperbaric oxygen has been used in some cases.
- i. **Neonatal purpura fulminans.** Treatment of neonatal purpura fulminans includes the following:
 - i. **For initial management of homozygous protein C deficiency:** Either 10 to 20 mL/kg of FFP every 12 hours or protein C concentrate when available at 20 to 60 U/kg until the clinical lesions resolve. After initial stabilization: long-term treatment with vitamin K antagonists, LMWH, protein C replacement, or liver transplantation.
 - ii. **For initial management for protein S deficiency:** FFP is used.
 - iii. **Long-term management:** Anticoagulation therapy with heparin or oral warfarin.
 - iv. **Other treatments:** Include case reports of subcutaneous protein C concentrate and liver transplantation.

85 ABO Incompatibility

- I. **Definition.** Isoimmune hemolytic anemia may result when ABO incompatibility occurs between the mother and the newborn infant. This disorder is **most common with blood type A or B infants born to type O mothers**. The hemolytic process begins in utero and is the result of active placental transport of maternal isoantibody. In type O mothers, isoantibody is predominantly 7S-IgG (immunoglobulin G) and is capable of crossing the placental membranes. Because of its larger size, the mostly 19S-IgM (immunoglobulin M) isoantibody found in type A or type B mothers cannot cross. Symptomatic clinical disease, which usually does not present until after birth, is a compensated mild hemolytic anemia with reticulocytosis, microspherocytosis, and early-onset unconjugated hyperbilirubinemia.
- II. **Incidence.** Risk factors for ABO incompatibility are present in 12% to 15% of pregnancies, but evidence of fetal sensitization (positive direct Coombs test) occurs in only 3% to 4%. Symptomatic ABO hemolytic disease occurs in <1% of all newborn infants but accounts for approximately two-thirds of observed cases of hemolytic disease in the newborn.
- III. **Pathophysiology.** Transplacental transport of maternal isoantibody results in an immune reaction with the A or B antigen on fetal erythrocytes, which produces characteristic **microspherocytes**. This process eventually results in complete extravascular hemolysis of the end-stage spherocyte. The ongoing hemolysis is balanced by compensatory reticulocytosis and shortening of the cell cycle time, so that there is overall maintenance of the erythrocyte indices within physiologic limits. A paucity of A or B antigenic sites on the fetal (in contrast to the adult) erythrocytes and competitive binding of isoantibody to a myriad of other antigenic sites in other tissues may explain the often mild hemolytic process that occurs and the usual absence of progressive disease with subsequent pregnancies.
- IV. **Risk factors**
 - A. **A₁ antigen in the infant.** Of the major blood group antigens, the A₁ antigen has the greatest antigenicity and is associated with the greater risk of symptomatic disease. However, the hemolytic activity of anti-B antibodies is higher than that of anti-A antibodies and may produce a more severe disease, in particular among infants of African American descent.
 - B. **Elevated isohemagglutinins.** Antepartum intestinal parasitism or third-trimester immunization with tetanus toxoid or pneumococcal vaccine may stimulate isoantibody titer to A or B antigens.
 - C. **Maternal immune serum globulin anti-A/B titers.** Anti-A/B titers >512% are significantly associated with the risk of ABO hemolytic disease of the newborn and may be an early indicator for therapy.
 - D. **Birth order.** Birth order is not considered a risk factor. Maternal isoantibody exists naturally and is independent of prior exposure to incompatible fetal blood group antigens.
- V. **Clinical presentation**
 - A. **Jaundice.** Icterus is often the sole physical manifestation of ABO incompatibility with a clinically significant level of hemolysis. The onset is usually within the first 24 hours of life. The jaundice evolves at a faster rate over the early neonatal period than nonhemolytic physiologic pattern jaundice.

B. Anemia. Because of the effectiveness of compensation by reticulocytosis in response to the ongoing mild hemolytic process, erythrocyte indices are maintained within a physiologic range that is normal for asymptomatic infants of the same gestational age. Additional signs of clinical disease (eg, hepatosplenomegaly or hydrops fetalis) are extremely unusual but may be seen with a more progressive hemolytic process (see Chapter 119). Exaggerated physiologic anemia may occur at 8 to 12 weeks of age, particularly when treatment during the neonatal period required phototherapy or exchange transfusion.

VI. Diagnosis. Obligatory screening for infants with unconjugated hyperbilirubinemia includes the following studies:

A. Blood type and Rh factor in the mother and the infant. These studies establish risk factors for ABO incompatibility. Noninvasive prenatal typing can now be done using cell-free fetal DNA genotyping.

B. Reticulocyte count. Elevated values after adjustment for gestational age and degree of anemia, if any, support the diagnosis of hemolytic anemia. For term infants, normal values are 4% to 5%; for preterm infants of 30 to 36 weeks' gestational age, values are 6% to 10%. In ABO hemolytic disease of the newborn, values range from 10% to 30%.

C. Direct Coombs test (direct antiglobulin test). Because there is very little antibody on the red blood cell (RBC), the direct Coombs test is often only weakly positive at birth and may become negative by 2 to 3 days of age. A strongly positive test is distinctly unusual and would direct attention to other isoimmune or autoimmune hemolytic processes.

D. Blood smear. The blood smear typically demonstrates **microspherocytes**, **polychromasia** proportionate to the reticulocyte response, and **normoblastosis** above the normal values for gestational age. An increased number of nucleated RBCs in the cord blood could be a sign of ABO incompatibility.

E. Bilirubin levels (fractionated or total and direct). Indirect hyperbilirubinemia is mainly present and provides an index of the severity of disease. The rate at which unconjugated bilirubin levels are increasing suggests the required frequency of testing, usually every 4 to 8 hours until values plateau.

F. Additional laboratory studies. Supportive diagnostic studies may be indicated on an individual basis if the nature of the hemolytic process remains unclear.

1. Antibody identification (indirect Coombs test). The indirect Coombs test is more sensitive than the direct Coombs test in detecting the presence of maternal isoantibody and identifies antibody specificity. The test is performed on an eluate of neonatal erythrocytes, which is then tested against a panel of type-specific adult cells.

2. Maternal IgG titer. The absence in the mother of elevated IgG titers against the infant's blood group tends to exclude a diagnosis of ABO incompatibility.

VII. Management

A. Antepartum treatment. Because of the low incidence of moderate to severe ABO hemolytic disease, invasive maneuvers before term is reached (eg, amniocentesis or early delivery) are usually not indicated.

B. Postpartum treatment

1. General measures. The maintenance of adequate hydration and evaluation for potentially aggravating factors (eg, sepsis, drug exposure, or metabolic disturbance) should be considered.

2. Phototherapy. Once a diagnosis of ABO incompatibility is established, phototherapy may be initiated before exchange transfusion is given. Because of the usual mild to moderate hemolysis, phototherapy may entirely obviate the need for exchange transfusion or may reduce the number of transfusions required. For guidelines on phototherapy, see Table 63-1 and Figure 99-2.

3. Exchange transfusion. See Table 63-1 and Figure 99-3 for guidelines on exchange transfusion and Chapter 34 for exchange transfusion procedure.

4. **Tin porphyrin.** This can decrease the production of bilirubin and reduce the need for exchange transfusion and duration of phototherapy. It is an inhibitor of heme oxygenase, which is the enzyme that allows the production of bilirubin from heme. The dose of stannoporphin is 6 $\mu\text{mol/kg}$ intramuscularly as a single dose given within 24 hours of birth with severe hemolytic disease, and it is available via compassionate use protocol. (*Note:* In May 2018, the US Food and Drug Administration advisory committee recommended that the risk–benefit profile of stannoporphin does not support the approval for treatment of newborns ≥ 35 weeks of gestational age at risk for hyperbilirubinemia.)
 5. **Intravenous immunoglobulin.** By blocking neonatal reticuloendothelial Fc receptors and thus decreasing hemolysis of the antibody-coated RBCs, high-dose intravenous immunoglobulin (IVIG; 1 g/kg over 4 hours) reduces serum bilirubin levels and the need for blood exchange transfusion with ABO or Rh hemolytic diseases. AAP recommends IVIG 0.5 to 1 g/kg over 2 hours if the TSB is rising despite intensive phototherapy or if the TSB level is within 2 to 3 mg/dL of the exchange level, can be repeated in 12 hours. Cochrane review (2018) does not recommend routine use of IVIG in alloimmune HDN because of low quality of evidence. Caution should be used when considering treatment with IVIG as there are emerging reports of increased incidence of necrotizing enterocolitis in term and late preterm infants with hemolytic disease of the newborn and isoimmune neonatal thrombocytopenia who were treated with IVIG.
- VIII. Prognosis.** For infants with ABO incompatibility, the overall prognosis is excellent. Timely recognition and appropriate management of the rare infant with aggressive ABO hemolytic disease may avoid any potential morbidity or severe hemolytic anemia and secondary hyperbilirubinemia and the inherent risks associated with exchange transfusion with the use of blood products.

86 Acute Kidney Injury

- I. **Definition.** There is no unified definition of acute kidney injury (AKI), previously termed acute renal failure, in neonates. Historically, neonatal AKI is defined as absolute serum creatinine ≥ 1.5 mg/dL, regardless of age or urine output, with normal maternal renal function. In 2013, a panel of experts at a National Institutes of Health-sponsored workshop proposed the adaptation of the categorical modified Kidney Disease: Improving Global Outcomes (KDIGO) definition to predict neonatal clinical outcomes (Table 86–1). According to neonatal KDIGO definition, AKI is defined as an absolute rise of ≥ 0.3 mg/dL or a $\geq 50\%$ rise from lowest baseline serum creatinine. AKI can be **anuric** (absence of urinary output by 24–48 hours of age), **oliguric** (urine output of < 1.0 mL/kg/h over 24 hours), or **nonoliguric** (> 1.0 mL/kg/h). AKI can present with normal urinary output (seen in asphyxiated neonates). Normal urine output is approximately 1 to 3 mL/kg/h with almost all infants voiding within 24 hours of birth. See Table 73–1.
- II. **Incidence.** In some studies, as many as 30% of neonatal intensive care unit–admitted neonates have some degree of renal failure. **Prerenal is the most common type in the neonate**, which may be identified in up to 85% of cases. Intrinsic renal disease incidence is 11%, and postrenal incidence is 3% to 5%.
- III. **Pathophysiology.** The normal newborn kidney has poor concentrating ability (maximum urine concentration is approximately 700 mOsm/L in the first few days after birth as compared to 1200 mOsm/L at 1 year of age). Renal injury leads to problems

Table 86–1. NEONATAL KDIGO (KIDNEY DISEASES: IMPROVING GLOBAL OUTCOMES) ACUTE KIDNEY INJURY DEFINITION

Stage	Serum Creatinine (SCr)	Urine Output Over 24 Hours
0	No change in SCr or rise <0.3 mg/dL	>1 mL/kg/h
1	SCr rise ≥ 0.3 mg/dL within 48 hours or SCr rise ≥ 1.5 to $1.9\times$ reference SCr within 7 days	>0.5 and ≤ 1 mL/kg/h
2	SCr rise ≥ 2 to $2.9\times$ reference SCr	>0.3 and ≤ 0.5 mL/kg/h
3	SCr rise $\geq 3\times$ reference SCr or SCr ≥ 2.5 mg/dL or Receipt of dialysis	≤ 0.3 mL/kg/h

Reference SCr is the lowest prior SCr measurement (serving as baseline SCr).

with volume overload, hyperkalemia, acidosis, hyperphosphatemia, and hypocalcemia. Neonatal AKI is traditionally divided into 3 categories:

- A. Prerenal failure is due to decreased renal blood flow/perfusion, which leads to a decreased renal function in a normal kidney.** Any condition that causes inadequate renal perfusion can cause prerenal AKI. **Common causes include:** hemorrhage, dehydration, septic shock, congestive heart failure, patent ductus arteriosus, and necrotizing enterocolitis. Other causes include respiratory distress syndrome, hypoxia, congenital heart disease, hypoalbuminemia, perinatal asphyxia, ECLS, and hypotension. Medications in neonates that can decrease renal blood flow include indomethacin, ibuprofen, angiotensin-converting enzyme (ACE) inhibitors, and phenylephrine eye drops. Maternal use of nonsteroidal anti-inflammatory drugs (NSAIDs), ACE inhibitors, or cyclooxygenase-2 inhibitors can also decrease renal blood flow.
 - B. Intrinsic renal failure refers to direct damage to the glomeruli, renal tubules, vessels, or interstitium of the kidneys.** Prolonged prerenal and postrenal AKI often results in some degree of intrinsic renal dysfunction. **Etiologies of intrinsic renal failure include:** acute tubular necrosis (ATN), congenital anomalies, vascular lesions, and infections/exogenous toxins. ATN is the most common cause, and it can be due to prolonged poor renal perfusion, ischemia or hypoxia, sepsis, cardiac surgery (blood product transfusions), or nephrotoxins (aminoglycosides, NSAIDs, amphotericin B, contrast agents, or acyclovir). **Congenital anomalies** (eg, bilateral renal agenesis, polycystic kidney disease, congenital nephrotic syndrome of the Finnish type, renal hypoplasia/dysplasia), **vascular lesions** (eg, bilateral renal vein/artery thrombosis, cortical necrosis, disseminated intravascular coagulation [DIC]), **infections** (congenital: syphilis, toxoplasmosis; candidiasis, pyelonephritis), and **exogenous toxins** (eg, uric acid nephropathy, myoglobinuria, hemoglobinuria) are the other causes.
 - C. Postrenal/obstructive uropathy involves obstruction of urinary outflow secondary to intrinsic obstruction, extrinsic compression, or congenital anomalies of the urinary tract.** Congenital causes include posterior urethral valves, prune belly syndrome, bilateral ureteropelvic junction obstruction, unilateral obstruction of a solitary kidney, and large ureterocele. Other postnatal causes include urethral strictures, meatal stenosis, neurogenic bladder, such as due to myelomeningocele, and blocked urinary drainage catheters. Rare causes in neonates include intrinsic obstruction (nephrolithiasis, bilateral fungal bezoar) and extrinsic tumor compression of the bladder or ureters (sacroccygeal teratoma, neurofibromatosis).
- IV. Risk factors.** Include dehydration; sepsis; perinatal asphyxia; administration of nephrotoxic drugs; prematurity; very low birthweight (<1000 g) infants; congenital heart disease affecting systemic circulation, especially those undergoing cardiopulmonary

bypass; and ECLS. Maternal diabetes may increase the risk for renal vein thrombosis and subsequent renal insufficiency.

V. Clinical presentation

- A. **Decreased or absent urine output.** Low or absent urine output is usually the presenting problem. Virtually all infants with normal renal function void by 24 hours after birth.
- B. **Family history.** History of urinary tract disease in other family members; history of oligohydramnios, which frequently accompanies urinary outflow obstruction or severe renal dysplasia or agenesis; and history of maternal diabetes should be obtained.
- C. **Physical examination**
 1. **Abdominal mass** may be due to a distended bladder, polycystic kidneys, hydro-nephrosis, or tumors.
 2. **Potter facies** is associated with renal agenesis.
 3. **Meningomyelocele** is associated with neurogenic bladder.
 4. **Pulmonary hypoplasia** is due to severe oligohydramnios in utero.
 5. **Urinary ascites** may be seen with posterior urethral valves and severe upper urinary tract obstruction.
 6. **Prune belly syndrome.** Hypoplasia of the abdominal wall musculature, cryptorchidism, and dilated upper urinary tracts.
 7. **Edema,** anasarca, or unexpected weight gain.

VI. Diagnosis

- A. **Urethral catheterization.** Use a 5- or 8-F feeding tube to measure volume of retained urine to monitor output (see Chapter 30).
- B. **Laboratory studies**
 1. **Blood urea nitrogen and creatinine**
 - a. **Blood urea nitrogen.** A level of 15 to 20 mg/dL suggests dehydration or renal insufficiency.
 - b. **Creatinine.** Normal serum creatinine values are 0.8 to 1.0 mg/dL at 1 day, 0.7 to 0.8 mg/dL at 3 days, and <0.6 mg/dL by 7 days of life. Higher values suggest renal disease except in low birthweight infants, in whom a creatinine level of <1.6 mg/dL is considered normal. (Rule of thumb: for every doubling of the creatinine, renal function is reduced by 50 %.)
 2. **Urinary indices** (Table 86–2) are used to assess prerenal versus intrinsic renal disease. Due to the immaturity of newborn kidney, particularly in the preterm

Table 86–2. URINARY INDICES IN THE NEONATE USED IN THE EVALUATION OF ACUTE KIDNEY INJURY

Urinary Indices	Prerenal	Intrinsic
Urine osmolality (mOsm/L)	>1400	≤400
Urine sodium (mEq/L)	<30	>60
Urine specific gravity	>1.020	<1.010
Urine/plasma creatinine ratio	29 ± 16	10 ± 4
Blood urea nitrogen/creatinine ratio	>30	<20
Fractional excretion of sodium (FE_{Na}) (%) ^a	<2	>2.5
Fractional excretion of urea (FE_{Urea}) (%)	<35	>50
Renal failure index (RFI)	<3.0	>3.0
Response to volume challenge	UO >2 mL/kg/h	No change in UO

UO, urinary output.

^a FE_{Na} cutoff values are gestational age (GA) dependent. The following cutoff values indicate intrinsic acute kidney injury: >3% in infants >30 weeks' GA, >6% in infants 29 to 30 weeks' GA.

FE_{Na} is not used in infants <28 weeks' GA. In the presence of diuretics, FE_{Urea} is used instead of FE_{Na} .

infant, urine indices are less useful than in older infants; urine indices may suggest intrinsic disease even with prerenal etiology. A spot urine osmolality, serum and spot urine sodium, and serum and urine creatinine are used to calculate the fractional excretion of sodium (FE_{Na}). These indices are of limited value if measured while the effects of diuretics, such as furosemide, are present. In the presence of diuretics, fractional excretion of urea (FE_{Urea}) may be helpful instead.

$$FE_{Na} = \frac{(\text{Urine sodium} \times \text{Plasma creatinine})}{(\text{Plasma sodium} \times \text{Urine creatinine})} \times 100$$

$$FE_{Urea} = \frac{(\text{Urine urea} \times \text{Plasma creatinine})}{(\text{Plasma urea} \times \text{Urine creatinine})} \times 100$$

3. Complete blood count and platelet count. May reveal thrombocytopenia, which is seen with sepsis or renal vein thrombosis.

4. Serum potassium. May be increased with renal insufficiency.

5. Urinalysis. May reveal hematuria (associated with renal vein thrombosis, tumors, or DIC); pyuria, suggesting urinary tract infection; or muddy brown casts suggestive of ATN.

6. Biomarkers. Biomarkers allow for earlier identification of neonates with AKI, before the 48 hours it takes serum creatinine to rise. Neutrophil gelatinase-associated lipocalin (NGAL) and cystatin C (CysC) are most studied in neonates and both show higher sensitivity than creatinine. These are usually abnormally expressed proteins in renal injury. Other biomarkers studied include serum CysC, urinary interleukin-18 (IL-18), serum and urinary NGAL, kidney molecule-1 (KIM-1), osteopontin, β_2 -microglobulin, and angiotensinogen. Some of these markers in the urine are higher in those with AKI (NGAL, osteopontin, CysC, β_2 -microglobulin, KIM-1, epithelial growth factor, osteopontin, uromodulin, clusterin, α -glutathione S-transferase). Some of the serum and urine levels are early predictive biomarkers for AKI (serum and urine NGAL and CysC, urinary IL-18, KIM-1). These markers in the urine and/or serum are higher in AKI and may be predictive for AKI. Some of the biomarkers correlate with drug-induced AKI. The use of omics (genomics, proteomics, metabolomics) in neonatal nephrology is increasing.

C. Diagnostic fluid challenge. If the patient does not have clinical volume overload or congestive failure, give a fluid challenge. Administer normal saline or colloid solution, 5 to 10 mL/kg as an intravenous (IV) bolus, and repeat once as needed. If there is no response, give furosemide 1 mg/kg IV. If there is still no increase in urine output, obstruction above the level of the bladder must be ruled out by ultrasound examination. If there is no evidence of obstruction, and the patient does not respond to these maneuvers, the most likely cause of anuria or oliguria is intrinsic renal failure.

D. Imaging studies

1. Abdominal ultrasonography. May identify urinary tract dilation, renal vein thrombosis, abdominal masses, or a distended bladder.

2. Abdominal radiograph studies. May show spina bifida or sacral agenesis, which may be associated with a neurogenic bladder. Displaced bowel loops suggest the presence of a space-occupying mass.

3. Radionuclide scanning. May be used to assess function of renal parenchyma but is less accurate in infants <6 weeks old due to immature kidneys.

VII. Management. See also Chapter 73.

A. General management

1. Keep strict intake and output and frequent weights.

2. Total fluid goal should be insensible fluid losses (preterm, 50–70 mL/kg/d; term, 30 mL/kg/d) plus fluid output (urine and gastrointestinal tract) replacement.

3. Monitor serum sodium and potassium levels frequently. Hyponatremia in setting of AKI is often due to dilutional factors and is best treated with fluid restriction rather than sodium supplementation. Acute hyperkalemia can be

a lethal complication of AKI. Correction of acidosis can be helpful to improve hyperkalemia.

4. **Nutrition.** Breast milk and Similac PM 60/40 are ideal because of the low phosphorus and potassium content and reduced osmotic load for those with polyuric renal failure.
5. **Hyperphosphatemia and hypocalcemia frequently coexist.** To control hyperphosphatemia, nutrition can be switched to Similac PM 60/40. Once phosphate is normalized, calcium (with or without vitamin D supplementation) is usually needed.
6. **For tetany or convulsions, acute intravenous calcium replacement** with 10% calcium gluconate, 40 mg/kg, or 10% calcium chloride will increase the serum calcium 1 mg/dL. Monitor ionized calcium.
7. **Metabolic acidosis may require chronic oral bicarbonate supplementation.** The immature or injured kidney is unable to reclaim bicarbonate effectively. Serum bicarbonate should be kept in the normal range with supplementation provided as necessary to offset renal losses.

$$\text{Bicarbonate deficit} = (24 - \text{observed}) 0.5 \times \text{body weight (kg)}$$

8. **Hypertension** can be seen with AKI, particularly in the setting of volume overload. Blood pressure should be monitored serially because these infants are always at risk for chronic hypertension.

B. Definitive management

1. **Prerenal failure.** Treated by providing volume to increase and restore renal perfusion and to treat the underlying cause.
2. **Postrenal failure.** Acute management involves bypassing the obstruction with a bladder catheter or by percutaneous nephrostomy drainage, depending on the level of the obstruction. Urinary tract infection prophylaxis may be indicated. Consult with pediatric urology early for evaluation and potential surgical intervention. Watch for the development of polyuria once obstruction is relieved.
3. **Intrinsic renal disease.** Stop or adjust doses of any nephrotoxic medications if possible. Supportive therapy is indicated (see previous text). Diuretics (furosemide, 1–2 mg/kg/dose) may increase urine output and aid in fluid management, but studies show that it does not improve the course of kidney injury. Observe for hyponatremia, hyperkalemia, hyperphosphatemia, hypocalcemia, and metabolic acidosis as they can occur frequently in intrinsic renal disease. Follow blood pressure because hypertension can occur (more common in renal artery/venous thrombosis). Renal feeding formulas that have a low renal solute and phosphorus should be considered. Pediatric nephrology should be consulted.
4. **Renal replacement therapy (peritoneal dialysis, hemodialysis, hemofiltration with or without dialysis).** This is used if other measures fail. Modality of choice is often center based and dependent on stability of the patient. Peritoneal dialysis is often technically easiest because of the difficulty in securing large-caliber IV dialysis catheters in newborns.

VIII. **Prevention.** In preterm infants at risk of AKI, the follow measures should be taken:

- A. **Avoidance of nephrotoxic agents.**
- B. **Strict fluid management.**
- C. **Avoidance of intravascular volume depletion.**
- D. **The Kidney Disease: Improving Global Outcomes acute kidney injury guidelines** suggest that a single dose of theophylline at a dose of 5 to 8 mg/kg may be given in neonates in the first hour of life with severe perinatal asphyxia who are at high risk of AKI.
- E. **Early administration of caffeine** is associated with decreased incidence and severity of AKI in preterm neonates. However, the optimal timing and dosage of caffeine are still under investigation.

- IX. Prognosis.** The prognosis for AKI depends on the underlying cause, the extent of damage, and gestational age. If renal disease is caused by toxins or ATN, renal function may recover to some extent with time. Chronic renal failure may ensue in 16.6% of neonates with AKI. Factors that increase morbidity and mortality in newborns include hypotension, need for mechanical ventilation, dialysis, use of vasopressors, hemodynamic instability, and multiorgan failure. Follow-up by a pediatric nephrologist with monitoring of urine, blood pressure, and renal function is necessary for early detection of long-term complications such as proteinuria, hypertension, and chronic kidney disease, respectively.

87 Air Leak Syndromes

- I. Definition.** The **pulmonary air leak syndromes** (pneumomediastinum, pneumothorax, pulmonary interstitial emphysema [PIE], pneumatocele, pneumopericardium, pneumoperitoneum, and pneumoretroperitoneum) compose a spectrum of diseases with the same underlying pathophysiology. Overdistention of alveolar sacs or terminal airways leads to disruption of airway integrity, resulting in dissection of air into extra-alveolar spaces. Very rarely, air can enter pulmonary vasculature (pulmonary veins) and cause air embolus. Air can also leak into the subcutaneous layers of the skin, especially skin of the chest, neck, and face, causing subcutaneous emphysema.
- II. Incidence.** The exact incidence of the air leak syndromes is difficult to determine. **Pneumothorax is the most common of the air leak syndromes**, reported to occur spontaneously in 1% to 2% of all neonates. The incidence increases in preterm infants to about 6%. The incidence also increases to 9% to 10% in infants with underlying lung disease (eg, respiratory distress syndrome [RDS], meconium aspiration, pneumonia, and pulmonary hypoplasia) who are on ventilatory support and in infants who had vigorous resuscitation at birth.
- III. Pathophysiology.** Overdistention of terminal air spaces or airways can result from uneven alveolar ventilation, air trapping, or injudicious use of alveolar-distending pressure in infants on ventilatory support. As lung volume exceeds physiologic limits, mechanical stresses occur in all planes of the alveolar or respiratory bronchial wall, with eventual tissue rupture. Air can track through the perivascular adventitia, causing **PIE**, or dissect along vascular sheaths toward the hilum, causing a pneumomediastinum. Rupture of the mediastinal pleura and into the thoracic cavity results in a **pneumothorax**. **Pneumoretroperitoneum and pneumoperitoneum** may occur when mediastinal air tracks downward to the extraperitoneal fascial planes of the abdominal wall, mesentery, and retroperitoneum and eventually ruptures into the peritoneal cavity. The mechanism by which **pneumopericardium** develops is probably due to passage of air along vascular sheaths.
- A. Barotrauma.** The **common denominator of the air leak syndromes is barotrauma/volutrauma**. Barotrauma results whenever positive pressure is applied to the lung. It cannot be avoided in the ill newborn infant needing ventilatory support, but its effects should be minimized. Peak inspiratory pressure (PIP), positive end-expiratory pressure (PEEP), inspiratory time (IT), respiratory rate, and the inspiratory waveform play important roles in the development of barotrauma. Contributing factors include high PIP, large tidal volume, and a long IT. It is difficult to determine which of these parameters is the most damaging and which plays the largest role in the development of the air leaks.

B. Other causes of lung overdistention. Barotrauma is not the only cause of lung overdistention. Atelectatic alveoli in RDS may cause uneven ventilation and subject the more distensible areas of the lung to receive high pressures, placing them at risk for rupture. Small mucous plugs in the airway in meconium aspiration may cause gas trapping secondary to a ball-valve effect. Other events, such as inappropriate intubation of the right mainstem bronchus, failure to wean after surfactant replacement therapy, and vigorous resuscitation or the development of high opening pressures with the onset of air breathing, can also lead to overdistention, with rupture of airway integrity at birth.

C. Lung injury

- 1. Large tidal volume.** It has long been considered that lung injury is primarily a result of high-pressure ventilation (barotrauma). Although reports show variable relationships between airway pressures and lung injury, more recent studies support the concept that lung overdistention resulting from high maximal lung volume (“volutrauma”) and transalveolar pressure, rather than high airway pressure, is the harmful factor.
- 2. Atelectasis.** The alveolar units in patients with RDS are subjected to a cycle of recruitment and derecruitment. Strategies to decrease this mechanism of atelectatic trauma, optimizing lung recruitment and decreasing lung injury and severity of lung disease, lessen the risk for pulmonary air leak.

IV. Risk factors

A. Ventilatory support. Infants on ventilatory support, such as preterm infants and infants with underlying pulmonary disease, have an increased risk of developing one of the air leak syndromes. Various reports have indicated an incidence as high as 41%, and as low as 9% for infants receiving some form of mechanical ventilatory assistance. Factors that contribute to the development of air leak include high inspiratory pressure, large tidal volume, long IT, excessive PEEP, and high-frequency ventilation with resultant insufficient expiratory time.

B. Meconium staining. Other infants at risk include those who are meconium stained at birth. In these infants, meconium may partially plug the airways, with resultant air trapping. During inspiration, the airway expands, allowing air to enter; however, during exhalation, the resultant smaller airway diameter will lead to alveolar gas being trapped behind the meconium plugs.

C. Failure to wean after surfactant therapy. Studies have shown that prophylactic use of surfactant therapy in infants at risk for RDS is associated with a decrease in the incidence of pneumothorax and PIE. Similar findings were noted in treating premature newborns with established RDS. With the return of pulmonary compliance after receiving surfactant, appropriate decreases in pressure support and more cautious ventilatory management of these infants are necessary immediately after therapy. The clinician must closely watch for improvement in the infant’s arterial blood gas levels and must wean ventilatory support as required.

V. Clinical presentation. Air leak syndromes are potentially lethal, and a high index of suspicion is necessary for the diagnosis. On clinical grounds, respiratory distress or a deteriorating clinical course strongly suggests air leak. See Section IX below for clinical presentation of specific air leak syndromes.

VI. Diagnosis. The **definitive diagnosis** of all of these syndromes is made **radiographically**. An anteroposterior (AP) chest radiograph along with a cross-table lateral film is essential in diagnosing an air leak (see Chapter 12 for various radiographic examples). Ultrasound may be useful in diagnosing air leaks in the neonate (eg, lung ultrasound to diagnose a pneumothorax and abdominal ultrasound can diagnose a pneumoperitoneum.) (See Chapter 44.)

VII. Management. The best mode of treatment for all of the air leak syndromes is prevention and judicious use of ventilatory support, with close attention to distending pressure, PEEP, and IT. Barotrauma remains a prominent disadvantage to ventilatory support. The careful use of ventilatory pressures and the adjustment of ventilator

settings to provide a minimum of barotrauma are extremely important in the neonatal intensive care unit. The use of surfactant therapy for RDS substantially decreases the incidence of pneumothorax and PIE. Earlier treatment is more beneficial than later treatment. A review of 6 randomized trials found that early surfactant administration with extubation to nasal continuous positive airway pressure (CPAP) was associated with significant reductions in the need for mechanical ventilation and fewer air leak syndromes compared with later selective surfactant administration and continued mechanical ventilation in infants with RDS. In infants with established PIE, high-frequency jet ventilation (HFJV) can facilitate resolution of the air leak.

VIII. Prognosis. The prognosis for the infant in whom an air leak develops depends on the underlying condition. In general, if the air leak is treated rapidly and effectively, the long-term outcome should not change; however, it must be remembered that early-onset PIE (<24 hours of age) is associated with a high mortality rate. Chronic lung disease of the newborn (bronchopulmonary dysplasia) is also associated with severe pulmonary air leak syndromes. Pneumothorax is also described as a risk factor for intraventricular hemorrhage, cerebral palsy, and delayed mental development.

IX. Specific air leaks

A. Pneumomediastinum

- 1. Definition.** A pneumomediastinum is air in the mediastinum from ruptured alveolar air that enters the perivascular sheaths dissecting into the hilum, through the visceral pleura, into the loose connective tissue spaces of the mediastinum.
- 2. Incidence.** The actual incidence of pneumomediastinum is uncertain because it is usually asymptomatic and may go undetected. It has been reported to occur spontaneously in 25 of 10,000 live births in asymptomatic infants; otherwise, the exact incidence varies with the degree of ventilatory support and other associated air leaks (eg, pneumothorax or PIE).
- 3. Pathophysiology.** Pneumomediastinum is preceded by alveolar air rupture. After alveolar rupture, air traverses the fascial planes and passes into the mediastinum.
- 4. Risk factors.** See Section IV earlier in this chapter.
- 5. Clinical presentation.** Unless accompanied by a pneumothorax, a pneumomediastinum may be totally asymptomatic. **Spontaneous pneumomediastinum** may develop in term infants not on ventilatory support and may be accompanied by mild respiratory distress. Physical findings in addition to respiratory distress may include an increase in AP diameter of the chest and distant heart sounds.
- 6. Diagnosis.** (See Figure 12–23.) Radiographically, a pneumomediastinum may present in several ways. The **classic description** is that of a “**wind-blown spinnaker sail**” (a lobe or lobes of the thymus being elevated off the heart), most likely to be seen on a left lateral oblique view. In other cases, a halo may be seen around the heart in the AP projection. This must be distinguished from a pneumopericardium in which air completely surrounds the heart, including the inferior border. The cross-table lateral projection will show an anterior collection of air that may be difficult to distinguish from a pneumothorax.
- 7. Management.** In isolated pneumomediastinum, close observation is required because it can progress to a pneumothorax. One should resist the temptation to insert a drain into the mediastinum because it will not be beneficial and may cause more problems than it will solve.
- 8. Prognosis.** The prognosis is good because recovery is frequently spontaneous without treatment.

B. Pneumothorax. See also Chapter 75 on-call problem discussing pneumothorax.

- 1. Definition.** A pneumothorax is air between the visceral pleura of the lungs and the parietal pleura of the chest wall.
- 2. Incidence.** The incidence of pneumothorax varies between units. It occurs more frequently in the neonatal period than in any other time of life with an incidence of 1% to 2%. With the advent of neonatal ventilator care, however, the incidence

has risen dramatically. Although the exact incidence is difficult to determine, it is directly related to the degree of ventilatory support delivered. The incidence has been as high as 30% to 40%, but in recent years, the incidence has declined to a range of 9% to 11% and is reflective of the underlying pulmonary disease, especially in patients who require mechanical ventilation. In a population of 288 infants with birthweights of 1000 to 1600 g (circa 2004–2008) who received surfactant therapy and/or early CPAP, the overall incidence of pneumothorax or PIE was 5.4%.

3. Pathophysiology

- a. **Term infant not on ventilatory support.** A pneumothorax may develop spontaneously. It usually occurs at delivery, when a large initial opening pressure is necessary to inflate fluid-filled alveolar sacs. It is thought to result from uneven inflation of alveoli throughout the lung, combined with the high negative intrathoracic pressure that occurs during the first breath.
 - b. **Infant on ventilatory support** has alveolar overdistention secondary to either injudicious use of distending pressure or failure to wean ventilatory pressure when compliance begins to return. A pneumothorax is usually preceded by rupture of the alveoli, with the interstitial air traversing via fascial planes into the mediastinum. Air breaks through the mediastinal pleura to form a pneumothorax.
4. **Risk factors.** See Section IV earlier in this chapter.
5. **Clinical presentation.** The clinical presentation of the neonate with a pneumothorax depends on the setting in which it develops.
- a. **Term infants with a spontaneous pneumothorax** may be asymptomatic or only mildly symptomatic. These infants usually have tachypnea and mild oxygen needs early, but they may progress to the classic signs of respiratory distress (grunting, flaring, retractions, and tachypnea).
 - b. **Infant on ventilatory support** generally has a sudden, rapid clinical deterioration characterized by cyanosis, decreased oxygen saturation, hypotension, bradycardia, hypoxemia, hypercarbia, and respiratory acidosis. Other clinical signs may include decreased breath sounds on the involved side, shifted heart sounds, asynchrony of the chest, and abdominal distention from displaced diaphragm. When compression of major veins and decreased cardiac output occur because of downward displacement of the diaphragm, signs of shock may be evident.
6. **Diagnosis.** A high index of suspicion is necessary for the diagnosis of pneumothorax.
- a. **Transillumination of the chest.** (See Chapters 44 and 75.) With the aid of transillumination, the diagnosis of pneumothorax may be made without a chest radiograph. A fiberoptic light probe placed on the infant's chest wall will illuminate the involved hemithorax. Although this technique is beneficial in an emergency, it should not replace a chest radiograph as the means of diagnosis.
 - b. **Chest radiograph.** (See Figure 12–24.) Radiographically, a pneumothorax is diagnosed based on the following characteristics:
 - i. **Presence of air in the pleural cavity** separating the parietal and visceral pleura. The area appears hyperlucent with absence of pulmonary markings.
 - ii. **Collapse of the ipsilateral lobes.**
 - iii. **Displacement of the mediastinum** toward the contralateral side.
 - iv. **Downward displacement of the diaphragm.** In infants with RDS, the compliance may be so poor that the lung may not collapse, with only minimal shift of the mediastinal structures. The AP radiograph may not demonstrate the classic radiographic appearance if a large amount of the intrapleural air is situated just anterior to the sternum. In these situations,

the cross-table lateral radiograph will show a large lucent area immediately below the sternum, or the lateral decubitus radiograph (with the suspected side up) will show free air.

7. Management. Treatment of a pneumothorax depends on the clinical status of the infant. In infants without respiratory distress, continuous air leak, or need for assisted ventilation, close monitoring and observation may be all that is needed. The pneumothorax typically resolves in 1 to 2 days. If the pneumothorax affects <15% of a patient's hemithorax, the pneumothorax most likely will resolve spontaneously; otherwise, the air must be removed.

a. Oxygen supplementation. In the term infant who is mildly symptomatic, an oxygen-rich environment is often all that is necessary. The inspired oxygen facilitates nitrogen washout of the blood and tissues and thus establishes a difference in the gas tensions between the loculated gases in the chest and those in the blood. A diffusion gradient results for resorption of the loculated gas and resolution of the pneumothorax. The pneumothorax usually resolves within 1 to 2 hours. This mode of therapy is not appropriate in the preterm infant because of the high oxygen levels needed for washout and the resulting increase in oxygen saturation, making it unsuitable for premature infants with a high risk for retinopathy of prematurity. Recent reviews show that high concentration of oxygen does not show any benefit over targeted oxygen therapy.

b. Decompression. In the symptomatic neonate or the neonate on mechanical ventilatory support, immediate evacuation of air is necessary. The technique is described in Chapter 75. Placement of a chest tube of appropriate size will eventually be necessary (see Chapter 31 on chest tube placement).

8. Prognosis. See Section VIII earlier in this chapter.

C. Pulmonary interstitial emphysema

1. Definition. PIE is dissection of air into the perivascular tissues of the lung from alveolar overdistention or overdistention of the smaller airways.

2. Incidence. This disorder arises almost exclusively in the very low birthweight infant on ventilatory support. It may also emerge in the extremely low birthweight infant without mechanical ventilation but receiving ventilatory support by CPAP. Although localized persistent PIE is rarely reported in infants not receiving ventilatory support, it must be considered in any infant with cystic lung lesions. PIE has been reported to occur in at least a third of infants <1000 g who have RDS on the first day of life and are receiving mechanical ventilator support. PIE frequently develops in the first 48 to 72 hours of life.

3. Pathophysiology. PIE may be the precursor of all other types of pulmonary air leaks. With overdistention of the alveoli or conducting airways, or both, rupture may occur, and there may be dissection of the air into the perivascular tissue of the lung. The interstitial air moves in the connective tissue planes and around the vascular and lymphatic axes, particularly the venous ones. Once in the interstitial space, the air moves along bronchioles, lymphatics, and vascular sheaths or directly through the lung interstitium to the pleural surface. The extrapulmonary air is trapped in the interstitium (PIE), or it may extend and cause pneumomediastinum, pneumopericardium, or pneumothorax. PIE may exist in 2 forms, either localized (which involves 1 or more lobes) or diffuse (bilateral).

4. Risk factors. See Section IV earlier in this chapter.

5. Clinical presentation. The patient in whom PIE develops may have sudden deterioration accompanied by bradycardia and hypotension. More commonly, however, the onset of PIE is heralded by slow, progressive deterioration of arterial blood gas levels (hypoxemia, hypercarbia, acidosis) and the apparent need for increasing ventilatory support. The response to increased ventilatory support in the face of poor arterial blood gas levels may lead to worsening of PIE and further clinical deterioration.

6. Diagnosis. In infants with PIE, the chest radiograph generally reveals radiolucencies that are either linear or cyst like. The linear radiolucencies vary in length and do not branch. They are seen in the periphery of the lung as well as medially and may be mistaken for air bronchograms. The cyst-like lucencies vary from 1.0 to 4.0 mm in diameter and can be lobulated. (See Figure 12–25.) In severe cases, chest radiograph film may also reveal overexpanded lung fields and a decreased heart shadow.

7. Management

a. Lessening lung injury. In general, once PIE is diagnosed, an attempt should be made to decrease ventilatory support and lessen lung trauma. Decreasing the PIP, decreasing the PEEP, or shortening the IT may be required. When decreasing these settings, some degree of hypercarbia and hypoxia may have to be accepted.

b. Positioning of the infant with the involved side down. This has also proved beneficial in some cases of unilateral PIE.

c. Other treatments. Suctioning of the endotracheal tube and manual positive-pressure ventilation should be minimized. More invasive measures include selective collapse of the involved lung on the side with the worse involvement, with selective intubation or even the insertion of chest tubes before the development of pneumothorax. In cases of severe PIE, surgical resection of the affected lobe may be considered.

d. High-frequency ventilation. Both high-frequency oscillatory ventilation (HFOV) and mostly HFJV are used effectively in the treatment of PIE and other types of air leak syndromes. Although these treatment modalities may improve survival of the infant with PIE, the long-term outcome remains uncertain.

8. Prognosis. See Section VIII earlier in this chapter.

D. Pneumopericardium

1. Definition. A pneumopericardium is air in the pericardial sac, which is usually secondary to passage of air along pulmonary vascular sheaths. It is most often a complication of mechanical ventilation and often results in fatal cardiac tamponade.

2. Incidence. A pneumopericardium is a rare occurrence and the least common form of pulmonary air leak in the neonatal period. The incidence in a study involving very low birthweight neonates was reported at 2%.

3. Pathophysiology. A pneumopericardium is usually preceded by pneumomediastinum or other air leaks such as PIE or pneumothorax. It is associated with the use of extremely high PIPs or a catastrophic sudden obstruction of the expiratory part of the mechanical respiratory circuit. The mechanism by which a pneumopericardium develops is probably due to passage of air along vascular sheaths. From the mediastinum, air can travel along the fascial planes in the subcutaneous tissues of the neck, chest wall, and anterior abdominal wall and into the pericardial space, causing a pneumopericardium.

4. Risk factors. See Section IV earlier in this chapter.

5. Clinical presentation. A pneumopericardium is rarely asymptomatic and more often presents as a full picture of cardiac tamponade. The first sign of a pneumopericardium may be a decrease in blood pressure or a decrease in pulse pressure. There may also be an increase in heart rate with distant heart sounds. Absent peripheral pulses, marked abdominal distention due to massive hepatomegaly, and severe hypoxemia, with breath sounds that are adequate and equal on both sides of the chest, are likely to develop shortly thereafter.

6. Diagnosis. A pneumopericardium has the most classic radiographic appearance of all the air leaks (see Figure 12–22). **A broad radiolucent halo completely surrounds the heart, including the diaphragmatic surface.** This picture is easily distinguished from all the other air leaks by its extension completely around the heart in all projections.

7. **Management.** Treatment of a pneumopericardium requires the urgent placement of a pericardial drain or repeated pericardial taps. Tube drainage is recommended for all neonates because of a high rate of reaccumulation (as much as 50% of the time). The procedure is described in Chapter 41. Successful pericardiocentesis in most instances should result in 75% to 80% survival.
 8. **Prognosis.** See Section VIII earlier in this chapter.
- E. **Pneumoperitoneum.** See also Chapter 74.
1. **Definition.** A pneumoperitoneum is air in the peritoneal cavity that is usually caused by gastrointestinal perforation, but it can also be caused by air that has ruptured from the mediastinum into the peritoneum.
 2. **Incidence.** A pneumoperitoneum from passage of air into the chest is rare. It has been reported to occur in approximately 1% of mechanically ventilated children in intensive care units.
 3. **Pathophysiology.** A pneumoperitoneum in the newborn most commonly arises from a perforated hollow viscus or a preceding abdominal operation. It can also be secondary to ventilator-assisted pulmonary air leakage. Air from ruptured alveoli can flow transdiaphragmatically along the great vessels and esophagus into the retroperitoneum. When air accumulates in the retroperitoneum, rupture into the peritoneal cavity can occur.
 4. **Risk factors.** See Section IV earlier in this chapter.
 5. **Clinical presentation.** Depending on the cause and severity, a pneumoperitoneum can present with or without associated abdominal findings. Because a pneumoperitoneum can occur as a result of pneumothorax, pneumomediastinum, and PIE, infants generally present with increasing signs of respiratory distress.
 6. **Diagnosis.** A pneumoperitoneum can be detected in radiographic films as free air under the diaphragm. (See Figure 12–26.)
 7. **Management.** Conservative management may be strongly considered if evidence of pulmonary air leak precedes or simultaneously appears with pneumoperitoneum. See Chapter 40 for air removal technique.
 8. **Prognosis.** See Section VIII earlier in this chapter.
- F. **Pneumoretroperitoneum.** A pneumoretroperitoneum is the presence of air in the retroperitoneal space. **An isolated pneumoretroperitoneum is rare in neonates.** It can occur when massive intrathoracic pressure from a pneumothorax or pneumomediastinum causes free air to dissect into the retroperitoneal space from the chest. On radiograph, one sees air around the kidneys and in the perinephric space.
- G. **Pneumatocele.** A pneumatocele represents subpleural or intraparenchymal cystic lesions in the lungs. They are thin-walled, air-filled cysts and mainly result from ventilator-induced lung injury in preterm infants. Pneumatocèles also can occur as a sequela of acute pneumonia. Causative agents include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli*. Most pneumatocèles are asymptomatic. They rarely require any surgical intervention. Traumatic pneumatocèles caused by positive-pressure ventilation commonly resolve spontaneously; however, it is important to follow them closely, because high pressures during mechanical ventilation can cause a sudden increase in their size and result in a pneumothorax.
- H. **Subcutaneous emphysema.** Subcutaneous emphysema occurs when an air leak dissects into tissues beneath the skin (tissue planes of the face, neck, and upper chest). It can be seen as a smooth bulging of the skin and detected by palpation of crepitus in the involved area. Usually it does not cause any clinical deterioration, but in extremely low birthweight infants, subcutaneous emphysema can result in compression of the airway. Subcutaneous emphysema is of clinical importance as it may signify a more serious underlying air leak.

88 Anemia

- I. **Definition.** Anemia developing during the neonatal period (0–28 days of life) in infants >34 weeks of gestational age is indicated by a central venous hemoglobin <13 g/dL or a capillary hemoglobin <14.5 g/dL.
- II. **Incidence.** Anemia is the **most common hematologic abnormality** in the newborn. Specific incidence depends on the cause of the anemia.
- III. **Pathophysiology**
 - A. **Normal physiology.** At birth, normal values for the central venous hemoglobin in infants of >34 weeks of gestational age are 14 to 20 g/dL, with an average value of 17 g/dL. Reticulocyte count in the cord blood of infants ranges from 3% to 7%. The average mean corpuscular volume of red blood cells (RBCs) is 107 fL (femtoliters). Premature infants have slightly lower hemoglobin and higher mean corpuscular volume and reticulocyte counts. In healthy term infants, **hemoglobin values remain unchanged until the third week of life and then decline, reaching a mean nadir of 11 g/dL** (but may be as low as 9 g/dL) **at 8 to 12 weeks**. This is known as the “**physiologic anemia of infancy**.” In preterm infants, this decline is more profound, reaching a nadir of 7 to 9 g/dL at 4 to 8 weeks. This exaggerated physiologic anemia of prematurity is related to a combination of decreased RBC mass at birth, increased iatrogenic losses from laboratory blood sampling, shorter RBC life span, inadequate erythropoietin production, and rapid body growth. In the absence of clinical complications associated with prematurity, infants remain asymptomatic during this process.
 - B. **Etiologies of anemia.** Anemia in the newborn infant results from 1 of 3 processes: **loss of RBCs, or hemorrhagic anemia**, the most common cause; **increased destruction of RBCs, or hemolytic anemia**; or **underproduction of RBCs, or hypoplastic anemia**.
 1. **Hemorrhagic anemia**
 - a. **Antepartum period** (1 in 1000 live births)
 - i. **Loss of placental integrity.** Abruptio placentae, placenta praevia, or traumatic amniocentesis (acute or chronic) may result in loss of placental integrity.
 - ii. **Anomalies of the umbilical cord or placental vessels.** Velamentous insertion of the umbilical cord occurs in 10% of twin gestations and almost all gestations with >3 fetuses. Communicating vessels (vasa praevia), umbilical cord hematoma (1 in 5500 deliveries), or entanglement of the cord by the fetus may also cause hemorrhagic anemia.
 - iii. **Twin-twin transfusion.** This is observed only in monozygotic (MZ) multiple births. MZ twin pregnancies account for approximately 30% of spontaneously conceived twins. The occurrence of MZ twins is 0.4% to 0.45% of nonstimulated in vivo conceptions. The incidence of monochorionic twins is rising due to the increase in the use of assisted reproductive technology (ART). The use of ART has been associated with a 2- to 12-fold increase in the conception of MZ twins. In the presence of a monochorionic placenta, 5% to 30% of twin pregnancies are associated with twin-twin transfusion leading to a hemoglobin concentration difference in excess of >5 g/dL. The anemic donor twin may develop congestive heart disease, whereas the recipient plethoric twin may manifest signs of the hyperviscosity syndrome. In utero laser photocoagulation, which interrupts the vascular connections on the chorionic plate, has improved the low survival rate for twin-twin transfusion diagnosed before 26 weeks’ gestation.

b. Intrapartum period

- i. Fetomaternal hemorrhage.** Fetomaternal hemorrhage (FMH) is a common event during pregnancy, demonstrable in approximately 75% of gestations. The risk is increased with preeclampsia, with the need for instrumentation, and with cesarean delivery. In approximately 8% of pregnancies, the volume of the hemorrhage is >10 mL. Clinically significant FMH has traditionally been set at a cutoff of 30 mL. At this cutoff, the incidence of FMH has been estimated to be 3 per 1000 births. One in 2000 pregnancies is associated with FMH of ≥ 100 mL, which carries a 70% perinatal mortality rate. The severity of the FMH is related to the size of the bleed in relation to the overall fetal blood volume, as well as the rate at which this blood is lost, and whether the event is acute or chronic.
- ii. Cesarean delivery.** In elective cesarean deliveries, there is a 3% incidence of anemia. The incidence is increased in emergency cesarean deliveries.
- iii. Traumatic rupture of the umbilical cord.** Rupture may occur if delivery is uncontrolled or unattended.
- iv. Failure of placental transfusion.** Failure is usually caused by umbilical cord occlusion (eg, a nuchal cord or an entangled or prolapsed cord) during vaginal delivery. Blood loss may be 25 to 30 mL in the newborn.
- v. Obstetric trauma.** During a difficult vaginal delivery, occult visceral or intracranial hemorrhage may occur. It may not be apparent at birth. Difficult deliveries are more common with large for gestational age infants, breech presentation, or difficult extraction.

c. Neonatal period

- i. Enclosed hemorrhage.** Hemorrhage severe enough to cause neonatal anemia suggests obstetric trauma, severe perinatal distress, or a defect in hemostasis. See Figure 7-3 for examples of intracranial hemorrhages in a newborn.
 - (a) Caput succedaneum** is relatively common and may result in benign hemorrhage.
 - (b) Cephalhematoma** is found in up to 2.5% of births. It is associated with vacuum extraction and primiparity (5% risk of associated linear nondepressed skull fracture).
 - (c) Subgaleal (subaponeurotic) hemorrhage** is a rare but potentially lethal medical emergency caused by a rupture of the emissary veins, which are connections between the dural sinuses and the scalp veins. Blood accumulates between the epicranial aponeurosis of the scalp and the periosteum. This potential space extends forward to the orbital margins, backward to the nuchal ridge, and laterally to the temporal fascia. In term infants, this subaponeurotic space may hold as much as 260 mL of blood (40 mL per every 1-cm increase in head circumference). Subgaleal hemorrhage is most often associated with vacuum extraction and forceps delivery, but it may also occur spontaneously from an associated coagulopathy.
 - (d) Intracranial hemorrhage** may occur in the subdural, subarachnoid, or subependymal space.
 - (e) Visceral parenchymal hemorrhage** is uncommon. It is usually the result of obstetric trauma (eg, difficult breech extraction) to an internal organ, most commonly the liver, but it also can involve the spleen, kidneys, or adrenal glands.

- ii. **Defects in hemostasis.** Defects in hemostasis may be congenital, but more commonly, hemorrhage occurs secondary to consumption coagulopathy, which may be caused by the following:
 - (a) **Congenital coagulation factor deficiency**
 - (b) **Consumption coagulopathy**
 - (i) **Disseminated congenital or viral infection**
 - (ii) **Bacterial sepsis**
 - (iii) **Intravascular embolism of thromboplastin** (as a result of a dead twin, maternal toxemia, necrotizing enterocolitis, or others)
 - (c) **Deficiency of vitamin K-dependent coagulation factors (factors II, VII, IX, and X)**
 - (i) **Failure to administer vitamin K at birth** usually results in a bleeding diathesis at 3 to 4 days of age.
 - (ii) **Use of antibiotics** may interfere with the production of vitamin K by normal gastrointestinal flora.
 - (iii) **Maternal ingestion of anticonvulsants** (carbamazepine, phenytoin, and barbiturates but not valproic acid), antituberculosis agents (isoniazid, rifampicin), and vitamin K antagonists.
 - (d) **Thrombocytopenia.** See Chapter 128.
 - (i) **Immune thrombocytopenia may be isoimmune or autoimmune.**
 - (ii) **Congenital thrombocytopenia with absent radii** is a syndrome frequently associated with hemorrhagic anemia in the newborn.
 - (iii) **Iatrogenic blood loss.** Anemia may occur if blood loss resulting from repeated venipuncture is not replaced routinely. Symptoms may develop if a loss of >20% occurs within a 48-hour period.
2. **Hemolytic anemia**
- a. **Immune hemolysis**
 - i. **Isoimmune hemolytic anemia.** Caused mostly by Rh incompatibility.
 - ii. **Autoimmune hemolytic anemia.**
 - b. **Nonimmune hemolysis**
 - i. **Bacterial sepsis** may cause primary microangiopathic hemolysis.
 - ii. **Congenital TORCH** (toxoplasmosis, other, rubella, cytomegalovirus, and herpes simplex virus) infections (see Chapter 148).
 - c. **Congenital erythrocyte defect**
 - i. **Metabolic enzyme deficiency**
 - (a) **Glucose-6-phosphate dehydrogenase deficiency**
 - (b) **Pyruvate kinase deficiency**
 - ii. **Thalassemia.** Hemolytic anemia secondary to thalassemia is invariably associated with homozygous α -thalassemia and presents at birth. The disorders in β -thalassemia become apparent only after 2 to 3 months of age.
 - iii. **Hemoglobinopathy.** May be characterized as unstable hemoglobins or congenital Heinz body anemia.
 - iv. **Membrane defects.** Usually autosomal dominant.
 - (a) **Hereditary spherocytosis** (1 in 5000 neonates) commonly presents with jaundice and less often with anemia.
 - (b) **Hereditary elliptocytosis** (1 in 2500 neonates) rarely presents in the newborn infant.
 - d. **Systemic diseases**
 - i. **Galactosemia**
 - ii. **Osteopetrosis**

e. **Nutritional deficiency.** Vitamin E deficiency occurs with chronic malabsorption but usually does not present until after the neonatal period.

3. Hypoplastic anemia

a. Congenital disease

i. **Diamond-Blackfan syndrome (congenital hypoplastic anemia)**

ii. **Atransferrinemia**

iii. **Congenital leukemia**

iv. **Sideroblastic anemia**

b. Acquired disease

i. **Infection.** Rubella and syphilis are the most common causes.

ii. **Aplastic crisis.**

iii. **Aplastic anemia.**

IV. **Risk factors.** Prematurity, certain race and ethnic groups, and hereditary blood disorders (see Section III earlier in this chapter).

V. Clinical presentation

A. **Symptoms and signs.** The 4 major forms of neonatal anemia may be demonstrated by determination of the following factors: age at presentation of anemia, associated clinical features at presentation, hemodynamic status of the infant, and presence or absence of compensatory reticulocytosis.

1. **Hemorrhagic anemia.** Often dramatic in clinical presentation when acute but may be more subtle when chronic. Both forms have significant rates of perinatal morbidity and mortality if they remain unrecognized. Neither form has significant elevation of bilirubin levels or hepatosplenomegaly.

a. **Acute hemorrhagic anemia.** Presents at birth or with internal hemorrhage after 24 hours. There is pallor not associated with jaundice and often without cyanosis (<5 g of deoxyhemoglobin) and unrelieved by supplemental oxygen. Tachypnea or gasping respirations are present. Vascular instability ranges from decreased peripheral perfusion (a 10% loss of blood volume) to hypovolemic shock (20%–25% loss of blood volume). There is also decreased central venous pressure and poor capillary refill. Normocytic or normochromic RBC indices are present, with reticulocytosis developing within 2 to 3 days of the hemorrhagic event.

b. **Chronic hemorrhagic anemia.** Presents at birth with unexplained pallor, often without cyanosis (<5 g of deoxyhemoglobin), and unrelieved by supplemental oxygen. Minimal signs of respiratory distress are present. The central venous pressure is normal or increased. Microcytic or hypochromic RBC indices are present, with compensatory reticulocytosis. The liver is often enlarged because of compensatory extramedullary erythropoiesis. Hydrops fetalis or stillbirth may occur with failure of compensatory reticulocytosis or intravascular volume maintenance.

c. **Asphyxia pallida (severe neonatal asphyxia).** Not associated with hemorrhagic anemia at presentation. This disorder must be distinguished clinically from acute hemorrhage because specific immediate therapy is needed for each disorder. Asphyxia pallida presents at birth with pallor and cyanosis which improves with supplemental oxygen delivery, respiratory failure, bradycardia, and normal central venous pressure.

2. **Hemolytic anemia.** Jaundice is often seen before diagnostic levels of hemoglobin are obtained, in part because of the compensatory reticulocytosis that is invariably present. The infant usually presents with pallor after 48 hours of age. However, severe Rh isoimmune disease or homozygous α -thalassemia presents at birth with severe anemia and, in many cases, hydrops fetalis. Unconjugated hyperbilirubinemia of >10 to 12 mg/dL, tachypnea, and hepatosplenomegaly may be seen with hemolytic anemia.

3. **Hypoplastic anemia.** Uncommon and characterized by presentation after 48 hours of age, absence of jaundice, and reticulocytopenia.

4. Other forms of anemia

- a. **Anemia associated with twin-twin transfusion.** If chronic hemorrhage is occurring, there is often a >20% difference in the birthweights of the 2 infants, with the donor being the smaller twin.
- b. **Occult (internal) hemorrhage**
 - i. **Intracranial hemorrhage.** Signs include a bulging anterior fontanel and neurologic signs (eg, a change in consciousness, apnea, or seizures).
 - ii. **Visceral hemorrhage.** Most commonly, the liver has been injured. An abdominal mass or distention is seen.
 - iii. **Pulmonary hemorrhage.** Partial or total radiographic opacification of a hemithorax and bloody tracheal secretions are seen. (See Chapter 79.)

B. History

1. Anemia at birth

- a. **Hemorrhagic anemia.** There may be a history of third-trimester vaginal bleeding or amniocentesis. Hemorrhagic anemia may be associated with multiple gestation, maternal chills or fever postpartum, and nonelective cesarean delivery.
 - b. **Hemolytic anemia.** May be associated with intrauterine growth restriction (IUGR) and Rh-negative mothers.
2. **Anemia presenting after 24 hours of age** is often associated with obstetric trauma, unattended delivery, precipitous delivery, perinatal fetal distress, or a low Apgar score.
 3. **Anemia presenting with jaundice** suggests hemolytic anemia. There may be evidence of drug ingestion late in the third trimester; IUGR; a family member with splenectomy, anemia, jaundice, or cholelithiasis; maternal autoimmune disease; or Mediterranean or Asian ethnic background.

VI. Diagnosis

A. Obligatory initial studies

1. Hemoglobin

2. Red blood cell indices

- a. **Microcytic or hypochromic red blood cell indices** suggest FMH, twin-twin hemorrhage, or α -thalassemia (mean corpuscular volume <90 fL; normal 107 fL).
 - b. **Normocytic or normochromic red blood cell indices** are suggestive of acute hemorrhage, systemic disease, intrinsic RBC defect, or hypoplastic anemia.
3. **Reticulocyte count (corrected).** An elevated reticulocyte count is associated with antecedent hemorrhage or hemolytic anemia. A low count is seen with hypoplastic anemia. The following formula is used:

$$\text{Corrected reticulocyte count} = \frac{\text{Observed reticulocyte count} \times \text{Observed hematocrit}}{\text{Normal hematocrit for age}}$$

4. Blood smear

- a. **Spherocytes** are associated with ABO isoimmune hemolysis or hereditary spherocytosis.
 - b. **Elliptocytes** are seen in hereditary elliptocytosis.
 - c. **Pyknocytes** may be seen in glucose-6-phosphate dehydrogenase deficiency.
 - d. **Schistocytes or helmet cells** are most often seen with consumption coagulopathy.
5. **Direct antiglobulin test (direct Coombs test).** This test is positive in isoimmune or autoimmune hemolysis.

B. Other selected laboratory studies

1. **Isoimmune hemolysis.** The blood type and Rh type should be determined, and an eluate of neonatal cells prepared.
2. **Fetomaternal hemorrhage.** The **Kleihauer-Betke test** should be performed. Using an acid elution technique, a maternal blood smear is stained with eosin. Fetal RBCs containing hemoglobin F resistant to acid elution stain darkly. Adult

RBCs voided of their acid-sensitive hemoglobin A do not stain and appear as “ghost cells.” A 50-mL loss of fetal blood into the maternal circulation shows up as 1% fetal cells in the maternal circulation. **ABO incompatibility between mother and infant results in an increased clearance rate of fetal cells from the maternal circulation, giving a falsely low result.** Conversely, the Kleihauer-Betke test may overestimate the extent of the hemorrhage, with maternal conditions leading to the overproduction of maternal hemoglobin F such as hereditary sickle cell anemia and β -thalassemia trait. Immunofluorescence flow cytometry is an alternative diagnostic test that circumvents some of the problems associated with the Kleihauer-Betke screen. This technology quantifies the number of fetal cells present by measuring the fluorescence intensity of monoclonal antibodies binding to hemoglobin F or to other surface antigens (eg, carbonic anhydrase) differentially expressed in fetal compared with adult erythrocytes. **The College of American Pathologists has published a tool, accessible online at <http://capatholo.gov/RHIG> (accessed September 9, 2018), that allows users to plug in the percentage of fetal cells observed by the Kleihauer-Betke test or flow cytometry and the maternal height and weight to calculate the FMH volume.**

3. **Congenital hypoplastic or aplastic anemia.** Bone marrow aspiration is usually indicated.
4. **TORCH infection**
 - a. **Skull and long-bone films**
 - b. **Immunoglobulin M levels**
 - c. **Acute or convalescent serology**
 - d. **Urine culture for cytomegalovirus**
5. **Consumption coagulopathy**
 - a. **Prothrombin time and partial thromboplastin time**
 - b. **Platelet count**
 - c. **Thrombin time or fibrinogen assay**
 - d. **Factor V and factor VIII levels**
 - e. **Fibrin split products (D-dimers)**
6. **Occult hemorrhage**
 - a. **Pathologic examination of the placenta**
 - b. **Cranial or abdominal ultrasonography will help identify the site of bleeding**
7. **Intrinsic red blood cell defect**
 - a. **Red blood cell enzyme studies**
 - b. **Analysis of the globin chain ratio**
 - c. **Studies of red blood cell membrane**

VII. Management. Treatment of neonatal anemia may involve, individually or in combination, simple replacement transfusion, exchange transfusion, nutritional supplementation, or treatment of the underlying primary disorder.

A. Simple replacement transfusion

1. **Indications**
 - a. **Acute hemorrhagic anemia.**
 - b. **Ongoing deficit replacement.**
 - c. **Maintenance of effective oxygen-carrying capacity.** There are no universally accepted guidelines; however, those presented next are fairly representative of most common practice.
 - i. **Hematocrit <35% with severe cardiopulmonary disease** (eg, intermittent positive-pressure ventilation with mean airway pressure >6 cm H₂O).
 - ii. **Hematocrit <30%.**
 - (a) **With mild to moderate cardiopulmonary disease** (FiO₂ >35%, continuous positive airway pressure).
 - (b) **With significant apnea** (>9–12 hours or apnea requiring bag-and-mask ventilation).

- (c) **“Symptomatic anemia”**: Weight gain <10 g/kg/d at full caloric intake and heart rate >180 beats/min persisting for 24 hours.
 - (d) **If undergoing major surgery.**
 - iii. **Hematocrit $<21\%$.** Asymptomatic but with low reticulocyte count ($<2\%$).
2. **Emergency transfusion at birth only. Use type O, Rh-negative packed RBCs.**
 - a. **Adjust the hematocrit to 50%.**
 - b. **If a medical emergency exists,** blood that has not been cross-matched may be given; if time permits, blood may be cross-matched to the mother’s blood.
 - c. **Alternative replacement fluids** include normal saline, fresh-frozen plasma, and 5% albumin in saline. Timely infusion of packed RBCs or partial exchange transfusion should follow.
 - d. **Perform umbilical vein catheterization** to a depth of 4 to 5 cm or until free blood flow is established (see Chapter 48).
 - e. **Draw initial blood samples for diagnostic studies.** Obtain a complete blood count and differential, blood type and Rh type, direct Coombs test, and, if indicated, total bilirubin levels. In a medical emergency, transfusion may be started before the results of laboratory testing are known.
 - f. **Infuse 10 to 15 mL/kg of replacement fluid over 10 to 15 minutes if emergency measures are needed.** Once the infant’s status is stable, reassess the diagnostic studies, physical examination, and obstetric history.
 - g. **Calculate the red blood cell volume.** Under controlled circumstances or if simple transfusion is indicated, calculate the volume of packed RBCs needed to achieve the desired increase in RBC mass (see page 624). **The volume of a single transfusion should not exceed 10 to 20 mL/kg.**
- B. Exchange transfusion**
1. **Indications**
 - a. **Chronic hemolytic anemia or hemorrhagic anemia** with evidence of tissue hypoxia (poor perfusion, metabolic acidosis, oliguria).
 - b. **Severe isoimmune hemolytic anemia** with circulating sensitized RBCs and isoantibody.
 - c. **Consumption coagulopathy.**
 2. **Technique.** See Chapter 34 for the technique of exchange transfusion in neonates.
- C. Nutritional replacement**
1. **Iron.** Iron replacement is useful in the following situations:
 - a. **Fetomaternal hemorrhage** of significant volume.
 - b. **Chronic twin-twin transfusion** (in the donor twin).
 - c. **Incremental external blood loss** (if unreplaced).
 - d. **Preterm infant** (<36 weeks’ gestational age).
 2. **Folate.** Especially with serum levels <0.5 ng/mL.
 - a. **Premature infants weighing** <1500 g or <34 weeks’ gestational age.
 - b. **Chronic hemolytic anemias** or conditions involving “stress erythropoiesis.”
 - c. **Infants receiving phenytoin (Dilantin).**
 3. **Vitamin E.** Preterm infants of <34 weeks’ gestational age, unless they are being breast fed.
- D. Prophylactic**
1. **Recombinant human erythropoietin (controversial).** High doses of erythropoietin are capable of increasing neonatal erythropoiesis and have very few adverse side effects. It decreases the requirement for “late” transfusions (those required past the age of 2–3 weeks); it will not compensate for the anemia secondary to phlebotomy losses. Its use in the very low birthweight infant continues to be **controversial** because the severity of anemia in this group can be more effectively minimized by a restrictive policy for blood sampling and the use of micromethods in the laboratory. The need for transfusions is also reduced when

a consistent “protocolized” approach for transfusions is available in the neonatal intensive care unit. It has been also argued that what needs to be avoided, more than the transfusion itself, is the exposure to multiple donors. The allocation of a single donor for each high-risk infant, for a 42-day period, is the most effective way to reach that former goal. Early and late strategies have been used for erythropoietin treatment. (See doses in Chapter 155.)

- a. **Early.** Starting on day 1 or 2, 1200 to 1400 U/kg/wk. Recombinant human erythropoietin is added to the total parenteral nutrition solution, and 1 mg/kg/d of iron is added.
- b. **Late.** 500 to 700 U/kg/wk given 3 to 5 times per week subcutaneously. Supplemental oral iron needs to be provided at 3 mg/kg/d in 3 divided doses. The iron dose is increased to 6 mg/kg/d as soon as the infant is tolerating full enteral feeds.
- c. **Darbepoetin.** This new molecule was more recently created by biologically modifying 5 amino acids of the original protein in order to generate 5 carbohydrate binding sites compared with 3 in recombinant erythropoietin. This modification resulted in a half-life more than twice that of recombinant erythropoietin and increases the erythropoietin activity of recombinant erythropoietin with less frequent dosing.

2. Nutritional supplementation

- a. **Elemental iron.** 1 to 2 mg/kg/d, beginning at 2 months of age and continuing through 1 year of age.
- b. **Folic acid.** 1 to 2 mg/wk for preterm infants; 50 mcg/d for term infants.
- c. **Vitamin E.** 25 IU/d until a corrected age of 4 months is reached.

E. Treatment of selected disorders

1. Consumption coagulopathy

- a. **Treat the underlying cause (eg, sepsis).**
- b. **Give blood replacement therapy.** Perform exchange transfusion or give fresh-frozen plasma, 10 mL/kg every 12 to 14 hours. Platelet concentrate, 1 U, may be used as a substitute for plasma transfusion.
- c. **Perform coagulation studies.** Monitor the partial thromboplastin time, prothrombin time, and fibrinogen and D-dimers levels and the platelet count.

2. Immune thrombocytopenia

a. Isoimmune thrombocytopenia

- i. **Consider performing cesarean delivery if the diagnosis has been confirmed** and there is an older sibling with immune thrombocytopenia (75% risk of recurrence).
- ii. **Give maternal washed platelets when indicated for bleeding diathesis** in an infant with a platelet count $<20,000$ to $30,000/\text{mm}^3$. Exchange transfusion may be used as an alternative.
- iii. **Corticosteroid therapy and intravenous immune globulin are controversial.**

b. Autoimmune thrombocytopenia

- i. **Cesarean delivery.** Consider if the maternal platelet count is $<100,000/\text{mm}^3$ or the fetal platelet count is $<50,000/\text{mm}^3$.
- ii. **Use of corticosteroids is controversial.** Under the conditions just mentioned, consider giving corticosteroids to the mother several weeks before delivery. Transfusion of random donor platelets may be given when indicated.

VIII. Prognosis. Depends on the underlying cause, its severity, and how acutely the anemia develops.

89 Apnea

Apnea is common and a significant clinical problem in preterm neonates. It is manifested by an unstable respiratory rhythm, reflecting the immaturity of the respiratory control system. Apnea can also be secondary to other pathologic conditions that need to be excluded before the diagnosis of apnea of prematurity (AOP) is assumed. In contrast, periodic breathing is a benign condition and does not merit any treatment. (See also on-call problem Apnea and Bradycardia in Chapter 52.)

- I. **Definition.** AOP is most widely defined as cessation of breathing for >20 seconds or a shorter respiratory pause if associated with hypoxemia and/or bradycardia in infants who are younger than 37 weeks' gestation. Apnea that lasts for <10 seconds is considered "significant" if it is associated with a decrease in oxygen saturation (SpO_2) to $\leq 80\%$ or 85% , whereas "significant" bradycardia has been defined as a decrease in heart rate to <80 beats/min or less than two-thirds of baseline.
 - A. **Central apnea:** Related to immaturity of the central nervous system, central apnea is characterized by total cessation of inspiratory effort with no evidence of obstruction to airflow.
 - B. **Obstructive apnea:** Presents clinically with the preservation of chest wall movement while airflow is obstructed. The primary site of airway obstruction is the pharynx. Lack of coordination of respiratory musculature, neck flexion, or nasal obstruction may further enhance the severity of this impairment of airway airflow.
 - C. **Mixed apnea:** Consists of both obstructive and central apnea, with 1 type triggering the onset of the second type of apnea.
 - D. **Periodic breathing:** Periodic breathing is a normal breathing pattern characterized by ventilatory cycles of 10 to 15 seconds followed by respiratory pause for 5 to 10 seconds without change in heart rate or skin color. It is due to an imbalance between the opposite response of peripheral and central chemoreceptors on ventilatory drive stimuli. Periodic breathing in premature infants is often due to excessive stimulation by the peripheral chemoreceptors promoting a breathing instability. Prevalence of periodic breathing approaches 100% in preterm infants <1000 g. It is more frequent during active sleep. The prognosis is good, although severe hypoxic events are noted to be often preceded by hypoventilation or arterial oxygen saturations of $\leq 90\%$ associated with a short apneic pause or periodic breathing.
- II. **Incidence.** The incidence of apnea increases with decreasing gestational age. Practically all infants born at <29 weeks will develop apnea, whereas by 30 weeks, this proportion will decrease to 85% and is further reduced to 20% among those born at 34 weeks. **Mixed is the most common type of apnea (50%), followed by central (40%) and then obstructive (10%).**
- III. **Pathophysiology.** AOP is a developmental disorder and generally resolves by 36 to 37 weeks in infants born beyond 27 weeks' gestation. Among more immature infants, apnea can often persist past term gestation. It reflects a "physiologic" rather than "pathologic" immature state of respiratory control.
 - A. **Fetal to neonatal transition.** Peripheral chemoreceptors are active only at the low oxygen levels in the fetal life and thus become essentially silent in the immediate postnatal period following the increase in partial pressure of oxygen from <30 mm Hg to 50 to 70 mm Hg. Peripheral chemoreceptors undergo a progressive reset postnatally, and chemoreceptor drive is significant at the relatively hypoxic level of 50 to 70 mm Hg. This postnatal adjustment may be delayed when neonates are exposed to 100% oxygen during resuscitation. These infants can become apneic when their inspired oxygen is increased sufficiently to produce a physiologic denervation of peripheral chemoreceptors, resulting in a brief delay in the onset of spontaneous breathing.

- B. Ventilatory response to hypoxia.** In contrast to adults who show a sustained increase in ventilation in response to hypoxia, preterm infants exhibit a biphasic ventilatory response where the initial increase in ventilation is transient (approximately 1 minute) and is followed by a late sustained decrease in spontaneous breathing. This unique response to hypoxia may last for several weeks in response to hypoxic episodes after birth. This late ventilatory depression is likely an expression of delayed synaptogenesis or myelination within the brainstem and the reticular activated system.
- C. Ventilatory response to laryngeal chemoreflex.** The laryngeal chemoreflex is mediated through the superior laryngeal nerve afferents and is assumed to be a protective reflex. An exaggerated response brought about during feedings may also contribute to apneic episodes.
- D. Neurotransmitters and apnea.** Increased sensitivity to inhibitory neurotransmitters such as γ -aminobutyric acid (GABA), adenosine, serotonin, and prostaglandins may be related to apnea.
- E. Genetic variability and apnea.** Genetic and environmental factors may lead to apnea. Heritability of AOP was 87% among same-gender twins. The congenital hypoventilation syndrome, defined by a lack of carbon dioxide (CO_2) responsiveness during sleep, is thought to occur due to the mutation of the developmental transcription factor PHOX2b.
- F. Sleep-related apnea.** Most apnea occurs during active sleep. Preterm infants are asleep 80% of time, and 50% of sleep is active. This relationship lasts until 6 months of age. During active sleep, there is low-voltage electrocortical activity, decreased arousal from sleep, decreased muscular tone, absence of upper airway adductor activity, and decreased respiratory drive. Irregular breathing and inspiratory chest wall distortion associated with decreased ventilatory drive cause slight elevation in arterial partial pressure of CO_2 . The ventilatory response to hypoxia and ventilatory sensitivity to CO_2 are more depressed during active sleep. Activation of serotonin-containing neurons, which are part of the arousal system of the brainstem, decreases by nearly half during slow-wave sleep and becomes nearly silent during rapid eye movement sleep via activation of GABAergic inputs.
- G. Siblings of infants with sudden infant death.** The Collaborative Home Infant Monitoring Evaluation (CHIME) study showed that the incidence of apnea was the same in siblings of infants with sudden infant death syndrome and normal term infants.
- H. Gastroesophageal reflux and apnea.** Most studies have shown no clear temporal relationship between gastroesophageal reflux (GER) and apnea. A decreased lower esophageal sphincter tone and increased GER following apnea have been documented. Apnea with desaturation events can lead to relaxation of the gastroesophageal junction and may explain the presence of formula often found in the pharynx of infants suctioned during an apneic event. Only a small minority of apneic preterm infants are likely to benefit from antireflux therapy. If therapy is started, it should only be continued in the face of clear benefit and discontinued if symptoms fail to improve.
- IV. Risk factors**
- A. Physiologic immaturity of the respiratory center.** This condition is usually present after 1 to 2 days of life and is often referred to as AOP.
- B. Secondary causes**
- 1. Neurologic:** Birth trauma, meningitis, intracranial hemorrhage, seizures, perinatal asphyxia, congenital myopathies or neuropathies, placental transfer of narcotics, magnesium sulfate, or general anesthetics.
 - 2. Pulmonary:** Surfactant deficiency, pneumonia, pulmonary hemorrhage, obstructive airway lesions, pneumothorax.
 - 3. Cardiac:** Cyanotic congenital heart disease, hyper- or hypotension, congestive heart failure, patent ductus arteriosus, increased vagal tone, and prostaglandin therapy.

4. **Gastrointestinal:** Necrotizing enterocolitis (NEC), GER.
 5. **Hematologic:** Anemia.
 6. **Hypothermia or hyperthermia.**
 7. **Metabolic:** Acidosis, hypoglycemia, hypocalcemia, and hypo- or hypernatremia.
 8. **Inborn errors of metabolism.**
 9. **Sepsis.**
- V. **Clinical manifestations.** It is difficult to separate clinical manifestations of apnea from its consequences. Symptoms and signs depend on the duration and frequency of apnea and most are related to hypoxia. Other clinical manifestations depend on the etiology of apnea such as feeding intolerance, lethargy, temperature instability, jitteriness, poor feeding, central nervous system depression, irritability, desaturation tachypnea, bradycardia, hypotonia, and seizures.
- VI. **Diagnosis**
- A. **History and physical examination** must include a review of maternal risk factors, medications, birth history, and feeding intolerance. Physical examination should include a search for abnormal neurologic signs and signs of sepsis.
 - B. **Laboratory studies**
 1. **Complete septic workup.**
 2. **Screening for metabolic disorders.**
 3. **Imaging** to look for pneumonia, air leak, and NEC and cranial ultrasound to detect intracranial hemorrhage or congenital abnormalities.
 4. **Electroencephalogram to rule out seizures**, because apnea may be the sole presentation of seizures.
- VII. **Management.** Treatment strategies for AOP should be based on modulating an unstable respiratory rhythm into a more stable one.
- A. **Pharmacologic management**
 1. **Methylxanthines.** Methylxanthines have been the mainstay of pharmacologic treatment of apnea for decades. The primary mechanism of action is thought to be blockade of inhibitory adenosine A_1 receptors with resultant excitation of respiratory neural output. Initially, theophylline (aminophylline) was the standard of treatment, and it required close monitoring of serum levels. **Caffeine citrate has largely replaced theophylline as the first drug for AOP.** Its longer half-life makes for a convenient once-a-day dosing regimen without the need for monitoring blood levels at the recommended dosing.

Methylxanthines increase minute ventilation, improve CO_2 sensitivity, decrease hypoxic depression, enhance diaphragmatic activity, and decrease periodic breathing. Common side effects include tachycardia, feeding intolerance, emesis, jitteriness, restlessness, and irritability. Toxic effects may produce arrhythmias and seizures. Methylxanthines increase metabolic rate and oxygen consumption and have a mild diuretic effect. In general, caffeine is recommended for all infants born at ≤ 28 weeks' gestation. Some recommend treating all infants born between 29 and 32 weeks, since most of them have apnea. In a large multicenter randomized study, caffeine treatment was associated with a significant reduction in the incidence of bronchopulmonary dysplasia and retinopathy of prematurity, as well as the duration of mechanical ventilation. Furthermore, a significant decrease in the incidence of cerebral palsy in the caffeine-treated group was observed by 2 years of age. The early beneficial effect on cognitive function was not sustained, but caffeine exposure was associated with a sustained beneficial effect on developmental coordination disorders at 5 years of age and a lesser frequency of motor impairment by 11 years of age. See Chapter 155 for dosing.
 2. **Doxapram.** Doxapram is a potent nonspecific respiratory stimulant. It stimulates peripheral chemoreceptors at low dose and central chemoreceptors at high dose. Doxapram increases tidal volume and minute ventilation. Studies have shown effectiveness of doxapram in reducing apnea when refractory to

methylxanthines. As a result of its poorly defined enteral absorption, it is generally administered as a continuous intravenous infusion. Side effects include increases in blood pressure, abdominal distension, irritability, jitteriness, gastric residuals, and emesis. See Chapter 155 for dosing.

B. Nonpharmacologic management

1. Evidence based

- a. **Prone head-elevated positioning.** The chest wall is stabilized and thoracoabdominal asynchrony is reduced in the prone position. Prone position along with the head elevated in a tilt position showed reduction in apnea and bradycardia.
- b. **Continuous positive airway pressure.** Continuous positive airway pressure (CPAP) at 4 to 6 cm H₂O has proven to be a safe and effective therapy of AOP. It is effective primarily against the obstructive components of apneic episodes. CPAP appears to be effective by “splinting” the upper airway with positive pressure and decreasing the risk of pharyngeal or laryngeal obstruction. Lung functional residual capacity, often reduced in preterm infants, increases with the application of CPAP. As such, an increase in pulmonary oxygen stores may reduce the severity and duration of apnea-induced hypoxemia. Devices that provide high-flow delivery of gas through nasal cannula can produce a similar benefit while enhancing the mobility of the infant. The safety of high-flow delivery devices is of concern because the resultant airway pressures generated are relatively unregulated.
- c. **Synchronized nasal ventilation.** An extension of CPAP is administration of nasal intermittent positive-pressure ventilation, which delivers intermittent lung inflations set to a peak pressure delivered through nasal prongs or mask. Its use has been shown to decrease the need for and duration of endotracheal (invasive) mechanical ventilation.

2. Other interventions with unclear efficacy

- a. **Orogastric versus nasogastric feeding tube placement.** A nasogastric tube increases nasal resistance by 50%; therefore, orogastric feeding tubes are sometimes preferred in preterm infants with apnea.
- b. **Kangaroo mother care.** Studies have shown that infants receiving kangaroo mother care had decreased episodes of apnea and bradycardia. The effect of kangaroo mother care in improvement of apnea and bradycardia is the same as that seen with prone positioning.
- c. **Stable environmental temperature.** Provision of a stable thermal environment avoids temperature fluctuations, which can precipitate apneic episodes.
- d. **Tactile stimulation.** Synchronization of respiration may be achieved between the infant's own breathing rhythm and an external rhythm generator (eg, inflatable mattress connected to a respirator). Recently, stochastic mechanosensory stimulation using actuators embedded in a specially designed mattress for subcutaneous stimulation has been shown to decrease the duration of oxygen desaturation.
- e. **Red blood cell transfusion.** An increase in respiratory drive resulting from an increased tissue oxygenation is one of the proposed mechanisms for red blood cell transfusion to ameliorate AOP. Over the past 30 years, there have been few and often conflicting studies on the association between red blood cell transfusions and apnea. Many of these studies defined apnea events from nursing charts, which have been demonstrated to underreport and inaccurately identify apnea events. Its potential beneficial effect on the frequency of apnea is mitigated by the concern that blood transfusion may be associated with an increased risk for NEC.
- f. **Oxygen administration.** Supplemental oxygen should be provided as needed to avoid hypoxia and maintain SpO₂ between 88% and 94%, because hypoxia can lead to severe desaturation episodes. Risk of hyperoxia and retinopathy of prematurity should limit this modality of treatment.

- g. **Treating gastroesophageal reflux.** Some treat GER due to the belief that GER precipitates episodes of apnea. The mechanism could be secondary to the laryngeal chemoreflex. Studies on pharmacologic treatment have not shown any association or benefit.

VIII. Discharge planning and follow-up

- A. **Consider stopping caffeine at 34 weeks of postmenstrual age.**
- B. **A more aggressive approach is to stop when the infant is apnea free** for a period of 5 to 7 days irrespective of age.
- C. **If asymptomatic for 5 to 7 days after stopping methylxanthines,** the infant may be discharged without further therapy. Measurement of serum caffeine levels may be necessary beforehand as these levels may not become subtherapeutic until 11 to 12 days after cessation of treatment.
- D. **Considerations for home apnea monitoring**
1. **Persistent, symptomatic apnea at >36 weeks of postmenstrual age.**
 2. **History of severe apparent life-threatening event and abnormal polysomnography.**
 3. **Technology-dependent infant (eg, home mechanical ventilation).**
 4. **Home oxygen administration.**
 5. **Central hypoventilation syndromes.**
- IX. **Prognosis.** AOP resolves with maturation. Physiologic basis for resolution of apnea is believed to be myelination of the brainstem. Poor neurodevelopmental outcome is associated with a delay in myelination in infants with AOP. Otherwise, in most infants, apnea resolves without the occurrence of long-term deficiencies.

90 Bronchopulmonary Dysplasia/Chronic Lung Disease

- I. **Definition.** Classic bronchopulmonary dysplasia (BPD) is a neonatal form of chronic pulmonary disorder. BPD was solely defined as persistent oxygen dependency up to 28 days of life. The severity of BPD-related pulmonary dysfunction and neurodevelopmental impairment in early childhood is more accurately predicted by an oxygen dependence at 36 weeks' postmenstrual age (PMA) in infants <32 weeks' gestational age (GA) and at 56 days of age in infants with older GA. **BPD is thus classified at this later postnatal age according to the type of respiratory support required to maintain a normal arterial oxygen saturation (>89%) among infants who had been requiring supplemental oxygen during the first 28 days of life.**
- A. **Mild bronchopulmonary dysplasia.** Infants who have been weaned from supplemental oxygen.
- B. **Moderate bronchopulmonary dysplasia.** Infants who continue to need up to 30% oxygen.
- C. **Severe bronchopulmonary dysplasia.** Infants whose requirements exceed 30% and/or include continuous positive airway pressure (CPAP) or mechanical ventilation. However, recently, it has been suggested to further classify severe BPD (sBPD) into **type 1 sBPD**, which consists of oxygen dependency of >30% or need for nasal CPAP/high-flow nasal cannula, and **type 2 sBPD** if mechanical ventilation was needed, regardless of the degree of oxygen dependency, at or beyond 36 weeks' PMA.

- II. Evolution.** The old or “classic” form of BPD was described by Northway in 1967 during the presurfactant era and prior to the use of “gentler” mechanical ventilation strategies. It consisted of tissue damage in both airways and alveoli. In contrast, the recent and new form of BPD consists of no injuries but rather arrested lung growth and lack of both alveolar septation and vascular simplification (remodeling).
- III. Incidence.** The incidence of BPD is influenced by many risk factors, the most important of which is degree of immaturity. The incidence of BPD increases with decreasing birthweight and affects approximately 30% of infants with birthweights <1000 g. The large variability in rates among centers is partly related to differences in clinical practices, such as criteria used for the management of mechanical ventilation.
- IV. Pathophysiology.** A primary lung injury is not always evident at birth. The secondary development of a persistent lung injury is the result of abnormal repair process of recurrent injuries occurring during a critical window of lung development.
- A. The major factors contributing to bronchopulmonary dysplasia are as follows:**
- 1. Inflammation.** Central to the development of BPD. An exaggerated inflammatory response (alveolar influx of numerous proinflammatory cytokines as well as macrophages and leukocytes) occurs in the first few days of life in infants in whom BPD subsequently develops.
 - 2. Mechanical ventilation.** Volutrauma/barotrauma is 1 of the key risk factors for the development of BPD. Minimizing the use of mechanical ventilation by the use of early nasal CPAP, noninvasive ventilatory support (nasal intermittent positive-pressure ventilation), and early use of methylxanthines (caffeine) has led to fewer days of mechanical ventilation, lesser use of postnatal steroids, and lower rates of sBPD.
 - 3. Oxygen exposure.** Classic BPD observed before the availability of exogenous surfactant treatment was always associated with prolonged exposure (>150 hours) to a fraction of inspired oxygen >60%. Today, in the postsurfactant era, exposure to prolonged high oxygen is limited, and a new form of BPD has been reported. For this “new” BPD, the association between persistent need for mechanical ventilation and supplemental oxygen in the first 2 weeks of life is not as strong as it was in the past. For instance, a third of the preterm infants receiving either supplemental oxygen or intermittent positive-pressure ventilation at 14 days did not develop BPD, whereas 17% of the infants on room air at 14 days of age did.
- B. Pathologic changes.** Compared with the presurfactant era, lungs of infants currently dying from BPD have normal-appearing airways, less fibrosis, and more uniform inflation. However, these lungs have deficient septation, leading to fewer and larger alveoli with possible reduced pulmonary capillarization that may lead to pulmonary hypertension.
- V. Risk factors.** Major risk factors are prematurity, white race, male sex, chorioamnionitis, tracheal colonization with *Ureaplasma*, and the increased survival of the extremely low birthweight infant. Other risk factors are chorioamnionitis, respiratory distress syndrome (RDS), small for gestation, excessive early intravenous fluid administration, symptomatic patent ductus arteriosus (PDA), sepsis, oxygen therapy, and vitamin A deficiency.
- VI. Clinical presentation.** BPD is usually suspected in infants with progressive and idiopathic deterioration of pulmonary function. Infants in whom BPD develops often require oxygen therapy or mechanical ventilation beyond the first week of life. Severe cases of BPD are usually associated with poor growth, pulmonary edema, and a hyperreactive airway.
- VII. Diagnosis**
- A. Physical examination**
- 1. General signs.** Worsening respiratory status is manifested by an increase in the work of breathing, in oxygen requirement, in apnea-bradycardia, or in a combination of these signs.

2. **Pulmonary examination.** Retractions and diffuse fine rales are common. Wheezing or prolongation of expiration may also be noted.
 3. **Cardiovascular examination.** A right ventricular heave, single S_2 , or prominent P_2 may accompany cor pulmonale.
 4. **Abdominal examination.** The liver may be enlarged secondary to right-sided heart failure or may be displaced downward into the abdomen secondary to lung hyperinflation.
- B. Laboratory studies.** These studies are intended to rule out the differential diagnosis such as sepsis or PDA during the acute nature of the disease and to detect problems related to BPD or its therapy.
1. **Arterial blood gas levels.** Frequently reveal carbon dioxide retention. However, if the respiratory difficulties are chronic and stable, the pH is usually subnormal (pH ≥ 7.25).
 2. **Electrolytes.** Abnormalities of electrolytes may result from chronic carbon dioxide retention (elevated serum bicarbonate), diuretic therapy (hyponatremia, hypokalemia, or hyponchloremia), or fluid restriction (elevated urea nitrogen and creatinine), or all 3.
 3. **Complete blood count and differential.** To diagnose neutropenia or an elevated white blood count in sepsis.
 4. **B-type natriuretic peptide.** After 6 weeks of age, monitoring B-type natriuretic peptide (BNP) levels biweekly may help in an early detection of pulmonary hypertension, which if unrecognized will lead to cor pulmonale. A rise in BNP plasma levels suggests a need to perform an echocardiogram.
 5. **Urinalysis.** Microscopic examination may reveal the presence of red blood cells, which might suggest nephrocalcinosis as a result of prolonged loop diuretic treatment.
- C. Imaging and other studies.** To detect problems related to BPD or its therapy.
1. **Chest radiograph.** Radiographic findings may be quite variable. Most frequently, BPD appears as diffuse haziness and lung hypoinflation in infants who were very immature at birth and have persistent oxygen requirements. In other infants, a different picture is seen, reminiscent of that originally described by Northway: streaky interstitial markings, patchy atelectasis intermingled with cystic area, and severe overall lung hyperinflation. Because those findings persist for a prolonged period, new changes (eg, a secondary infection) are difficult to detect without the benefit of comparison to previous radiographs. (See Figure 12–21 for an example of BPD.)
 2. **Renal ultrasonography.** Radiologic studies of the abdomen should be considered during loop diuretic therapy to detect the presence of nephrocalcinosis. It should be performed when red blood cells are present in the urine.
 3. **Echocardiography.** Screening echocardiograms are indicated monthly in non-improving or weekly in worsening BPD. Echocardiograms can detect pulmonary hypertension, manifested by right ventricular hypertrophy and elevation of pulmonary artery pressure (increased tricuspid regurgitant jet velocity), increased right systolic time intervals, thickening of the right ventricular wall, and abnormal right ventricular geometry (ventricular septal wall flattening).
- ## VIII. Management
- A. Prevention of bronchopulmonary dysplasia**
1. **Prevention of prematurity and respiratory distress syndrome.** Therapies directed toward decreasing the risk of prematurity and lowering the incidence of RDS include improved prenatal care and antenatal corticosteroids.
 2. **Reducing exposure to risk factors.** Successful measures should include minimizing exposure to oxygen by limiting arterial oxygen saturation to 90% to 95%, ventilation strategies that minimize the use of excessive tidal volume ($>4\text{--}6\text{ mL/kg}$), prudent administration of fluids, aggressive closure of PDA (*controversial*), and adequate nutrition. **Early surfactant replacement therapy may be**

beneficial, but the avoidance of intubation and mechanical ventilation with the initiation of CPAP shortly after birth may prove to be an effective preventive strategy. Lesser invasive methods of pulmonary administration of surfactant through methods such as LISA (less invasive surfactant administration: surfactant via thin diameter tubes under direct vision using laryngoscopes) or INSURE (intubation and surfactant administration followed by immediate extubation) **both in conjunction with CPAP are associated with the lowest likelihood of the composite outcome of death or BPD at 36 weeks**. A similar beneficial effect has been reported when surfactant is intratracheally co-administered with budesonide.

3. **Vitamin A.** Low blood levels of vitamin A seen in extremely low birthweight infants have been associated with increased risk of BPD. Vitamin A supplementation, 5000 IU administered intramuscularly 3 times per week for 4 weeks, showed modest reduction in the rate of BPD. The number needed to treat to prevent 1 BPD was 15; however, no long-term beneficial respiratory or neurodevelopmental outcomes have been found.
 4. **Caffeine.** Methylxanthines decrease the frequency of apnea and allow for shorter duration of mechanical ventilation, leading to a reduced rate of BPD.
 5. **Inhaled nitric oxide.** At present, routine use of inhaled nitric oxide (iNO) for preterm infants at risk for BPD is not recommended.
- B. Treatment of bronchopulmonary dysplasia.** Once BPD is present, the goal is to prevent further injury by minimizing respiratory support, improving pulmonary function, preventing cor pulmonale, and emphasizing growth and nutrition.

1. Respiratory support

- a. **Supplemental oxygen.** Maintaining adequate oxygenation (oxygen saturation 90%–95%) is important in the infant with BPD to prevent alveolar hypoxia-induced pulmonary hypertension, bronchospasm, cor pulmonale, and growth failure. However, the least-required oxygen should be delivered to minimize oxygen toxicity. Routine blood gas measurements are important for the assessment of trends in pH, arterial partial pressure of carbon dioxide (PaCO_2), and serum bicarbonate, but they are of limited use in monitoring oxygenation because they provide information about only 1 point in time.
- b. **Positive-pressure ventilation.** Mechanical ventilation should be used only when clearly indicated. Similarly, inspiratory pressure needs to be limited at the expense of tolerating PaCO_2 of 50 to 60 mm Hg (*controversial*). Nasal CPAP and noninvasive nasal ventilation can be useful as an adjunctive therapy after extubation.

2. Improving lung function

- a. **Fluid restriction.** Restricting fluid to 120 mL/kg/d is often required. It can be accomplished by concentrating proprietary formulas to 24 kcal/oz. Increasing the caloric density further to 27 to 30 kcal/oz may require the addition of fat (eg, medium-chain triglyceride oil or corn oil) and carbohydrate (eg, Polycose) to avoid excessive protein intake.
- b. **Diuretic therapy.** See Chapter 155 for dosing.
 - i. **Furosemide.** Furosemide (1–2 mg/kg every 12 hours, orally or intravenously) is a potent diuretic that is particularly useful for rapid diuresis and acute improvement in lung mechanical properties. There is less evidence for its long-term pulmonary benefit. Its chronic use is associated with side effects such as electrolyte abnormalities, calciuria with bone demineralization, renal stone formation, and ototoxicity. When used as a chronic medication, Na^+ and K^+ supplementation is often required.
 - ii. **Bumetanide.** Bumetanide 0.015 to 0.1 mg/kg daily or every other day, orally or intravenously. When administered orally, 1 mg of bumetanide (Bumex) has a diuretic effect similar to that of 40 mg of furosemide. Whereas furosemide's bioavailability is 30% to 70%, bumetanide's

bioavailability is >90%. Bumetanide produces side effects similar to those of furosemide, except that it may produce less ototoxicity and less interference with bilirubin-albumin binding.

iii. **Chlorothiazide and spironolactone.** When used in doses of 20 mg/kg/d (chlorothiazide) and 2 mg/kg/d (spironolactone), a good diuretic response can often be achieved. Although less potent than furosemide, this combination is often better suited for chronic management because it has relatively fewer side effects. In the absence of the need for sodium supplementation, it may be the diuretic combination of choice when the calciuric effect of furosemide has led to the development of nephrocalcinosis.

c. **Bronchodilators.** See doses in Table 9–3.

i. **β_2 -Agonists.** Inhaled β_2 -agonists (eg, albuterol, levalbuterol) produce acute improvements in lung mechanics and gas exchange in infants with BPD exhibiting symptoms of increased airway tone. Their effect is usually time limited. Because of their side effects (eg, tachycardia, hypertension, hyperglycemia, and possible arrhythmia), their use should be limited to the management of acute exacerbations of BPD. **Levalbuterol (Xopenex)** is a nonracemic form of albuterol. The difference between levalbuterol and albuterol is modest, but levalbuterol has fewer side effects. If bronchodilators are being used long term, a frequent reevaluation of their benefits is essential.

ii. **Anticholinergic agents.** The best studied and most widely available inhaled quaternary anticholinergic is **ipratropium bromide** (nebulized Atrovent). Its bronchodilatory effect is more potent than that of atropine and similar to that of albuterol. Combined albuterol and ipratropium therapy has a greater effect than either agent alone. Unlike atropine, systemic effects do not occur because of its poor systemic absorption.

d. **Corticosteroids.** Several randomized controlled trials have demonstrated that among infants at risk for BPD, treatment with systemic corticosteroids facilitates extubation and improves lungs mechanical properties. There is a significant heterogeneity regarding the type, dose, and duration of corticosteroid treatment. Although very efficient, the use of postnatal steroids should be limited to infants who are at high risk for mortality secondary to severe lung disease. There are concerns regarding the short- and long-term side effects of systemic steroids. These include hyperglycemia, hypertension, hypertrophic cardiomyopathy, gastrointestinal hemorrhage and perforation (in conjunction with prostaglandin inhibitors such as indomethacin), enhanced catabolism and growth failure, nephrocalcinosis, poor bone mineralization, and susceptibility to infection. Parents should be informed that the use of postnatal steroids could be associated with impaired brain and somatic growth and increased incidence of cerebral palsy. Although dexamethasone has been the most studied postnatal steroid in the treatment of BPD, various therapy regimens and using milder types of steroids have been proposed, in hopes of decreasing the observed adverse effects.

i. **Dexamethasone.** Initiate at >7 days of age at 0.25 mg/kg twice daily for 3 days and then gradually taper by 10% every 3 days for a total course of 42 days. It is one of the original regimens that have been proven efficacious in the treatment of BPD. When the risk of BPD is less than approximately 33%, this treatment significantly increased the risk of death or cerebral palsy. At a higher probability to develop BPD (approximately >60%), the same therapy reduced the risk of death or cerebral palsy. Lower doses and shorter duration of dexamethasone have been attempted to decrease its undesirable effects such as a 10-day tapering course of dexamethasone for a total of 0.89 mg/kg over 10 days.

- ii. **Hydrocortisone.** 5 mg/kg/d divided every 6 hours for 1 week, and then gradually tapered for the following 2 to 5 weeks (>7 days of age). In contrast to infants treated with dexamethasone, when compared with controls, hydrocortisone therapy has not been associated with adverse neurodevelopmental outcome or with brain abnormalities on magnetic resonance imaging in long-term follow-up studies of patients up to 5 to 8 years of age. Recently, early (first 10 days of age) low-dose hydrocortisone (1 mg/kg/d for 7 days, then 0.5 mg/kg/d) was found to be helpful and safe.
 - iii. **Prednisolone and methylprednisolone (Solu-Medrol)** have also been used.
 - iv. **Nebulized corticosteroids.** Nebulized corticosteroids (beclomethasone or budesonide) produced fewer side effects than oral or parenteral forms but are much less efficacious in the treatment of BPD when given at a late stage. Earlier onset of treatment has been shown to be more efficient, but concern about a possible poorly explained increase in mortality has been raised.
 - e. **Tracheostomy.** For infants who have failed several attempts at extubation and have become large enough for their head movements to interfere with artificial ventilation. It provides respiratory stability, helps in involving families in infant care, and facilitates home discharge
- 3. Pulmonary hypertension**
- a. **The “new” bronchopulmonary dysplasia** is characterized by defects in alveolarization as well as a defect in angiogenesis, leading to the development of pulmonary hypertension. Pulmonary hypertension has been reported to be associated with BPD in nearly 20% of extremely preterm babies overall and in 50% of those with severe chronic lung disease (sBPD). A high index of suspicion needs to be present whenever a progressive increase in the level of respiratory support is noticed. Screening echocardiograms for evidence of pulmonary hypertension by echocardiography should be performed in all patients with sBPD. Subsequent echocardiograms should be performed in patients with sBPD at 1- to 2-month intervals until the respiratory status of the patient is significantly improved. Changes in serial blood BNP and N-terminal pro-BNP levels may provide additional guides.
 - b. **Treatment.** Periods of acute hypoxemia, whether intermittent or prolonged, contribute to the pathogenesis of late pulmonary hypertension in sBPD; therefore, oxygen saturation limits may need to be changed to avoid intermittent or sustained hypoxemia with targets generally between 92% and 95%.
 - c. **Current therapies used for pulmonary hypertension therapy in infants with BPD** generally include iNO, phosphodiesterase type 5 inhibitors, endothelin receptor antagonists, calcium channel blockers, endothelin receptor antagonists, and prostacyclin analogs (see Chapter 115 on pulmonary hypertension).
- 4. Growth and nutrition.** Because growth is essential for recovery from BPD, adequate nutritional intake is crucial. Infants with BPD frequently have high caloric needs (≥ 120 –150 kcal/kg/d) because of increased metabolic expenditures. Concentrated formula is often necessary to provide sufficient calories and prevent pulmonary edema. In addition, specific micronutrient supplementation, such as antioxidant therapy, may also enhance pulmonary and nutritional status. Enteral docosahexaenoic acid supplementation may increase the risk for BPD.
- C. Discharge planning.** Care plans for older infants with BPD should include adapting their routine for home life and involving the parents in their care. All parents should be instructed in cardiopulmonary resuscitation.
- 1. **Oxygen therapy** can often be discontinued before discharge from the neonatal intensive care unit. However, home oxygen therapy can be a safe alternative

to long-term hospitalization. The need for home respiratory, heart rate, and oxygen monitoring must be decided on an individual basis but is generally recommended for infants discharged home on oxygen.

2. **Immunizations.** Immunizations should be given at the appropriate chronologic age. Synagis (palivizumab, humanized monoclonal antibodies against respiratory syncytial virus [RSV]) should be given monthly (15 mg/kg administered intramuscularly) throughout the RSV season. All parents should be instructed in cardiopulmonary resuscitation. **Periodic screening** for chemical evidence of rickets and echocardiographic evidence of pulmonary hypertension is recommended
3. **Assessment by a developmental specialist** and occupational or physical therapist, or both, can be useful for prognostic and therapeutic purposes.

IX. Prognosis. The prognosis for infants with BPD depends on the degree of pulmonary dysfunction and the presence of other medical conditions. Most deaths occur in the first year of life as a result of cardiorespiratory failure, sepsis, or respiratory infection or as a sudden, unexplained death.

A. Pulmonary outcome. The short-term outcome of infants with BPD, including those requiring oxygen at home, is surprisingly good. Weaning from oxygen is usually possible before their first birthday, and infants demonstrate catch-up growth as their pulmonary status improves. However, in the first year of life, rehospitalization is necessary for approximately 30% of patients for treatment of wheezing, respiratory infections, or both. Although upper respiratory tract infections are probably no more common in infants with BPD than in normal infants, they are more likely to be associated with significant respiratory symptoms. Most adolescents and young adults who had moderate to severe BPD in infancy have some degree of pulmonary dysfunction, consisting of airway obstruction, reactive airway disease, and hyperinflation.

B. Neurodevelopmental outcome. Children with moderate to severe BPD appear to be at an increased risk for adverse neurodevelopmental outcome compared with comparable infants without BPD. Neuromotor and cognitive dysfunction appears to be more common. In addition, children with BPD may be at higher risk for significant hearing impairment and retinopathy of prematurity. They are also at risk for later problems, including learning disabilities, attention deficits, and behavior problems.

91 Calcium Disorders (Hypocalcemia, Hypercalcemia)

Abnormalities of calcium (Ca^{2+}) and magnesium (Mg^{2+}) metabolism are not infrequent occurrences among infants admitted for neonatal intensive care. Moreover, the disturbances of Ca^{2+} may be mirrored by Mg^{2+} , or conversely, as in hypocalcemia and hypomagnesemia. Infants of diabetic mothers (IDMs) and infants with fetal growth restriction (FGR) may present with low serum levels of either Ca^{2+} or Mg^{2+} or both. Serum values for Ca^{2+} and Mg^{2+} above or below accepted normal values are of concern in any infant and warrant further clinical studies. Magnesium disorders are discussed in Chapter 105.

I. Hypocalcemia

A. Definition. Hypocalcemia is determined by either **total serum calcium (tCa)** or **ionized calcium (iCa) values**. Clinical chemistry values for serum levels vary by units (ie, mEq/L, mmol/L, or mg/dL), by gestational age, and by day of age following

the immediate newborn period. Reference textbooks reflect considerable variance of serum values for Ca^{2+} and Mg^{2+} . Interpretation of serum values for any given patient is dependent on recognition of one's institution laboratory values and range of acceptable values.

A generally accepted value for hypocalcemia is <2.0 mmol/L (<8.0 mg/dL) for a term infant or <1.75 mmol/L (<7.0 mg/dL) for a preterm infant. A typical range of normal values for a term newborn can be 2.25 to 2.65 mmol/L (9.0–10.6 mg/dL) throughout the first week of life. Preterm infant tCa levels closely parallel those for term infants. Of greater significance is the ionized fraction of Ca^{2+} . It is the active physiologic component and is dependent on the interaction of tCa^{2+} , acid-base status, and serum albumin. Typical iCa^{2+} values for term infants over the first 72 hours of life are 1.22 to 1.24 mmol/L (4.88–4.96 mg/dL). Preterm infant mean values are similar for 24 to 72 hours: 1.21 to 1.28 mmol/L (4.84–5.12 mg/dL). Thereafter, preterm infants have slightly increased iCa^{2+} levels, whereas term infants experience a slight decline. **iCa levels of <1.2 mmol/dL (4 mg/dL) are considered hypocalcemic.**

- B. Incidence.** Hypocalcemia is likely the most common disorder of either Ca^{2+} or Mg^{2+} in newborn infants, and it affects both preterm and term infants. It occurs in up to 30% of infants with birthweight <1500 g. Late-onset hypocalcemia is more common in developing countries where cow's milk or formulas with phosphate concentrations are used.
- C. Pathophysiology.** iCa^{2+} is the biologically important form of calcium. The tCa^{2+} levels have been repeatedly shown to not be predictive of iCa^{2+} levels. Therefore, tCa^{2+} levels are unreliable as criteria for true hypocalcemia. In premature infants, it has been shown that tCa^{2+} levels as low as ≤ 6 mg/dL correspond to iCa^{2+} levels >3 mg/dL.
- D. Risk factors**

- 1. Early-onset neonatal hypocalcemia.** During the third trimester of pregnancy, the human fetus receives at least 120 to 150 mg/kg/d of elemental Ca^{2+} via the umbilical cord. Most of this Ca^{2+} is readily incorporated into the newly forming bones. After delivery, this massive supply of Ca^{2+} is suddenly stopped, and Ca^{2+} must be given enterally.
 - a. A full-term infant receiving 100 to 120 mL of normal formula** would be receiving 50 to 60 mg/kg/d of Ca^{2+} orally. Despite this drop in supply, full-term infants tolerate the change well and do not become hypocalcemic.
 - b. Premature (especially <28 weeks) or sick infants** often become hypocalcemic during the first 3 days of life. Total serum Ca^{2+} levels can drop to <7 mg/dL and occasionally fall below 6 mg/dL.
 - c. Calcium levels** (both iCa^{2+} and tCa^{2+}) usually return to normal within 48 to 72 hours regardless of whether supplemental Ca^{2+} is given. Immunoreactive parathyroid hormone is often low at birth but rises to higher levels within 24 to 72 hours after delivery. Intravenous (IV) Ca^{2+} supplementation suppresses this increase in immunoreactive parathyroid hormone; thus, some centers for neonatal care do not use early IV calcium supplementation.
- 2. Perinatal stress.** Term or preterm infants who have perinatal asphyxia can present with hypocalcemia secondary to elevated blood calcitonin level. Resuscitation and the use of alkali to correct acidosis (bicarbonate therapy), even though used less frequently since the new Neonatal Resuscitation Program guidelines, may result in alkalosis that increases the affinity of albumin for calcium and thereby decreases the concentration of ionized calcium.
- 3. Infant of diabetic mother.** Onset of hypocalcemia is usually early (1–3 days) and may recur throughout the first week. The mechanism for IDM hypocalcemia is unknown. Related factors that have been identified are increased calcitonin levels, decreased bone Ca^{2+} flux, hypomagnesemia, hypoparathyroidism, and hyperphosphatemia. The occurrence and severity of IDM hypocalcemia follow the severity of maternal diabetes and the prenatal management for euglycemic control.

4. **Intrauterine growth restriction.** Sporadic hypocalcemia occurs and may be associated with ≥ 1 of the known complications of IUGR (eg, hypoglycemia, asphyxia, hypothermia, polycythemia, or placental insufficiency).
 5. **Nutritional deprivation.** Infants unable to take enteral feeds by 3 days of age will need calcium supplementation. Breast milk or calcium-enriched formulas provide adequate Ca^{2+} intake. Because hypocalcemia is related to hypomagnesemia, both elements require supplementation to prevent a secondary suppression of parathormone leading to the recurrence of hypocalcemia.
 6. **Hypomagnesemia.** May be secondary to maternal gestational magnesium losses or to impaired intestinal uptake. Hypomagnesemia frequently occurs with hypocalcemia and must be looked for in any at-risk infant.
 7. **Congenital abnormalities.** The DiGeorge sequence with absence of parathyroid glands and related craniofacial and cardiac anomalies often presents with hypocalcemia. Other rare conditions may include familial isolated hypoparathyroidism.
 8. **Maternal hyperparathyroidism.** This causes transient hypoparathyroidism in the infant due to fetal parathyroid suppression.
 9. **Other therapeutic modalities.** These include furosemide-induced hypercalciuria; citrated blood transfusions, which reduce iCa^{2+} due to a citrate-calcium complex and alkalosis following metabolism of citrate; and inadequate prenatal vitamin D supplementation of the mother or the infant during the first 6 months of life. Maternal use of anticonvulsants such as phenobarbital can cause increased hepatic catabolism of vitamin D, resulting in maternal vitamin D deficiency and subsequent neonatal hypocalcemia.
- E. Clinical presentation**
1. **Early-onset hypocalcemia (first week of life)**
 - a. Apnea
 - b. Stridor
 - c. Irritability, jitteriness, tremors, or hyperreflexia
 - d. Clonus, tetany, or seizures
 - e. Arrhythmia secondary to prolonged QT interval
 2. **Late-onset hypocalcemia (any time after first week)**
 - a. Lethargy, apnea
 - b. Feeding intolerance
 - c. Abdominal distention
 - d. Bone demineralization, increased alkaline phosphatase
 - e. Skeletal fractures
 3. **Paradoxically, neonatal hypocalcemia is often asymptomatic.** Only an index of suspicion based on risk factors will lead to a correct diagnosis.
- F. Diagnosis**
1. **Laboratory studies**
 - a. **Total and ionized calcium levels** should be available for the neonatal intensive care unit patient. Serum tCa levels of <1.75 mmol/L (7.0 mg/dL) are diagnostic and iCa levels of <1.10 mmol/L (4.4 mg/dL) are confirmatory of hypocalcemia.
 - b. **Serum magnesium levels** of <1.5 mg/dL are indicative of hypocalcemia because they often coexist.
 - c. **Elevated alkaline phosphatase levels.**
 - d. **Urinary calcium losses of >4 mg/kg/24 h** are indicative of hypercalciuria.
 - e. **Testing for vitamin D** metabolites, parathyroid hormone level, calcitonin, and genetic screening (eg, microarray for 22q deletion) should also be considered to determine the etiology of hypocalcemia.
 2. **Imaging studies for bone demineralization, metaphyseal lucencies, and rib and long bone fractures** may be helpful for late hypocalcemia. More acutely, the absence of a thymic shadow on chest radiograph will suggest the DiGeorge sequence. For late-onset hypocalcemia and rickets, dual-energy X-ray

absorptiometry scan and quantitative ultrasonography using broadband ultrasonographic measurement, speed of sound, or bone transmission time have been employed to assess bone density.

3. **Electrocardiographic studies** will identify arrhythmias due to QT interval changes.

G. Management

1. **Acute treatment.** Reserved for the symptomatic hypocalcemic infants with apneic spells, seizures, or cardiac failure with arrhythmia. Dosage is 100 to 200 mg/kg of 10% calcium gluconate *slowly* by peripheral IV over 15 to 20 minutes with constant cardiac monitoring (see Chapter 155 for dosing information).

2. **Maintenance treatment.** For infants with limited enteral intake or who are dependent on parenteral calcium intake, an IV dosage of 20 to 60 mg/kg/d of elemental calcium with a calcium-to-phosphate ratio ranging from 1.3:1.0 to 2:1 is adequate for promoting both calcium and phosphate retention. Parenteral fluids cannot approximate the intrauterine level of Ca^{2+} intake (~140 mg/kg/d of elemental calcium) without some precipitation in solution. Therefore, early and continuous maintenance treatment is essential until milk or formula feeds can be successfully initiated.

3. **Vitamin D supplementation.** Should be started along with parenteral nutrition at 400 IU/d.

4. **Intravenous calcium administration.** This is not without some risk for complications. The potential problems include extravasation of calcium solution and resulting subcutaneous calcium deposition with limited joint movement, sloughing of skin, nephrocalcinosis, cardiac arrhythmias with prolonged QT intervals, or bradycardia if Ca^{2+} gluconate is given too quickly.

5. **Hypocalcemia secondary to blood/exchange transfusions.** This may require supplementation with Ca^{2+} gluconate but may result in rebound hypercalcemia.

6. **Hypocalcemia secondary to diuretic therapy.** Infants receiving loop diuretics have an increased urinary loss of calcium. This loss can be demonstrated by the urine calcium-to-creatinine ratio (>0.21–0.25). If hypercalciuria exists, an attempt should be made to substitute furosemide or bumetanide with chlorothiazide. Thiazide diuretics cause calcium retention and tend to offset the calciuric effect of loop diuretics in the absence of sodium supplementation.

H. **Prognosis.** No long-term effects of neonatal hypocalcemia are seen as attributable to known adverse neurobehavioral or neurologic outcomes of preterm or sick term infants. Both hypocalcemia and hypomagnesemia have a generally good outcome if diagnosed promptly and treated adequately. The exception is a clinical presentation that includes seizures for either hypocalcemia or hypomagnesemia associated with asphyxia or an underlying endocrine or genetic disorder.

II. Hypercalcemia

A. **Definition.** Hypercalcemia is defined as an iCa^{2+} serum level >1.35 mmol/L (5.4 mg/dL) for any infant, irrespective of a tCa serum level. The iCa^{2+} level is the physiologically active component of serum Ca^{2+} and thus the most important determination. Although tCa^{2+} is indicative of hypercalcemia at levels >2.75 mmol/L (11 mg/dL), it is not a reliable measure.

B. **Incidence.** Uncommon and a specific occurrence rate is unknown. It occurs much less often in infants than adults.

C. **Pathophysiology.** Hypercalcemia may be due to parathyroid-related causes or to mechanisms unrelated to the parathyroid. A number of cases of hypercalcemia have recently been reported in neonatal units due to subcutaneous fat necrosis following therapeutic hypothermia as treatment for hypoxic ischemic encephalopathy. A number of cases of hypercalcemia are related to clinical management due to excessive supplementation of vitamin A or D, calcium salts, or thiazide diuretics. A rare condition due to polymorphisms of calcium-sensing receptors can also result in hypercalcemia. Two forms involving calcium receptors are familial hypocalciuric hypercalcemia and neonatal hyperparathyroidism.

D. Risk factors**1. Congenital hyperparathyroidism**

- a. **Primary.** Due to genetic defects as either familial hypocalciuria, hypercalcemia, or severe neonatal hyperparathyroidism.
- b. **Secondary.** Due to maternal hypoparathyroidism.

2. Maternal hypocalcemia**3. Subcutaneous fat necrosis****4. Therapeutic hypothermia****5. Idiopathic infantile hypercalcemia****6. Williams syndrome****7. Hypophosphatasia****8. Hyper- or hypothyroidism****9. Malignancy (very rare in the newborn)****10. Distal renal tubular acidosis, Jansen metaphyseal chondrodysplasia****11. Iatrogenic**

- a. Hypophosphatemia due to inadequate dietary intake of phosphorus, especially in preterm infants
- b. Excessive vitamin D intake
- c. Excessive calcium intake
- d. Thiazide diuretics
- e. Extracorporeal life support

E. Clinical presentation. Mostly hypercalcemia is asymptomatic unless severe hypercalcemic levels have been reached and signs as described below appear.

1. Feeding intolerance, constipation, failure to thrive
2. Polyuria, dehydration
3. Hematuria, nephrocalcinosis, nephrolithiasis
4. Lethargy, hypotonia, seizures (rare, only in the most severe hypercalcemia)
5. Bradycardia, short QT interval, hypertension

F. Diagnosis**1. Laboratory studies**

- a. Serum calcium for levels as given previously
- b. Serum total protein and albumin-globulin ratio for hypoproteinemia
- c. Blood gases for acid-base status
- d. Serum phosphorus for hypophosphatemia
- e. Urine calcium and phosphorus
- f. Parathyroid hormone, 25-hydroxy (OH) vitamin D, 1, 25-OH vitamin D
- g. Thyroid studies
- h. Alkaline phosphatase for hypophosphatasia
- i. Serum creatinine

2. Imaging studies

- a. Renal ultrasound for calcifications
- b. Long bone x-rays for demineralization secondary to hyperparathyroidism or osteosclerotic lesions secondary to hypervitaminosis

G. Management. Treatment depends on the cause and severity of hypercalcemia. Hypercalcemia is usually mild, and a conservative approach is prudent. Immediate steps are to calculate calcium and vitamin D intake and correct excess doses or discontinue. After hypercalcemia has been resolved, dietary calcium, phosphorus, and vitamin D intakes can be recalculated and administered according to basic daily requirements. An endocrine consult is recommended.**1. Acute symptomatic hypercalcemia**

- a. **Discontinue any parenteral intake of calcium.**
- b. **Increase fluid intake as intravenous normal saline.**
- c. **Augment calcium loss** (calciuria) using furosemide with IV saline intake; exercise caution to monitor urine output and serum electrolytes.

2. **Less acute but severe hypercalcemia.** Consider:
 - a. **Calcitonin** (limited newborn/neonatal experience).
 - b. **Glucocorticoids** are effective on a short-term basis but are not recommended.
 - c. **Intravenous bisphosphonates** are promising (limited newborn/neonatal experience). Recently, there have been some case reports of successful use of bisphosphonates in neonates for therapy of hypercalcemia occurring in infants receiving therapeutic hypothermia due to hypoxic ischemic encephalopathy.
 3. **Refractory hypercalcemia.** In extreme situations, parathyroidectomy has been the last resort.
- H. Prognosis.** Hypocalcemia generally has a good outcome if diagnosed promptly and treated adequately. The exception is a clinical presentation that includes seizures. Follow-up studies have suggested 20% or greater incidence of neurologic abnormalities. If unrecognized and not treated, it may result in renal and central nervous system damage.

92 Coagulation Disorders

Bleeding and thrombosis are the 2 extremes of the physiologic process of coagulation disorders. Despite major differences in the levels of individual components of the hemostatic system, neonatal coagulation is equal to or somewhat more rapid than that observed in adults. This suggests the existence of a delicately balanced hemostatic system in neonates, with uncommon bleeding or thrombosis in healthy term infants. However, a number of perinatal or neonatal conditions can disrupt this balance and increase the risk for either hemorrhage or thrombus formation. The presence of bleeding in a healthy term or late preterm infant, especially in an infant with a normal platelet count, is strongly suggestive of a congenital bleeding disorder.

In general, coagulation disorders in the neonate can be classified as **inherited bleeding disorders** (hemophilia A and B, von Willebrand disease, or isolated factor II, VII, X, VIII, or XIII deficiencies) or **acquired bleeding disorders** (vitamin K deficiency bleeding, disseminated intravascular coagulation [DIC], liver disease, or extracorporeal life support related). The inherited disorders **hemophilia A and B and von Willebrand disease** account for 95% to 98% of congenital bleeding disorders.

PRINCIPLES OF HEMOSTASIS

I. Normal physiology of hemostasis

- A. **The primary phase.** This is the production of the platelet plug. It involves platelet adhesion (to the injured vessel's subendothelium) and their activation mediated by platelet surface glycoprotein (Ib, IIb/IIa) and von Willebrand factor (vWF).
- B. **The secondary phase.** Results in the formation of a cross-linked fibrin clot. Coagulation proteins (factors XII to V) circulating as inactive precursor forms (zymogens) are converted to active forms through limited proteolysis. These activated proteins then further activate other zymogen factors in a chain reaction. Ultimately, the activation of factors V and X leads to cleavage of prothrombin (factor II) to thrombin (factor IIa). Cleavage of fibrinogen (factor I) to fibrin (factor Ia) by thrombin results in the formation of the blood clot.
- C. **The third phase.** Modulates and limits the interactions of activated platelets and the clotting cascade (and Ca^{2+}) that give rise to a clot. This includes the removal of activated factors (through the reticuloendothelial system) and the control of

activated procoagulants by natural antithrombotic pathways (antithrombin III, protein C, protein S). Furthermore, restoration of vessel patency is triggered by the fibrinolytic pathway that generates plasmin from plasminogen. This is stimulated by tissue plasminogen activator (tPA) and limited by α_2 -antiplasmin and plasminogen activator inhibitor. Plasmin is a proteolytic enzyme that degrades fibrin into fibrin split products such as D-dimers. Defects in fibrinolytic factors that result in excessive plasmin generation can lead to bleeding.

II. Newborn hemostasis

- A. **Neonatal platelets are reported to be hyporeactive;** however, this deficiency is balanced by increased vWF activity, resulting in overall normal platelet function.
- B. **Factor VIII, factor V, fibrinogen, and factor XIII levels are normal at birth.**
- C. **Vitamin K-dependent factors (II, VII, IX, and X) and contact factors (XI and XII) are reduced to about 50% of normal adult values** and are further reduced in preterm infants. Similarly, concentrations of the naturally occurring anticoagulants antithrombin, protein C, and protein S are low at birth. As a consequence, both thrombin generation and thrombin inhibition are reduced in the newborn period.
- D. **Neonatal fibrinolytic activity is intact,** despite the decreased concentrations and functional activity of plasminogen. Very low levels of histidine-rich glycoprotein (a physiologic inhibitor of plasminogen binding) and delayed inactivation of neonatal plasmin partially compensate for the reduced plasmin capacity. On the other hand, the increased plasma levels of plasminogen activator inhibitor may explain the high rate of thromboembolic phenomena associated with intravascular devices in newborns. Most coagulation factors reached adult levels by 6 months of life with the exception of protein C levels, which remain low until later in childhood.

III. Hemostatic testing in neonates.

Correct interpretation of coagulation tests in the newborn is fraught with difficulties. The following precautions are needed for the appropriate interpretation of neonatal coagulation testing.

- A. **Gestational and postnatal age reference ranges.** Vital to adequately interpret coagulation results in preterm and term neonates (Table 92-1).
- B. **A free-flowing blood specimen.** Specimens must be obtained from an atraumatic venipuncture. Samples obtained through intravascular catheters may be contaminated with heparin as it adheres tightly to the walls of the tubing. This sample contamination with trace amounts of heparin will result in a prolonged activated partial thromboplastin time (aPTT) and sometimes prothrombin time (PT), unless heparin is degraded in the specimen. Additionally, small clots can form within the catheter or at the tip, resulting in consumption of clotting factors and alteration of coagulation testing. A difficult venipuncture can hamper sample integrity and lead to platelet clumping that produces a falsely low platelet count.
- C. **Special sample tubes should be prepared for coagulation testing in infants with a hematocrit >55% or <25%.** This allows for a correct amount of anticoagulant to be added to the blood sample (citrate-to-blood ratio of 1:9). Similarly, an insufficient filling of adequately citrated tube (<80%) can produce falsely prolonged coagulation time.
- D. **A stepwise approach to the neonate with suspected coagulation disorders is key to a correct diagnosis.**
 - 1. **Initial screening.** Consists of a complete blood count (CBC) with platelets, PT/ international normalized ratio (INR), aPTT, and fibrinogen level.
 - 2. **Prolonged prothrombin time.** Reflects decreased plasma concentrations of vitamin K-dependent factors.
 - 3. **Prolonged activated partial thromboplastin time.** Results from decreased plasma levels of contact factors (V and VIII to XI) as well.
 - 4. **Bleeding neonate who has no laboratory abnormality.** Factor XIII and α_2 -antiplasmin activity should be assessed.

Table 92-1. REFERENCE VALUES FOR COAGULATION STUDIES IN HEALTHY FULL-TERM AND PRETERM INFANTS DURING THE FIRST 30 DAYS OF LIFE

Tests	Healthy Full Term (Mean \pm SD)			Healthy Preterm (30-36 wks) Infant: Mean (range)		
	Day 1	Day 5	Day 30	Day 1	Day 5	Day 30
PT (seconds)	13.0 \pm 1.43	12.4 \pm 1.46	11.8 \pm 1.25	13 (10.6-16.2)	12.5 (10.0-15.3)	11.8 (10.0-13.6)
aPTT (seconds)	42.9 \pm 5.80	42.6 \pm 8.62	40.4 \pm 7.42	53.6 (27.5-79.4)	50.5 (26.9-74.1)	44.7 (26.9-62.5)
TCT (seconds)	23.5 \pm 2.38	23.1 \pm 3.07	24.3 \pm 2.44	24.8 (19.2-30.4)	24.1 (18.8-24.4)	24.4 (18.8-29.9)
Fibrinogen (g/mL)	2.83 \pm 0.58	3.12 \pm 0.75	2.70 \pm 0.54	2.43 (1.50-3.73)	2.8 (1.60-4.18)	2.54 (1.50-4.14)
Factor II (U/mL)	0.48 \pm 0.11	0.63 \pm 0.15	0.68 \pm 0.17	0.45 (0.20-0.77)	0.57 (0.29-0.85)	0.57 (0.36-0.95)

aPTT, activated partial thromboplastin time; HMW-K, high molecular weight kininogen; PT, prothrombin time; SD, standard deviation; TCT, thrombin clotting time; vWF, von Willebrand factor.

Adapted with permission from Andrew M, Monagle PT, Brooker L. *Thromboembolic Complications During Infancy and Childhood*. Hamilton, Ontario: BC Decker; 2000.

5. **D-dimers.** Elevated as an acute-phase reaction in all patients with infection or systemic inflammatory response syndrome (SIRS). A negative D-dimer assay is relatively accurate in ruling out thrombosis.

IV. Bleeding disorders in neonates

- A. **Clinical presentation.** Persistent oozing from the umbilical stump, excessive bleeding from peripheral venipuncture/heel stick sites, large caput succedaneum and cephalhematoma or subgaleal hemorrhage occurring without significant birth trauma history, and prolonged bleeding following circumcision are common presentations of neonatal bleeding disorders. The presence of an intracranial hemorrhage in a term or late preterm infant without history of birth trauma should be investigated for possible coagulation defect. Gastrointestinal bleeding must be distinguished from swallowed maternal blood (see page 528). Pulmonary hemorrhages are most frequently hemorrhagic pulmonary edema not associated with specific coagulation anomaly. Similarly, major abdominal organ bleeding such as from the liver or spleen is more often related to a traumatic injury or local lesion (eg, teratoma) than any coagulopathy.
- B. **Maternal, family, and neonatal history.** A history of any prior pregnancies and their outcomes can be a clue for disorders such as neonatal alloimmune thrombocytopenia. Maternal medication use can also lead to immune-mediated thrombocytopenia. Parental ethnic background and whether there is consanguinity are significant. However, absence of family history for a bleeding disorder cannot exclude occurrence of severe bleeding disorders. Perinatal complications can result in coagulation activation and DIC. Although giving vitamin K to neonates is almost a universal routine, it is still important to ascertain that the vitamin K was indeed administered.
- C. **Physical examination.** An otherwise normal neonate with thrombocytopenia is suggestive of alloimmune thrombocytopenia. Skeletal abnormalities such as absence of thumb or radii are important clues for conditions such as thrombocytopenia with absent radii or Fanconi anemia. Cardiac defects may be associated with factor V deficiency. Delayed cord separation and persistent oozing from the umbilical stump are typical for infants with defective fibrinogen production or function and factor XIII deficiency. Acquired consumptive coagulopathy is generally a secondary event in a “sick” acting infant. Bacterial or viral infection and metabolic disorders (eg, tyrosinemia) are a few of the conditions that then need to be considered.

INHERITED BLEEDING DISORDERS: HEMOPHILIA A AND B

- I. **Definition.** Hemophilia A and B are inherited as sex-linked (X chromosome) recessive traits and are characterized by deficiencies of factor VIII or IX. However, one-third of cases will occur in the absence of a positive family history. Factor VIII deficiency is 5 times as common as factor IX deficiency.
- II. **Incidence.** Hemophilia A occurs in 1 per 5000 males, and hemophilia B occurs in 1 per 25,000 males; it is very rare in females.
- III. **Pathophysiology.** Deficiency of factor VIII or IX interferes with coagulation cascade.
- IV. **Risk factors.** Male sex, family history of hemophilia or bleeding disorders.
- V. **Clinical presentation.** The pattern of hemophilia-associated bleeding differs from that seen in older children. Hemarthroses are rare, and many bleeds are iatrogenic in origin (eg, oozing or hematoma following venipuncture or vitamin K intramuscular [IM] administration, prolonged bleeding following circumcision). Major bleeding, both intracranial (mostly subdural) and extracranial, is also occasionally seen. **Severe factor VIII deficiency (factor VIII activity <1%)** is the most common congenital coagulation disorder to present in the neonatal period. A third of cases will present with bleeding manifestations during the first month of life.
- VI. **Diagnosis.** Screening coagulation test shows a prolonged aPTT, whereas PT and platelet counts are within normal range. Factor VIII normally approaches adult level at birth; thus, a low level reliably diagnoses hemophilia A. On the other hand, the diagnosis of

moderate hemophilia B requires testing beyond the neonatal age because factor IX levels are low at birth ($\approx 15\%$), reaching adult values at 2 to 6 months.

VII. Management

A. The treatment for hemophilia A or B is recombinant factor VIII or factor IX concentrate, respectively. Fresh-frozen plasma (FFP) should be used only in the instance of acute hemorrhage when confirmatory testing is not yet available.

B. Desmopressin has been used for mild hemophilia A and for von Willebrand disease type 1 or 2 to increase release of factor VIII and von Willebrand factor from endothelial stores. The antifibrinolytic agents α -aminocaproic acid (Amicar) and tranexamic acid can be used in mucocutaneous bleeding to stabilize the fibrin clot and retard fibrinolysis. These agents are contraindicated in hematuria because of concerns about obstruction of urine flow by thrombi.

VIII. Prognosis. In most Western countries, people with hemophilia have a life expectancy not different from that of the male population without hemophilia. The optimal schedule for lifelong prophylaxis treatment continues to be *controversial* and onerous, and the development of inhibitors to factor VIII is still a major unresolved problem.

INHERITED BLEEDING DISORDERS: VON WILLEBRAND DISEASE

von Willebrand disease rarely presents during the neonatal period, because healthy neonates have higher plasma concentrations of vWF activity and an increased proportion of high molecular weight vWF multimers compared with adults. The condition is divided into 3 types. Type 3, an autosomal recessive disorder where vWF concentrations are almost absent, is the only type presenting with severe neonatal bleeding.

INHERITED BLEEDING DISORDERS: ISOLATED FACTOR II, VII, X, VIII, OR XIII DEFICIENCIES

Isolated factor II, VII, X, VIII, or XIII deficiencies can present in the neonatal period. These rare coagulation deficiencies have an autosomal recessive inheritance (except factor XIII) and present with abnormal coagulation screening tests.

ACQUIRED BLEEDING DISORDERS: VITAMIN K DEFICIENCY BLEEDING

I. Definition. Vitamin K deficiency bleeding (VKDB) in the newborn.

II. Incidence. Rare in the United States with routine administration of vitamin K.

III. Pathophysiology. Vitamin K, a fat-soluble vitamin, is required for carboxylation of glutamic acid residues on precursors of vitamin K-dependent coagulation proteins (factors II, VII, IX, and X and proteins C and S). Vitamin K exists in 2 forms: vitamin K1 or phyloquinone (the plant form of the vitamin) and vitamin K2, a series of compounds synthesized by bacteria and referred to as menaquinones. In contrast to human milk, infant formula contains large amounts of vitamin K (10 vs 65–100 mcg/L). Newborn infants are at risk for vitamin K deficiency because of vitamin K's poor placental transfer, insufficient endogenous production from the intestinal bacterial flora prior to complete colonization of the neonatal colon, and inadequate dietary intake among solely breast-fed infants.

IV. Risk factors. Additional risk factors are liver disease, cholestasis, and maternal short-gut syndrome.

V. Clinical presentation

A. Mild vitamin K deficiency. Manifests as an isolated prolongation of PT, with more severe deficiency characterized by prolongation of aPTT. The diagnosis can be confirmed by high serum level of an abnormal form of prothrombin (protein induced by vitamin K absence-II [PIVKA-II]).

- B. Early vitamin K deficiency bleeding.** Occurs in the first 24 hours among infants born to mothers on oral anticoagulants, anticonvulsants, or antituberculosis therapy and presents generally as serious bleeding such as intracranial hemorrhage (ICH).
 - C. Classic disease.** Presents between days 1 and 7 with gastrointestinal bleeding, ICH, skin bruising, and bleeding following circumcision and tends to occur in infants who did not receive vitamin K at birth and are breast fed or receiving inadequate overall milk intake. In the absence of vitamin K prophylaxis, the incidence of classic VKDB is 0.25% to 1.7%.
 - D. Late vitamin K deficiency bleeding.** Presents between 2 and 12 weeks of life. These infants are exclusively breast-fed infants who received no or only 1 oral dose of vitamin K or have an associated disease process that interferes with the absorption or supply of vitamin K (intestinal malabsorption defects, cholestatic jaundice, cystic fibrosis, biliary atresia, α_1 -antitrypsin deficiency). The majority of cases of late VKDB, the incidence of which is 4 to 7 per 100,000 births, present with ICH.
- VI. Diagnosis.** No routine test is diagnostic. Increased PT with normal platelet and fibrinogen levels is typical.
- VII. Management**
- A. Infants who present with a non-life-threatening bleed only need to be treated with vitamin K1** given slowly intravenously (IV) or subcutaneously (no IM injection) at a dose of 250 to 300 mcg/kg to restore PT to 30% to 50% of its normal value within an hour.
 - B. Treatment of serious bleeding** includes FFP (20 mL/kg), a prothrombin complex concentrate (50 U/kg), or recombinant factor VIIa (100 mcg/kg).
 - C. The American Academy of Pediatrics recommends** that all infants receive 1 mg of IM vitamin K on the first day of life (0.3 mg for infants <1000 g and 0.5 mg for infants >1000 g but <32 weeks). This single parenteral dose prevents both classic and late VKDB.
 - D. The safety of intramuscular vitamin K was questioned** because of its reported possible association with increased incidence of childhood cancer. Subsequent studies have disproved this risk. Nevertheless, an alternative oral regimen of a 2-mg dose at birth followed by a 1-mg dose given weekly for 3 months has been suggested. Its efficacy has not been well established.
- VIII. Prognosis.** Depends on the severity and location of the bleeding.

ACQUIRED BLEEDING DISORDERS: DISSEMINATED INTRAVASCULAR COAGULATION

- I. Definition.** DIC is the result of excessive and inappropriate activation of the hemostatic system related to exposure of blood to a source of tissue factor. It is a secondary manifestation of an underlying problem such as bacterial or viral infection, asphyxia, or necrosis.
- II. Incidence.** The most common causes of DIC in the newborn are sepsis, severe respiratory distress syndrome, asphyxia, and necrotizing enterocolitis.
- III. Pathophysiology.** Massive thrombin generation with widespread fibrin deposition and consumption of coagulation proteins and platelets leads to multiple organ dysfunction.
- IV. Risk factors.** Concurrent bacterial or viral infection, asphyxia, or necrosis.
- V. Clinical presentation.** The presence of DIC in a neonate without any evidence of sepsis or history of asphyxia should warrant the evaluation for a capillary hemangioma.
- VI. Diagnosis.** The diagnosis of DIC is made in an ill neonate with thrombocytopenia, prolonged PT and aPTT, reduced fibrinogen, and increased D-dimers.

VII. Management

- A. **The most important therapeutic intervention** is to treat the underlying cause of the disseminated intravascular coagulation.
- B. **Focus on the acute hematologic management is to support adequate hemostasis to limit hemorrhage.** This is usually achieved with platelet transfusions, FFP, or cryoprecipitate, with a goal of maintaining platelets $>50,000$ to $100,000/\text{mm}^3$, PT <3 seconds above the upper limit of normal, and fibrinogen >100 mg/dL.
- C. **Anticoagulant therapy is not generally used.** The benefit has not proved to outweigh the added risk for hemorrhage.
- D. **The use of activated protein C is controversial (may increase risk of intracerebral hemorrhage).**
- E. **Recombinant factor VIIa (40–300 mcg/kg).** This has been used successfully to treat severe bleeding in infants with DIC. In the presence of endothelial damage, recombinant factor VIIa (rFVIIa) binds to exposed tissue factor to activate factor X and thus generate thrombin. The potential for thrombotic complications makes its use limited to life-threatening hemorrhagic situations.

VIII. **Prognosis.** Related to the underlying cause of the DIC.

ACQUIRED BLEEDING DISORDERS: LIVER DISEASE

Vitamin K-dependent factors (II, VII, IX, and X) as well as factor V are synthesized by the liver, and hepatic damage can result in lower levels. The diagnosis of acute liver disease should include elevated liver enzymes, direct hyperbilirubinemia, and elevated ammonia concentration. A low factor VII associated with low factor V will distinguish between vitamin K deficiency and hepatic dysfunction. A normal factor VIII may differentiate between liver disease and DIC where all clotting factors are depleted. On the other hand, liver disease may trigger DIC, and ascites may lead to a loss of all clotting factors.

ACQUIRED BLEEDING DISORDERS: EXTRACORPOREAL LIFE SUPPORT RELATED

Systemic anticoagulation with heparin is performed during the duration of ECLS to minimize the potential for clotting within the circuit. Monitoring to prevent bleeding complications is essential. This is done by the activated coagulation time, a rapid, whole blood point-of-care test. Patients are usually maintained close to a target time of 200 seconds.

THROMBOEMBOLIC DISEASE IN NEONATES

Thrombotic complications are more frequent in neonates than in any other pediatric age group. Depending on the type of thrombosis and screening methods used, incidences of 0.5 events per 10,000 live births or 2.4 clinically apparent events (excluding stroke) per 1000 neonatal intensive care unit (NICU) admissions have been reported.

ARTERIAL THROMBOSIS: PERINATAL AND PRENATAL ARTERIAL ISCHEMIC STROKE

- I. **Definition.** An arterial ischemic stroke (AIS) is a cerebrovascular event occurring between 28 weeks of gestation and 28 days of birth with radiologic or pathologic evidence of focal arterial infarction of the brain.
- II. **Incidence.** The incidence of cerebral arterial occlusion may range from 0.5 to 1 per 1000 live births. Most occur within the middle cerebral artery of the left hemisphere.

- III. **Pathophysiology.** Paradoxical embolism (through the foramen ovale) from the fetal placental circulation is believed to be the most common etiology. Clotting activation originating from the placenta could release thrombin or small fibrin clots into the fetal circulation.
- IV. **Risk factors.** Twin-to-twin transfusion syndrome, fetal heart rate abnormality, and hypoglycemia are independent risk factors.
- V. **Clinical presentation.** Approximately 60% of the cases are perinatal AIS and present with symptoms in the first few days of life, chiefly seizures and apnea. **AIS is the second most common underlying etiology of neonatal seizures in the full-term newborn.** Presumed prenatal stroke, asymptomatic at birth, presents with asymmetrical motor development, hemiplegia, or seizures several months postnatally.
- VI. **Diagnosis.** Magnetic resonance imaging (MRI) with diffusion-weighted imaging is the most sensitive technique for the early detection of acute cerebral infarction. Magnetic resonance angiography allows for the detection of thrombosed cerebral vessels. Cranial ultrasound has a poor sensitivity for the detection of AIS.
- VII. **Management.** In adults with AIS, recombinant tissue plasminogen activator (rTPA) has shown efficacy in restoring cerebral blood flow when delivered within 3 hours of its onset. In the neonate with AIS, the determination of time of onset is challenging, and there is currently no evidence for the efficacy of any form of anticoagulation treatment.
- VIII. **Prognosis.** Many newborns with symptomatic AIS appear clinically normal after recovery from the acute event. On follow-up, one-third will exhibit hemiparesis, and another third will exhibit cognitive abnormalities affecting speech and language.

ARTERIAL THROMBOSIS: IATROGENIC/SPONTANEOUS ARTERIAL THROMBOSIS

- I. **Definition.** An arterial thrombosis is classified as catheter related or non-catheter related.
- II. **Incidence.** Spontaneous arterial thrombosis is extremely rare. The incidence of catheter-related (mostly umbilical arterial catheter [UAC]) thrombosis has been reported as being as high as 30% depending on the method used for diagnosis (eg, ultrasound, angiography). The incidence of major clinical symptoms attributable to UAC thrombus is approximately 1% to 5% of catheterized infants.
- III. **Pathophysiology.** An arterial thrombosis usually involves the aorta and tends to mimic congenital heart disease (eg, coarctation). Iatrogenic arterial thrombosis is mainly related to complications from indwelling catheters.
- IV. **Risk factors.** Presence of UACs and peripheral arterial catheters.
- V. **Clinical presentation.** Findings suggestive of an acute thrombosis include line dysfunction, extremity blanching and/or cyanosis, decreased pulse, and persistent thrombocytopenia.
- VI. **Diagnosis.** Ultrasound Doppler is the method more frequently used in sick preterm infants, although contrast angiography may be more accurate when feasible.
- VII. **Management**
 - A. **Suspicion or confirmation of an arterial thrombosis.** Warrants prompt removal of the catheter unless local instillation of tPA into the thrombus is contemplated.
 - B. **Recommendations for umbilical artery catheter-related thrombosis.** Treat with heparin. rTPA thrombolysis may be attempted for life-, limb-, or organ-threatening conditions (see pages 849–850).
- VIII. **Prognosis.** Most symptomatology attributed to thrombus formation will resolve with prompt removal of the catheter.

ARTERIAL THROMBOSIS: PURPURA FULMINANS

- I. **Definition.** Purpura fulminans (PF) is a rare syndrome of diffuse intravascular thrombosis and hemorrhagic infarction of the skin that is rapidly progressive and often fatal.
- II. **Incidence.** The incidence of severe protein C deficiency is 1 per 1,000,000 live births.

- III. Pathophysiology.** Based on severe genetic (or acquired) protein C and/or protein S deficiency. Acquired PF may result from conditions triggering acute reduction of protein C activity such as bacterial infection.
- IV. Risk factors.** Protein C deficiency.
- V. Clinical presentation.** Extensive venous and arterial thrombosis with ecchymosis is present soon after delivery and can result in skin necrosis.
- VI. Diagnosis.** Laboratory tests yield results consistent with DIC (thrombocytopenia, hypofibrinogenemia, and increased PT and aPTT) and show no measurable protein C or S.
- VII. Management.** Early treatment is paramount for successful outcome and consists of FFP, protein C concentrate, or activated protein C and lifelong anticoagulation.
- VIII. Prognosis.** PF is associated with a high mortality rate.

VENOUS THROMBOSIS: CEREBRAL SINOVENOUS THROMBOSIS

- I. Definition.** Cerebral sinovenous thrombosis (CSVT) typically involves the thrombosis of cerebral veins or the dural sinus with cerebral parenchymal lesions or central nervous system (CNS) dysfunction.
- II. Incidence.** The incidence of CSVT has been reported as 0.4 per thousand live births.
- III. Pathophysiology.** Thrombophilic factors (Table 92–2) may play a role in perinatal stroke. The superior and lateral sinuses are the most frequently involved vessels, and up to 30% of cases have venous infarction with subsequent hemorrhage.
- IV. Risk factors.** Often associated with perinatal asphyxia, coagulopathy, maternal diabetes, and infection.
- V. Clinical presentation.** The symptoms of CSVT are those of a perinatal stroke and include seizures, apnea, and lethargy.

Table 92–2. THROMBOPHILIC CONDITION MARKERS FOR THROMBOPHILIA AND PREVALENCE IN HEALTHY POPULATION

Condition/Marker	Testing Methods	Prevalence (%)
Genetic		
Factor V Leiden mutation	PCR	4–6
Prothrombin G20210A mutation	PCR	1–2
Elevated plasma lipoprotein(a)	ELISA	
Acquired or genetic		
Antithrombin deficiency	Chromogenic (functional) assay	0.019
Protein C deficiency	Chromogenic (functional) assay	0.023
Protein S deficiency	ELISA for free protein S antigen	0.037
Elevated factor VIII	One-stage clotting assay (aPTT based)	
MTHR enzyme gene mutation	Hyperhomocysteinemia	9
Maternal lupus	ELISA for antiphospholipid antibodies	
Activate protein resistance	Clotting assay (aPPT based)	

aPTT, activated partial thromboplastin time; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

Modified with permission from Goldenberg NA, Bernard TJ: Venous thromboembolism in children, *Hematol Oncol Clin North Am.* 2010 Feb;24(1):151-166.

- VI. **Diagnosis.** Diagnosis of CSVT is best made through diffusion MRI and magnetic resonance venography.
- VII. **Management.** Heparin anticoagulation is indicated only when there is evidence of thrombus propagation, multiple emboli, or a severe prothrombotic state, but is contraindicated in the presence of intracerebral hemorrhage.
- VIII. **Prognosis.** Based on extent of cerebral defect.

VENOUS THROMBOSIS: UPPER AND LOWER VENOUS SYSTEM DEEP VEIN THROMBOSIS

- I. **Definition.** Thrombus in a major vein in the upper or lower extremity with or without central extension.
- II. **Incidence.** The true incidence of neonatal deep vein thrombosis (DVT) is difficult to determine, and many central venous lines (CVLs) related to venous thrombosis are clinically “silent.” Thrombosis and infection have been reported to occur in 2% to 22% of neonates with indwelling CVLs, with a higher incidence reported in studies applying regular ultrasound screening.
- III. **Pathophysiology.** Infants are at increased risk of thrombosis, with indwelling catheters further increasing the risk of venous thrombosis.
- IV. **Risk factors.** Nearly one-third of cases are associated with systemic infection, whereas prematurity is also correlated with higher prevalence of DVT. Other risk factors may include polycythemia, dehydration, repair of congenital heart disease, hypoxia, and parenteral nutrition.
- V. **Clinical presentation.** Upper or lower venous DVT in neonates may present as swelling and discoloration of the associated limb, swelling of the face and head, chylothorax, and superior vena cava syndrome. Thrombocytopenia may be present.
- VI. **Diagnosis.** Doppler ultrasound is the technique most frequently used for confirmation of neonatal DVT, although a venogram might be a more sensitive diagnostic method.
- VII. **Management**
 - A. **Suspicion or confirmation of a venous thrombus.** This warrants prompt catheter removal. However, due to the risk for emboli, delaying CVL removal until 3 to 5 days after the start of anticoagulant therapy may be considered (*controversial*).
 - B. **Anticoagulation and thrombolytic treatment are equally *controversial*.** The decision needs to take into account the degree of threat to limbs or vital organs.
 - C. **Role of thrombophilia screening in neonatal deep vein thrombosis.** In light of its poor yield and the low risk and predictability of DVT recurrences, this remains *controversial* as well.
- VIII. **Prognosis.** Short-term morbidities include pulmonary embolism and neonatal stroke from emboli or brain hemorrhagic infarction.

VENOUS THROMBOSIS: RIGHT ATRIAL THROMBOSIS

- I. **Definition.** Thrombosis of the superior vena cava with extension into the right atrium.
- II. **Incidence.** Right atrial thrombosis (RAT) accounts for 6% of all neonatal thromboses.
- III. **Pathophysiology.** Despite early administration of aspirin, this has become a common complication in infants undergoing repair of complex congenital heart disease. There is a strong association of the location of the catheter tip in the right atrium and the development of RAT.
- IV. **Risk factors.** The most important risk factor is an indwelling CVL. Other associated risk factors include prematurity, administration of parenteral nutrition, sepsis, and congenital heart disease.

- V. **Clinical presentation.** More than half of the cases are asymptomatic and are detected incidentally during echocardiography performed for other reasons such as investigation for a persistent infection focus. The remaining cases may present with respiratory distress, new heart murmur, heart failure symptoms, or tachyarrhythmia.
- VI. **Diagnosis.** The diagnostic method of choice for RAT is echocardiography. Documentation of the size, mobility, and shape of the thrombus, as well as the concomitant cardiac function, is essential in helping to decide on treatment and predict outcome.
- VII. **Management**
 - A. **Asymptomatic and hemodynamically stable infants with small, immobile right atrial thromboses** may need no treatment except close echocardiography follow-up.
 - B. **For symptomatic patients or RATs that are large, mobile, pedunculated, or snake shaped,** treatment should include systemic anticoagulation therapy.
 - C. **Thrombolytic therapy or surgical embolectomy** may be indicated in life-threatening conditions.
- VIII. **Prognosis.** Thrombolytic therapy in preterm infant with infective endocarditis carries a high risk for ICH.

VENOUS THROMBOSIS: RENAL VEIN THROMBOSIS

- I. **Definition.** Renal vein thrombosis (RVT) is the most common cause of non-catheter-associated thrombosis and usually presents in the first week of life.
- II. **Incidence.** RVT accounts for up to 10% of venous thromboses in newborns.
- III. **Pathophysiology.** Unilateral left-sided RVTs are the most common.
- IV. **Risk factors.** Risk factors for the development of RVT include perinatal asphyxia, dehydration, maternal diabetes, and male sex.
- V. **Clinical presentation.** The **classic clinical triad of RVT** includes hematuria, palpable abdominal mass, and thrombocytopenia. Other features include hypertension, proteinuria, and renal impairment. Patients with thrombus extension and caval occlusion may also develop bilateral lower limb edema.
- VI. **Diagnosis.** The diagnosis of RVT is usually made via ultrasound with Doppler. Ultrasonographic features of RVT include enlarged, echogenic kidneys with attenuation or loss of corticomedullary differentiation. Color flow Doppler shows absence of flow in the main or arcuate renal veins.
- VII. **Management.** The treatment for RVT is **controversial**. Renal outcomes appear to be similar between supportive treatment and anticoagulation therapy. Similar proportions of affected kidneys that received supportive care or received anticoagulation became atrophic on follow-up. Possible exceptions to exclusive supportive treatment may include the following:
 - A. **Low molecular weight heparin therapy** for unilateral RVT with inferior vena cava extension for 6 weeks to 3 months. (See page 851.)
 - B. **Bilateral renal vein thrombosis with caval extension** may warrant thrombolytic therapy. (See page 852.)
- VIII. **Prognosis.** Acute complications of RVT include adrenal hemorrhage, extension of the clot into the inferior vena cava, renal failure, hypertension, and death. Chronically, cortical or segmental infarction of the affected kidney and/or hypertension is common.

VENOUS THROMBOSIS: PORTAL VEIN THROMBOSIS

- I. **Definition.** Thrombus in the portal vein usually associated with umbilical vein catheterization.
- II. **Incidence.** The incidence of portal vein thrombosis (PVT) has been reported as 3.6 per 1000 NICU admissions. The incidence of PVT in neonates associated with the insertion of umbilical venous catheters (UVCs) varies between 1% and 43%, depending on imaging protocols.

- III. **Pathophysiology.** Hypercoagulability of the newborn coupled with UVC entering the liver in an area of relatively low flow.
- IV. **Risk factors.** Risk factors include umbilical infection as well as position of the tip of the UVC. The UVC tip should be kept outside the low-flow portal venous system and placed at the level of inferior vena cava/right atrium, or below the level of the umbilical-portal confluence. Its position needs to be ascertained by imaging.
- V. **Clinical presentation.** Most thromboses in the portal venous system are clinically silent and spontaneously resolve within a short period of time after catheter removal.
- VI. **Diagnosis.** Large studies have shown that PVT can usually be detected by ultrasound within the first week of a UVC insertion.
- VII. **Management.** Use of anticoagulation is *controversial* (see Prognosis). For dosing, see page 850.
- VIII. **Prognosis.** Long-term outcome of neonatal PVT and whether anticoagulation has any benefit in the outcome is unknown. Left lobe atrophy and portal hypertension are the most important sequelae. PVT is the major cause of extrahepatic portal hypertension in children, and a history of neonatal umbilical venous catheterization is frequently found among those children.

VENOUS THROMBOSIS: THROMBOPHILIA

- I. **Definition.** Thrombophilia is a term used to describe known inherited or congenital blood coagulation disorders that may predispose to thrombosis.
- II. **Incidence.** Rare.
- III. **Pathophysiology.** Conditions that predispose to thrombophilia are noted in Table 92–2. Despite a high prevalence of multiple thrombophilic gene mutations, the majority of neonates with these traits do not develop thrombosis.
- IV. **Risk factors.** Central venous and arterial catheters constitute the greatest acquired risk for the development of thromboembolic events in neonates, in addition to those noted in Table 92–2.
- V. **Clinical presentation.** Thrombophilia should be considered in any neonate who presents with thrombotic events or extensive thrombosis in the absence of identifiable environmental risk factors (intravascular catheter, neonatal sepsis, or shock).
- VI. **Diagnosis.** The evaluation of a neonate with a significant thromboembolic event for a prothrombotic disorder is *controversial*.
- VII. **Management.** See Management of Thrombosis section that follows.
- VIII. **Prognosis.** Neonates with multiple traits of thrombophilia and symptomatic thrombosis are at an increased risk for thrombus recurrence, although recurrences usually occur in the setting of other comorbidities, such as infection, surgery, or trauma.

MANAGEMENT OF THROMBOSIS: GENERAL GUIDELINES

The optimal treatment modality for neonates with thrombosis is *controversial*. Information on treatment of neonatal thrombosis is limited to case reports and small case series. Dosing information is often extrapolated from children or adult data. Available options include observation, anticoagulation (unfractionated heparin [UFH] or low molecular weight heparin [LMWH]), thrombolytic therapy, and surgical thrombectomy. Treatment should be limited to clinically significant thrombosis with the goal of preventing clot expansion or embolism.

I. Unfractionated heparin

A. Pharmacology

1. **Unfractionated heparin is a heterogeneous mixture** of negatively charged glycosaminoglycans with a molecular weight ranging from 5000 to 30,000 kDa. The anticoagulant properties are via conformational change in antithrombin, converting it to a more efficient (1000-fold) inhibitor of factors IIa, IXa, Xa, XIa, and XIIIa.

Table 92–3. DOSAGE OF UNFRACTIONATED HEPARIN IS MODULATED ACCORDING TO POSTCONCEPTIONAL AGE

Postconceptional Age	<28 Weeks	28–37 Weeks	>37 Weeks
Loading dose IV over 10 minutes	25 U/kg	50 U/kg	10 U/kg
Maintenance dose IV	15 U/kg/h	15 U/kg/h	28 U/kg/h

IV, intravenous.

2. **The anticoagulant activity of heparin** is variable because of the differential clearance of the various sizes of heparin moieties, as well as its propensity to bind to other positively charged noncoagulation proteins, as well as to platelets and endothelial surfaces.
 3. **The most important anticoagulant actions of heparin** are the potentiation of antithrombin inhibition of thrombin (IIa) and factor Xa.
- B. Dosage.** See Table 92–3.
1. **The half-life of unfractionated heparin, secondary to increased clearance, is short in neonates.** Infants with the most significant thromboses demonstrate the highest clearance.
 2. **The efficacy of unfractionated heparin might be decreased in neonates because of the physiologically low antithrombin plasma concentration.** Antithrombin supplementation with FFP is sometimes suggested.
 3. **Neonates require continuous intravenous therapy.** Higher doses than those used in older patients are required to achieve therapeutic adult aPTT levels. Anticoagulation is recommended for 10 to 14 days.
- C. Monitoring**
1. **The goal for anticoagulation is to maintain activated partial thromboplastin time at 1.5 to 2 times the upper limit of age values.** When feasible, anti-factor Xa level monitoring is preferable, with its level kept at 0.3 to 0.7 U/mL.
 2. **Following the initial dose, anti-factor Xa or activated partial thromboplastin time level is assessed 4 or 6 hours later, respectively, and once daily thereafter.** If the level of anticoagulation is below or above target values, the test is repeated 4 to 6 hours after appropriate dose adjustment. In general, a 10% rate adjustment is made when levels are inappropriate. An additional 50 U/kg may be given if aPTT is <50 seconds.
 3. **A complete blood count, platelet count, and coagulation screening** (including activated partial thromboplastin time, prothrombin time, and fibrinogen) should be performed before starting unfractionated heparin therapy. Platelet count and fibrinogen levels should be repeated daily for 2 to 3 days once therapeutic levels are achieved and twice weekly thereafter.
- D. Complications**
1. **The most important adverse effect from heparin therapy is bleeding.** A 2% risk has been reported in term infants, and the risk is higher among preterm infants.
 2. **Accidental overdose of unfractionated heparin is a major safety issue.** This occurs when an inappropriately diluted, supposedly low-dose UFH is used to flush a vascular access device.
 3. **Heparin-induced thrombocytopenia rarely occurs in neonates.**
 4. **Treatment of hemorrhage**
 - a. **Usually, due to unfractionated heparin's short half-life, it only requires cessation of the infusion.**
 - b. **If bleeding continues following cessation of the infusion.** A full coagulation assessment should be performed, and hemostatic deficiencies should be replaced as indicated.

- c. **Protamine.** One milligram of protamine will neutralize 100 U of UFH. The amount to be administered is based on the time elapsed since the last heparin injection. A full neutralizing amount is to be given if that time was <30 minutes. This dose is reduced by 50% for every hour past the last time heparin had been given. A repeat aPTT is required 15 minutes later.
- E. **Advantages over low molecular weight heparin**
1. **Because of its short half-life,** it can be used as the first-line agent in patients whose anticoagulation may need to be stopped rapidly.
 2. **Antidote (protamine sulfate) is available.**
 3. **At doses <100 U/kg,** its elimination is unaffected by renal dysfunction.
- II. **Low molecular weight heparin**
- A. **Pharmacology**
1. **Low molecular weight heparin is a glycosaminoglycan of smaller molecular weight (2000–8000 kDa) than unfractionated heparin.** As such, it lacks a binding site for thrombin.
 2. **Primary action of low molecular weight heparin** is to potentiate the anti-thrombin inhibition of factor Xa with little effect on the antithrombin inhibition of thrombin. Consequently, aPTT is unaffected at therapeutic LMWH doses.
- B. **Dosage of low molecular weight heparin (enoxaparin)**
1. **Dosing recommendations for enoxaparin:** 1.7 mg/kg every 12 hours in term neonates and 2.0 mg/kg every 12 hours in preterm neonates.
 2. **Low molecular weight heparin can be administered by subcutaneous injection.** Frequent needle pricks can be minimized with the use of an extremely low dead space subcutaneous catheter (Insuflon, Unomedical/ConvaTec). Local bruising, induration, and leakage occur in 10% of neonates.
- C. **Monitoring.** See Table 92–4.
1. **Low molecular weight heparin works largely by inhibiting factor Xa;** thus, dosing must be titrated to anti-factor Xa activity and not to the aPTT.
 2. **The goal of treatment is to maintain an anti-factor Xa level of 0.5 to 1.0 U/mL.**
 3. **Levels should be obtained 4 hours after the second dose and then weekly.**
- D. **Advantage over unfractionated heparin.** LMWH (specifically, enoxaparin) has become an increasingly popular alternative to UFH following studies in adults that demonstrated at least comparable efficacy and safety.
1. **Pharmacokinetics** of LMWH are more predictable, making the need for monitoring less frequent.
 2. **Lesser risk of bleeding complications.**
 3. **Low molecular weight heparin is given subcutaneously,** which eliminates the requirement for IV access.

Table 92–4. LOW MOLECULAR WEIGHT HEPARIN (ENOXAPARIN) ADJUSTMENT^a

Anti-Factor Xa Level (U/mL)	Hold Next Dose	Dose Change
>0.35	No	Increase by 25%
0.35–0.49	No	Increase by 10%
0.5–1.0	No	No change
1.1–1.5	No	Decrease by 20%
1.6–2.0	3 hours	Decrease by 30%
>2.0	Until anti-factor Xa 0.5 U/mL	Decrease by 40%

^aA repeat anti-factor Xa needs to be measured after every individual adjustment.

Modified with permission from Andrew M, de Veber G. *Pediatric Thromboembolism and Stroke Protocols*. Hamilton, Ontario: BC Decker; 1997.

4. **Low molecular weight heparin has a lesser risk of heparin-induced thrombocytopenia** as well as a reduced risk of osteoporosis that is associated with long-term use of UFH.

III. Thrombolytic therapy. The goal of thrombolytic therapy is to degrade fibrin and dissolve the fibrin clot. Systemic thrombolytic therapy should be strongly considered for clots that have a high risk of morbidity and mortality. The rate of vascular patency following anticoagulant therapy in older children has been reported at 50%; following thrombolysis, it is >90%.

A. Pharmacology

1. **Recombinant tissue plasminogen activator** facilitates conversion of plasminogen to plasmin to enhance degradation of fibrin, fibrinogen, and factors V and VII; it is the most commonly used agent.
2. **Systemic tissue plasminogen activator is effective** when administered within 2 weeks of symptomatic clot onset and is only partially effective beyond 2 weeks.
3. **Direct instillation of potent thrombolytic agents into clots via an infusion catheter** has been shown to result in significant increases in vessel patency rates in adults. It also carries the potential advantage of less exposure to the bleeding risks of systemic thrombolysis.

B. Dosage. Based on a limited number of studies, the following protocol is proposed:

1. **Systemic low doses.** Starting dose of 0.06 mg/kg/h with possible escalation up to 0.24 mg/kg/h over the next 48 to 96 hours.
2. **Alternatively, use 1 of the following local treatments:**
 - a. **Bolus.** Initial dose of 0.25 to 0.5 mg/kg for 15 minutes to be followed by 0.1 to 0.4 mg/kg/h for a maximal period of 72 hours.
 - b. **Single dose.** A dose of 0.7 mg/kg over 30 to 60 minutes.
3. **Repeat echocardiogram/Doppler** every 6 to 8 hours to assess the presence of the clot to guide the escalation of thrombolytic treatment or its cessation.
4. **Heparin.** Because thrombolysis does not inhibit clot propagation or directly affect hypercoagulability, simultaneous treatment with low-dose UFH (5–10 U/kg/h) or LMWH (0.5 mg/kg twice a day) is recommended.
5. **Plasminogen supplementation.** Prolonged thrombolytic therapy is likely to exhaust the low plasminogen neonatal supplies more readily than in adults. With thrombolytic therapy lasting >24 hours, consideration should be given to either monitoring plasminogen concentrations or empiric infusion of FFP (10–20 mL/kg) to optimize thrombolysis.
6. **Fibrinogen.** Fibrinogen concentration decreases by 25% to 50% in response to systemic thrombolytic therapy. If fibrinogen concentrations are <100 mg/mL, dose reductions of the thrombolytic agent and infusion of replacement therapy in the form of cryoprecipitate or FFP should be considered.
7. **Platelet counts.** Need to be maintained over 50,000/mm³.
8. **D-Dimer and fibrinogen degradation product** plasma concentrations are expected to increase as a response to effective thrombolytic action.
9. **Daily head sonograms.**
10. **Avoid intramuscular injections and urinary catheterizations.**

C. Exclusion criteria for tissue plasminogen activator thrombolysis

1. **Major surgery or central nervous system bleeding within 10 days.**
2. **Major asphyxial event within 7 days (usually birth asphyxia).**
3. **An invasive procedure within 72 hours.**
4. **Seizures within 48 hours.**

D. Adverse effects

1. **Bleeding complications** have been reported in nearly two-thirds of pediatric patients; half of those patients required replacement blood transfusions.
2. **Most frequently, bleeding is at sites of invasive procedures.** Gastrointestinal, pulmonary, and intraventricular hemorrhages are reported in about 1% of term infants and 14% of preterm infants.

3. **The frequency and severity of bleeding** may be dose and duration (<6 hours) dependent.
 4. **Concurrent low-dose heparin treatment and fresh-frozen plasma (10 mL/kg)** given a half hour before each tPA infusion may lessen those bleeding risks.
- IV. Surgical thrombectomy.** The small size of neonatal blood vessels, the rarity of thrombosis in neonates, and the severity of illness in neonates with thrombosis preclude the use of surgical thrombectomy in the majority of neonates. However, with the use of microsurgical techniques combined with thrombolytic regimens, thrombectomy has been successfully used in neonates in isolated cases.

93 Common Multiple Congenital Anomalies: Syndromes, Sequences, and Associations

- I. Definition.** A **congenital anomaly** (also called **birth defect**, **congenital malformation**, or **congenital abnormality**) is defined as a **structural or functional defect** that is present at birth and different from what is considered normal. A **structural defect** is an abnormality in the structure of the parts of the body (skeleton and organs). Structural defects most often occur during the critical period of fetal development in the first trimester. Structural defects include heart defects, cleft palate, neural tube defects, club foot, and others. A **functional defect** is defined as a defect in how the body system works (eg, metabolic disorders, brain and nervous system problems, degenerative disorders, immune disorders, sensory disorders). This chapter will discuss only structural defects; functional defects are discussed elsewhere.
- II. Classification of anomalies**
 - A. Classification based on major and minor anomalies.** An anomaly can be further divided into **major anomalies** that require medical and surgical care (eg, congenital heart defects, anencephaly, gastroschisis, cleft lip/palate, meningomyelocele) and **minor anomalies** that do not have medical significance (eg, single palmar crease, epicanthal folds, fifth digit clinodactyly). Approximately 75% of newborns with major congenital anomalies present with an isolated anomaly, and approximately 25% have more than 1 major anomaly. Neonates can have both major and minor anomalies.
 - B. Classification based on developmental process.** Congenital anomalies can be classified based on the **developmental process** involved in their formation and may be described as **malformations, deformations, disruptions, dysplasias, syndromes, associations, or sequences** (see Table 93–1 for definitions). It is also important to understand that these may not be entirely mutually exclusive.
- III. Incidence.** Approximately 3% of all newborns have a congenital anomaly in the United States, and worldwide, approximately 6% of all newborns have a congenital anomaly. Approximately 0.7% of infants have multiple major anomalies. The **most common congenital anomalies** are congenital heart defects, neural tube defects, and Down syndrome. Congenital malformations account for 20% of the cases of neonatal deaths.
- IV. Causes of congenital anomalies** include **genetic causes** (chromosomal disorders, single-gene defects, autosomal dominant or recessive inheritance, and others), **maternal conditions during pregnancy** (infections, chronic maternal diseases, smoking,

Table 93–1. TYPES OF CONGENITAL ANOMALIES

Malformation: The morphologic defect of an organ or larger region of the body resulting from an intrinsically abnormal developmental process. A primary defect.
Deformation: An alteration in shape and/or structure caused by biomechanical forces that distort an otherwise normally developing structure. A secondary defect.
Disruption: A structural defect resulting from an extrinsic insult to an originally normal developmental process.
Dysplasia: An abnormality in the organization or differentiation of cells within a specific tissue type that results in clinically apparent structural changes.
Syndrome: A recognizable pattern of anomalies considered to have a specific cause.
Association: A nonrandom, statistically significant association of multiple anomalies for which no specific etiology has been described.
Sequence: A pattern of multiple anomalies derived from a single abnormality followed by a cascade of secondary effects.

medications, poor nutrition, environmental factors, TORCHZ (toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus, and Zika virus), hyperthermia, alcohol and drug use), **multifactorial causes** (genetic plus environment), and **unknown etiologies**.

- V. General approach to diagnosis.** In the management of congenital anomalies, the neonatologist must deal with complex clinical issues calling for a wide range of diagnostic skills. Identifying the correct unifying diagnosis related to the congenital anomaly can help guide management, ensuring that interventions are appropriate and effective. This also facilitates realistic counseling about prognosis and recurrence risk. Only a few common syndromes associated with **multiple congenital abnormalities** are life-threatening in the neonatal period. It is important to note, however, that **congenital malformations are the most common cause of death at this critical point** in the life span. When overt malformations are present, a **syndromic association** will be suspected much earlier, and diagnostic efforts will start sooner. However, if external features of the disorder are subtle or nonspecific and the usual procedures associated with intensive newborn support have been started, a syndromic diagnosis may not be recognized until later. The diagnostic approach to congenital anomalies in neonates is no different from that in older children. Many of these affected children are intubated with multiple lines and tubes, which often makes a detailed assessment of physical characteristics challenging. Clinical photographs are extremely helpful, especially when a clinical geneticist is not available locally. If specialists in these fields are not available, a telephone call to a university medical center for expert advice is often useful. If the infant is critically ill and suspicion for a syndromic association is present, looking for other major malformations is important (eg, echocardiogram, renal/abdominal ultrasound, brain imaging). **The basis for diagnosis of a genetic syndrome in a neonate involves a combination of defining the physical manifestations and diagnostic genetic testing.** It is important to note that approximately 25% of all congenital anomalies may have a genetic cause. Identifying an underlying diagnosis may be delayed because immediate efforts tend to emphasize therapy. Nevertheless, clarifying the complete clinical picture often facilitates or guides therapy more efficiently. One study revealed that molecular diagnoses in congenital malformations directly affected medical management in approximately 50% of neonates.

VI. Diagnosis

- A. Prenatal diagnosis.** There are multiple screening evaluations available prenatally that can help with early detection of a congenital anomaly. Prior to and

during early pregnancy, carrier screening can be used to determine risk for disorders, often based on ethnic background. These include noninvasive and invasive testing.

1. **Noninvasive testing** includes ultrasound, standard anomaly scan at 18 to 20 weeks, fetal echocardiography, magnetic resonance imaging, and screening tests (noninvasive prenatal screening using cell-free fetal DNA analysis, multiple marker screening for aneuploidy [nuchal translucency measurement, pregnancy-associated plasma protein A, and β -human chorionic gonadotropin], and screening for neural tube defects [maternal α -fetoprotein]). A sequential screen can determine risk of Down syndrome, trisomy 18, and open neural tube defects.
 2. **Invasive techniques** include embryoscopy, fetoscopy during the second trimester, amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling, and fetal tissue sampling. Chromosomal analysis (karyotyping), fluorescence in situ hybridization (FISH), and chromosomal microarray analysis can be done prenatally. Molecular genetic testing can be done prenatally using amniocytes, chorionic villi, or fetal blood cells looking for genetic mutations/deletions.
- B. **Detailed family history is of utmost importance.** Any consanguinity? Stillborn? Miscarriage? Other family members with anomaly? Ethnic origin? Doing a pedigree is recommended.
 - C. **Detailed pregnancy history.** Were there any exposures to drugs, toxins, or chemicals? Did the mother have any chronic medical condition? Did the infant grow normally?
 - D. **Detailed physical examination** to rule out multiple malformations and to look for clues to help diagnose a syndrome or a sequence. See Table 93–2 for symptoms and signs that might indicate a congenital anomaly and Chapter 7. Look for clues for specific syndromes such as webbed or wide neck (Turner/Noonan

Table 93–2. SYMPTOMS AND SIGNS IN NEONATES THAT MIGHT INDICATE A MULTIPLE CONGENITAL ANOMALY SYNDROME

Prenatal

Oligohydramnios

Polyhydramnios

Decreased or unusual fetal activity

Abnormal fetal problem/position

Postnatal

Abnormalities of size: small for gestational age or large for gestational age, microcephaly or macrocephaly, large or irregular abdomen, small chest, limb-trunk disproportion, asymmetry

Abnormalities of tone: hypotonia, hypertonia

Abnormalities of position: joint contractures, fixation of joints in extension, hyperextension of joints

Midline aberrations: hemangiomas, hair tufts, dimples or pits

Problems of secretion, excretion, or edema: no urination, no passage of meconium, chronic nasal or oral secretions, edema (nuchal, pedal, generalized, ascites)

Symptoms: unexplained seizures, resistant or unexplained respiratory distress

Metabolic disorders: resistant hypoglycemia, unexplained hypo- or hypercalcemia, polycythemia, hyponatremia, thrombocytopenia

syndrome), redundant nuchal folds, tongue protrusion (Down syndrome), microcephaly (TORCHZ infection), hypotelorism and polydactyly (trisomy 13, Down syndrome), pectus excavatum, and arachnodactyly (Marfan syndrome).

E. Laboratory evaluation

1. **Evaluate for infections if indicated** (TORCHZ). Serologic testing (specific immunoglobulin [Ig] G, IgM, IgA) and polymerase chain reaction assays can be performed.

2. **Diagnostic genetic testing is recommended if a genetic defect is suspected.**

a. **Array comparative genomic hybridization or chromosomal microarray analysis** is the **initial (first-tier) test** recommended for infants with ≥ 1 congenital anomalies, without an obvious single-gene syndromic diagnosis. It is a cytogenetic technique used to detect chromosomal deletions or duplications and assesses all regions of the chromosomes including subtelomeric and pericentromeric regions.

b. **High-resolution karyotype.** Analysis of chromosomes obtained from white blood cells present in the peripheral blood sample. This test can take up to 2 weeks for completion. Used to detect differences in the number of whole chromosomes (aneuploidy), large chromosomal deletions/duplications, and translocations. This test remains the standard for confirming a well-recognized syndrome associated with aneuploidy, such as trisomies (Down syndrome) and monosomy X (Turner syndrome).

c. **Fluorescence in situ hybridization.** A cytogenetic technique in which a fluorescently labeled probe can be used to detect specific DNA sequences. This test can detect small submicroscopic chromosomal deletions. The turn-around time is much faster than high-resolution karyotyping with results typically available in about 48 hours. FISH is often used to quickly confirm a diagnosis in a critically ill infant with trisomy 13, 18, or 21 or Turner syndrome or to confirm genetic sex in an infant with a suspected disorder of sexual development.

d. **Multigene panel** is used for disorders where variants occur in multiple genes (eg, Noonan syndrome).

e. **Genomic sequencing. Whole-exome sequencing and whole-gene sequencing** may be considered for infants with multiple congenital anomalies with suspected monogenic disorders, typically after nondiagnostic cytogenetic testing. This is a rapidly evolving field and is reviewed in detail in Chapter 17.

F. **Imaging.** The following tests may be required: computed tomography scan, magnetic resonance imaging, magnetic resonance angiography, skeletal survey, bone age, abdominal ultrasound, and echocardiogram.

G. **Subspecialty consultations.** Ophthalmology evaluation is important to rule out ocular abnormalities. An audiology evaluation is needed to rule out hearing loss. Any other consults depending on the specific need of the infant (eg, cardiology, orthopedics, endocrinology, pediatric surgery, pediatric urology)

VII. **Genetic counseling.** For infants with congenital anomalies, counseling can be complex and requires a great deal of sensitivity. Appropriate genetic counseling is reliant on having a specific diagnosis, if possible. The next step is to establish the parents' understanding of the entire situation and what information they have received from other professionals or gathered on their own. Be sure you know what questions the parents want answers to before the factual counseling begins. Do not give excessive details, and avoid specific predictions regarding timing and the presence or absence of certain future problems. Leave some degree of hope, but be honestly realistic, particularly if the parents clearly demand it. Be sure to offer follow-up counseling sessions, and outline a long-term program for the child's care and evaluations. Recurrence risk figures and the availability of prenatal diagnosis for subsequent pregnancies should also be discussed. Remember, medical providers may view the child's problems much differently than the parents, and it is important to work with the family from their perspective.

VIII. Selected examples of congenital anomalies based on their causes

A. Chromosomal syndromes. The most common causes of syndromes associated with multiple congenital abnormalities diagnosed in the neonatal period are chromosomal abnormalities. Chromosomal abnormalities (extra or missing chromosomes or pieces of chromosomes) are identified in approximately 10% of children with congenital anomalies. Common chromosomal syndromes seen in the neonatal period include the following:

1. Trisomy 21 (Down syndrome)

- a. Incidence.** Trisomy 21 is one of the most common syndromes, occurring in about 1 in 800 live births.
- b. Neonatal mortality.** This has decreased significantly with time but is relatively high for neonates who are very low birthweight and have severe congenital heart defects.
- c. Physical findings.** Findings include hypotonia, a poor or absent Moro reflex, flat facial profile, upslanting palpebral fissures, Brushfield spots, small, unusual ears, protruding tongue, excess nuchal skin, fifth-digit brachydactyly/clinodactyly, and a single transverse palmar crease.
- d. Associated anomalies.** Include congenital heart defects (~50%), most commonly an atrioventricular canal defect or ventricular septal defect. Major gastrointestinal malformations include Hirschsprung disease, duodenal or esophageal atresia, imperforate anus, and renal and urinary tract anomalies.

2. Trisomy 18 (Edwards syndrome)

- a. Incidence.** Approximately 1 in 5000 live births. There is a 3:1 female-to-male ratio.
- b. Neonatal mortality.** Median survival time is about 14 days, and 50% of infants die in the first month. Survival beyond the first year is rare; however, there are reports of affected children living older than 10 years of age.
- c. Physical findings.** Common findings include prenatal and postnatal growth deficiency, decreased subcutaneous fat, initial hypotonia followed by hypertonia, microcephaly, dolichocephaly with a prominent occiput, micrognathia, malformed auricles, short sternum with widely spaced nipples, overlapping digits with hypoplastic nails, and clubbed or rocker-bottom feet.
- d. Associated anomalies.** Congenital heart disease is typically present (95% incidence) and is usually complex. Less frequent anomalies include cryptorchidism, horseshoe kidney, umbilical or inguinal hernia.

3. Trisomy 13 (Patau syndrome)

- a. Incidence.** Approximately 1 in 16,000 live births.
- b. Neonatal mortality.** Median survival is about 7 days, and 90% die within the first year. Survival beyond the first year is rare. Individuals with trisomy 13 mosaicism are often more mildly affected, and survival is usually longer.
- c. Physical findings.** Common findings include low birthweight, microcephaly with sloping forehead, scalp cutis aplasia, microphthalmia, cleft lip and palate, dysplastic ears, redundant nuchal skin, postaxial polydactyly, and overlapping and flexed fingers with hyperconvex nails.
- d. Associated anomalies.** Congenital heart disease is typically present (80% incidence) and usually complex. Renal abnormalities are common and can include polycystic kidneys, hydronephrosis, hydronephrosis, or horseshoe kidney. Holoprosencephaly, cryptorchidism, a single umbilical artery, and inguinal or umbilical hernias are common.

4. Monosomy X (Turner syndrome)

- a. Incidence.** Approximately 1 in 2500 live-born females.
- b. Neonatal mortality.** Turner syndrome is usually compatible with survival if the child reaches term. Approximately 98% to 99% of pregnancies in which a fetus has Turner syndrome end as miscarriages or stillbirths.

- c. **Physical findings.** Epicanthal folds, prominent ears, micrognathia, low posterior hairline, excess nuchal skin, webbed neck, broad chest with wide-spaced nipples, hypoplastic nails, peripheral lymphedema of the hands and feet, and pigmented nevi.
 - d. **Associated anomalies.** Include congenital heart defects, typically a bicuspid aortic valve or aortic coarctation, horseshoe kidney, and gonadal dysgenesis.
5. **22q11.2 Deletion syndrome (DiGeorge syndrome, velocardiofacial syndrome).** It is now understood that the phenotypes of DiGeorge syndrome (congenital heart disease, hypocalcemia, and immunodeficiency), velocardiofacial syndrome (velopharyngeal incompetence, congenital heart disease, and characteristic facial features), and conotruncal anomaly facial syndrome are all encompassed by and result from the chromosome 22q11.2 microdeletion.
- a. **Incidence.** Approximately 1 in 4000 live births.
 - b. **Neonatal mortality.** Neonatal deaths occur in about 8% of cases and are almost exclusively due to cardiac defects.
 - c. **Physical findings.** Include a range of malformations including:
 - i. **Congenital heart disease (~75%).** Conotruncal malformations including tetralogy of Fallot, interrupted aortic arch, ventricular septal defects, or truncus arteriosus.
 - ii. **Palatal abnormalities (~70%).** Velopharyngeal incompetence, submucosal cleft palate, and cleft palate.
 - iii. **Immune function (~75%).** Immunodeficiency occurs because of thymic hypoplasia and secondary T-cell abnormalities.
 - iv. **Craniofacial features.** Include microcephaly, malar flattening, mandibular retrusion, overfolded or squared-off helices, prominent nasal root, bulbous nasal tip, hooded eyelids, and hypertelorism. However, the facial features are not typically suggestive of the diagnosis during the neonatal period, especially in persons not of Caucasian ancestry.
 - d. **Associated anomalies.** Hypocalcemia (~50%), significant feeding problems (~30%), renal anomalies (~33%), hearing loss (both conductive and sensorineural), and hyperextensibility of hands and fingers.
6. **Williams syndrome (7q11.23 deletion)**
- a. **Incidence.** Approximately 1 in 7500 to 1/20,000 live births.
 - b. **Neonatal mortality.** Quite small and mostly due to severe cardiac anomalies.
 - c. **Physical findings.** Flat midface, medial eyebrow flare, short palpebral fissures, epicanthal folds, depressed nasal bridge, anteverted nostrils, long philtrum, thick lips, and blue irides with a stellate pattern.
 - d. **Associated anomalies.** Include congenital heart defects (~80%), inguinal or umbilical hernias, hypercalcemia, and feeding difficulties.
- B. **Common sequences seen in the neonatal period**
1. **Oligohydramnios sequence (Potter sequence)**
- a. **Incidence.** Approximately 1 in 4000 live births.
 - b. **Neonatal mortality.** Almost all of these infants die.
 - c. **Pathophysiology.** The initial malformations in this sequence are varied, but all lead to oligohydramnios. Primary malformations can include bilateral renal agenesis, severe polycystic kidneys, or a urinary tract obstruction. The resultant oligohydramnios then results in deformations and disruptions including compression deformities of the face and limbs, pulmonary hypoplasia with pneumothoraces, wrinkled skin, and growth restriction. Absent abdominal musculature (prune belly) and cryptorchidism may also be present.
 - d. **Associated anomalies.** Include congenital heart defects, esophageal and duodenal atresia, imperforate anus, sirenomelia, hypoplastic nails, Pierre

Robin sequence, large fontanelles, wide sutures, flexion contractures, and clubfeet.

2. Amniotic band sequence

- a. **Incidence.** Approximately 1 in 1200 to 15,000 live births.
- b. **Neonatal mortality.** Variable based on affected tissues and organs.
- c. **Pathophysiology.** The effects of early amnion rupture with entanglement of body parts in bands or strands of amnion is the primary event. The resulting biomechanical forces can lead to disruptions, deformations, and malformations. Viscera that are normally outside the fetus in early embryonic development may be hindered in their return, giving rise to an omphalocele and other anomalies.
- d. **Physical findings.** Examination of the placenta and amniotic membranes is diagnostic. Aberrant bands or strands are noted, and remnants of the amnion may be tangled within the umbilical cord.
 - i. **Extremities.** Anomalies of the extremities include congenital amputations, constrictions, and distal swellings (Figure 93–1).
 - ii. **Craniofacies.** Craniofacial anomalies include microcephaly, encephaloceles, and facial clefts.
 - iii. **Viscera.** Visceral anomalies include omphaloceles, ectopia cordis, thoracoschisis, and abdominoschisis.

3. Arthrogryposis multiplex congenita (multiple joint contractures)

- a. **Incidence.** Approximately 1 in 3000 to 1 in 5000 live births.
- b. **Neonatal mortality.** Variable based on etiology.
- c. **Pathophysiology.** Arthrogryposis is essentially a descriptive diagnosis related to hundreds of diseases with varying etiologies. Factors that lead to reduced movement, including primary neurologic, muscular, or orthopedic problems, can all lead to arthrogryposis. Joint contractures can also be secondary to factors that are extrinsic to the developing fetus, such as fetal crowding and constraint. Neurologic abnormalities include meningomyelocele, prenatal

FIGURE 93–1. Amniotic band syndrome. (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children's Hospital of Philadelphia Division of Dermatology.)

spasticity, anencephaly, and hydranencephaly. Muscle abnormalities include muscle agenesis and fetal myopathies. Orthopedic abnormalities include synostosis, joint laxity with dislocations, and aberrant soft tissue fixations.

d. Clinical presentation. The newborn infant may present with a combination of joint contractures and/or dislocations. Those with arthrogryposis of central nervous system origin are at increased risk for aspiration and inadequate respiratory movement. (See also Chapter 112.)

4. Pierre Robin sequence. This sequence can occur in isolation or as part of a larger multiple congenital abnormality syndrome. The most common associated syndrome is Stickler syndrome.

a. Incidence. Approximately 1 in 8500 to 14,000 live births.

b. Neonatal mortality. Small and mostly due to severe upper airway obstruction at birth.

c. Pathophysiology. The primary event of this sequence is hypoplasia of the mandible, which results in secondary glossoptosis. The glossoptosis then leads to both upper airway obstruction and the development of a cleft palate.

d. Clinical presentation. Infants have micrognathia or a receding chin with a cleft palate. Respiratory distress can occur because of upper airway obstruction. Low-set ears may also be present.

C. Miscellaneous associations and syndromes seen in the neonatal period

1. VATER/VACTERL association. VATER is an acronym that stands for vertebral defects, *a*nal atresia, *t*racheoesophageal fistula, and *r*adial or renal dysplasia. VACTERL is an acronym that stands for *v*ertebral defects, *a*nal atresia, *c*ardiac malformations, *t*racheoesophageal fistula, *r*enal dysplasia, and *l*imb abnormalities.

a. Incidence. Estimated at 1 in 10,000 to 40,000 live births.

b. Neonatal mortality. Small and mostly due to severe cardiac or renal anomalies.

c. Clinical presentation. Aside from the defects described in the acronyms, other features of these disorders include a single umbilical artery and prenatal growth deficiency.

2. CHARGE syndrome. CHARGE is an acronym that stands for *c*oloboma, *h*eart defects, *c*hoanal *a*tresia, *r*etarded growth and development, *g*enital abnormalities, and *e*ar anomalies. CHARGE is an autosomal dominant disorder that results from mutations in the *CHD7* gene.

a. Incidence. Approximately 1 in 8500 to 10,000 live births.

b. Neonatal mortality. Variable based on the degree of upper airway obstruction and congenital heart disease. Feeding difficulties are a major cause of morbidity in all age groups.

c. Physical findings. The major features of CHARGE syndrome include unilateral or bilateral coloboma of the iris, retina, choroid, and/or discs with or without microphthalmos (80%–90%); cardiovascular malformations including conotruncal defects (75%–85%); unilateral or bilateral choanal atresia or stenosis (50%–60%); and developmental delay and hypotonia (~100%); growth deficiency is typically postnatal with or without growth hormone deficiency (70%–80%). Genital abnormalities include cryptorchidism in males and hypogonadotropic hypogonadism in both males and females. Ear anomalies are both external with anomalous auricles and internal with ossicular malformations, Mondini defect of the cochlea, and absent or hypoplastic semicircular canals.

d. Associated anomalies. Include cranial nerve dysfunction resulting in hyposmia or anosmia, unilateral or bilateral facial palsy (40%) and/or swallowing problems (70%–90%), and tracheoesophageal fistula (15%–20%).

3. Beckwith-Wiedemann syndrome

a. Incidence. Approximately 1 in 137,000 live births.

- b. **Neonatal mortality.** Infants have an approximately 20% mortality rate, mainly caused by complications of prematurity.
 - c. **Physical findings.** Perinatal findings include polyhydramnios, premature birth, macroglossia, linear ear creases, and macrosomia. Hemihyperplasia may be present at birth but can develop over time. Neonatal hypoglycemia is often present and clinically important. Anterior abdominal wall defects, including omphalocele and umbilical hernia, are common.
 - d. **Associated anomalies.** Include renal anomalies and an increased risk of mortality associated with Wilms tumor and hepatoblastoma. The estimated risk for tumor development in children with Beckwith-Wiedemann syndrome is 7.5%. This increased risk for neoplasia seems to be concentrated in the first 8 years of life. Tumor development is uncommon in affected individuals >8 years of age.
- D. Teratogenic malformation syndromes.** Few drugs have a known teratogenic effect on the infant. These include alcohol, phenytoin (Dilantin), valproic acid, retinoic acid, warfarin, cocaine, thalidomide, lithium, and antifolates. (See also Table 94–2 for teratogens associated with heart defects.)
1. **Fetal alcohol syndrome.** In the United States, the incidence is approximately 0.5 to 2 per 1000 live births, but it is estimated to be more common in certain areas of the United States and in other countries (1%–5%). Features include prenatal and postnatal growth deficiency, irritability in infancy, microcephaly, short palpebral fissures, smooth philtrum with thin and smooth upper lip, joint anomalies, and congenital cardiac defects. Brain development and function are the most serious consequences of prenatal alcohol exposure. (See also Chapter 102.)
 2. **Fetal hydantoin (Dilantin) syndrome.** When phenytoin is taken during pregnancy, it results in a 2- to 3-fold increased risk for congenital malformations. Approximately 5% to 10% of exposed fetuses manifest the embryopathy. Features include mild to moderate prenatal growth deficiency, microcephaly, wide anterior fontanelle, low-set hairline, hirsutism, hypertelorism, strabismus, broad and depressed nasal bridge, cleft lip and palate, digit and nail hypoplasia, and umbilical and inguinal hernias. Similar craniofacial features are also associated with prenatal exposure to carbamazepine, mysoline, and phenobarbital.
 3. **Fetal valproate syndrome** was described when an association was recognized between maternal ingestion of valproic acid during the first trimester and neural tube defects. Additional anomalies of fetal valproate syndrome include narrow bifrontal diameter; epicanthal folds; telecanthus; midface hypoplasia; broad, low nasal bridge with a short nose; long philtrum; micrognathia; long, thin fingers; congenital heart defects; genitourinary anomalies; and clubfeet.
 4. **Fetal retinoid syndrome.** The most common cause is maternal use of isotretinoin, an active metabolite of vitamin A, for severe cystic acne. An estimated 20% to 35% of fetuses exposed to isotretinoin have a major malformation. Fetal anomalies include congenital heart defects, hydrocephalus, microcephaly, cranial nerve deficits, microtia, and a cleft palate. Pregnancy should wait until 2 years after treatment with isotretinoin. Ingestion of large amounts of vitamin A may result in the same adverse effects to the fetus.
 5. **Fetal warfarin syndrome** causes eye abnormalities, nasal hypoplasia, stippled epiphyses, and intellectual disability.
 6. **Fetal cocaine syndrome** causes microcephaly, fetal growth restriction (FGR), neurobehavioral disorders prematurity, and cerebral infarction. (See also Chapter 102.)
 7. **Other medications that cause malformations:** **Thalidomide** (abnormal development of limbs), **lithium carbonate** (neural tube defects, cardiovascular

anomalies [Ebstein anomaly]), **antifolates** (IUGR; skeletal defects; central nervous system malformations; neural tube, cardiovascular, and urinary tract defects), **angiotensin-converting enzyme inhibitors** (renal hypoplasia/agenesis, skull defects), **methotrexate/aminopterin** (skeletal defects, craniosynostosis, syndactyly, cleft, growth restriction, dysmorphic features).

- E. Maternal conditions that can cause congenital malformations in the neonate**
- 1. Diabetic embryopathy.** Children born to insulin-dependent diabetic mothers have a 2- to 3-fold risk for congenital malformations. The cardiovascular, genitourinary, and central nervous systems are the most frequently affected systems. Cardiovascular anomalies include ventricular septal defect, transposition of great arteries, single umbilical artery, and situs inversus. Anomalies of the genitourinary system consist of renal agenesis and hypospadias, and anomalies of the central nervous system include spina bifida and anencephaly.
 - 2. Infants of mothers with myotonic dystrophy** vary in their clinical presentation from mild hypotonia and feeding problems to severe respiratory insufficiency causing death. Other abnormalities include a history of polyhydramnios and decreased fetal movement, multiple joint contractures, clubfeet, and facial weakness. The mutation identified to be the cause of myotonic dystrophy is a trinucleotide-containing cytosine-thymidine-guanosine that undergoes expansion in females with each transmission from an affected mother to a child. The severity of symptoms and onset of disease increase with transmission of this disorder to family members in subsequent generations.
 - 3. Maternal phenylketonuria.** If the mother has an elevated serum phenylalanine level during pregnancy, the infant can have microcephaly, severe heart defects, and intellectual disability.
 - 4. Maternal systemic lupus.** The infant can have cardiac conduction abnormalities.
 - 5. Elevated maternal temperature.** Can cause growth retardation and developmental defects.
 - 6. Maternal thyroid disease** (see Chapter 129).
- F. Infectious agents that can cause congenital malformations.** TORCHZ infections are the first thought when discussing infections and congenital anomalies. Besides toxoplasmosis, rubella, cytomegalovirus, herpes, and now Zika, the “other” infections of TORCHZ include syphilis, parvovirus B19 (case reports only of congenital anomalies), varicella-zoster, and human immunodeficiency virus. Syphilis and rubella are major causes of congenital anomalies in low-income countries. Congenital Zika syndrome is a new syndrome that has been described and can cause multiple anomalies. Intracerebral calcifications seen on ultrasound are suspicious for an intrauterine infection. Details are found in other chapters in this book.
- 1. Toxoplasmosis:** Microcephaly, intellectual disability, microphthalmia.
 - Rubella:** Microcephaly, IUGR, congenital cataracts, deafness, congenital heart disease, intellectual disability, microphthalmia.
 - Herpes simplex virus:** Hydranencephaly, chorioretinitis.
 - Syphilis:** Hydrocephalus, congenital deafness, intellectual disability.
 - Varicella:** Hydrocephalus, eye malformations, limb scarring and paresis, intellectual disability.
 - Human immunodeficiency virus:** Microcephaly, hypertelorism, growth failure, prominent forehead, microphthalmia.
 - Cytomegalovirus:** microcephaly, chorioretinitis, sensorineural hearing loss, hydrocephaly, intellectual disability.
 - Zika virus;** Severe microcephaly, hypertonia, congenital contractures, ocular abnormalities, decreased brain tissue and brain damage.

94 Congenital Heart Disease

The diagnostic dilemma of the newborn with congenital heart disease (CHD) must be resolved quickly because therapy may prove lifesaving for many of these infants. CHD occurs in approximately 1% of live-born infants. Nearly half of all cases of CHD are diagnosed during the first week of life, or now that fetal echocardiogram is becoming so widespread and available, diagnosis is made in utero (up to 70%). In patients with complex CHD, neonatal hospital mortality can be as high as 7%. These patients have a high frequency of multiple congenital anomalies, genetic syndromes, low birthweight, and prolonged length of stay. The most frequently occurring anomalies seen during this first week are patent ductus arteriosus, dextro-transposition of the great arteries, hypoplastic left heart syndrome (HLHS), tetralogy of Fallot, and pulmonary atresia.

I. Classification. Symptoms and signs in newborns with heart disease permit grouping according to levels of arterial oxygen saturation based on the hyperoxia test (see later in this chapter). Further classification (based on other physical findings, laboratory testing) facilitates delineation of the exact cardiac lesion present.

A. Cyanotic heart disease. Infants with cyanotic heart disease are usually unable to achieve a partial pressure of oxygen (PaO_2) of >100 mm Hg after breathing 100% inspired oxygen for 10 to 20 minutes (hyperoxia test).

B. Acyanotic heart disease. Infants with acyanotic heart disease achieve PaO_2 levels of >100 mm Hg under the same conditions as noted in Section I.A.

II. Cyanotic heart disease. See Figure 94–1. (See also Chapter 56, “Cyanosis.”)

A. Hyperoxia test. (See Chapter 56, pages 489 and 490.) Because of obligate total mixing, the newborn with cyanotic CHD (in contrast to the infant with pulmonary disease) is unable to raise the arterial saturation, even in the presence of increased ambient oxygen.

1. Determine partial pressure of oxygen while the infant is on room air by arterial blood gas.

2. Give 100% oxygen for 10 to 20 minutes by mask, hood, or endotracheal tube.

3. Obtain an arterial blood gas level while the infant is breathing 100% oxygen.

4. Interpret results. See page 490 for hyperoxia test interpretation.

B. Pulse oximetry screen. See also Chapter 7 and Figure 7–1, page 61. This is the test to screen for critical CHD that will require early intervention. It was endorsed by the US Department of Health and Human Services and American Academy of Pediatrics in 2011 as part of routine universal screening.

1. Determine pulse oximetry in right hand and foot in infants 24 to 48 hours of age.

a. If pulse oximetry is $<90\%$ in right hand or foot, this is a **positive screen** and further evaluation is needed.

b. If pulse oximetry is $>95\%$ in right hand or foot or there is a $\leq 3\%$ difference between right hand and foot, this is a **negative screen**.

c. If pulse oximetry is between 90% and 95% in right hand and foot or there is a $>3\%$ difference between right hand and foot, repeat in 1 hour. Can repeat up to 3 times; if these findings continue, further evaluation is needed.

C. Cyanosis. Care must be taken in evaluating cyanosis by skin color because polycythemia, jaundice, racial pigmentation, or anemia may make clinical recognition of cyanosis difficult (see Chapter 56).

D. Murmur. The infant with cyanotic CHD often does not have a distinctive murmur. The most serious of these anomalies may not be associated with a murmur at all.

Echo findings

- a: **Tetralogy of Fallot/Pulmonary Atresia with VSD**– A large VSD with an overriding aorta. The right ventricular outflow tract will be narrow with obstruction (complete in the case of pulmonary atresia with VSD). The branch pulmonary arteries will be small.
- b: **Tricuspid Atresia**– linear density in the location of the tricuspid valve.
- c: **Pulmonary Atresia with intact septum**– Imperforated pulmonary valve with no defect in the ventricular septum. These patients often have connections between the coronary arteries and ventricle which need to be delineated with angiography.
- d: **Ebstein Anomaly**– displacement of the tricuspid valve toward the apex, atrialization of the right ventricle so one may see dilation of the right atrium and a smaller right ventricle.
- e: **Total Anomalous Pulmonary Venous Connection (TAPVC)**– pulmonary veins do not drain to the left atrium. The pulmonary veins will drain to a confluence and can drain back to the right atrium in different ways: the confluence may drain directly to the right atrium through the coronary sinus (cardiac), to a vertical vein that drains to the left innominate vein and then to the SVC (supracardiac), or to a vein that then joins the portal vein, hepatic veins, or IVC (infracardiac). The pulmonary veins can be obstructed or nonobstructed which can give different findings on echo (beyond the scope of this text).
- f: **HLHS**– small left ventricle that does not extend to the apex. The endocardium often appears echo bright. The aortic valve may be patent. The mitral valve is often imperforate. The ascending aorta is small.
- g: **Truncus Arteriosus**– A single vessel arising from the heart. The pulmonary arteries can be seen originating from this single vessel as it is further examined. A ventricular septal defect can also be seen.
- h: **Transposition of the Great Vessels**– The great vessels will be in parallel with the posterior vessel demonstrating early branching typical of the pulmonary artery.
- i: **Aortic Stenosis/Pulmonic Stenosis**– thickened aortic/pulmonic valve leaflets. There will be restricted motion of the valve during systole and doming of the valve leaflets. One can measure the velocity of blood flow through the valve to quantify the severity of stenosis.
- j: **Coarctation of the Aorta**– Narrowing of the descending aorta just distal to the left subclavian artery.
- k: **AtrioVentricular Canal**– There are many variants but one should always see a defect in the inlet ventricular septum and inferior displacement of atrioventricular valves so valves are at the same level. The 4 chamber view will also allow visualizing the defect in the lower atrial septum. (there are many other echo characteristics noted in this defect but beyond the scope of this text.)

FIGURE 94–1. Cyanotic congenital heart disease ($\text{PaO}_2 < 100 \text{ mm Hg}$ in 100% FiO_2). ECG, electrocardiography; HLHS, hypoplastic left heart syndrome; LAD, left axis deviation; LVH, left ventricular hypertrophy; PDA, patent ductus arteriosus; PGE₁, prostaglandin E₁; RBBB, right bundle branch block; RVH, right ventricular hypertrophy; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; TI, tricuspid incompetence; TOF, tetralogy of Fallot; TS, tricuspid stenosis; VSD, ventricular septal defect.

- E. Other studies.** Cyanotic infants may be further classified based on pulmonary circulation on chest radiograph and electrocardiographic and echocardiographic findings.
- F. Diagnosis and treatment.** Figure 94–1 outlines the diagnosis and treatment of cyanotic heart disease.
- G. Specific cyanotic heart disease abnormalities**
- 1. Dextro-transposition of the great arteries.** This is the most common cardiac cause of cyanosis in the first year of life, with a male-to-female ratio of 1.5:1 to 3.2:1. The aorta comes from the right ventricle and the pulmonary artery from the left ventricle, with resultant separate systemic and pulmonary circuits. With modern newborn care, the 1-year survival rate is >90%.
 - a. Physical examination.** Typical infant is large and vigorous, with cyanosis but little or no respiratory distress. There may be no murmur or a soft, systolic ejection murmur.
 - b. Chest radiograph.** This study may be normal, but typically, it reveals a very narrow upper mediastinal shadow (“egg on a stick” appearance).
 - c. Electrocardiography.** There are no characteristic electrocardiography (ECG) findings.
 - d. Echocardiography is diagnostic.** Typical findings include branching of the anterior great vessel into the innominate, subclavian, and carotid vessels and branching of the posterior great vessel into the right and left pulmonary arteries.
 - e. Cardiac catheterization.** Like echocardiography, this study is diagnostic and often therapeutic, as outlined next.
 - f. Treatment.** If severe hypoxia or acidosis occurs, urgent balloon atrial septostomy can be done under echocardiogram guidance in the nursery. Cardiac catheterization with balloon septostomy and subsequent arterial switch operation are methods of treatment. Prostaglandin E₁ (PGE₁) may increase shunting and should still be initiated while awaiting definitive treatment.
 - 2. Tetralogy of Fallot.** Tetralogy of Fallot is characterized by 4 anomalies: pulmonary stenosis, ventricular septal defect, overriding aorta, and right ventricular hypertrophy (RVH). There is a slight male predominance. Cyanosis usually signifies complete or partial atresia of the right ventricular outflow tract or extremely severe pulmonary stenosis with hypoplastic pulmonary arteries. The degree of right ventricular outflow obstruction is inversely proportional to pulmonary blood flow and directly proportional to the degree of cyanosis. Tetralogy of Fallot with an absent pulmonary valve may present with respiratory distress or poor feeding (because of compression of the esophagus or bronchi by the large pulmonary arteries).
 - a. Physical examination.** The patient is cyanotic with a systolic ejection murmur along the left sternal border. Loud murmurs are associated with more flow across the right ventricular outflow tract and milder degrees of desaturation. Softer murmurs are associated with less flow and more hypoxia.
 - b. Chest radiograph.** The chest radiograph film reveals a small, often “boot-shaped” heart, with decreased pulmonary vascular markings. A right aortic arch is seen in approximately 20% of these infants, often associated with 22q11 microdeletion.
 - c. Electrocardiography.** The ECG may be normal or may demonstrate RVH. The only sign of RVH may be an upright T wave in V₄R or V₁ after 72 hours of age.
 - d. Echocardiography.** Usually diagnostic, with an overriding aorta, ventricular septal defect (VSD), and small right ventricular outflow tract.
 - e. Treatment.** Pulmonary blood flow may be ductal dependent with severe cyanosis and may respond to ductal dilation using PGE₁ (see dosing information in Chapter 155). This measure allows more flexibility for planning

cardiac catheterization and surgical correction. Surgery (possibly initially with shunting followed by total correction or just total correction) may be considered. Total surgical correction involves closure of the VSD and ensuring pulmonary blood flow is adequate through different methods (beyond the scope of this chapter).

3. **Truncus arteriosus.** Truncus arteriosus is characterized by a single artery that gives rise to systemic, pulmonary, and coronary arteries. There are different classifications based on how the pulmonary arteries originate from the single vessel (beyond the scope of this chapter). There is almost always a VSD associated with this defect, and the truncal valve is often abnormal.
 - a. **Physical examination.** Depends on the amount of pulmonary blood flow. If there is increased pulmonary blood flow, the infant will present with symptoms of heart failure (tachycardia, dyspnea, diaphoresis) and be acyanotic. If pulmonary blood flow is limited, then the infant will be cyanotic. Patients will usually have bounding pulses. A click followed by a systolic murmur is often heard with a loud single S_2 . A diastolic murmur may be appreciated if there is significant truncal insufficiency.
 - b. **Chest radiograph.** The chest radiograph typically reveals moderate cardiomegaly and increased pulmonary vascular markings. A right aortic arch is seen in up to 30% of these infants, often associated with 22q11 microdeletion.
 - c. **Electrocardiography.** There is usually a normal QRS axis, with possibly a minimal rightward axis and biventricular hypertrophy.
 - d. **Echocardiography.** Usually diagnostic with a single arterial vessel giving rise to all 3 blood supplies and a VSD.
 - e. **Treatment.** Surgical correction is necessary and is performed preferably in the first few weeks of life. If surgery is delayed, early pulmonary vascular disease and death can result. Surgical correction involves closure of the VSD, connection between the right ventricle and pulmonary arteries with a conduit, and potentially intervention on the truncal valve.
4. **Total anomalous pulmonary venous return.** Total anomalous pulmonary venous return is characterized by the pulmonary veins having no connection with the left atrium. There are different classifications based on how pulmonary venous flow returns to the heart (beyond the scope of this chapter) and whether or not the pulmonary veins are obstructed. For the majority of cases, there is no sex predilection. These patients can have associated syndromes including asplenia, polysplenia, and cat's eye syndrome.
 - a. **Physical examination.** Depends on whether there is associated pulmonary venous obstruction. Infants can be asymptomatic at birth with mild cyanosis that is difficult to assess (unobstructed) versus cyanotic and tachypneic (obstructed).
 - b. **Chest radiograph.** There is evidence of increased pulmonary blood flow. A "figure 8" or "snowman" appearance can be present when the pulmonary veins drain to the innominate vein (supracardiac), although this may not be seen in the neonate. The right heart can be enlarged in unobstructed venous return.
 - c. **Electrocardiography.** RVH is usually present. Rightward axis and right atrial enlargement may be seen.
 - d. **Echocardiography** will demonstrate no pulmonary venous return to the left atrium. Determining the pulmonary vein confluence and where this confluence drains to the heart can sometimes be a challenge.
 - e. **Treatment.** Surgical correction in infancy should be performed with redirection of pulmonary venous flow to the left atrium (technique depends on where pulmonary veins drain into).
5. **Single ventricle.** Because single-ventricle physiology is a complete mixing lesion, it can be considered as a cyanotic lesion, although infants may not be

obviously cyanotic. There are many variants including tricuspid atresia, unbalanced atrioventricular (AV) canal, and HLHS. Most of this discussion is beyond the scope of the chapter, but see later section on HLHS for more information on single-ventricle management/palliation.

III. Acyanotic heart disease (Figure 94–2)

A. Hyperoxia test. See Section II.A.

B. Murmur. The infant who is not cyanotic may have either a heart murmur or symptoms of congestive heart failure, or these may develop over time.

C. Diagnosis and treatment. See Figure 94–2.

D. Specific acyanotic heart disease abnormalities

1. Ventricular septal defect. The second most common congenital heart abnormality with equal sex distribution. Murmurs may be heard at birth but typically appear between 3 days and 3 weeks of age. Congestive heart failure is unusual before 4 weeks of age but may develop earlier in premature infants. Symptoms and physical findings vary with patient age and defect size. Spontaneous closure occurs in half of the patients. Surgical correction is reserved for large, symptomatic VSDs only.

2. Atrial septal defect. Not an important cause of morbidity or mortality in infancy. Occasionally, congestive heart failure can occur in infancy but not usually in the neonatal period, and rarely without additional cardiac or pulmonary abnormalities. Surgical correction is reserved for only large atrial septal defects (ASDs) and is usually not performed in the newborn period.

3. Endocardial cushion defects. Includes ostium primum–type ASD with or without a cleft mitral valve and an AV canal. These defects are commonly associated with multiple congenital anomalies, especially Down syndrome. If marked AV valve insufficiency is present, the patient may have congestive heart failure at birth or in the neonatal period.

a. Physical examination. On physical examination, a systolic murmur resulting from AV valve insufficiency may be heard. Cyanosis may be present but is often not severe. Infants with severe pulmonary arterial hypertension may have little or no murmur.

b. Chest radiograph. Variable findings may include a dilated pulmonary artery or a large heart secondary to atrial dilatation.

c. Electrocardiography. Left axis deviation (left superior vector) is *pathognomonic*; the PR interval may be long, or there may be an RSR' pattern in V_4R and V_1 .

d. Echocardiography. Usually diagnostic; the echocardiogram usually demonstrates a common AV valve with inlet VSD or a defect in the septum primum with an abnormal mitral valve. Subtype classifications exist but are beyond the scope of this text.

e. Treatment. Congestive heart failure is treated primarily with diuretics or angiotensin-converting enzyme inhibitors (or angiotensin receptor blockers), (for dosages, see Chapter 155); early cardiac catheterization with corrective surgery may be needed to prevent pulmonary vascular obstructive disease. Surgical correction involves closure of the ASDs and VSDs with creation of 2 AV valves (in the complete form; other forms may include reconstruction of the left AV valve).

4. Bicuspid aortic valve. The most common congenital heart defect. A cleft and a murmur may be appreciated. Unless there is significant stenosis or insufficiency associated with the valve, it rarely presents with complications in the neonatal period. However, it is heavily associated with 2 more severe congenital heart defects: coarctation of the aorta and Shone complex.

5. Coarctation of the aorta. Usually a discrete stenosis of the proximal thoracic aorta, although more widespread narrowing of the arch can occur. Clinical presentation will depend on severity and extent of narrowing.

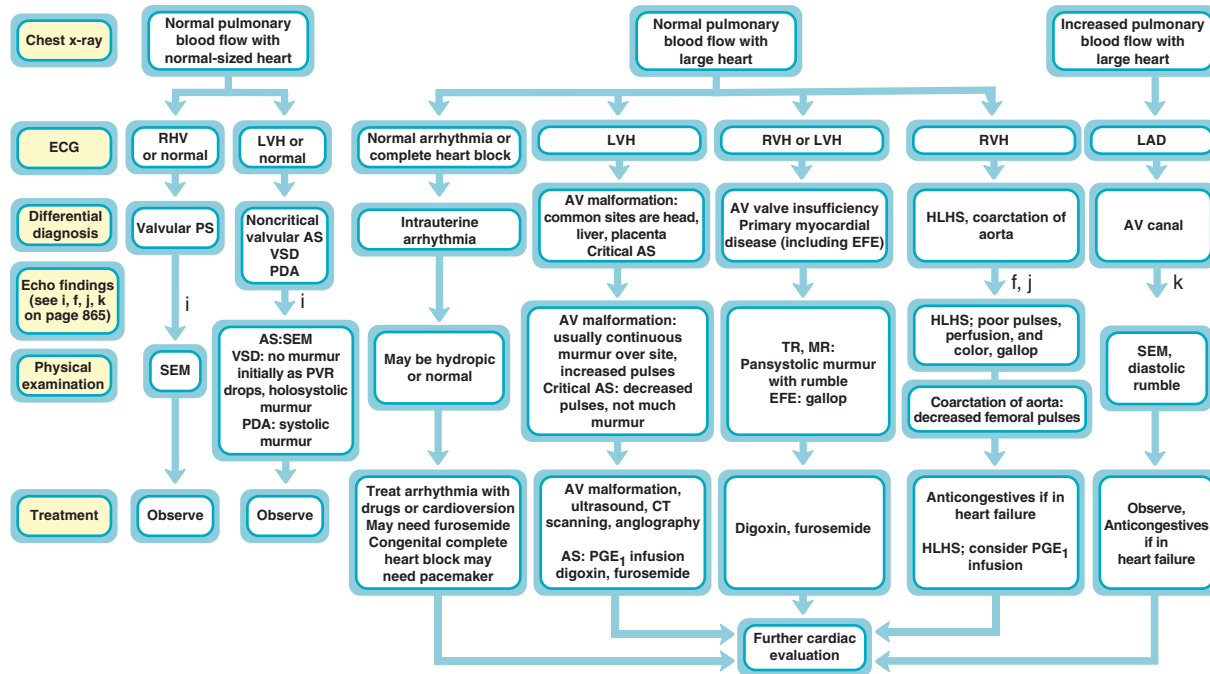

FIGURE 94-2. Acyanotic congenital heart disease ($\text{PaO}_2 > 100$ mm Hg in 100% FiO_2). AS, aortic stenosis; AV canal, atrioventricular canal; AV malformation, arteriovenous malformation; AV valve, atrioventricular valve; CT, computed tomography; ECG, electrocardiogram; EFE, endocardial fibroelastosis; HLHS, hypoplastic left heart syndrome; LAD, left axis deviation; LVH, left ventricular hypertrophy; MI, myocardial infarction; PDA, patent ductus arteriosus; PGE₁, prostaglandin E₁; PS, pulmonary stenosis; RVH, right ventricular hypertrophy; SEM, systolic ejection murmur; TI, tricuspid incompetence; VSD, ventricular septal defect.

- a. **Physical examination.** A systolic murmur resulting from the narrowing of the aorta will be present with radiation toward the back. Patients will have decreased pulses in the lower extremities. Pulse oximetry will have an increased difference between lower and upper extremity. If severe, newborns can present with heart failure with associated symptoms including tachycardia, dyspnea, diaphoresis, and hepatomegaly.
 - b. **Chest radiograph.** In infancy, this is nonspecific with findings of cardiomegaly and increased pulmonary vascular markings. Typical rib notching seen in older children is not seen in infants because collateral circulation is not yet developed.
 - c. **Electrocardiography.** Generally normal. In infancy, there may be increased right-sided forces and RVH. If the ECG shows left ventricular hypertrophy with a strain pattern, then aortic stenosis should be considered.
 - d. **Echocardiography.** Usually diagnostic; the echocardiogram usually demonstrates a narrowing of the arch just distal to the left subclavian artery.
 - e. **Treatment.** There are 3 different options for treatment including surgery, balloon angioplasty, or stent placement. In the newborn period, however, surgical intervention is standard.
- IV. Hypoplastic left heart syndrome.** Occurs in both cyanotic and acyanotic forms. In 15% of cases, the foramen ovale is intact and thus prevents mixing at the atrial level, causing cyanosis. Infants with mixing at the atria are acyanotic. HLHS accounts for 25% of all cardiac deaths during the first week of life.
- A. **Physical examination.** The infant is typically pale and tachypneic, with poor perfusion and poor to absent peripheral pulses. A loud single S_2 is present, usually with a gallop and no murmur. There is hepatomegaly, and metabolic acidosis is usually present by 48 hours of age.
 - B. **Electrocardiogram.** Demonstrates small or absent left ventricular forces.
 - C. **Chest radiograph.** Moderate cardiomegaly is present, often with a large main pulmonary artery shadow.
 - D. **Echocardiography.** A diagnostic study demonstrates a small or slit-like left ventricle with a hypoplastic ascending aorta.
 - E. **Treatment.** Systemic blood flow is ductal dependent; therefore, PGE_1 is of value. Oxygen should not be given, as the resultant dilatation of the pulmonary vessels increases pulmonary blood flow. Respiratory compromise and subsequent dilatation and reduced right ventricular function are undesired effects of oxygen administration. In fact, infants with HLHS and pulmonary overcirculation may require oxygen concentrations <21%. Frequent monitoring of blood gases and lactate is required preoperatively. Surgical correction is done in 3 stages. The first is palliation (the Norwood procedure), redirecting the blood flow so that the right ventricle serves as the “systemic ventricle” and a surgically constructed “shunt” provides pulmonary blood flow. Some surgeons prefer to do a Sano modification of the Norwood, which involves placing a Gore-Tex tube from the right ventricle to the main pulmonary artery. The second stage usually consists of a hemi-Fontan or bidirectional Glenn operation, routing superior vena cava blood to the lungs and closing the systemic-to-pulmonary artery shunt. The third stage (the Fontan procedure) directs the remaining systemic venous return directly to the pulmonary circulation. In the past decade, the “hybrid procedure” has become possible as an alternative to the stage 1 Norwood procedure for infants with HLHS or single-ventricle equivalent with multiple areas of left heart obstruction. Time will tell which procedure will become the operation of choice for these babies. Neonatal cardiac transplantation is another option, but shortage of organs is a significant deterrent. Compassionate care (keeping the infant comfortable until death) may be appropriate in select instances.
- V. Associated anomalies and syndromes (Table 94–1).** A discussion of heart disease in neonates would not be complete without the inclusion of common multiple congenital

Table 94–1. CONGENITAL ANOMALIES ASSOCIATED WITH HEART DEFECTS

Congenital Anomaly	Heart Defect
Chromosomal anomaly	
Trisomy 21 (Down syndrome)	Atrioventricular canal, ventricular septal defect
Trisomies 13, 15, and 18	Ventricular septal defect, patent ductus arteriosus
Syndrome associated with 4p–	Atrial septal defect, ventricular septal defect
Syndrome associated with 5p– (cri du chat syndrome)	Variable
X0 (Turner syndrome)	Coarctation of aorta, aortic stenosis
Syndromes with predominantly skeletal defects^a	
Ellis-van Creveld syndrome	Atrial septal defect, single atrium
Laurence-Moon-Biedl syndrome	Tetralogy of Fallot, ventricular septal defect
Carpenter syndrome	Patent ductus arteriosus, ventricular septal defect
Holt-Oram syndrome	Atrial septal defect, ventricular septal defect
Fanconi syndrome	Patent ductus arteriosus, ventricular septal defect
Thrombocytopenia–absent radius syndrome	Atrial septal defect, tetralogy of Fallot
Syndromes with characteristic facies^a	
Noonan syndrome (long arm of chromosome 12)	Pulmonary stenosis, atrial septal defect, hypertrophic cardiomyopathy
Chromosome 22q11 deletion (DiGeorge syndrome)	Tetralogy of Fallot, aortic arch anomalies, right aortic arch, vascular rings
Smith-Lemli-Opitz syndrome	Ventricular septal defect, patent ductus arteriosus
Cornelia de Lange syndrome	Tetralogy of Fallot, ventricular septal defect
Goldenhar syndrome	Tetralogy of Fallot, variable
Williams syndrome	Supravalvular aortic stenosis, peripheral pulmonary artery stenosis
Asymmetric crying facies	Variable

^aNot all infants with these syndromes have heart defects.

anomaly syndromes associated with heart defects. Often, recognition of multiple congenital anomaly syndromes facilitates identification of the heart defect. Syndromes that tend to present after the newborn period have not been included. See Chapter 93 for a complete discussion of anomalies and syndromes.

VI. Teratogens and heart disease. Several teratogens associated with CHD have been identified (Table 94–2), although there is not a 100% relationship between exposure and heart defects. A history of teratogen exposure may help in the diagnosis.

VII. Abnormal situs syndromes. Syndromes of abnormal situs are associated with CHD. For example, an infant with situs inversus totalis and dextrocardia has the same incidence of CHD as the general population. If, however, there is disparity between thoracic and abdominal situs, the incidence of CHD is >90%. (Check the chest radiograph to see that the cardiac apex and the stomach bubble are on the same side. Both should

Table 94–2. TERATOGENS ASSOCIATED WITH HEART DEFECTS

Teratogen	Heart Defect
Drugs	
Alcohol	Ventricular septal defect, tetralogy of Fallot, atrial septal defect
Anticonvulsants	Variable, ventricular septal defect, tetralogy of Fallot
Retinoic acid	Aortic arch anomalies
Lithium	Ebstein anomaly of the tricuspid valve
SSRIs	Slightly increased risk septal defects
Environmental agents	
Irradiation	Variable
High altitude	PDA; others variable
Maternal factors	
Diabetes	Variable
Maternal lupus	Complete (third-degree) AV block
Maternal PKU	Ventricular septal defect, coarctation
Infections	
Rubella syndrome	PDA, peripheral pulmonary stenosis
Parvovirus, coxsackie	Cardiomyopathy
Other viruses	Variable

AV, atrioventricular; PDA, patent ductus arteriosus; PKU, phenylketonuria.

be on the left.) Some of these syndromes involve bilateral left-sidedness (2 bilobed lungs or multiple spleens) and complex cyanotic CHD, whereas others have bilateral right-sidedness (2 trilobed lungs or an absent spleen) and complex cyanotic CHD.

VIII. Other imaging modalities

A. Fetal echocardiography

1. **General considerations.** Fetal echocardiography is now possible in many centers. The optimal gestational age to perform echocardiography is between 18 and 20 weeks when structural abnormalities and arrhythmias can be detected. This is being pushed earlier with developing technology. Some centers are performing fetal echocardiograms as early as 8 to 12 weeks. With early detection of cardiac abnormalities, arrangements can be made for delivery at a center with pediatric cardiac and surgical facilities that can possibly affect neonatal mortality. If the anomaly is not consistent with life, some families may elect termination of pregnancy.
2. **Indications for fetal echocardiography**
 - a. **Maternal factors.** Oligohydramnios or polyhydramnios, diabetes, collagen vascular disease, maternal drug/teratogen exposure, or a previous child with CHD.
 - b. **Fetal factors.** Suspected cardiac abnormality on obstetric ultrasound examination, pleural fluid, pericardial fluid, fetal hydrops, heart rate abnormalities, fetal growth restriction, or other abnormality on obstetric ultrasound examination.
 - c. **Genetic factors.** Familial history of chromosomal disorders or CHD.

B. Magnetic resonance imaging/computed tomography. Although magnetic resonance imaging (MRI) is enjoying increasing utility in the identification of CHD in children, MRI of the neonatal heart is of limited availability. The rapid heart rate of neonates makes gating for image acquisition difficult but not impossible. It does require intubation and anesthesia. Computed tomography (CT) and CT angiography (CTA) may help identify anomalies of pulmonary venous return. CTA has become the gold standard of evaluation of vascular rings, but these do not usually present in the immediate neonatal period.

IX. General principles of management

- A. Emergency therapy.** Once the specific lesion has been identified as emergent, a decision about therapy must be made. As an example, if confronted with a very cyanotic infant with no murmur, a normal chest radiograph, and a normal ECG and it is believed that the diagnosis of dextro-transposition of the great arteries is likely, it is necessary to prepare for a **balloon septostomy**.
- B. Prostaglandins.** As a general principle, if an infant is cyanotic and has decreased pulmonary blood flow, the PaO₂ will be improved by promoting flow through the ductus arteriosus via a drip of **prostaglandin E₁** (alprostadil or Prostin VR Pediatric). Maintaining patency of the ductus may enable stabilization of the infant and subsequent catheterization or surgery to be planned on an urgent rather than emergent basis. Similarly, if poor peripheral pulses and acidosis from poor perfusion are present, infusion of prostaglandin, using the same dose, may reopen the ductus arteriosus and allow right ventricular blood flow to augment the systemic circulation. This measure is beneficial in critical aortic stenosis, coarctation of the aorta, and HLHS. (For dosage information, see Chapter 155.)
- C. Antiarrhythmic drugs.** Rapid arrhythmias may occur during intrauterine life or after delivery (see full discussion in Chapter 53). Arrhythmias are a cause of fetal hydrops and intrauterine death; most often, the rhythm disturbance is a rapid supraventricular tachycardia with a 1:1 ventricular response. Occasionally, atrial flutter with 2:1 block presents before or just after birth. Some antiarrhythmia medications given to mothers can cross the placenta, enabling fetal treatment. **Digoxin, flecainide, sotalol, and propranolol** have been successful antiarrhythmic agents in newborns, but treatment with adenosine or electrical cardioversion (see Chapter 32) is also sometimes necessary. Digoxin is contraindicated in Wolff-Parkinson-White syndrome.
- D. Pacemaker.** Fetal hydrops can result from congenital complete heart block. If cardiovascular demise is imminent, delivery and **temporary transvenous ventricular pacing may be lifesaving**. It should be followed by urgent surgical placement of a permanent pacemaker. Mothers may have anti-Rho or anti-LA antibodies.
- E. Other considerations.** Optimal care of the infant prior to and immediately after heart surgery determines overall outcome. A perfectly executed corrective procedure cannot succeed without support of the infant postoperatively. Drugs that manipulate pulmonary vascular resistance (nitric oxide, sildenafil, oxygen) and have a favorable influence on cardiac output and its distribution are required more often than not. Milrinone as an afterload reducer is often used and can be transitioned to the oral enalapril. Nesiritide (Natrecor), a recombinant form of human B-type natriuretic peptide, has both vasodilation and diuretic properties and can be safely used for shorter periods of time than milrinone. Levosimendan, a calcium-sensitizing agent, has inotropic and vasodilator effects. Studies with small numbers of infants/neonates have, to date, shown no advantage of levosimendan over milrinone in low cardiac output states following open-heart surgery. Milrinone use after surgical ductal ligation treats hemodynamic instability, facilitating central nervous system and gut perfusion.

95 Disorders of Sex Development

- I. **Definition.** Atypical genitalia are present when the sex of an infant is not readily apparent after examination of the external genitalia. If the appearance resembles neither a male with a normal phallus and palpable testes nor a female with an unfused vaginal orifice and absence of an enlarged phallic structure, the genitalia are atypical, and investigation before gender assignment is indicated. These conditions are now referred to as **disorders of sex development** (DSDs, more recently also as **differences in sex development**). The term **atypical genitalia** instead of *ambiguous genitalia* has been suggested. Definitions and classifications are very complex; for the purpose of this on-call manual, the embryology and pathophysiology are only reviewed as relevant to the initial evaluation and treatment of neonatal patients.
- II. **Incidence.** The quoted incidence of atypical genitalia varies according to the source and definition, and it can vary for different ethnic groups; it appears to be around 1 in 5000. Congenital adrenal hyperplasia is often considered the most common cause, followed by androgen insensitivity and mixed gonadal dysgenesis. Hypospadias has a frequency of about 1 in 300 births, but only a minority of these patients have DSDs (usually presenting with hypospadias in combination with cryptorchidism).
- III. **Embryology.** The early fetus, regardless of the genetic sex (XX or XY), is bipotential and can undergo either male or female differentiation. The innate tendency of the embryo is to differentiate along female lines.
 - A. **Development of the gonads.** Gonadal development occurs during the embryonic period (the third through the eighth week of gestation).
 1. **Testicular differentiation.** Gonadal differentiation is determined by the absence or presence of the Y chromosome. If the **Y chromosome** (more specifically, the sex-determining region of the Y or *SRY* gene) is present, the gonads differentiate as testes. The testes then produce and release testosterone, which is converted to dihydrotestosterone (DHT) in the target organ cells by 5 α -reductase. DHT induces male differentiation of the external genitalia (see Section III.B.1). The testes descend behind the peritoneum and normally reach the scrotum by the eighth or ninth month.
 2. **Ovarian differentiation.** In the female fetus, where the Y chromosome/*SRY* gene is absent, the gonads form ovaries (even in 45,X Turner syndrome, histologically normal ovaries are present at birth). As ovaries do not produce testosterone, female differentiation proceeds. Two X chromosomes are needed for differentiation of the primordial follicle. If part or all of the second X chromosome is missing, ovarian development fails, resulting in atrophic streaky gonads by 1 to 2 years of age.
 - B. **Development of external genitalia.** This part of sexual differentiation occurs in the fetal period, beginning in the eighth week of gestation, and proceeds up to the 14th week.
 1. **Normal male.** At approximately 9 weeks of postconceptional age, in the presence of systemic androgens (especially DHT), masculinization begins with lengthening of the anogenital distance. The urogenital and labioscrotal folds fuse in the midline (beginning caudally and progressing anteriorly), leading to the formation of the scrotum and the penis.
 2. **Normal female.** In the female fetus, the anogenital distance does not increase. The urogenital and labioscrotal folds do not fuse and instead differentiate into the labia majora and minora. The urogenital sinus divides into the urethra and the vagina.

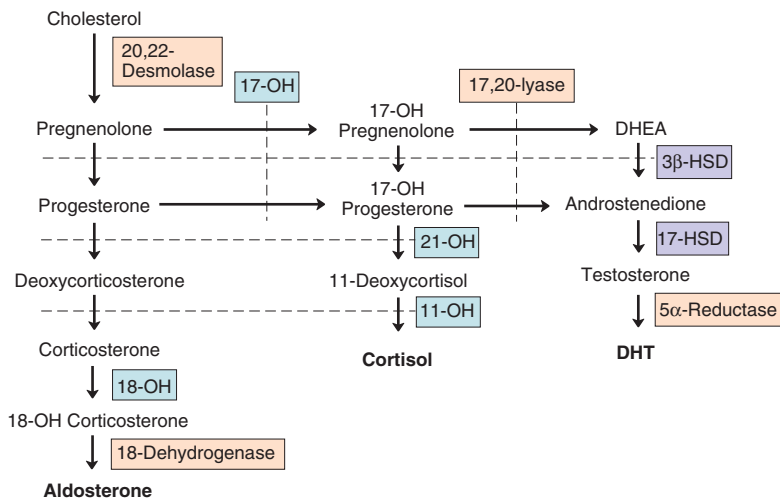

FIGURE 95–1. Adrenal metabolic pathways relevant to normal sex development. 11-OH, 11-hydroxylase; 17-OH, 17-hydroxylase; 18-OH, 18-hydroxylase; 21-OH, 21-hydroxylase; 3β-HSD, 3β-hydroxysteroid dehydrogenase; 17-HSD, 17-hydroxysteroid dehydrogenase (17-ketosteroid reductase); DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone.

IV. Pathophysiology

A. Virilization of female infants (female pseudohermaphroditism). Many neonates with DSDs belong to this group. They have a 46,XX karyotype, are *SRY* negative, and have exclusively ovarian tissue. The degree of masculinization depends on the potency of the androgenic stimulation, the stage of development at the time of initial exposure, and the duration of exposure.

- 1. The most common cause of excess fetal androgens** is an autosomal recessively inherited **enzymatic deficiency in the cortisol pathway**, leading to excessive corticotropin (adrenocorticotropic hormone [ACTH]) stimulation with **congenital adrenal hyperplasia (CAH)** and excessive production of adrenal androgens (dehydroepiandrosterone and androstenedione) and testosterone (Figure 95–1). Most common is **21-hydroxylase deficiency**, which causes inadequate cortisol levels, leading to excessive ACTH stimulation (through feedback to the hypothalamus and pituitary), adrenal hyperplasia, and excessive production of adrenal androgens (dehydroepiandrosterone and androstenedione) and testosterone, producing virilization. **Two forms of CAH are seen in neonates, depending on the associated relative or absolute aldosterone deficiency: a simple virilizing form and a salt-losing form.** In the first form, the salt loss is mild and adrenal insufficiency tends not to occur, except in stressful circumstances. In the second, adrenal insufficiency occurs under basal conditions and tends to manifest in the neonatal period or soon thereafter as an adrenal crisis. The electrolyte status of all infants with 21-hydroxylase deficiency should be monitored because the extent of virilization is not a reliable indicator of the degree of adrenal insufficiency. **11-Hydroxylase enzyme deficiency** is less common and associated with salt retention, volume expansion, and hypertension.
- 2. Other, less common causes.** Virilizing maternal or fetal tumors or maternal androgen ingestion or topical use.

B. Inadequate virilization of male infants (male pseudohermaphroditism). This condition is caused by inadequate androgen production or incomplete end-organ response to androgen. These patients have a 46,XY karyotype and exclusively testicular tissue. These abnormalities are rare, and most require extensive laboratory investigation before an exact diagnosis can be determined.

1. Decreased androgen production. This can be caused by 1 of several rare enzyme defects that are inherited (autosomal recessive). Some of these defects also cause cortisol deficiency and **nonvirilizing adrenal hyperplasia**, and others are specific to the testosterone pathway. Other causes of decreased androgen production include **deficiency of Müllerian-inhibiting substance** (the most common presentation is a male infant with inguinal hernias that contain a uterus or fallopian tubes); **testicular unresponsiveness to human chorionic gonadotropin (hCG) and luteinizing hormone (LH)**; and **anorchia** (absent testes caused by loss of vascular supply to the testis during fetal life). Presence of **microphallus/micropenis** and **hypoglycemia** suggests a **pituitary deficiency** with absence of gonadotropins, ACTH, and/or growth hormone.

2. Decreased end-organ response to androgen. Also referred to as **testicular feminization**, can be caused by a defect in the androgen receptor or an unknown defect with normal receptors. It can be total (labial testes with otherwise normal-appearing female genitalia) or, more commonly, partial (incomplete virilization of a male).

3. 5 α -Reductase deficiency. Results in failure of the external genitalia to undergo male differentiation because of the lack of DHT (see Figure 95-1). The outcome is a neonate with a 46,XY karyotype and female or atypical genitalia with internal testes and male ducts.

C. Disorders of gonadal differentiation

1. True hermaphroditism. The presence of both a testis and an ovary (or ootestes) in the same individual is a rare cause of atypical genitalia. Most individuals with true hermaphroditism have a 46,XX karyotype, but mosaics of 46,XX/45,X/46,XY/multiple X/multiple Y have all been reported. The appearance of the genitalia is variable.

2. Gonadal dysgenesis

a. Pure gonadal dysgenesis. Characterized by the presence of a streak gonad bilaterally (complete gonadal dysgenesis) or unilaterally (partial gonadal dysgenesis). It is important to distinguish the X-chromosomal from the Y-chromosomal form because the streak gonads in Y-positive patients carry a significant **risk for tumor development**.

b. Mixed gonadal dysgenesis. Characterized by the presence of a unilateral functioning testis and a contralateral streak gonad. All patients have a Y chromosome and some degree of virilization of the external genitalia; there is a high risk of **gonadal malignancy** in mid to late childhood.

D. Chromosome abnormalities, syndromes, and associations. Chromosomal abnormalities infrequently lead to atypical genitalia. However, disruption of normal sex development has been reported occasionally in **trisomies 13 and 18, triploidy, and a number of other chromosomal anomalies**. Note that Klinefelter and Turner syndromes (47,XXY, 45,X, and variants) are DSDs but are asymptomatic in newborns in regard to genital appearance. At least 90 single-gene disorders and syndromes have been associated with atypical genitalia. The list includes **Smith-Lemli-Opitz syndrome, Rieger syndrome, CHARGE syndrome** (coloboma, heart defects, choanal atresia, retarded growth and development, genital abnormalities, and ear anomalies), and **camptomelic/campomelic dysplasia**; atypical genitalia can be present in patient with **VATER/VACTERL association** (vertebral, anal, tracheal, esophageal, renal dysplasia, cardiac malformations, and limb abnormalities).

- V. **Risk factors.** The etiology of DSDs is mainly developmental/genetic. Behavioral risk factors (eg, excessive exposure to androgens) are rare; a history of relatives with genital anomalies, abnormal pubertal development, infertility, or neonatal/infant deaths could be relevant. The potential association of assisted reproduction, especially in vitro fertilization with intracytoplasmic sperm injection, with DSDs and other birth defects remains **controversial**; the underlying cause of infertility may be more pertinent than the process of assisted reproduction.
- VI. **Clinical presentation.** In 2006, after an International Consensus Conference on Intersex, a “Consensus Statement on the Management of Intersex Disorders” was published; there have been recent revisions and updates (see Selected References).
- A. **History.** Any **family history** of neonatal or early infancy deaths (death accompanied by vomiting and dehydration may be secondary to CAH) or female relatives with amenorrhea and infertility (male pseudohermaphroditism or chromosomal anomalies) is relevant, as are **consanguinity** of the parents (increased risk for autosomal recessive disorders) and **maternal history** of virilization or CAH and ingestion or topical use of drugs during pregnancy (particularly androgens or progestational agents).
- B. **Physical examination**
1. **General examination.** Note presence of any of the following: dysmorphic features (syndromes and chromosomal abnormalities), hypertension or hypotension, areolar hyperpigmentation, and signs of dehydration (as signs of CAH).
 2. **Genitalia.** The number, size, and symmetry of gonads should be evaluated. Palpable gonads below the inguinal canal are usually testes. Ovaries are not found in scrotal folds or in the inguinal region. However, testes may be intra-abdominal. **Phallus length:** Measured from the pubic ramus to the tip of the glands, a stretched penile length in a full-term infant should be ≥ 2.0 cm. Reference values for premature infants have been established; ethnic background may influence penile length. **Urethral meatus:** Look for hypospadias (usually accompanied by chordee). **Labioscrotal folds:** Labia majora are normally unfused but may show variable degrees of posterior fusion; the presence of a vaginal opening or urogenital sinus should be determined. The scrotum is normally fused or may be bifid.
- VII. **Diagnosis**
- A. **Laboratory studies**
1. **Initial evaluation.** An important test in the initial evaluation is the **chromosome analysis** (traditional cytogenetic analysis or array technology). **Fluorescent in situ hybridization techniques** allow for fast determination of the sex chromosome status using X- and Y-specific probes. Buccal smears are unreliable and obsolete. Further diagnostic evaluation depends on the sex chromosome status. Blood for **basic biochemical studies** can be obtained at the same time as the karyotype, including 17-hydroxyprogesterone (17-OHP), testosterone, DHT, sodium, and potassium levels. Further tests may be indicated and are discussed below in the context of the different chromosomal constellations.
 2. **Normal 46,XX karyotype.** This finding implies virilization of a genetic female and is caused by excessive maternal or fetal androgen. If the mother is not virilized, the infant most likely has **virilizing adrenal hyperplasia**; to confirm the diagnosis, measure:
 - a. **17-Hydroxyprogesterone.** This is the immediate precursor to the enzyme defect in 21-hydroxylase enzyme deficiency and a precursor 1 step further removed in 11-hydroxylase enzyme deficiency. In infants with either defect, serum or plasma levels of 17-OHP will be 100 to 1000 times the normal infant level. Because 17-OHP levels may be elevated some in normal infants within the first 24 hours of life, a repeat level several days later may

be indicated while fluid status and electrolytes are monitored. Newborn screening programs in the United States and elsewhere use 17-OHP for CAH screening.

- b. Electrolyte monitoring.** Infants with 21-hydroxylase enzyme deficiency usually have relative or absolute aldosterone deficiency and begin to demonstrate hyperkalemia at days 3 to 5 and hyponatremia 1 to 2 days later. If hyperkalemia becomes clinically significant before the 17-OHP result is available, empirical treatment with intravenous saline, cortisol, and fludrocortisone may be needed (for dosages, see Section VIII.B.1.a and b).
- c. Serum testosterone.** About 3% of infants with atypical genitalia are true hermaphrodites (most have a 46,XX karyotype). Without elevation of 17-OHP and in absence of maternal virilization, a high testosterone level suggests hermaphroditism or a fetal testosterone-producing tumor.
- 3. Normal 46,XY karyotype.** The differential diagnosis of an **incompletely virilized genetic male** is extremely complex and includes in utero testicular damage, defects of testosterone synthesis, end-organ resistance, and an enzymatic defect in the conversion of testosterone to DHT. The laboratory evaluation is correspondingly complex and usually proceeds through a number of steps.
- a. Testosterone and dihydrotestosterone.** These hormone levels should be measurable and are higher in newborns than later in childhood. In the male pseudohermaphrodite, testosterone is low in any defect in testosterone production. The testosterone-to-DHT ratio should be between 5:1 and 20:1 when expressed in similar units. A high testosterone-to-DHT ratio suggests 5 α -reductase deficiency (see also Section VII.A.3.c). **Androstenedione** levels are measured to diagnose **17-ketosteroid reductase deficiency**.
- b. Luteinizing hormone and follicle-stimulating hormone.** These hormones are also higher in infancy than they are in childhood. A diagnosis of gonadotropin deficiency is suspected if these values are low in a reliable assay but can be confirmed in infancy only if there are **other pituitary hormone deficits** (see Section VII.A.3.d). Note that growth hormone and ACTH deficiency may manifest in the newborn period as **hypoglycemia**. In primary gonadal defects and some androgen-resistant states, LH and follicle-stimulating hormone are elevated.
- c. Human gonadotropin stimulation test.** Administration of hCG to assess the stimulation of gonadal steroid production when testosterone values are low (as in gonadotropin deficiency or a defect in testosterone synthesis). Specifics are beyond the scope of this manual; the test should be performed under the guidance of a specialist. Gonadal response to hCG is assessed: a rise in the testosterone level confirms the presence of Leydig cells and, by implication, testicular tissue. In patients with 5 α -reductase deficiency, the basal testosterone-to-DHT ratio may be normal but elevated after hCG stimulation. Other steroid intermediates may be measured as per request of the specialist involved.
- d. Assessment of pituitary function.** If gonadotropin deficiency due to impairment of pituitary function is suspected (eg, microphallus/micropenis combined with hypoglycemia), thyroid function tests, growth hormone levels, ACTH stimulation test, and imaging studies of the pituitary gland may be indicated.
- 4. Abnormal karyotype.** Mixed gonadal dysgenesis with a dysplastic gonad may be present in infants with abnormal karyotype and atypical genitalia. Hormone studies are unlikely to be revealing in this scenario. **Conventional karyotypes, fluorescent in situ hybridization, and microarray analysis** are often used initially; note that a normal karyotype from peripheral white blood cells does not

exclude tissue mosaic chromosomal abnormalities. Recently, **DNA panels and genomic analysis** play an increasing role in the diagnosis of DSDs. Genetic analysis allows detection of *SRY* gene material in 46,XX phenotypic males and can determine whether Y material is present in a 45,X individual, placing the patient at risk for gonadoblastoma.

B. Radiographic studies

1. **Ultrasonography** to evaluate adrenal and pelvic structures. Although a uterus is sometimes palpable on rectal examination shortly after birth (because of enlargement in response to maternal estrogen), ultrasonography is more reliable and less invasive. Although ultrasonography does not always provide definitive answers, when the structures are found, it can confirm the presence and localization of gonads. Adrenal ultrasonography is sufficiently sensitive to determine adrenal abnormalities in the majority of patients with untreated adrenal hyperplasia.
2. **Contrast studies** to outline the internal anatomy (sinography, urethrography, vesico-cysto-ureterography, and intravenous urography) may be indicated in complex cases and before reconstructive surgery.
3. **Magnetic resonance imaging** has been used to evaluate patients with DSDs, but, at least in the neonatal period, sensitivity may only be marginally improved over ultrasound.

VIII. Management

- ### A. General considerations.
- The presence of any DSD is likely to cause significant emotional and social stresses and anxieties for the family. It is very important to protect the privacy of child and parents while diagnostic studies are in progress. A multidisciplinary team should assist the patient and family throughout the diagnostic process and beyond. Once a diagnosis has been established, gender should be assigned (see Section IX) and a team of specialists should supervise medical treatment (eg, steroid replacement, gonadal removal, reconstructive surgery) and treatment of psychosocial aspects. **Circumcision should be delayed in any infant with a DSD until completion of multidisciplinary evaluation and gender assignment.**

1. **Early interactions with the parents and general care.** As soon as atypical genitalia are noted, a senior physician responsible for the infant should be notified and the parents should be informed. During the initial counseling of the family, gender-neutral terms such as “your infant” should be used; gender-specific pronouns should be avoided. A phrase often recommended in this situation is to refer to the genitalia as “incompletely developed.” Parents should be informed that it is not possible without further tests to identify the sex of their child. Meet with the parents as soon as possible to discuss the situation in more detail (the delivery room is usually not appropriate for an in-depth discussion). The feelings, impressions, and biases perceived at the time parents first learn about the diagnosis of a sex differentiation disorder often persist. Examining the infant together with the parents may be beneficial, but any attempts to identify the sex of the child on the basis of appearance should be resisted, although there may be pressures to do so from parents, relatives, and hospital personnel. It is important not to complete the birth certificate or make any reference to gender in any of the permanent medical records of the mother or the child. It may be advisable to isolate the child and parents from the inquiries of certain nonessential hospital personnel and the community, but any actions implying that the condition is shameful or should be “hidden” must be avoided. Parents may want to delay sending out birth announcements and telling anyone outside the immediate family that the infant has been born until a gender assignment has been made. Be aware that many children live the majority of their lives in the community of their birth, and confusion about gender assignment because of premature release of information may

have long-term consequences. Parents should be reassured that in most cases the gender will be determined as soon as test results are available, and some specialists discourage the assignment of unisex/epicene names in the early neonatal period.

2. **Early referral.** It is advisable to seek consultation from a specialist in the evaluation of children with DSDs (the first specialist involved is often a pediatric endocrinologist) as soon as feasible. It is usually not appropriate to discharge a child from the nursery before a detailed evaluation is done. In most cases, a complete diagnosis, assignment of the sex of rearing, and a plan for future treatment can be accomplished before discharge.

B. Medical management in the neonatal period and early infancy

1. **Congenital adrenal hyperplasia.** The question of whether a neonate with atypical genitalia has CAH needs to be addressed quickly as the onset of adrenal insufficiency occurs between days 3 and 14 in 50% of affected patients. All forms of adrenal hyperplasia have absolute or relative cortisol deficiency and require early diagnosis and replacement therapy to prevent potential life-threatening complications such as vascular collapse.

- a. **Glucocorticoid therapy.** Should be initiated as soon as possible. Maintenance cortisol replacement therapy is often given orally. **Hydrocortisone** is the oral preparation of choice. Initial doses usually range from 10 to 20 mg/m²/d given as 3 divided doses and often require adjustments for growth and during periods of stress. Alternatively, intramuscular **cortisone acetate** is sometimes used in children <6 months of age out of concern that oral hydrocortisone may be absorbed erratically in young infants. Supervision of replacement therapy and long-term follow-up with a pediatric endocrinologist are advised; institutional practices may vary.

- b. **Mineralocorticoid therapy.** Fludrocortisone acetate at a dose of 0.05 to 0.1 mg daily (given orally) is often used. Unlike hydrocortisone, the dose of fludrocortisone does not change with increase of body size or during stress. Some endocrinologists also recommend sodium supplementation (1–5 mEq/kg/d).

- c. **Incompletely virilized genetic male.** Treatment with **depo-testosterone** might be considered by the team of specialists depending on the results of the diagnostic evaluation.

- #### **IX. Prognosis, gender assignment, long-term care.** Discussion surrounding issues of gender assignment are beyond the scope of this book. In general, the sex of rearing should be determined only after diagnostic evaluation by a specialist team. In the past, gender assignment had been approached as though individuals are psychosexually neutral at birth and as though healthy psychosexual development is related to the appearance of the external genitals. It is now believed that prenatal and early exposure of the brain to androgens, if present, influences gender-specific behavioral patterns and sexual identity in addition to the external appearance of the genitalia or their future function. Considering the significance of the decision for the affected patient's emotional, physical, and reproductive health, a highly specialized multidisciplinary team of pediatricians, urologists, endocrinologists, geneticists, psychiatrists, and others is needed, and each case must be approached individually. Specialized treatment centers should provide long-term care to optimize care and prognosis. The Consortium on Disorders of Sex Development maintains a website with clinical guidelines and information for families (www.dsdguidelines.org; accessed September 14, 2018), as do many other support groups such as the Intersex Society of North America (www.isna.org; accessed September 14, 2018), the Congenital Adrenal Hyperplasia Support and Education Foundation (www.caresfoundation.org; accessed September 14, 2018), and others.

96 Eye Disorders of the Newborn

- I. **Visual development.** Newborns are born with poor visual acuity, measuring 20/600 at birth, which then improves to 20/120 by 3 months and to 20/60 by 6 months of age. Binocularity begins developing by 3 to 4 months of age, and the ability to distinguish color begins at 5 months. The visual system does not reach maturity until 9 to 10 years of age. The time of development and plasticity between birth and visual maturity is known as the critical period, the time during which proper vision must develop in order to have normal visual acuity and binocular vision. Alterations or impediments to the image projected onto the retina profoundly affect visual development and can lead to vision-threatening and blinding diseases. It is, therefore, essential to identify such degradations early to prevent poor visual outcomes. Most vision loss is preventable or reversible with the right intervention for the individual etiology. The recovery depends on the maturity of the visual connections, the length of deprivation, and the age at which therapy is begun.
- II. **Eye examination.** The newborn eye examination is essential for identifying potentially blinding eye diseases early in life and to prevent permanent vision loss or impairment. The goal of the examination is to identify sight- and eye-threatening conditions such as orbital tumors, abnormal eyelid position or function, strabismus, cataracts, corneal opacities, congenital malformations, and retinal abnormalities, prompting referral to a pediatric ophthalmologist (see also Chapter 7).

The American Academy of Pediatrics recommends an age-appropriate assessment in the newborn period. Infants at high risk of eye problems (eg, those with prematurity, significant neurologic or developmental delays, metabolic or genetic diseases, positive family history of blinding eye diseases, any systemic diseases associated with eye abnormalities) should be referred for a specialized eye examination by a pediatric ophthalmologist. Normal findings that resolve include edema, lid eversion, bruising, subconjunctival hemorrhage, and nevus simplex. Any unexpected abnormalities on examination should be referred.

- A. **Ocular and family history.** A full history of family eye diseases should be obtained, including history of congenital cataracts, retinoblastoma, and hereditary retinopathies.
- B. **Vision assessment.** Even as a newborn, an infant will blink in response to a penlight; this reflex should be equal in both eyes. The ability to fixate on and follow an object, however, may not be present for the first few months of life.
- C. **External exam.** External inspection of the eyes (conjunctiva, sclera, cornea, and iris) and lids should be performed to identify congenital or acquired anomalies. The lids should be completely formed without deformity, ptosis, or retraction. The cornea should be clear and 9.5 to 10.5 mm in diameter. The iris should be present, and the color should be uniform and equal in both eyes. Subconjunctival hemorrhage and eyelid edema and ecchymosis may be present and usually resolve without intervention.
- D. **Motility.** Transient binocular nystagmus is common in infants <6 months, but monocular or constant nystagmus should prompt referral. Intermittent strabismus is also common in infants <6 months, but poor motility of the eye muscles or large, constant eye deviations should prompt referral.
- E. **Pupil examination.** The pupillary light response is present in newborns of 31 or more weeks' gestation. Newborn pupils are small as the pupillary reflex is still underdeveloped until age 5 months, but they should be equal, round, and reactive to light.
- F. **Red reflex.** A bright direct ophthalmoscope should be used to evaluate the red reflex of both eyes simultaneously in a darkened room. The reflex should be equal, bright reddish-yellow, or light gray in brown-eyed infants, with no opacifications.

III. Eye disorders

A. Anophthalmos/microphthalmos

1. **Definition.** Anophthalmos is absence of ocular tissue in the orbit. Microphthalmos describes an eye that measures <15 mm in diameter after birth.
2. **Incidence.** The prevalence of anophthalmos and microphthalmos is generally estimated to be 3 and 14 per 100,000 births, respectively. The combined prevalence may be up to 30 per 100,000 births.
3. **Pathophysiology.** Anophthalmos is caused by either failure of development of optic vesicle or regression after initiation of vesicle development and may occur in isolation or as part of a syndrome.
4. **Risk factors.** Advanced maternal age, multiple births, prematurity, and low birthweight.
5. **Clinical presentation.** Either the presence of no eye tissue or a small orbit defines the condition. Diagnosis is made by inspection, palpation, and imaging. Ultrasound is commonly used to determine length of the globe in microphthalmia. Computed tomography and magnetic resonance imaging can facilitate diagnosis of anophthalmia. Detectable function may be present in microphthalmic cases.
6. **Management.** Conservative approaches include refraction and treating any underlying amblyopia. In unilateral cases, the “good” eye must be protected and any visual deficit managed appropriately. Reconstructive surgical interventions allow for growth of the orbit and prevention of orbital hypoplasia.
7. **Prognosis.** Visual development depends on the degree of retinal development and other ocular characteristics in microphthalmic patients. Therapy is aimed at maximizing existing vision and enhancing cosmetic appearance rather than improving sight.

B. Coloboma

1. **Definition.** Colobomas are cleft-shaped fissures in the eyelid, iris, lens, ciliary body, retina, choroid, or optic nerve.
2. **Incidence.** Ocular colobomas occur in 1 per 2077 live births.
3. **Pathophysiology.** The condition results from incomplete embryologic closure of fetal fissures that may be associated with persistence of hyaloid vessels and pupillary membrane.
4. **Risk factors.** The majority are sporadic, but there is an increased incidence in infants with trisomy 13 and infants with CHARGE syndrome (coloboma, *h*earth defects, choanal *a*tresia, retarded growth and development, genital abnormalities, and *e*ar anomalies), or as a result of maternal ingestion of d-lysergic acid diethylamide or thalidomide. Eyelid colobomas are associated with Goldenhar syndrome and Treacher Collins syndrome. Familial colobomas are autosomal dominant.
5. **Clinical presentation.** A keyhole-shaped defect that may be seen in the ocular and adnexal structures listed earlier.
6. **Management.** Surgical intervention is indicated when an eyelid coloboma prevents adequate lid closure. In addition, if there is anisometropia (difference in the refractive error between the 2 eyes), eyeglasses should be prescribed. Patching the good eye may also help to rehabilitate the affected eye.
7. **Prognosis.** Visual potential is dependent on the location of the coloboma. A coloboma of the iris does not affect vision. A coloboma that includes the optic nerve, the macula, or other parts of the retina can cause legal blindness.

C. Congenital cataracts

1. **Definition.** Cataracts are an opacification of the crystalline lens that is present at birth.
2. **Incidence.** Estimates are 1.2 to 6.0 cases per 10,000 in the United States.
3. **Pathophysiology.** Any process that alters the glycolytic pathway or epithelial cell mitosis of the avascular lens causes cataracts.

4. **Risk factors.** About 25% of the cases are hereditary; the most frequent mode of transmission is autosomal dominant. About one-third of cases occur sporadically.
 - a. **Metabolic causes.** Hypoglycemia, hypoparathyroidism, mannosidosis, maternal diabetes, galactosemia, hypocalcemia, and vitamin A or D deficiency.
 - b. **Congenital infections.** Infants with rubella, cytomegalovirus, syphilis, toxoplasmosis, herpes simplex, and varicella can have congenital cataracts.
 - c. **Other causes.** In utero radiation exposure and associations with specific genetic syndromes (trisomy 21; Lowe, Alport, or Smith-Lemli-Opitz syndrome) can cause opacification.
5. **Clinical presentation.** The newborn presents with leukocoria (opacification of the red reflex). Lens opacities may be isolated or associated with other eye anomalies or systemic conditions.
6. **Management.** The initial workup includes the many causes and associations. Maternal and infant histories direct laboratory evaluation. An ophthalmologic slit lamp confirms the presence of a cataract. If the cataract directly threatens vision, then prompt surgical removal is indicated to avoid legal blindness from deprivation amblyopia. Infants will require significant visual rehabilitation after cataract extraction.
 - a. **Contact lenses or glasses are used to correct refractive error.**
 - b. **Occlusion therapy of the better eye to reverse amblyopia** may be necessary. Length of treatment depends on visual rehabilitation.
7. **Prognosis.** Cataracts lead to varying degrees of visual impairment from blurred vision to blindness, depending on the extent and location of the opacity and the promptness of and adherence to treatment.

D. Congenital glaucoma

1. **Definition.** Increased intraocular pressure due to impaired drainage of the aqueous humor that causes damage to the optic nerve and permanent vision loss.
2. **Incidence.** Occurs in 1 out of 10,000 births.
3. **Pathophysiology.** Primary congenital glaucoma is caused by structural abnormalities of the aqueous humor drainage channels. Secondary causes include aniridia, anterior segment dysgenesis, Sturge-Weber syndrome, retinopathy of prematurity, persistent fetal vasculature, congenital rubella, and homocystinuria.
4. **Risk factors.** In primary congenital glaucoma, males are found to have a higher incidence of the disease, composing approximately 65% of cases. The disease is typically sporadic or autosomal recessive. Secondary glaucomas can be inherited in a variety of patterns, including autosomal dominant, autosomal recessive, and sporadic. Infants with galactosemia, lysosomal storage disorders, and peroxisomal disorders can all present with glaucoma.
5. **Clinical presentation.** Signs and symptoms include corneal haze, photophobia, epiphora, buphthalmos, blepharospasm, and eye rubbing. The diagnosis is made by measuring intraocular pressure and inspecting the optic nerve.
6. **Management.** Infants usually require surgery to improve drainage.
7. **Prognosis.** Early intervention is essential to prevent blindness, which occurs in 2% to 15% of cases.

IV. Congenital ptosis

- A. **Definition.** Ptosis is a unilateral or bilateral decrease in the vertical distance between the upper and lower eyelids.
- B. **Incidence.** Congenital ptosis occurs in 1 in 842 births.
- C. **Pathophysiology.** It usually occurs due to dysfunction of the levator palpebrae muscle but can sometimes be due to denervation of the superior tarsal muscle (Müller muscle) as in Horner syndrome.

- D. **Risk factors.** It may be transmitted as an autosomal dominant condition or caused by third-nerve palsy.
 - E. **Clinical presentation.** Ptosis can affect 1 or both eyes. With partial dysfunction, the eyelid droops; with complete dysfunction of the muscle, there is no elevation of the eyelid. Infants with mild unilateral ptosis should be evaluated for Horner syndrome.
 - F. **Management.** Infants should be monitored for signs of amblyopia. Surgical correction of congenital ptosis can be undertaken at any age depending on the severity of visual impairment. Earlier intervention may be required if potential for significant amblyopia or torticollis is present.
 - G. **Prognosis.** Repair of congenital ptosis can produce excellent functional and cosmetic results. Of patients who require surgical intervention, 50% or more may require repeat surgery in 8 to 10 years following the initial surgery. With careful observation and treatment, amblyopia can be treated successfully.
- V. **Conjunctivitis.** See Chapter 58.
- VI. **Congenital nasolacrimal duct obstruction or congenital dacryoce.** See also Chapter 58.
- A. **Definition.** Congenital obstruction of the nasolacrimal duct.
 - B. **Incidence.** Congenital nasolacrimal duct obstruction (CNLDO) is found in 2% to 6% of all newborns. Congenital dacryoce occurs in 1 in 3884 live births and has a female predominance.
 - C. **Pathophysiology.** The obstruction is caused by an imperforate membrane at the valve of Hasner in the nasolacrimal duct. In a dacryoce, the lacrimal sac becomes distended and is blocked both at the common canaliculus superiorly and at the valve of Hasner inferiorly.
 - D. **Risk factors.** Children with Down syndrome, craniosynostosis, Goldenhar sequence, clefting syndromes, hemifacial microsomia, or any midline facial anomaly are at an increased risk.
 - E. **Clinical presentation.** Symptoms include increased mucus or mucopurulent discharge and epiphora. The periocular skin is sometimes irritated and erythematous. The eye is usually white. Pressure over the lacrimal sac produces a reflux of mucoid or mucopurulent material from the punctum. Newborns do not produce tears until 4 to 6 weeks of age; therefore, obstruction often does not become apparent until then.
A congenital dacryocystocele presents as a bluish swelling inferior and nasal to the medial canthus. The nose should also be inspected to assess for concurrent intranasal mucocele.
 - F. **Management.** Treatment of CNLDO consists of initial observation for resolution followed by surgical probing of children with persistent duct obstruction past 12 months of age. Medical management includes observation, lacrimal massage, and treatment with topical antibiotics. A dacryoce often requires decompression to relieve obstruction as infection and local inflammation usually develop within the first week of life. In addition, marsupialization of concurrent nasal mucocele is often required to prevent respiratory problems.
 - G. **Prognosis.** Ninety-five percent of CNLDOs will resolve spontaneously by the first birthday. Surgical intervention of both persistent CNLDO and congenital dacryoce has a high rate of success.
- VII. **Retinopathy of prematurity.** See Chapter 118.
- VIII. **Retinoblastoma**
- A. **Definition.** A cancerous tumor of the retina.
 - B. **Incidence.** Retinoblastoma affects 1 in every 15,000 to 30,000 live babies who are born in the United States. It is the most common primary cancer of the eye in children.
 - C. **Pathophysiology.** In all cases, it is caused by an abnormality in chromosome 13, which is responsible for controlling cell division.
 - D. **Risk factors.** Sixty percent of cases are due to somatic mutations, whereas approximately 33% are due to germline mutations. The mutation is transmitted

in an autosomal dominant fashion. It affects children of all races and both boys and girls.

- E. **Clinical presentation.** The majority of infants present with leukocoria. Other signs are strabismus, poor vision, enlarged pupils, or inflammation of tissue around the eye. Most cases (75%) involve only 1 eye. Bilateral cases are usually due to germline mutations.
- F. **Management.** Diagnosis is made during an ophthalmologic examination under general anesthesia. Treatment is customized for each patient. Systemic and intra-arterial chemotherapy are the treatment modalities currently in use. Radiation, laser therapy, and cryotherapy are also used in some cases. Enucleation is reserved for advanced disease in which there is high chance of metastases, and there is poor prognosis for visual recovery.
- G. **Prognosis.** Long-term prognosis is good. In the United States, nearly 98% of children survive. Long-term ocular and pediatric examinations are necessary because recurrence is common.

97 Hydrocephalus and Ventriculomegaly

- I. **Definition.** **Hydrocephalus** is the progressive enlargement of the ventricular system secondary to excessive cerebrospinal fluid (CSF) volume. It is caused by an imbalance between CSF production, absorption, and impaired CSF circulation. Hydrocephalus is associated with increased intracranial pressure (ICP) and an enlarging head. Typically, an occipitofrontal head circumference of >2 standard deviations of normal is consistent with macrocephaly due to hydrocephalus. Hydrocephalus occurs when the ventricles are >15 mm wide. Occasionally, hydrocephalus can present with normal head size but with marked ventricular dilatation.

Ventriculomegaly (VM) is an enlargement of the cerebral ventricles. In a normal fetal brain the ventricles are <10 mm wide (mean diameter of normal atrium is 7.6 mm). In mild VM, ventricles are between 10 and 15 mm wide; in severe VM, ventricles are >15 mm wide. VM may or may not be associated with macrocephaly. Increased ventricular dimension can be due to increased intraventricular pressure (as in hydrocephalus) or the result of passive ventricular enlargement caused by loss of periventricular white matter (such as diffuse leukomalacia). **Early diagnosis of fetal VM and hydrocephalus remains a diagnostic dilemma.**

Cerebrospinal fluid is primarily produced in the choroid plexus that lines the ventricles (mostly by lateral ventricles in humans). Approximately 80% is choroid plexus in origin, and the remainder is contributed from substances of the brain and spinal cord. Cerebral fluid acts as a buffer between the brain and the skull. Normally secretion of CSF occurs at a rate of 0.3 to 0.4 mL/min (500 mL/d). Total volume of CSF ranges from 10 to 30 mL for preterm infants and 40 mL for full-term infants; 99% of CSF is water. Sodium is a major cation. Replacement occurs every 4 to 6 hours. The mean CSF opening pressure in neonates and preterm infants is typically lower (100 mm H₂O and 95 mm H₂O, respectively). CSF values for cell count, protein, and glucose concentrations vary with gestational age (GA) and postmenstrual age (PMA). CSF protein concentrations decrease with both advancing PMA and postnatal age. The white blood cell count is higher in the CSF of neonates as compared with older children. CSF drains from lateral ventricles via the foramen of Monro into the third ventricle, via the aqueduct of Sylvius into the fourth ventricle, and then into the subarachnoid space via

the foramina of Luschka and Magendie. CSF enters the venous circulation by way of the absorptive arachnoid villi that line the superior sagittal sinus. Disruption in this pathway can cause hydrocephalus. **Two mechanisms exist to explain the pathologic accumulation of CSF:**

- A. Noncommunicating (or obstructive) hydrocephalus.** This may be any blockage along the ventricular CSF pathway that keeps it from reaching the subarachnoid space or disrupts the normal resorptive function of the arachnoid villi. For example, blockage may be from aqueductal stenosis, ventriculitis, or a clot following an extensive intraventricular hemorrhage resulting in noncommunicating hydrocephalus.
- B. Communicating (absorptive) hydrocephalus.** Results when CSF is able to pass through all the foramina, including the foramina at the base of the skull (cisterna magna), but is not absorbed into the venous drainage of the cerebral circulation because of the obliteration of the arachnoid villi, as in bacterial meningitis or following an extensive subarachnoid hemorrhage.

II. Incidence. The incidence of neonatal hydrocephalus alone is unknown. When included in the diagnosis of spina bifida, it occurs in 2 to 5 births per 1000. The incidence of VM is between 0.3 and 1.5 per 1000 births.

III. Pathophysiology

A. Congenital hydrocephalus. Congenital hydrocephalus (CH) is a state of progressive ventricular enlargement that starts before birth and is apparent on the first day of life. CH is noncommunicating (obstructive) in presentation and results from developmental malformations of the brain that disturb CSF pathways. Most malformations occur between 6 and 17 weeks of gestation. CH is usually accompanied by other anomalies of the brain, namely holoprosencephaly or encephalocele. Fifty percent of CH cases presenting as fetal hydrocephalus are associated with myelomeningocele, Arnold-Chiari malformation, aqueduct stenosis, or Dandy-Walker malformation.

B. Postinfectious hydrocephalus. May be either communicating or noncommunicating. Bacterial meningitis (eg, group B *Streptococcus*, *Escherichia coli*, or *Listeria monocytogenes*) and subsequent arachnoiditis cause communicating hydrocephalus due to loss of the CSF absorptive sites. However, a ventriculitis leads to obstruction within the ventricular system, usually the floor of the third ventricle and within the aqueduct of Sylvius (tuberculosis or toxoplasmosis). Indirectly related to the CSF circulatory disturbance can be the formation of postinfectious subdural effusion with increased ICP and subsequent hydrocephalus.

C. Posthemorrhagic ventricular dilation and posthemorrhagic hydrocephalus. It is important to distinguish between posthemorrhagic ventricular dilation (PVD) and posthemorrhagic hydrocephalus (PHH). Progression of ventricular enlargement and evidence of increased ICP are major factors. PVD follows more severe germinal matrix/intraventricular hemorrhage (GM/IVH) in nearly one-third of all cases and presents as asymmetric or symmetric dilation of the lateral ventricles.

1. Posthemorrhagic ventricular dilation. PVD may present early as an acute ventricular dilation within the first week of hemorrhage or develop slowly over ≥ 2 weeks. By definition, hydrocephalus must present with some signs of increased ICP. PVD does not present with signs of increased pressure; moreover, recognizing PVD and following it closely will reveal whether it is self-limiting and possibly self-resolving without intervention. It may simply represent VM due to disturbed CSF flow after hemorrhage. Hemorrhagic blood and clots may dissipate and allow resumption of CSF circulation.

2. Posthemorrhagic hydrocephalus. PHH may acutely complicate a massive IVH, but more typically, it evolves after hemorrhage and presents as either communicating or noncommunicating hydrocephalus with ICP. A helpful overview by Goddard-Feingold et al suggests the following outcomes of VM after GM/IVH:

- a. Posthemorrhagic ventricular dilation that resolves,** leaving normal ventricles.

VI. Diagnosis

- A. Antenatal diagnosis.** Fetal hydrocephalus may be detected by fetal ultrasound as early as 15 to 18 weeks' gestation. Amniocentesis is advisable to evaluate chromosomal abnormalities (trisomy 13 and 18), fetal sex (X-linked aqueductal stenosis), and α -fetoprotein levels. Maternal serology may establish a suspected intrauterine infection (toxoplasmosis, syphilis, or cytomegalovirus).
- B. Newborn physical examination.** Head growth of 2 cm/wk is a sign of progressive ventricular dilation.
- 1. Make a note of the parents' head sizes.** Some parents may have a constitutionally large head size, and so might their infant. Normal HC for adult women is 54 ± 3 cm, and for men, it is 55 ± 3 cm. No further evaluation of the infant is needed unless there are risk factors for an enlarging head or signs of increasing ICP.
 - 2. Infants with X-linked aqueductal stenosis** may have a characteristic flexion deformity of the thumb.

3. **Infants with Dandy-Walker malformation** have occipital cranial prominence.
 4. **Funduscopic evaluation** may reveal chorioretinitis indicative of intrauterine infection.
- C. **Cerebral bruit.** May be a sign of arteriovenous malformation of the vein of Galen or a transmitted sound from a cardiac murmur.
- D. **Cranial ultrasound.** The most important screening tool for premature infants at risk for VM or hydrocephalus (see Figures 12–4D, E, and F). Ventricular dilation may precede clinical signs of hydrocephalus by days and weeks. Clearly, signs of increasing HC dictate a screening cranial ultrasound (CUS). Likewise, infants with difficult labor and delivery or those who may have needed resuscitation measures are candidates for screening CUS. Ventricular size, change in shape, rate of posthemorrhagic ventricular dilation, and the clinical picture guide the management.
1. **In our institution, initial cranial ultrasound** is obtained for every infant ≤ 32 weeks' GA between days 10 and 14.
 2. **Cranial ultrasound can be considered sooner than 10 days** under certain conditions (eg, infant with multiple clinical complications).
 3. **If initial cranial ultrasound is normal**, a second CUS is obtained at 36 weeks' GA or at discharge, whichever comes sooner.
 4. **If initial cranial ultrasound is abnormal**, consider weekly CUS to monitor progression of hemorrhage and posthemorrhagic hydrocephalus. Continue weekly monitoring until the injury is stable.
- E. **Computed tomography cranial scanning** remains useful for image studies in selected patients. It provides the following information:
1. **Ventricular dilation identification**
 2. **Determination of size of the cerebral mantle**
 3. **Detection of associated central nervous system anomalies**
 4. **Detection of parenchymal destruction (calcification or cyst)**
 5. **Determination of a likely site of disturbance of cerebrospinal fluid dynamics**
- F. **Magnetic resonance imaging.** Magnetic resonance imaging (MRI) has become the most effective means of detailing brain injury, hypoxic ischemic events, hemorrhage, malformations, and VM. Fetal brain imaging with new ultrafast MRI studies negates the motion artifact of the fetus. Ultrafast MRI now lends itself to in utero imaging for congenital anomalies of the brain and fetal hydrocephalus. For infants with GM/IVH and at risk for PVHI, studies by MRI are more accurate at documenting parenchymal loss and the formation of porencephalic cysts. Disadvantages of MRI are poor identification of calcifications and possible requirement of sedation and transport.
- ## VII. Management
- A. **Fetal hydrocephalus**
1. **If fetal pulmonary maturity can be assured**, consider prompt cesarean delivery.
 2. **If the lungs are immature**, there are 3 options:
 - a. **Immediate delivery with the risk of prematurity.**
 - b. **Delayed delivery until the lungs are mature** with the risk of persistently increasing ICP. Antenatal steroids can be administered for induction of lung maturity, with delivery of the infant as soon as lung maturity is established.
 - c. **Fetal surgery options** of in utero ventricular drainage with ventriculoamniotic shunt or transabdominal external drainage.
 3. **Consultation.** Ideal management calls for a team approach with the obstetrician, neonatologist, neurosurgeon, ultrasonographer, geneticist, ethicist, and family members.
- B. **Congenital aqueductal stenosis or neural tube defects.** Decompress by prompt placement of a ventricular bypass shunt into an intracranial or extracranial compartment.

C. Posthemorrhagic hydrocephalus

1. **Mild hydrocephalus.** Usually arrests within 4 weeks of progressive ventricular dilation or returns to normal within the first few months of life.
2. **Temporizing measures**
 - a. **Serial lumbar punctures** may be instituted if there is communicating hydrocephalus. Removal of 10 to 15 mL/kg CSF is frequently necessary. Approximately two-thirds of infants undergo arrest with partial or total resolution, and one-third still require extracranial shunting of CSF.
 - b. **Drainage, irrigation, and fibrinolytic therapy** is advocated as another means of minimizing clot obstruction with improved outcomes of neurodevelopmental function at 2 years of age.
 - c. **Ventricular drainage.** This can be done by direct or tunneled external ventricular drain or by a subcutaneous ventricular catheter that drains to a reservoir or to subgaleal or supraclavicular spaces. This is indicated for infants who have not responded adequately to lumbar puncture and who are not good candidates for placement of extracranial shunt. The incidence of infection with these devices is approximately 5%.
 - d. **Ventriculostomy.** Of more recent development has been the success of a third ventricle ventriculostomy. It is an endoscopic procedure that creates a communication (stoma) from the floor of the third ventricle directly into the subarachnoid space at the level of the foramina of the cistern magna. It is a redirection of CSF and a preservation of the subarachnoid to venous pathway for CSF resorption. It has been particularly promising for obstructive PHH with occlusion of the aqueduct of Sylvius.
3. **Surgical management.** The method of choice is placement of a ventriculoperitoneal (VP) shunt. The outcome may be better with “early” shunting. It remains *controversial* whether elevated CSF protein level increases the risk of shunt complications and whether shunting should be delayed in patients with a high CSF protein content. VP shunt placement is indicated in nearly all cases to facilitate control of occipital frontal circumference, improved head control, skin care, general nursing care, and patient comfort. VP shunt function depends on shunt valve integrity. The Holter valve was a standard device for almost 50 years, but its limitations included overdrainage of CSF, causing symptoms of headache and dizziness, and renewed obstruction because of collapse of the ventricles (the slit ventricle syndrome). Newer shunts combine programmable magnetic valves with added antisiphon controls for protection against overdrainage when the patient is in the upright position. In many institutions, VP shunts usually are placed when the patient reaches 2 kg of body weight.
4. **Long-term complications of shunts.** Include scalp ulceration, infection (usually staphylococcal), arachnoiditis, occlusion, development or clinical worsening of an inguinal hernia or hydrocele, organ perforation (secondary to intraperitoneal contact of a catheter with a hollow viscus), blindness, endocarditis, and renal and heart failure. The age of <6 month appears to be a major risk factor for shunt infection in infants.

VIII. Prognosis

- A. **Outcomes have significantly improved with modern neurosurgical techniques for posthemorrhagic hydrocephalus.** Long-term survival now approaches 90% with functioning shunts in place.
- B. **Predictors of unfavorable outcome**
 1. **Cerebral mantle with <1 cm before shunt placement.**
 2. **Regarding the cause of hydrocephalus, prognosis decreases in the following order:** communicating hydrocephalus and myelomeningocele > aqueduct stenosis > Dandy-Walker malformation.
 3. **Reduced size of the corpus callosum** is associated with decreased nonverbal cognitive skills and motor abilities.

4. **Mean intelligence quotient is low** compared with that of the general population.
5. **Accelerated pubertal development** is noted in patients with meningocele or shunted hydrocephalus due to increased gonadotropin production.
6. **Visual problems**, such as strabismus, visual field defects, visuospatial abnormalities, and optic atrophy with decreased acuity due to increased ICP, are common.
7. **In preterm infants with posthemorrhagic hydrocephalus**, poor long-term outcome is directly correlated with the severity of IVH, the presence of PVHI or cystic periventricular leukomalacia, the need for VP shunt, shunt infections, and a high number of shunts.

98 Hyperbilirubinemia: Conjugated

Hyperbilirubinemia presents as either unconjugated hyperbilirubinemia or conjugated hyperbilirubinemia. The two forms involve different pathophysiologic causes with distinct potential complications. In contrast to unconjugated hyperbilirubinemia, which can be transient and physiologic in the newborn period, **conjugated hyperbilirubinemia is always pathologic and requires thorough investigation**. See Chapter 99 for a discussion of unconjugated hyperbilirubinemia and Chapters 62 and 63 for rapid “on-call” assessment and management.

Bilirubin is the end product of the catabolism of heme derived primarily from the breakdown of red blood cell hemoglobin in the reticuloendothelial system. Bilirubin circulates in the blood predominantly bound to serum albumin (unconjugated) before uptake in the liver where it becomes conjugated. Inside liver cells, unconjugated bilirubin is bound immediately to intracellular proteins, the most important one being ligandin. It is then converted into an excretable and soluble form through the process of conjugation that consists of transfer of 1 or 2 glucuronic acid residues from uridine diphosphate glucuronic acid to form a monoglucuronide or diglucuronide conjugate. Uridine diphosphate glucuronyl transferase (UDPGT) is the major enzyme involved in this process. Conjugation is impaired in newborns due to reduced UDPGT activity and a relatively low level of uridine diphosphate glucuronic acid. Conjugated bilirubin is water soluble and can be excreted in the urine, but most of it is rapidly excreted as bile into the intestine. Conjugated bilirubin is further metabolized by bacteria in the intestine into urobilin/stercobilin and excreted in feces (and urine).

- I. **Definition. Conjugated hyperbilirubinemia** is defined as direct reacting bilirubin of >1.0 mg/dL (>17 $\mu\text{mol/L}$) if the total serum bilirubin is ≤ 5 mg/dL, or $>20\%$ of total serum bilirubin when the total bilirubin is >5 mg/dL. It is a biochemical marker of reduced bile flow/formation leading to biliary substance retention within the liver, a condition called **cholestasis**.
- II. **Incidence.** Conjugated hyperbilirubinemia affects approximately 1 in every 2500 infants and is much less common than unconjugated hyperbilirubinemia.
- III. **Pathophysiology.** Normal bile production involves 2 main processes: bile acid uptake by the hepatocytes from the blood and bile excretion into the biliary canaliculus. Bile uptake from the blood is an active process facilitated by 2 main receptors at the basolateral membranes, whereas bile secretion at the canalicular membrane is mediated largely by the bile salt export pump. In healthy newborns, the cellular processes that regulate bile flow are immature and do not function at the normal adult level, making them more susceptible to cholestasis.
- IV. **Risk factors.** Well-known risk factors include congenital infections, sepsis, neonatal hepatitis, hemolysis (biliary sludging), trisomy 21, and the use of parenteral nutrition (PN).

V. Clinical presentation. Prolonged clinical jaundice is the main presenting feature of conjugated hyperbilirubinemia, along with pale (acholic) stools and dark urine. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and European Society for Paediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) guideline for the evaluation of cholestatic jaundice in infants recommends that any infant noted to be jaundiced at 2 weeks of age be evaluated for cholestasis with fractionated bilirubin. Breast-fed infants who have a normal history and physical examination and can reliably be monitored could be evaluated for cholestasis at 3 weeks of age, if jaundice is persistent. No single screening test can predict which infant will develop cholestasis; however, various screening tools have been implemented in some countries. In Taiwan, use of a stool color card proved to be effective with 95% sensitivity for pale stools. Similar findings were reported from Japan and Canada. Very few cholestatic disorders (galactosemia, fatty acid oxidation defects, cystic fibrosis) are picked up through the newborn metabolic screen

The differential diagnosis of cholestasis is extensive. It can be classified based on the anatomic location of the pathologic process (extrahepatic vs intrahepatic causes), or it can be categorized into broad etiologic causes, such as infectious, familial, metabolic, toxic, chromosomal, vascular, and bile duct anomalies. The recent understanding in molecular genetics has pointed to new directions of investigations that resulted in identification of the molecular mechanisms of a subset of hepatobiliary diseases that often can lead to ongoing liver dysfunction. The most common differential diagnoses of neonatal cholestasis are listed in Table 98–1.

A. Specific diseases

1. **Biliary atresia.** Biliary atresia (BA) is the most common cause of cholestasis in the first 3 months of life and remains the single most common reason for liver transplantation in children. It is a progressive idiopathic inflammatory process that leads to chronic cholestasis and fibrosis of both the intrahepatic and extrahepatic bile ducts and subsequent biliary cirrhosis. Estimated worldwide incidence is 1 in 15,000 live births, with the highest incidence in Taiwan and French Polynesia (1 in 3000 live births). BA is classified into:
 - a. **Nonsyndromic form.** It is the most common and occurs in approximately 84% of cases;
 - b. **Syndromic form with laterality defects (10%).** The syndromic form with laterality defects is commonly associated with splenic abnormalities.
 - c. **Biliary atresia with at least 1 malformation identified but without laterality (6%).** The most common anomalies found include cardiovascular, gastrointestinal, and genitourinary. The etiology of BA is not known; theories of pathogenesis include bile duct dysmorphogenesis due to genetic predisposition, viral infections, toxins, and chronic inflammatory or autoimmune bile duct injury. It is critical to confirm or exclude the diagnosis of BA as the cause of conjugated hyperbilirubinemia by 45 to 60 days of age. Evidence suggests that early surgical intervention with Kasai hepatic portoenterostomy (KHPE) leads to a better outcome and prognosis. If the KHPE is performed within the first 60 days of life, approximately 70% of patients will establish bile flow; after 90 days of life, <25% of patients will have bile flow. “Red flags” that mandate evaluation for BA include acholic stools, high γ -glutamyl transpeptidase (GGTP), cholestasis without alternative etiology, and abnormal or absence of gallbladder on ultrasound.
2. **Choledochal cysts/biliary cysts** usually present with cholestasis, but sometimes infants develop cholangitis and present with fever, elevation of GGTP, and direct hyperbilirubinemia. They can be easily diagnosed with ultrasonography; as opposed to BA, the intrahepatic bile ducts are normal or dilated rather than sclerosed and the gallbladder appears normal. However, a diagnosis of a choledochal cyst in a cholestatic neonate should always prompt careful evaluation for BA (atresia of the distal common bile duct

Extracorporeal life support

^aBiliary atresia and idiopathic neonatal hepatitis are the 2 most common causes; each accounts for approximately 25% of the cases.

accompanied by cystic dilation: type 1 BA). Rarely, choledochal cysts can coincide with BA.

3. Genetic intrahepatic cholestasis. There are multiple forms of genetic intrahepatic cholestasis, each with different clinical features and variable clinical

presentation and prognosis. Some progressive familial forms (eg, progressive familial intrahepatic cholestasis [PFIC]) are potentially fatal; the syndromic paucity of intrahepatic bile ducts (Alagille syndrome [ALGS]) tends to have a more favorable prognosis. The pathogenetic mechanisms of this group of disorders have been defined only partially, and molecular genetics diagnostic techniques have only been recently applied.

a. Alagille syndrome. Also known as arteriohepatic dysplasia, ALGS is an autosomal dominant disorder with multisystem involvement characterized by paucity of the intrahepatic bile ducts (chronic cholestasis), cardiovascular anomalies (peripheral pulmonic stenosis), skeletal abnormalities (butterfly vertebrae), ophthalmologic finding (posterior embryotoxon), and “typical facies” (facial shape of an inverted triangle, with broad forehead, deep-set eyes, mild hypertelorism, straight nose with flattened tip, prominent chin, and small low-set malformed ears). It occurs secondary to defects in components of the Notch signaling pathway, most commonly due to mutation in *JAG1* (ALGS type 1) but in a small proportion of cases due to mutation in *NOTCH2* (ALGS type 2). The abnormality of bile ducts is considered to be the most consistent finding in ALGS; repeat liver biopsies may be needed in patients with clinically suspected diagnosis but not confirmed on initial histologic diagnosis. Long-term prognosis depends on severity and duration of cholestasis, severity of cardiovascular defect, and liver status as it relates to need for liver transplantation.

b. Progressive familial intrahepatic cholestasis. PFIC is a group of genetic disorders with autosomal recessive inheritance and characterized by progressive intrahepatic cholestasis. The predominant mechanism for the intrahepatic cholestasis is altered canalicular transport. Three types of PFIC are recognized:

i. PFIC-1 was originally called Byler disease. It is caused by *ATP8B1* gene deficiency, and GGTP is characteristically normal or low. It presents with conjugated hyperbilirubinemia early in life, typically within the first 3 months. Diarrhea, pancreatitis, and deficiency of fat-soluble vitamins are seen. Cirrhosis is seen by the first decade of life, and liver transplantation is usually needed by the second decade of life.

ii. PFIC-2 is caused by *ABCB11* gene defect resulting in bile salt export pump deficiency and altered bile acid transport. It has a presentation similar to PFIC-1 with no evidence of pancreatitis. As in PFIC-1, serum GGTP is not elevated despite severe cholestasis.

iii. PFIC-3 is due to multidrug resistance protein 3 (*MDR3*, also called *ABCB4*) gene deficiency, resulting in altered phospholipid transport into the canalculus. It is clinically similar to PFIC-1 and PFIC-2 but seems to present later in infancy or in early childhood, and GGTP level is elevated.

c. Bile acid synthesis disorders. Several enzymes are involved in the synthesis of bile acids from cholesterol precursor molecules. Bile acid synthesis disorders (BASDs) are rare but in many cases treatable. They present with variable cholestasis and normal or low GGTP. In contrast to other cholestatic disorders, total serum bile acids are usually low. They respond well to treatment with cholic acid and chenodeoxycholic acid.

4. Metabolic disorders. The most common metabolic disease that presents as cholestasis is α_1 -antitrypsin (A1AT) deficiency. Metabolic diseases that can present with rather fulminant liver dysfunction include galactosemia, tyrosinemia, and hereditary fructose intolerance. Hereditary fructose intolerance does not present in the neonatal period unless the infant was exposed to a fructose-containing diet.

- a. Galactosemia.** An autosomal recessive disorder of galactose metabolism that is caused by deficiencies in 1 of 3 enzymes involved in the metabolism of galactose: galactose-1-phosphate uridylyltransferase (GALT), galactokinase (GALK), and uridine diphosphate galactose-4-epimerase (GALE).
- i. Classical galactosemia** is the most common and most severe. It is caused by deficiency of the GALT enzyme. It affects approximately 1 in 10,000 to 1 in 30,000 live births. Deficiency of the GALT enzyme results in accumulation of galactose-1-phosphate and other metabolites that are thought to be toxic to the liver and other organ systems. The gold standard for diagnosis is measurement of GALT activity in erythrocytes. Clinical presentation is variable and nonspecific in the neonatal period (occurs after ingestion of galactose-containing formula) and includes vomiting, loose stools, prolonged jaundice, irritability, and poor weight gain. Continued ingestion of galactose results in multiorgan toxicity with hepatomegaly, worsening liver dysfunction, splenomegaly, renal dysfunction, and central nervous system involvement. While on lactose-containing formula, these infants have galactose in the urine, resulting in a positive reducing substance (Clinitest) but negative urine test for glucose (glucose oxidase). A cataract may be detected on examination. "Oil-drop" cataracts are highly typical of galactosemia and may resolve with treatment if diagnosed early. Neonatal sepsis due to *Escherichia coli* and other gram-negative organisms is more frequent in galactosemic infants. The reason for this unique predisposition remains unclear. Treatment for galactosemia consists of immediate removal of galactose from the diet as soon as diagnosis is suspected. Liver disease usually improves, but long-term neurodevelopmental complications may develop later despite good dietary control.
- ii. GALK deficiency** results in accumulation of galactose, galactitol, and galactonate and leads to early onset of juvenile bilateral cataract. Although uncommon, pseudotumor cerebri, mental retardation, hepatosplenomegaly, hypoglycemia, and seizures have been described in GALK-deficient patients.
- iii. GALE deficiency.** The rarest and most poorly understood among the 3 types of galactosemia is GALE deficiency. Natural history of GALE deficiency galactosemia is limited due to small number of patients reported to date. When a diet containing lactose is not removed immediately, infants typically present with generalized hypotonia, poor feeding, vomiting, weight loss, progressive cholestatic jaundice, hepatomegaly, liver dysfunction, aminoaciduria, and cataracts. Prompt removal of galactose from their diet resolves or prevents acute symptoms.
- b. Tyrosinemia.** Biochemical basis for this disorder is a defect in tyrosine metabolism due to lack of fumarylacetoacetate hydrolase. It is inherited as an autosomal recessive disorder that clinically presents with hepatocellular damage, renal tubular dysfunction, and neuropathy. Neonates with tyrosinemia may present with failure to thrive, vomiting, ascites, coagulopathy, hypoglycemia, and hyperbilirubinemia. One characteristic pattern of tyrosinemia is a very high α -fetoprotein. Patients who survive infancy are at high risk of developing hepatocellular carcinoma.
- c. Zellweger or cerebrohepatorenal syndrome.** This is a peroxisomal disorder characterized by the absence of peroxisomes and deranged mitochondria; it is inherited as an autosomal recessive trait and presents in the neonatal period with cholestasis, hepatomegaly, profound hypotonia, and dysmorphic features. Diagnosis is confirmed by the presence of abnormal levels of very-long-chain fatty acids in the serum. Most infants die within 1 year. Survivors beyond 1 year of age have severe mental retardation and seizures.

- d. α_1 -Antitrypsin deficiency.** The most common genetic cause of liver disease, inherited as autosomal dominant disorder, with an incidence of 1 in 1600 to 1 in 2000 live births in North American and European populations. A1AT is the most abundant proteinase inhibitor, and it acts by inhibiting destructive proteases. Clinical phenotypes include both liver and pulmonary manifestations with variable penetrance. Liver disease commonly presents in the newborn period. Diagnosis is made by protein phenotyping since serum level of A1AT is less reliable. A1AT is an acute-phase reactant; it can be elevated into the normal range during times of systemic inflammation and/or infection. A1AT phenotyping (Pi type) is the most specific and preferred diagnostic serum test. A1AT variants are named according to their isoelectric point pattern, with M normal and Z most deficient. The homozygous variant, PiZZ, is the most likely associated with neonatal liver disease and adult emphysema. Despite carrying the same mutation, only 10% to 15% of newborns present clinically. Treatment is mostly supportive or liver transplantation if cirrhosis is progressive. Outcome is related to severity of neonatal liver disease; 50% of children are clinically normal by 10 years of age, 5% to 10% require liver transplantation, and in 20% to 30% of patients, cholestasis resolves with residual evidence of cirrhosis that may eventually require liver transplantation.
- e. Mitochondrial hepatopathies.** Usually presents as metabolic crises with associated multiorgan dysfunction. However, mitochondrial disorders can be organ specific with subtle clinical findings to frank liver failure with or without signs of other organ involvement. Infants presenting with features suggestive of liver dysfunction, such as lactic acidosis, hypoglycemia, cholestasis, and coagulopathy, should be worked up for mitochondrial hepatopathies. Routine diagnosis from muscular biopsies and fibroblast may not reveal diagnosis if the dysfunction is primarily in the liver; 80% to 95% of patients with clinically suspected mitochondrial disease do not have a detectable pathogenic DNA mutation. Treatment is mainly supportive and, in some cases, liver transplantation.

5. Infection

- a. Congenital infections.** Congenitally acquired infections such as TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex virus) infections have a spectrum of manifestations including cholestasis but are usually asymptomatic. They share similar findings such as hepatosplenomegaly, jaundice, petechial rash, and intrauterine growth restriction. Liver dysfunction can occur with any of them, but it is most common with herpes simplex infection. Vertical transmission of hepatitis viruses (B and C) is generally asymptomatic, but clinical hepatitis, including hepatic failure, may develop later.
- b. Bacterial infections.** Inflammation-induced cholestasis has been linked predominantly with gram-negative infections (particularly *E coli*), although gram-positive infections can also lead to cholestasis. Studies point to lipopolysaccharide or endotoxins with subsequent release of cytokines during infections as the major factors in sepsis-associated cholestasis. **Disproportionate elevation of serum bilirubin in comparison with serum transaminases should make a clinician think of an underlying infection.** Infection should be part of the differential diagnosis of new-onset or worsening jaundice in any infant. Urinary tract infection in particular has been reported to be associated with persistent hyperbilirubinemia (both indirect and direct).

- 6. Parenteral nutrition-associated liver disease.** The frequency, not necessarily the severity, of cholestasis associated with PN is partly a function of the degree of prematurity. Cholestasis develops in >50% of infants with birthweight of <1000 g and <10% of term infants after prolonged hyperalimentation.

Of infants who require long-term PN for intestinal failure, 40% to 60% develop PN-associated liver disease (PNALD). Pathogenesis is unknown but thought to be multifactorial and directly related to prematurity, low birthweight, being small for gestational age, episodes of sepsis, and duration of PN use. One of the most important contributing factors is lack of enteral feeding leading to decreased gut hormone secretion, reduction of bile flow, and biliary stasis. Even small amounts oral feedings (continuous or bolus) during hyperalimentation may prevent or ameliorate PNALD. The resumption of normal enteral feeds is associated with improvement of cholestasis in 1 to 3 months, with minimal or no residual fibrosis and normal hepatic function. Hepatic complications are potentially reversible if PN is discontinued before significant liver damage has ensued. Not a single component of PN solution has been definitely identified as the cause of cholestasis; however, evidence suggests that soy bean lipid emulsion (predominantly omega-6 polyunsaturated fatty acids) contributes to hepatotoxicity. Evidence suggests that using fish oil—containing lipid may decrease bilirubin levels in children with intestinal failure on prolonged PN. Two approaches have been proposed for the treatment of PNALD: lipid restriction and lipid modification. Lipid restriction (≤ 1 g/kg/d) reduces exposure to parenteral soybean oil and may attenuate the deleterious effects. Lipid modification replaces parenteral soybean oil with parenteral fish oil. It is important to note that a diagnosis of BA has been made in infants thought to have PNALD initially; therefore, vigilance and exclusion of other diagnoses are needed when diagnosing PNALD.

7. **Inspissated bile.** The *inspissated bile syndrome* is the term traditionally used for conjugated hyperbilirubinemia resulting from severe jaundice associated with hemolysis due to Rh or ABO incompatibility, although a multifactorial cause cannot be entirely excluded. Intrahepatic cholestasis is found on liver biopsy, and cholestasis is probably related to direct hepatocellular damage produced by unconjugated hyperbilirubinemia. Prognosis is generally good.
8. **Gestational alloimmune liver disease (GALD)** was previously known as neonatal hemochromatosis or neonatal iron storage disease. It is a disorder characterized by hepatic failure and hepatic/extrahepatic iron accumulation (hemosiderosis) during the fetal and neonatal period. Newborns present with signs of severe liver failure, including coagulopathy, ascites, and hypoalbuminemia as well as hyperbilirubinemia. Hepatic cirrhosis is common, underscoring the antenatal timing of the hepatic insult. The diagnosis may be suspected on the basis of the iron studies (very high serum ferritin level) and early hypoalbuminemia. GALD occurs as a result of maternal alloimmune injury (analogous to erythroblastosis fetalis) resulting from transplacental passage of specific reactive immunoglobulin G that activates fetal complement cascade resulting in fetal liver injury. A high level of immunostaining for the anti-human C5b-9 complex (the terminal complement cascade) is a characteristic feature. The rate of recurrence of GALD in pregnancies subsequent to the index case is close to 90%. Maternal high-dose intravenous immunoglobulin (IVIg) is the treatment of choice if diagnosis is made antenatally followed by a combination of exchange transfusion and IVIg for symptomatic newborns postnatally.
9. **Idiopathic neonatal hepatitis.** This is defined as presence of prolonged conjugated hyperbilirubinemia with liver histology showing giant-cell multinucleated hepatocytes; no known infectious or metabolic/genetic cause has been found. Diagnosis is one of exclusion and appears to be declining with advancements in diagnostic evaluation and discovery of new etiologies with the use of available next-generation DNA sequencing technologies. Management is mostly supportive. Overall prognosis is difficult to estimate but generally good for infants whose liver disease resolves in the first year.

VI. Diagnosis. Infants who have persistent jaundice at 2 weeks of age should have complete evaluation that includes family history and gestational history of the mother, physical examination, inspection of stool color, and obtaining a fractionated bilirubin measurement. Although presence of jaundice is common in newborns and most likely physiologic in nature, continued presence of jaundice at this age should alert clinicians to the possibility of a pathologic process. Evaluation of cholestasis can be extensive; therefore, it should be individualized to establish a diagnosis efficiently and promptly. The presence of elevated serum direct/conjugated bilirubin levels is considered abnormal when values are >1.0 mg/dL (17 mmol/L). When cholestasis is suspected, immediate focused investigations are recommended (tier 1). Once cholestasis is confirmed, consultation with a pediatric gastroenterologist/hepatologist is a must for a disciplined and stepwise approach of targeted diagnostic workup (tier 2) (Figure 98–1).

A. Laboratory studies

- 1. Bilirubin levels (total and direct).** The most important initial investigation in a persistently jaundiced infant is determining the fractionated serum bilirubin levels. Presence of direct reacting bilirubin of >1.0 mg/dL is consistent with conjugated hyperbilirubinemia.
- 2. Liver enzymes.** Serum transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) are sensitive indicators of hepatocellular inflammation but are neither specific nor of any prognostic value. ALT is more specific for liver; an elevated serum AST without substantial increase in ALT, total bilirubin, or direct bilirubin may point to a hematologic or muscular process because AST is an enzyme present in red blood cells and myocytes. ALT/AST may be helpful in monitoring the course of the disease. Alkaline phosphatase is nonspecific because it is found in the liver, kidney, and bone.
- 3. Prothrombin time and partial thromboplastin time** are reliable indicators of liver synthetic function.
- 4. γ -Glutamyl transpeptidase** is an enzyme released from biliary epithelium. Elevated levels are a very sensitive marker of biliary obstruction or inflammation. A normal level makes BA an unlikely diagnosis. Normal levels of GGTP in the presence of cholestasis indicate failure of bile excretion at the canalicular level and can be seen with PFIC type 1 (*ATP8B1* deficiency) and 2 (*ABCB11* deficiency), BASDs, and tight-junction protein type 2 deficiency.
- 5. Complete blood count, C-reactive protein, and blood and urine bacterial cultures** should be considered as screening tools for infection.
- 6. Serum cholesterol, triglycerides, and albumin levels.** Triglyceride and cholesterol levels may aid in nutritional management and assessment of liver failure. Albumin is a long-term indicator of hepatic function.
- 7. Ammonia level** should be checked if liver failure is suspected.
- 8. Serum glucose level** should be checked if the infant appears ill. Metabolic disorders may present with hypoglycemia along with conjugated hyperbilirubinemia.
- 9. Urine testing for reducing substances.** A simple screening test that should always be performed to screen for metabolic disease, especially for galactosemia. Galactose results in a positive reducing substance in the urine on a Clinitest reagent tablet but has a negative urine test for glucose (glucose oxidase).
- 10. TORCH titers and urine cytomegalovirus culture or polymerase chain reaction.** The use of TORCH titers is less preferable; direct identification of viral infection or measurement of specific immunoglobulin M antibodies should be done for rapid diagnosis. Polymerase chain reaction–based diagnostic studies are extremely helpful and specific.
- 11. The Jaundice Chip resequencing array.** The advances in next-generation sequencing technology have produced newer and expanding cholestasis panels with a comprehensive genetic test menu for a wide range of heritable liver diseases. Diseases intended for screening include ALGS, A1AT deficiency, citrin

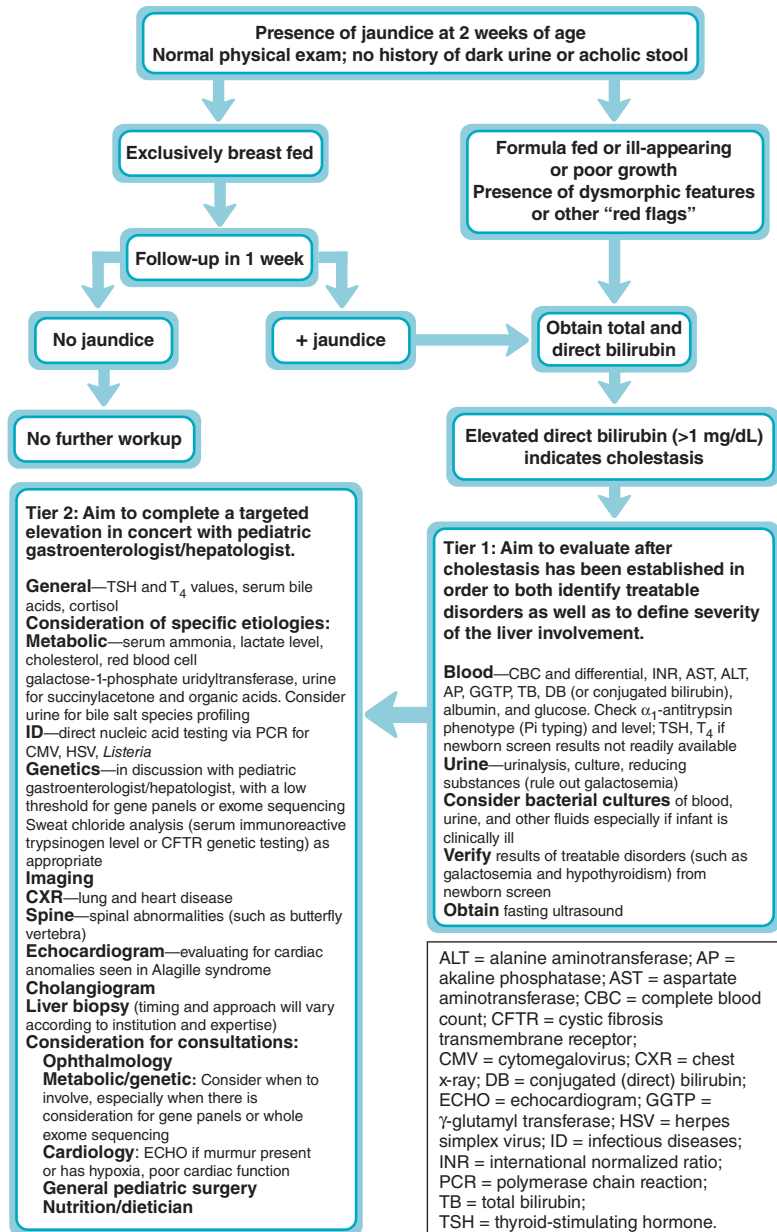

FIGURE 98-1. Approach in evaluation of infant with persistent neonatal jaundice and cholestasis. (Data from Fawaz R, Baumann U, Ekong U, et al: *Guideline for the Evaluation of Cholestatic Jaundice in Infants: Joint Recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition*, J Pediatr Gastroenterol Nutr. 2017 Jan;64(1):154-168.)

deficiency, PFIC, arthrogyrposis–renal dysfunction–cholestasis, neonatal ichthyosis and sclerosing cholangitis, and BASD.

12. Other tests. More specific tests are indicated in the investigation of the specific causes of conjugated hyperbilirubinemia.

a. Urine organic acids and plasma amino acids. Screen for inborn errors of metabolism as a cause of neonatal liver dysfunction. High concentrations of tyrosine and methionine, and their metabolic derivatives, are seen in the urine in cases of tyrosinemia.

b. α_1 -Antitrypsin serum level. Decreased serum A1AT concentration and/or presence of PiZZ, PiSZ, or rarely, PiSS phenotype confirms the diagnosis of A1AT deficiency. The classic histologic finding, although not pathognomonic in A1AT deficiency, is periodic acid–Schiff–positive, diastase-resistant, eosinophilic globules within the hepatocytes.

c. Sweat chloride test is done for confirmatory diagnosis of cystic fibrosis (CF) in infants older than 4 months. If CF is suspected before 4 months, genetic testing (mutation analysis) for common CF mutations can be done. Serum immunoreactive trypsinogen level can be used before 8 weeks of age and is approximately 80% sensitive.

B. Diagnostic imaging

1. Chest radiograph. Presence of cardiovascular or situs anomalies may be suggestive of BA. Skeletal abnormalities, such as butterfly vertebrae, may be consistent with a diagnosis of ALGS.

2. Fasting abdominal ultrasonography. A simple and noninvasive test that should be done in all infants presenting with cholestasis after a 4-hour fast; a small or absent gallbladder, triangular cord sign, and nonvisualization of the common bile duct are suggestive of BA. Findings such as abdominal heterotaxy, midline liver, polysplenia, asplenia, and preduodenal portal vein increase the concern for BA with malformations. However, it is imperative to remember that a normal ultrasound does not rule out nonsyndromic BA. Ultrasound is a sensitive method for recognizing other surgical causes of neonatal cholestasis, such as a choledochal cyst or structural abnormalities of the biliary tree.

3. Hepatobiliary scintigraphy. Contrast agents are taken up by the liver and excreted into the bile; they are technetium labeled and provide a clear image of the biliary tree after intravenous injection. Serial images are taken for up to 24 hours or until gut activity is visualized. Nonvisualization of contrast material within the intestine in 24 hours is considered an abnormal finding indicative of biliary obstruction or hepatocellular dysfunction. Sensitivity of this test for BA is high, but specificity is low because patients without an anatomic obstruction may not excrete the tracer. Neonatal hepatitis, hyperalimentation, and septo-optic dysplasia are reported causes of absent gastrointestinal contrast excretion and must be considered in the differential diagnosis. Administration of phenobarbital for few days prior to the study may improve the precision of the test.

4. Endoscopic retrograde cholangiopancreatography. Sensitivity and specificity are excellent. This procedure can be both diagnostic and therapeutic in cases of cholestasis caused by bile duct stones. It is technically demanding and currently has a limited role in the evaluation of cholestasis in neonates.

5. Magnetic resonance cholangiopancreatography. The few reports available to date regarding the use of magnetic resonance cholangiopancreatography in children are encouraging. The procedure requires deep sedation or general anesthesia. Based on current available data, this modality is not routinely recommended in the evaluation of cholestasis in neonates.

C. Histopathology. Liver biopsy remains the single most definitive procedure in the evaluation of neonatal cholestasis; interpretation by an experienced pathologist will provide correct diagnosis in 90% to 95% of cases. If a liver biopsy is obtained early in the course of BA, findings may be indistinguishable from hepatitis. The

classic histologic features of biliary obstruction are bile duct proliferation, bile plugs, portal or perilobular fibrosis, and edema, with preservation of the basic hepatic lobular architecture. In addition to its role in diagnosis, the liver biopsy may also reveal histologic features significant for prognosis such as the degree of fibrosis, which may help predict outcome following KHPE. Evidence supports that liver biopsy can be performed safely in young infants; therefore, it is recommended to be performed when noninvasive evaluation of persistent cholestasis is nonconclusive. In infants with histologic findings suggestive of biliary obstruction (ie, BA), **intraoperative cholangiogram** is typically performed to confirm nonvisualization of a patent extrahepatic biliary tree; when confirmed, this is typically followed by performing KHPE.

VII. Management. Rapid “on-call” assessment and management are discussed in Chapter 62.

A. Supportive medical management. Few conditions causing neonatal cholestasis are treatable, and these conditions (ie, BA and choledochal cyst) need timely diagnosis and management. Medical treatment is mostly supportive and should be directed toward promoting growth and development and in treating the other complications of chronic cholestasis, such as pruritus, malabsorption, nutritional deficiencies, and portal hypertension. Management involves dietary manipulation and fat-soluble vitamin support.

1. **Special formula.** Elemental formula containing medium-chain triglycerides is preferable because it can be better absorbed regardless of luminal concentration of bile acids. Infants with cholestasis must be given a caloric intake of approximately 125% more than the recommended dietary intake for healthy infants.
2. **Medium-chain triglycerides.** Infants with cholestasis often require a diet that includes medium-chain triglycerides (MCTs), which can be absorbed without the action of bile salts. Some formulas containing MCTs include Enfaport and Pregestimil. Breast-fed cholestatic infants should be given supplemental MCT.
3. **Vitamin supplementation.** Fat malabsorption interferes with maintenance of adequate levels of fat-soluble vitamins. Supplementation of vitamins A, D, E, and K is needed. Extra vitamin K supplementation may be necessary if a bleeding tendency develops.
4. **Dietary restrictions.** Removal of galactose and fructose from the diet may prevent the development of cirrhosis and other manifestations of galactosemia and hereditary fructose intolerance, respectively. Dietary restrictions may also be used to treat tyrosinemia but usually are less successful. Most other metabolic causes of cholestatic jaundice have no specific therapy.

B. Pharmacologic management. See Chapter 155 for drug dosages.

1. **Ursodiol (ursodeoxycholic acid, Actigall).** A naturally occurring dihydroxy bile acid that appears to help cholestasis in 2 ways: substitution in the bile acid pool for more hydrophobic bile acids, and stimulation of bile flow. It was found to lower levels of aminotransferases in patients with viral hepatitis and to lower biochemical markers and slow the progression of hepatic fibrosis in PFIC. Recommended dose is 20 mg/kg/d in divided doses. The only common side effect is diarrhea, which usually responds to dose reduction.
2. **Phenobarbital.** Its use is controversial. Presumed mode of action is enhancing bile acid synthesis, increasing bile flow, and inducing hepatic microsomal enzymes. Recommended dose is 3 to 5 mg/kg/d. Use is limited by its behavioral and sedative side effects.
3. **Cholestyramine.** It binds bile acids in the intestinal lumen, thereby decreasing enterohepatic circulation of bile acids, which leads to increased fecal excretion and increased hepatic synthesis of bile acids from cholesterol, which may lower serum cholesterol levels. Side effects include binding of fat-soluble vitamins, metabolic acidosis, and constipation.
4. **Rifampin.** It is effective in the management of pruritus due to cholestasis, but experience is very limited in neonates. Patients should be monitored for

hepatotoxicity and idiosyncratic hypersensitivity reaction, such as renal failure, hemolytic anemia, and thrombocytopenia.

C. Surgical management

1. **Kasai procedure.** Surgical procedures such as KHPE should be done to establish biliary drainage in patients diagnosed with BA. Optimal results are obtained if the procedure is done before 8 weeks of age. The most significant predictor of long-term outcome is resolution of jaundice. The procedure is usually used as a bridge to transplantation.
2. **Liver transplantation.** When end-stage liver disease is inevitable, liver transplantation is the last resort. BA remains the most common indication for liver transplantation in the United States. Overall, the success of liver transplantation has improved significantly. Due to continuing improvements in surgical and interventional techniques as well as neonatal and pediatric postoperative care, the number of patients transplanted within the first year of life continues to increase. According to the Studies of Pediatric Liver Transplantation registry of 1611 pediatric patients, the 1-year patient and graft survival rates were 88% and 82%, respectively, whereas the 4-year patient and graft survival rates were 83% and 74%, respectively. Long-term complications include immunosuppression, infection, renal failure, and growth retardation.

VIII. Prognosis depends on individual etiologies (see Section V). Diseases with relatively favorable prognosis include choledochal cyst, inspissated bile syndrome, ALGS, BASD, and PNALD. Infant with BA do better when KHPE is done before 2 months of age. In most patients, KHPE is used as a bridge to liver transplantation. A recent publication showed that among 1107 patients diagnosed with BA between 1986 and 2009 in France, 94% underwent the KHPE. Survival with the native liver (no transplantation) was 40% at 5 years, 36% at 10 years, and 30% at 20 years of age. Overall patient survival was 81% at 5 years, 80% at 10 years, and 77% at 20 years of age.

99 Hyperbilirubinemia: Unconjugated

- I. **Definition.** When the rate of bilirubin production exceeds the rate of elimination, the end result is a rise in the total serum bilirubin (TSB), a clinical condition called **hyperbilirubinemia**. The accumulation of bilirubin manifests as yellow discoloration of the skin, sclera, and mucosa called jaundice. Neonates with severe hyperbilirubinemia (defined as a TSB >25 mg/dL in late preterm and term infants) are at risk for **bilirubin-induced neurologic dysfunction (BIND)**, which occurs when bilirubin crosses the blood-brain barrier and binds to targeted brain tissues. Hyperbilirubinemia presents as either **unconjugated hyperbilirubinemia** or **conjugated hyperbilirubinemia**. The 2 forms involve different causes and complications. In contrast to unconjugated hyperbilirubinemia, which can be transient and physiologic in the newborn period, conjugated hyperbilirubinemia is always pathologic and requires thorough investigation. See Chapter 98 for a discussion of conjugated hyperbilirubinemia (direct) and Chapters 62 and 63 for rapid “on-call” assessment and management of the 2 conditions.
- II. **Incidence.** Neonatal hyperbilirubinemia is a common problem to address in the newborn period. It occurs in approximately 60% to 70% of term and approximately 80% of preterm infants in the first week of life. The incidence of severe hyperbilirubinemia is approximately 0.14%. Incidence is higher in populations living at higher altitudes and varying ethnicities such as East Asians, Greeks, and Native Americans; it is generally lower in African Americans.

III. Pathophysiology. Bilirubin is a product of heme degradation (80%–90% derived from hemoglobin found in red blood cells [RBCs]). The enzyme heme oxygenase catalyzes the breakdown of heme in reticuloendothelial system, resulting in the formation of equimolar quantities of carbon monoxide (CO) and biliverdin. Biliverdin then is converted to bilirubin by the enzyme biliverdin reductase. Bilirubin is carried bound to albumin for uptake in the liver, followed by conjugation and then excretion in the bile. Gut bacteria convert conjugated bilirubin into urobilin and stercobilin. There are 3 main basic pathophysiologic mechanisms responsible for development of unconjugated hyperbilirubinemia: overproduction, decreased uptake, and impaired conjugation.

A. “Physiologic” unconjugated hyperbilirubinemia. The pathophysiologic mechanisms of neonatal jaundice involve 2 major contributing factors. First is the greater production of bilirubin secondary to increased heme turnover. The other is decreased ability of the newborn liver to conjugate bilirubin. Both factors are interrelated and important. Because all newborns have transient immaturity of the conjugating enzyme uridine diphosphate glucuronyl transferase (UDPGT), overproduction becomes the determining factor of exaggerated physiologic or pathologic jaundice. Bilirubin can function as an antioxidant, and some degree of hyperbilirubinemia may be physiologic and beneficial. Accepted “normal” or physiologic ranges of TSB levels vary widely because levels are influenced by many diverse factors such as gestational age, birthweight, disease state, degree of hydration, nutritional status, racial background, breast feeding, and other genetic and epidemiologic factors. Although most of these infants are healthy and will not need therapy, they need to be monitored closely as severe unconjugated hyperbilirubinemia can become potentially toxic to the neurons. Published data suggest that upper limits of TSB levels (95th percentile) can be as high as 17 to 18 mg/dL. Preterm infants have no established “physiologic” bilirubin guidelines. Meaningful interpretation of bilirubin levels in the first several days of life has to be made in relationship to the infant’s age in hours.

1. Exclusion criteria for diagnosis of “physiologic” jaundice

- a. **Jaundice appearing within the first 24 hours of life.**
- b. **Total serum bilirubin level >95th percentile** for age in hours based on a nomogram for hour-specific serum bilirubin concentration (Figure 99–1).
- c. **Bilirubin level increasing at a rate** >0.2 mg/dL/h or >5 mg/dL/d.
- d. **Direct serum bilirubin level** >1.5 to 2.0 mg/dL or $>20\%$ of the TSB.
- e. **Jaundice persisting for >2 weeks in full-term infants.**

2. Mechanisms that predispose newborn infants to hyperbilirubinemia

- a. **Increased bilirubin synthesis** due to larger RBC mass, increased hemoglobin breakdown (2–3 times adult’s rate) due to shorter RBC life span in neonates, and increased rate of RBC degradation within the bone marrow before release to the circulation (ineffective erythropoiesis).
- b. **Decreased binding and transport.** Decreased hepatic uptake of bilirubin from plasma due to decreased plasma albumin and the liver transfer protein ligandin.
- c. **Impaired conjugation and excretion.** Reduced UDPGT activity (1% of adult level at 7 days of age) in the newborn liver results in decreased mono- and diglucuronide bilirubin conjugates that can be excreted in the bile.
- d. **Enhanced enterohepatic circulation.** Conjugated bilirubin is unstable and can be hydrolyzed by the intestinal enzyme β -glucuronidase to its unconjugated form; this can be readily absorbed through the intestinal mucosa and move back to the liver (enterohepatic circulation). Sterility of intestinal mucosa prevents further formation of the more excretable products namely, urobilin and stercobilin.

B. Breast milk and jaundice. The association between breast milk (BM) and hyperbilirubinemia has been well documented; it can be classified into 2 types

FIGURE 99–1. Nomogram for designation of risk in well newborns at ≥ 36 weeks' gestation with birthweight ≥ 2000 g or ≥ 35 weeks' gestational age with birthweight ≥ 2500 g based on the hour-specific serum bilirubin values. (Reproduced with permission from Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a pre-discharge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns, *Pediatrics*. 1999 Jan;103(1):6-14.)

based on the age of onset: **early-onset breast-feeding failure jaundice** and **late-onset BM jaundice**. Demographic, environmental, and genetic factors are involved in the development of hyperbilirubinemia in breast-fed neonates. Polymorphism and common mutations/variants in the *UGT1A1* gene as well as glucose-6-phosphate dehydrogenase (G6PD) deficiency (homo- or heterozygous) result in high risk for hyperbilirubinemia in breast-fed infants, especially if born via vaginal delivery.

- 1. Breast-feeding failure jaundice.** Begins in the first week of life due to dehydration, caloric deprivation, and increased enterohepatic circulation, and may occur in >1 in 10 exclusively breast-fed infants. The exact mechanism is unclear but may involve shifts in bilirubin pools, less efficient conjugation, and enhanced bilirubin absorption in the intestine.
- 2. Breast milk jaundice.** Breast-fed infants are much more likely than formula-fed infants to have jaundice that can extend beyond 3 to 4 weeks of life. Prolonged indirect hyperbilirubinemia has been reported to occur in up to 30% of breast-fed infants. Current literature supports genetic pathogenesis characterized by polymorphism of the *UGT1A1* gene. Some infants with prolonged BM jaundice have been found to have Gilbert syndrome. A high level of β -glucuronidase in BM is found in 20% to 40% of women; this can be a contributing factor. Although BM jaundice was considered by some experts as an extension of physiologic jaundice, it cannot be considered totally benign. Kernicterus has been reported in apparently healthy term and late preterm infants as a complication of BM jaundice.

C. Pathologic unconjugated hyperbilirubinemia

1. Disorders of production

a. **Immune-mediated hemolytic disease is the most common cause of pathologic hyperbilirubinemia in the newborn period.** The process may begin in fetal life or immediately after birth depending on the etiology.

i. **Rh (D antigen) incompatibility** as well as other antigens in the Rh blood-group system (c, C, e, E, cc, and Ce) can cause immune-mediated hemolytic disease. Alloimmunization occurs when as little as 0.1 mL of RBCs from an Rh(D)-positive fetus cross the placenta into the circulation of an Rh(D)-negative mother. The initial response in the maternal circulation is the production of immunoglobulin (Ig) M that does not cross the placenta, which is then later followed by IgG, which in subsequent pregnancies crosses the placenta and causes a hemolytic process that can begin in utero. The severe form of this process can result in erythroblastosis fetalis with hydrops.

ii. **ABO incompatibility** occurs in 3% of all infants. Antigens present on the surface of RBCs react with antibodies in the plasma of opposing blood types, resulting in ABO incompatibility with sensitization. Hemolysis is generally limited to group A or B infants born to group O mothers. Risk of recurrence can be as high as 88% in infants with the same blood type as their index sibling. ABO incompatibility is somewhat protective of Rh sensitization because the fetal ABO-incompatible RBCs are rapidly destroyed in the maternal circulation, thereby decreasing the opportunity of Rh antigen to mount an immune response (see Chapter 85).

b. Red blood cell enzyme deficiencies

i. **Glucose-6-phosphate dehydrogenase deficiency** is the most common RBC enzyme deficiency and affects millions of people. The major function of G6PD is preventing oxidative damage of cells. The G6PD gene is located on the X chromosome. Prevalence of hyperbilirubinemia is twice that of general population in males who carry the defective gene and in homozygous females. Although it is more common in the African, Middle Eastern, southern European, and Asian populations, the ease of migration and intermarriage has transformed G6PD deficiency into a global problem. The rapid rise in TSB in infants with this enzyme deficiency may not be accompanied by evidence of a hemolytic process.

ii. **Pyruvate kinase deficiency** is inherited in an autosomal recessive manner and most common in northern European descendants. It presents in the newborn period with jaundice, anemia, and reticulocytosis. This condition needs to be considered in a newborn with a nonspherocytic and direct antiglobulin test (DAT)-negative hemolytic anemia.

c. Red blood cell membrane defects

i. **Hereditary spherocytosis.** Hereditary spherocytosis (HS) is a result of heterogeneous alterations in 1 of 6 genes that encode for proteins involved in vertical associations that tie the RBC membrane skeleton to the lipid bilayer. It is characterized by spherical, doughnut-shaped RBCs in the peripheral blood. HS is mostly found in patients of northern European ancestry, but can be seen worldwide, with a prevalence of 1 in 2000 to 5000 births. The inheritance is dominant in 75% of the cases, but some cases of de novo mutations have also been reported. Jaundice associated with HS can range from mild to severe, causing kernicterus. A simple way to screen for HS in neonates is the ratio of mean corpuscular hemoglobin concentration (MCHC) to mean corpuscular volume (MCV), also called HS ratio (MCHC/MCV). A recent study found that an HS ratio >0.36 was 97% sensitive and 99% specific and had a negative predictive

value of 99%. The incubated osmotic fragility test is considered the gold standard for making the definitive diagnosis of HS.

- ii. **Hereditary elliptocytosis** is an autosomal dominant, clinically heterogeneous group of disorders that are characterized by the presence of elongated, oval, or elliptically shaped RBCs on the peripheral blood smear. It is caused by mutations of the RBC membrane cytoskeletal proteins (usually spectrin or protein 4.1). Hereditary elliptocytosis rarely causes hemolysis and jaundice except in cases of homozygotes or compound heterozygotes.
 - d. **Hemoglobinopathies.** Developmental differences in globin chain synthesis are responsible for the different clinical manifestations of α -chain and β -chain defects in the perinatal period. Although these conditions generally do not present in the newborn period, patients with deletion of 3 α -globin genes (hemoglobin H) are often born with hypochromic hemolytic anemia and are at risk for developing severe hyperbilirubinemia.
 - e. **Infection** causes hyperbilirubinemia by increasing bilirubin concentrations via hemolysis, and it may impair conjugation, leading to decreased excretion of bilirubin. Both early- and late-onset jaundice are reported to be some of the more common clinical manifestations of urinary tract infection.
 - f. **Increased erythrocyte load**
 - i. **Blood sequestration.** Extravascular blood can result in increased bilirubin production due to breakdown of RBCs. The catabolism of 1 g of hemoglobin yields 35 mg of bilirubin. Occult hemorrhages, such as bruising, cephalohematomas, and intracranial bleeding, can cause severe hyperbilirubinemia.
 - ii. **Polycythemia.** Increased RBC mass is a known risk factor for hyperbilirubinemia due to an increase in the bilirubin load presented to the liver for conjugation and excretion.
 - iii. **Infants of diabetic mothers.** Infants of diabetic mothers have high erythropoietin levels causing increased erythropoiesis, leading to polycythemia that contributes to hyperbilirubinemia.
- 2. Disorders of bilirubin clearance**
- a. **Crigler-Najjar syndrome type I.** Autosomal recessive disease characterized by almost complete absence of hepatic UDPGT activity. TSB is commonly >20 mg/dL. The diagnosis of Crigler-Najjar syndrome type I (CNS-I) can usually be made by microassay of UDPGT activity or by measurement of menthol glucuronide in urine after oral menthol. Treatment consists of exchange transfusion soon after birth, followed by daily phototherapy for 12 to 24 hours and liver transplantation later on. The use of tin protoporphyrin may help decrease the bilirubin level temporarily and may shorten the need for daily phototherapy. Oral calcium phosphate supplementation makes phototherapy more efficient (amorphous calcium phosphate traps unconjugated bilirubin in the gut). TSB is unresponsive to phenobarbital therapy.
 - b. **Crigler-Najjar syndrome type II**, also known **Arias disease**, is more common than CNS-I and typically benign. Crigler-Najjar syndrome type II (CNS-II) can occur as a result of autosomal recessive and dominant inheritance. It is caused by a single base pair mutation leading to decreased but not totally absent UDPGT enzyme activity. TSB rarely exceeds 20 mg/dL and is lowered by phenobarbital administration. A definitive diagnosis is made by identifying the genetic defect.

For routine clinical practice, CNS-I and CNS-II can be differentiated by their response to phenobarbital therapy and bile analysis. In CNS-I, bile is totally devoid of bilirubin conjugates, whereas bilirubin monoconjugates are present in CNS-II, and some diconjugates may be detectable after phenobarbital treatment.

- c. **Gilbert syndrome** is a relatively common (~9% of whites) disorder characterized by mild, lifelong, unconjugated hyperbilirubinemia in the absence of hemolysis or evidence of liver disease. Autosomal dominant and recessive patterns of inheritance have been suggested. Hepatic glucuronidation activity is 30% of normal, resulting in an increased proportion of monoglucuronide. Studies have shown that neonates who carry the genetic marker for Gilbert syndrome have a more rapid rise and duration of neonatal jaundice. It is important to remember that Gilbert syndrome is a condition with no consequences for adults, but it can put a neonate at significant risk for hyperbilirubinemia and the potential for complications of bilirubin encephalopathy.
- d. **Lucy-Driscoll syndrome**, also known as **transient familial neonatal hyperbilirubinemia**, is associated with TSB concentrations that usually reach ≥ 20 mg/dL. The sera of affected neonates and their mothers are found to contain a high concentration of an unidentified UDPGT inhibitor when tested in vitro.

3. Metabolic and endocrine disorders

- a. **Galactosemia.** Jaundice may be 1 of the presenting signs; however, infants with significant hyperbilirubinemia due to galactosemia typically have other presenting signs and symptoms such as poor feeding, vomiting, and lethargy. Hyperbilirubinemia during the first week of life is almost always unconjugated, and then it becomes mostly conjugated during the second week, reflective of developing liver disease.
- b. **Hypothyroidism.** Prolonged jaundice is found in up to 10% of newborns diagnosed with hypothyroidism. It is due to a deficient activity of UDPGT. Early-onset hyperbilirubinemia has been reported as the only presenting sign of congenital hypothyroidism. Treatment with thyroid hormone improves hyperbilirubinemia.

4. Increased enterohepatic circulation of bilirubin

- a. **Conditions that cause gastrointestinal obstruction** (eg, pyloric stenosis, duodenal atresia, annular pancreas) or a decrease in gastrointestinal motility may result in exaggerated jaundice due to increased enterohepatic recirculation of bilirubin. Blood swallowed during delivery and decreased caloric intake may also be contributing factors.
- b. **Breast-feeding jaundice and breast milk jaundice (discussed earlier).**

- 5. **Substances affecting binding of bilirubin to albumin.** Certain drugs occupy bilirubin-binding sites on albumin and increase the amount of free unconjugated bilirubin that can cross the blood-brain barrier. Drugs in which this effect may be significant include aspirin, moxalactam, ceftriaxone, sulfisoxazole, and other sulfonamides. Chloral hydrate competes for hepatic glucuronidation with bilirubin and thus increases serum unconjugated bilirubin. Common drugs used in neonates such as penicillin and gentamicin also compete with bilirubin for albumin-binding sites.

- IV. **Risk factors.** Sepsis, acidosis, lethargy, asphyxia, temperature instability, G6PD deficiency, hemolytic disease (ABO or G6PD deficiency), late preterm (34–36 weeks) and early term gestation (37–38 weeks), exclusive breast feeding, East Asian ethnicity, cephalohematoma or significant bruising, male sex, Native American infants, maternal diabetes, family history of neonatal jaundice, and use of oxytocin in labor.

V. Clinical presentation

A. Clinical assessment

- 1. **Monitor for jaundice.** Each nursery must have an established guideline for routine assessment of jaundice. Jaundice is clinically visible when the serum bilirubin level approaches 5 mg/dL. The yellow color is seen more easily in the “fingerprint” area than in the surrounding skin. Progression is cephalocaudal,

so that for a given bilirubin level, the face appears more yellow than the rest of the body.

2. **Clinical history.** Family history of jaundice, anemia, splenectomy, or metabolic disorder is significant and may suggest underlying etiology for jaundice. Maternal history of infection or diabetes may increase the newborn's risk for jaundice. Breast feeding and factors affecting normal gastrointestinal function in the newborn period increase the tendency for more severe jaundice.
3. **Physical examination.** Areas of bleeding such as cephalhematoma, petechiae, or ecchymoses indicate blood extravasations. Hepatosplenomegaly may signify hemolytic disease, liver disease, or infection. Physical signs of prematurity, plethora with polycythemia, pallor with hemolytic disease, and macrosomia with maternal diabetes all can be associated with jaundice. Omphalitis, chorioretinitis, microcephaly, petechiae, and purpuric lesions suggest infectious causes of increased serum bilirubin.
4. **Neurologic examination.** Severe hyperbilirubinemia can be toxic to the auditory pathways and to the central nervous system and can result in hearing loss and encephalopathy. The appearance of subtle abnormal neurologic signs heralds the onset of early bilirubin encephalopathy. Clinical signs may include lethargy, poor feeding, vomiting, hypotonia, and seizures. The progression of neurologic changes parallels the stages of bilirubin encephalopathy from acute to chronic and irreversible changes.

VI. Diagnosis

A. Basic laboratory studies

1. Total and direct serum bilirubin

- a. **Total serum bilirubin level determination** is indicated in all infants who develop jaundice in the first 24 hours of life. Jaundice appearing this early is almost always associated with a pathologic process.
- b. **Direct (conjugated) bilirubin fraction** has to be obtained as well, especially for those with progressive and/or prolonged jaundice.
- c. **During the first few days of life**, bilirubin levels should be interpreted based on age in hours (refer to nomogram Figure 99–1). This can also be determined online (bilitool.org; accessed September 14, 2018).

2. Blood type and Rh status in both mother and infant

- a. **ABO and Rh incompatibility** can be easily diagnosed by comparing infant and maternal blood types.
- b. **Cord blood** can be sent for DAT and routine blood typing.

3. Direct antiglobulin test is also known as direct Coombs test

- a. **Detects antibodies** bound to the surface of RBCs.
- b. **Usually positive in hemolytic disease** resulting from isoimmunization.
- c. **Does not correlate with severity** of jaundice.
- d. **Can be obtained from the cord blood.**

4. Complete blood count and differential

- a. **Presence of anemia** may be suggestive of a hemolytic process; polycythemia increases risk for exaggerated jaundice.
- b. **Evaluate red blood cell morphology**; spherocytes suggest ABO incompatibility or HS.
- c. **Look for mean corpuscular hemoglobin concentration and mean corpuscular volume**; MCHC/MCV ratio >0.36 is highly suggestive of congenital spherocytosis
- d. **Evaluate for indices suggestive of infection** (eg, leukopenia, neutropenia, and thrombocytopenia).

5. Reticulocyte count

- a. **Elevation suggests hemolytic disease.**
- b. **Can also be elevated in cases of chronic occult or overt hemorrhage.**

6. Other laboratory tests

- a. **Urine should be tested** for reducing substances (to rule out galactosemia if the infant is receiving a galactose-containing formula) and for infectious agents.
- b. **If evidence of hemolysis is present**, in the absence of ABO or Rh incompatibility, further testing by hemoglobin electrophoresis, G6PD level, or osmotic fragility testing may be required.

- c. **Prolonged jaundice** (>2 weeks of life) may require additional tests for thyroid and liver function, blood and urine cultures, and metabolic screening workup, such as plasma amino acid and urine organic acid measurements.

7. Measurement of serum albumin.

Bilirubin is mostly bound to albumin in the circulation; evidence suggests that neurotoxicity is caused by unbound bilirubin fraction. Therefore, **measurement of serum albumin** may help assess the fraction of unbound bilirubin in the circulation and thereby determine the need of an albumin infusion. It may be useful in the determination of exchange transfusion.

- B. **Transcutaneous bilirubinometry** (TcB) is a portable instrument that uses reflectance measurements on the skin to determine the amount of yellow color present in the skin. Several studies have shown that TcB measurement correlates well with laboratory TSB measurement and is a reasonable tool to provide an estimate of TSB levels in healthy newborns. However, a potential clinically relevant issue is that TcB levels may underestimate TSB at higher serum bilirubin levels, in contrast to the tendency to overestimate at lower bilirubin levels. A TcB value of >15 mg/dL should be correlated with TSB. TcB results should be interpreted with caution in newborns with birthweight <2500 g, particularly in the first 48 hours of life. Any jaundice noticeable within the first 24 hours of life should be confirmed with TSB level.

- C. **Expired carbon monoxide** breath measurement. An equimolar amount of CO is produced for every molecule of bilirubin formed from the degradation of heme. **Measurement of end-tidal CO (corrected for ambient CO) or end-tidal CO concentration (ETCOc) is an index of total bilirubin production.** This method can alert the attending physician to the presence of hemolysis irrespective of the timing of jaundice. Simultaneous measurement of ETCOc and bilirubin level in high-risk patients prior to discharge from the nursery may accurately identify patients with hemolysis. A commercial ETCOc instrument is now available and has been used at a number of institutions; however, adding ETCOc to hour-specific TSB does not improve the predictive ability of hour-specific TSB testing alone.

VII. Management of indirect hyperbilirubinemia in infants ≥ 35 weeks' gestation.

Three methods of treatment are commonly used to decrease the level of unconjugated bilirubin: phototherapy, pharmacologic therapy, and exchange transfusion. The American Academy of Pediatrics (AAP) has published guidelines on risk designation and when to start phototherapy for infants >35 to 36 weeks' gestation. Low birthweight and preterm infants are excluded from these guidelines. The authors suggest that each institution and its practicing physicians establish their criteria for phototherapy and exchange transfusion by gestational age, weight groups, postnatal age, and the infant's condition consistent with current standard of pediatric practice

- A. **Practice guidelines.** In 2004, the AAP put together evidence-based recommendations to reduce the incidence of severe hyperbilirubinemia and bilirubin-induced encephalopathy in infants ≥ 35 weeks' gestation (*Pediatrics*. 2004;114(1):297-316) that have become widely accepted. The recommendations include the following: to promote and support successful breast feeding, to perform a systematic risk assessment for severe hyperbilirubinemia prior to discharge, to provide early and focused follow-up for the high-risk patient, and to initiate immediate therapeutic intervention when indicated.

- B. **Phototherapy** reduces serum bilirubin level through structural (irreversible) isomerization to lumirubin, which is a more soluble substance that is excreted without conjugation into bile and urine. This is probably the principal mechanism by which

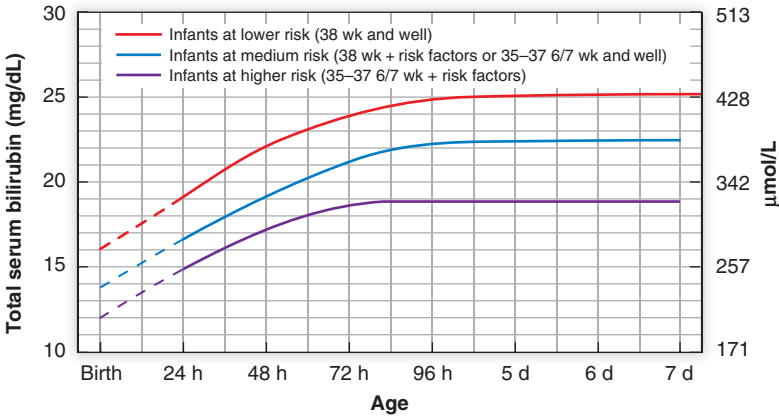

- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

FIGURE 99–2. Guidelines for phototherapy in hospitalized infants of ≥ 35 weeks' gestation. G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin. (Reproduced with permission from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, Pediatrics. 2004 Jul;114(1):297-316.)

phototherapy works. Other mechanisms include photoisomerization (reversible) and photo-oxidation of bilirubin to less toxic and more soluble forms that can be eliminated in bile and urine.

- 1. Indication.** Most infants with increasing jaundice are treated with phototherapy when it is believed that bilirubin levels could enter the toxic range (Figure 99–2).
- 2. Factors influencing effective phototherapy**
 - a. Spectrum of light delivered.** Bilirubin absorbs light most effectively in the blue region of the spectrum (460–490 nm). High-intensity light-emitting diodes (LEDs) are most effective in degrading bilirubin compared to conventional phototherapy devices.
 - b. Energy output.** Conventional phototherapy has an irradiance of 6 to 12 $\mu\text{W}/\text{cm}^2/\text{nm}$, whereas an intensive phototherapy has an irradiance of at least 30 $\mu\text{W}/\text{cm}^2/\text{nm}$. Because light intensity is affected by distance, the recommended distance of an infant from the light source is approximately 12 to 16 inches (~30–40 cm).
 - c. Surface area exposed.** To maximize skin exposure, systems that provide light above and under the infant are recommended; the infant should be naked in servo-controlled incubators.
- 3. Side effects.** Phototherapy is relatively safe and easy to use. Minor side effects include rashes, dehydration, and ultraviolet light irradiation. No changes in growth, development, and infant behavior have been reported.

- a. **Bronze baby syndrome.** With conjugated hyperbilirubinemia, phototherapy causes photodestruction of copper porphyrins, causing urine and skin to become bronze in color. Clinical significance is unknown, and bronze baby syndrome (BBS) is generally regarded as harmless; however, a recent report has indicated that BBS may pose an additional risk to development of kernicterus.
 - b. **Congenital erythropoietic porphyria** is a rare disease in which phototherapy is contraindicated. Exposure to visible light of moderate to high intensity produces severe bullous lesions on exposed skin and may lead to death.
 - c. **Retinal effects.** The retinal effects of phototherapy to the exposed infant's eyes are unknown; however, animal studies suggest that retinal degeneration may occur. Eye shields must be used. The infant's eyes should be covered with opaque patches for overhead lamp phototherapy.
 - d. **Potential long-term effects.** Some reports linked phototherapy exposure to an increased (albeit small) risk for childhood cancer.
- C. Exchange transfusion.** (See also Chapter 34.) **Double-volume exchange transfusion (DVET)** is used when the risk of kernicterus is significant. DVET replaces approximately 85% of the circulating RBCs and decreases the bilirubin level to about half of the pre-exchange value. Patient-to-patient variations for the permeability of the blood-brain barrier exist; this is affected by several factors including isoimmune hemolysis, asphyxia/acidosis, significant lethargy, temperature instability, sepsis, hypoalbuminemia, and prematurity. There is no specific elevated bilirubin level that can be considered safe. Clinical practice parameters published by the AAP in July 2004 provide guidelines for exchange transfusions in healthy newborns ≥ 35 weeks of gestation (Figure 99-3). Direct or conjugated fraction should not be subtracted from the TSB when considering exchange transfusion.
1. **Indications.** DVET should be considered in the following circumstances:
 - a. **There is evidence of an ongoing hemolytic process** and high TSB (exchange threshold) failed to decline by 1 to 2 mg/dL with 4 to 6 hours of intensive phototherapy.
 - b. **Rate of rise** indicates that the level will reach 25 mg/dL within 48 hours.
 - c. **High concentration of total serum bilirubin** and early signs of bilirubin encephalopathy.
 - d. **Hemolysis** causing anemia and hydrops fetalis.
 2. **General guidelines for exchange transfusion**
 - a. **Generally, type O Rh-negative blood** is used for ABO or Rh incompatibility. If the infant is type A or B and the mother is of the same blood type, then type-specific, Rh-negative donor blood can be used.
 - b. **Donor blood must always be crossmatched** with maternal serum.
 - c. **Donor blood should be warmed** to approximately 37°C.
 - d. **Use fresh blood** that is no more than 4 days old.
 - e. **Consider calcium gluconate** infusion during the course of the exchange transfusion because citrate (blood preservative) chelates calcium.
 - f. **Obtain parental consent.**
 3. **Bilirubin levels.** TSB can be decreased by 50% of the pre-exchange level. Rebound increase in TSB is expected after an exchange transfusion as bilirubin in tissues "migrates" back into circulation.
 4. **Adverse events.** Exchange transfusion is not risk free; therefore, the procedure should only be done after intensive phototherapy has failed and the risk of bilirubin encephalopathy outweighs the risk of the procedure. Adverse events include bloodborne infections (eg, cytomegalovirus), thrombocytopenia and coagulopathy, graft-versus-host disease, necrotizing enterocolitis, portal vein thrombosis, electrolyte abnormalities (eg, hypocalcemia and hyperkalemia), and cardiac arrhythmias. Risk of mortality is 0.5% to 2%.

- The dashed lines for the first 24 h indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is 5 mg/dL (85 μmol/L) above these lines.
- Risk factors: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.

Note that these suggested levels represent a consensus of most of the committee but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy.

The following B/A ratios can be used together with but not in lieu of the TSB level as an additional factor in determining the need for exchange transfusion:

	B/A Ratio at Which Exchange Transfusion Should Be Considered	
	Risk Category	TSB mol/L/Alb, mol/L
Infants 38 0/7 wk	8.0	0.94
Infants 35 0/7–36 6/7 wk and well or 38 0/7 wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	7.2	0.84
Infants 35 0/7–37 6/7 wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	6.8	0.80

If the TSB is at or approaching the exchange level, send blood for immediate type and crossmatch. Blood for exchange transfusion is modified whole blood (red cells and plasma) crossmatched against the mother and compatible with the infant.

FIGURE 99-3. Guidelines for exchange transfusion in infants ≥35 weeks’ gestation. B/A, bilirubin/albumin ratio; G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin. (Reproduced with permission from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, Pediatrics. 2004 Jul;114(1):297-316.)

D. Pharmacologic therapy

1. **Phenobarbital** affects the metabolism of bilirubin by increasing the concentration of ligandin in liver cells, inducing production of UDPGT and enhancing bilirubin excretion. It is used for treatment of CNS-II and Gilbert syndrome. It can also be used as an adjunct therapy for treatment of exaggerated unconjugated hyperbilirubinemia in the newborn period, but it takes 3 to 7 days to be effective; therefore, it is not helpful in acute management.
2. **Metalloporphyrins.** Synthetic metalloporphyrins are structural analogs of heme; they reduce bilirubin production by competitive inhibition of **heme oxygenase**, the rate-limiting enzyme in the catabolism of heme. Evidence suggests that a single dose of **tin mesoporphyrin (SnMP)** reduces the need for phototherapy and exchange transfusion. A recent (2016) clinical trial showed that prophylactic predischARGE administration of a single intramuscular injection of 4.5 mg/kg of SnMP decreased the duration of phototherapy, reversed total bilirubin trajectory, and reduced the severity of subsequent hyperbilirubinemia. A reported untoward effect noted was a non-dose-dependent transient erythema when used in conjunction with phototherapy. Long-term safety of SnMP remains to be studied. It remains an unlicensed drug and is available on an investigational or "compassionate" use basis in the United States.
3. **Albumin.** Neurotoxicity is caused by the unconjugated fraction of bilirubin not bound to albumin (**free bilirubin**). Administration of intravenous albumin (1 g/kg over 2–3 hours) increases bilirubin-binding capacity, resulting in reduced free bilirubin. An albumin level <3.0 g/dL can be considered as 1 risk factor for lowering the threshold for phototherapy. Albumin infusion may be considered when albumin level is <3.0 g/dL, when TSB/albumin ratio is >6, and prior to DVET.
4. **Intravenous γ -globulin.** Intravenous immunoglobulin (IVIG) works by competing with sensitized neonatal RBCs at the Fc receptors in the reticuloendothelial system thus preventing further hemolysis. It is recommended in patients with isoimmune hemolysis when TSB is rising despite intensive phototherapy. Dose is 1 g/kg given over 2 to 4 hours; it can be repeated if needed in 12 to 24 hours (2 doses). Studies have shown that the use of IVIG has decreased the use of exchange transfusion in hemolytic disease of the newborn.

VIII. Prognosis

- A. **General.** Outcome of hyperbilirubinemia is generally excellent, with minimal to no additional risk of adverse outcome if identified and treated appropriately. Unconjugated bilirubin in high concentration can cross the blood–brain barrier and lead to neuronal dysfunction and death. The exact mechanism of bilirubin-induced neuronal cell injury is not completely understood; high concentrations of unconjugated bilirubin can have neurotoxic effects on cellular membranes and intracellular calcium homeostasis, resulting in neuronal excitotoxicity and mitochondrial energy failure. Bilirubin concentrations that put a preterm infant at risk for kernicterus have not been identified; incidence of kernicterus in this group is unknown, and the relationship of serum bilirubin and neurodevelopmental outcome in the very low birthweight (VLBW) infant remains unclear.

B. Encephalopathy

1. **Transient.** Early BIND is transient and reversible. The auditory system serves as an objective window to assess the central nervous system in cases of severe hyperbilirubinemia. Auditory brainstem responses show significant prolongation of latency of specific wavelengths, it can be used as an early predictor of bilirubin encephalopathy. These changes may be reversed with either exchange transfusions or spontaneous decrease in bilirubin levels. TSB level of ≥ 22 mg/dL, Rh incompatibility, and early jaundice have been reported as independent predictors of abnormal development.

2. **Acute bilirubin encephalopathy** is a preventable neurologic sequela of untreated severe hyperbilirubinemia. It is an evolving encephalopathy that can progress in 3 clinical phases over several days. The major clinical features involve disturbances in level of consciousness, tone and movement, and brainstem function, especially relating to feeding and cry. The severity of abnormalities appears to correlate with both the severity and duration of hyperbilirubinemia.

a. **Initial phase.** Initial phase is noted by lethargy, hypotonia, decreased movement, and poor suck. Clinical findings are nonspecific. A high index of suspicion is needed to recognize these signs as a signal of impending acute bilirubin encephalopathy. Prompt therapeutic intervention is critical to prevent deterioration and poor prognosis.

b. **Intermediate phase** has cardinal signs of moderate stupor, irritability, and increased tone. Infant may exhibit backward arching of the neck (retrocollis) or of the back (opisthotonos). Fever has been reported to occur during this phase of the syndrome.

c. **Advanced phase** is characterized by deep stupor or coma, increased tone, inability to feed, and a shrill cry. Seizures may occur. This is an ominous stage of acute bilirubin encephalopathy, suggesting irreversible central nervous system injury and the later development of chronic bilirubin encephalopathy (kernicterus) in most infants.

3. **Chronic bilirubin encephalopathy (kernicterus)** is a devastating and disabling neurologic disorder characterized by the following clinical tetrad: choreoathetoid cerebral palsy; high-frequency sensorineural hearing loss; palsy of vertical gaze; and dental enamel hypoplasia. **Kernicterus** is a pathologic diagnosis, describing the yellow discoloration of the deep nuclei of the brain. Brain regions that are typically affected are the globus pallidus, subthalamic nucleus, metabolic sector of the hippocampus, oculomotor nuclei, ventral cochlear nuclei, and Purkinje cells of the cerebellar cortex. The pattern of involvement is similar across different ages of affected individuals. Clinical terminology is bilirubin encephalopathy. To simplify and unify the diagnosis of bilirubin toxicity based on pathophysiologic and clinical criteria, a new designation called **kernicterus spectrum disorder (KSD)** has been proposed, acknowledging that kernicterus is symptomatically broad and diverse. Severity varies from mild to severe in children and adults. Mildly affected individuals remain highly functional; moderately affected individuals have more prominent dystonia and are likely to have athetoid movements. Severely affected individuals have speech difficulty and a more disabling dystonia to the point of not being ambulatory. This is a form of static encephalopathy, in which the degree of disability may change slightly over time but only within limits and never dramatically. Bilirubin encephalopathy is not a reportable condition in the United States; therefore, its true prevalence is not known.

IX. Prematurity and hyperbilirubinemia. Premature infants are at greater risk for developing severe hyperbilirubinemia and BIND because they are more likely to be sicker and have lower serum albumin level than their term newborn counterparts. Since there has been no definitive evidence-based recommendation as to what level of bilirubin necessitates treatment in premature infants, it is a common practice to use a lower TSB level to initiate phototherapy and not uncommon to use of prophylactic phototherapy in extremely low birthweight (ELBW) infants. A post hoc analysis from the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network trial of aggressive versus conservative use of phototherapy in ELBW infants showed that at 18 to 22 months of corrected age, phototherapy was associated with a reduction in significant neurodevelopmental impairment (mental development index <50) for infants with birthweight of 501 to 750 g; however, marginal increased mortality was noted among the smallest infants. A consensus-based recommendation that provides a gestational age-guided approach to the use of phototherapy and exchange transfusion in preterm infants has been published (see Table 63-1).

Emerging evidence suggests that intermittent phototherapy is equally effective in lowering bilirubin level with potentially fewer side effects.

It is recommended that clinicians use the lower level of TSB from this guideline in initiating management of infants at greater risk of bilirubin toxicity. The following conditions increase risk of BIND:

- A. **Lower gestational age**
- B. **Serum albumin levels <2.5 g/dL**
- C. **Rapidly rising total serum bilirubin levels, suggesting hemolytic disease**
- D. **Evidence of hemolytic process**
- E. **Presence of overwhelming infection and clinical instability**

Recommendations for exchange transfusion apply to infants in whom intensive phototherapy failed to control a rapid rise in TSB or infants who are showing evidence of bilirubin toxicity (see part B of Section VIII). Clinical signs and symptoms of bilirubin toxicity may not be easily recognizable in VLBW infants.

100 Inborn Errors of Metabolism with Acute Neonatal Onset

Inborn errors of metabolism (IEMs) are a group of disorders highly relevant to practitioners treating newborns; immediate diagnosis and appropriate treatment of these conditions can be directly linked to patient outcome to the extremes of avoiding death or irreversible brain damage. Pediatricians may feel overwhelmed by the number and complexity of these disorders (Table 100–1) and the interpretation of laboratory tests needed to establish the diagnosis. To assist clinicians, this chapter focuses on the symptom patterns, laboratory tests and their interpretation, and the initial stabilization of the patient rather than discussing details of the specific biochemical and genetic defects or special treatment measures of IEMs. Usually, the patient's ongoing treatment is supervised by a geneticist specially trained in biochemical genetics.

I. Classification

- A. **Classification by time of onset.** In this neonatal manual, we concentrate on metabolic disorders with onset in the neonatal period and early infancy, but some IEMs may present later in infancy, childhood, or even adolescence and adulthood. Even with comprehensive and well-executed newborn screening programs, a number of IEMs may present clinically before they are detected by screening tests or before the test result is available to the treating physicians. The use of **tandem mass spectrometry (MS/MS)** in newborn screening is now common practice. Due to the large amount of biochemical information obtained through MS/MS analysis, physicians involved in newborn care are often involved in follow-up evaluations and referrals of patients with a positive screening test.
- B. **Classification by clinical presentation.** Categorizing IEMs by clinical presentation has great utility when establishing the diagnosis. It is noted that some **syndromes with dysmorphic features** are now known to be IEMs (eg, Smith-Lemli-Opitz syndrome or Zellweger syndrome [see Section IX.A and B]). Other classic examples of IEMs are discussed only briefly because they are clinically asymptomatic in the neonatal period (see Section XI; phenylketonuria [PKU]). Note that some **skeletal dysplasias** and disorders affecting bone and cartilage formation (not discussed here) are, strictly speaking, also IEMs (eg, rhizomelic chondrodysplasia punctata and hypophosphatasia). The following classification

Table 100–1. INBORN ERRORS OF METABOLISM PRESENTING IN THE NEONATAL PERIOD AND INFANCY

Disorders of carbohydrate metabolism	Argininosuccinate lyase deficiency
Galactosemia	Arginase deficiency
Fructose-1,6-bisphosphatase deficiency	<i>N</i> -Acetylglutamate synthetase deficiency
Glycogen storage disease (types IA, IB, II, III, and IV)	Lysosomal storage disorders
Hereditary fructose intolerance	GM ₁ gangliosidosis type I (β -galactosidase deficiency)
Disorders of amino acid metabolism	Gaucher disease (glucocerebrosidase deficiency)
Maple syrup urine disease	Niemann-Pick disease types A and B (sphingomyelinase deficiency)
Nonketotic hyperglycinemia	Wolman disease (acid lipase deficiency)
Hereditary tyrosinemia	Mucopolysaccharidosis type VII (β -glucuronidase deficiency)
Pyroglutamic acidemia (5-oxoprolinuria)	I-cell disease (mucopolipidosis type II)
Hyperornithinemia-hyperammonemia-homocitrullinemia syndrome	Sialidosis type II (neuraminidase deficiency)
Lysinuric protein intolerance	Fucosidosis
Methylene tetrahydrofolate reductase deficiency	Peroxisomal disorders
Sulfite oxidase deficiency	Zellweger syndrome
Disorders of organic acid metabolism	Neonatal adrenoleukodystrophy
Methylmalonic acidemia	Single enzyme defects of the peroxisomal β -oxidation
Propionic acidemia	Rhizomelic chondrodysplasia punctata
Isovaleric acidemia	Infantile Refsum disease
Multiple carboxylase deficiency	Miscellaneous disorders
Glutaric acidemia type II (multiple acyl-CoA dehydrogenase deficiencies)	Adrenogenital syndrome (21-hydroxylase and other deficiencies)
HMG-CoA lyase deficiency	Disorders of bilirubin metabolism (Crigler-Najjar syndrome and others)
3-Methylcrotonoyl-CoA carboxylase deficiency	Pyridoxine-dependent seizures
3-Hydroxyisobutyric aciduria	α_1 -Antitrypsin deficiency
Disorders of pyruvate metabolism and the electron transport chain	Fatty acid oxidation disorders (short, medium, and long chain)
Pyruvate carboxylase deficiency	Cholesterol biosynthesis defects (Smith-Lemli-Opitz syndrome)
Pyruvate dehydrogenase deficiency	Congenital disorders of protein glycosylation (carbohydrate-deficient glycoprotein syndromes)
Electron transport chain defects	Neonatal hemochromatosis
Disorders of the urea cycle	
Ornithine transcarbamylase deficiency	
Carbamyl phosphate synthetase deficiency	
Transient hyperammonemia of the neonate	
Argininosuccinate synthetase deficiency (citrullinemia)	

CoA, coenzyme A; HMG, 3-hydroxy-3-methylglutaryl.

system forms the basis for the more detailed sections of this chapter; IEMs may present with the following:

1. **Encephalopathy with or without metabolic acidosis** (see Section VI)
2. **Impairment of liver function** (see Section VII)
3. **Impairment of cardiac function** (see Section VIII)
4. **Dysmorphic syndromes** (see Section IX)
5. **Nonimmune hydrops fetalis due to inborn errors of metabolism (less common)** (see Section X)

C. **Classification according to the biochemical basis of the disease.** Subdividing IEMs according to their biochemical characteristics assists with understanding of the pathogenesis and different treatment approaches but is of limited utility for those providing patient care.

II. **Incidence.** By some estimates, IEMs may account for as much as 20% of disease among severely ill full-term infants not known to have been born at any risk. Cumulatively, an IEM may be present in >1 in 500 live births.

III. **Pathophysiology.** Metabolic processes are catalyzed by genetically encoded enzyme proteins. The classical mechanism of a metabolic defect is lack or deficiency of a functioning enzyme resulting in **substrate accumulation** and conversion of intermediary metabolites to products not usually present. In addition, end products of the normal pathway will be deficient. Symptoms may result from an increased level of the normal substrate (eg, in urea cycle disorders, the substrate ammonia is toxic and leads to cerebral edema, central nervous system [CNS] dysfunction, and eventually death). Additionally, a **lack of normal end products** of metabolism can lead to symptoms (eg, lack of cholesterol in Smith-Lemli-Opitz syndrome [see Section IX.A]). **Alternative products may interfere with normal metabolic processes** (eg, accumulated propionyl-coenzyme A [CoA] may be used as substrate instead of acetyl-CoA in propionic acidemia). Finally, an **inability to degrade end products of a metabolic pathway** may lead to symptoms (eg, myocardial dysfunction in glycogen storage disease type II or hepatomegaly in glycogen storage disease type I). The time of clinical presentation may be related to the question of whether metabolites can be transported across the placenta; metabolites of low molecular weight can transport across and are therefore prenatally removed from the fetus and cleared by the maternal metabolism.

IV. **Risk factors. IEMs are genetic disorders.** Therefore, behavioral or environmental factors are not causative for IEMs, but environment and especially nutrition may affect presentation. A history of relatives with intellectual disability, protein avoidance, and, for many disorders, neonatal or childhood deaths or severe illness (liver disease, abnormal heart function, mental and/or physical decline, episodic illness) could indicate an increased risk for IEMs. A history of protein avoidance, liver dysfunction/failure, or mental changes in pregnancy and labor may be seen in female carriers of X-linked inherited urea cycle defects. Presence of consanguinity and, for a number of inborn errors, ethnic background are also risk factors.

V. **Clinical presentation.** Although there are several specific presentations (listed next) in which an IEM must be considered, the best assumption in clinical practice is that **an IEM should be considered in any sick newborn**. The newborn has a “limited repertoire” of symptoms that are often nonspecific. The differential diagnosis of symptoms such as **poor feeding, lethargy, hypotonia, vomiting, hypothermia, seizures, and disturbances of breathing** is extensive. Because it is common, the diagnosis of sepsis often tops the differential diagnosis list. But it is in the best interest of the patient to consider and evaluate for other causes, including IEMs, at the same time that laboratory investigations are initiated to rule out infection. This is essential for a timely diagnosis and can be accomplished with a relatively small number of laboratory tests of moderate cost that are readily available in most hospitals, as discussed in the following sections.

A. **An inborn error of metabolism must be strongly considered under the following circumstances:**

1. **History of unexplained neonatal deaths in the family** (prior siblings or male infants on the mother's side of the family).
2. **Infants who are the offspring of consanguineous mating** (because of higher incidence of autosomal recessive conditions; autosomal recessive inheritance is common among IEMs).
3. **Onset of signs and symptoms after a period of good health** that may be as short as a few hours.
4. **Infants who are quite ill with a lack of perinatal events or birth history explaining their presentation.**
5. **Symptoms are related to the introduction and progression of enteral feedings.**
6. **Failure of usual therapies to alleviate the symptoms or inability to prove a suspected diagnosis** such as sepsis, CNS hemorrhage, or other congenital or acquired conditions.
7. **Progression of symptoms.**
8. **Although patients with an inborn error of metabolism might be born prematurely, they are typically full-term infants.** An exception is the diagnosis of transient hyperammonemia of the neonate, a condition that typically affects preterm infants. While the exact cause of the hyperammonemia in these patients remains unclear, it is related to prematurity rather than being a genetic IEM.

B. Signs and symptoms. See Table 100–2 for a summary of signs and symptoms of IEMs. Table 100–3 lists common misdiagnoses of infants with IEMs. **Symptoms may overlap with frequent neonatal conditions**; for example, a child with an IEM may have transient tachypnea of the newborn or be at risk for sepsis for unrelated reasons. Occasionally, 2 seemingly unrelated conditions may be associated for unclear reasons; an example is the increased incidence of *Escherichia coli* sepsis in infants with galactosemia.

C. Asymptomatic inborn errors of metabolism in the newborn. Untreated PKU does not cause any symptoms in the newborn. It causes irreversible brain damage while the patient appears clinically well. Thus, newborn screening testing with prompt follow-up of abnormal results is essential. Early detection of PKU in the newborn allows for treatment that prevents extreme intellectual disability. (See Section XI.)

D. To guide the clinician in the diagnostic workup, signs and symptoms are discussed in the following sections for 5 different major clinical presentations: IEM presenting with encephalopathy, IEM presenting with liver disease, IEM presenting with impairment of cardiac function, IEM presenting as dysmorphic syndromes, and IEM presenting as nonimmune hydrops (see Sections VI to X). Flow diagrams in Figures 100–1 and 100–2 are designed to assist in the diagnostic workup. Details regarding the different **laboratory tests** are outlined in Section XII.

VI. Major clinical presentation: inborn errors of metabolism presenting with encephalopathy. Encephalopathies associated with IEMs are clinically often indistinguishable from those caused by a hypoxic-ischemic insult or other CNS insult (hemorrhage or infectious disease). **Abnormal tone** (hypotonia as well as hypertonia may be of central origin) and **abnormal movements and seizures** clearly indicate CNS involvement. Clinically, seizures may present as lip smacking, tongue thrusting, bicycling movements of the lower extremities, opisthotonos, tremors, or generalized tonic-clonic movements. In severe encephalopathy, burst suppression pattern may be seen on **electroencephalography (EEG) using conventional multilead EEG or bedside monitoring with amplitude-integrated EEG (aEEG)**. Discontinuous patterns detected by aEEG may be seen with less severe encephalopathy.

A. Laboratory evaluation

1. **Acute evaluation.** In any patient with encephalopathy of any degree, careful evaluation of the acid-base status is advisable. Some IEMs present with

Table 100–2. SIGNS AND SYMPTOMS AND ASSOCIATED METABOLIC DISORDERS**Neurologic (hypotonia, lethargy, poor sucking, seizures, coma)**

Glycogen storage disease, galactosemia, organic acidemias, hereditary fructose intolerance, maple syrup urine disease, urea cycle disorders, hyperglycinemia, pyridoxine dependency, peroxisomal disorders, congenital disorders of glycosylation, fatty acid oxidation disorders, and respiratory chain defects

Hepatomegaly/liver dysfunction

Lysosomal storage diseases, galactosemia, hereditary fructose intolerance, glycogen storage disease, tyrosinemia, α_1 -antitrypsin deficiency, Gaucher disease, Niemann-Pick disease, Wolman disease, fatty acid oxidation defects, and respiratory chain defects

Hyperbilirubinemia

Galactosemia, hereditary fructose intolerance, tyrosinemia, α_1 -antitrypsin deficiency, Crigler-Najjar syndrome, and other disorders of bilirubin metabolism

Nonimmune hydrops

Gaucher disease, Niemann-Pick disease, GM₁ gangliosidosis, congenital disorders of glycosylation

Cardiomegaly/cardiomyopathy

Glycogen storage disease type II, fatty acid oxidation defects, and respiratory chain defects

Macroglossia

GM₁ gangliosidosis, glycogen storage disease type II

Abnormal odor

Maple syrup urine disease (odor of maple syrup or burnt sugar)

Isovaleric acidemia, glutaric acidemia (odor of sweaty feet)

HMG-CoA lyase deficiency (odor of cat urine)

Abnormal hair

Argininosuccinic acidemia, lysinuric protein intolerance, Menkes kinky hair syndrome

Hypoglycemia

Galactosemia, hereditary fructose intolerance, tyrosinemia, maple syrup urine disease, glycogen storage disease, methylmalonic acidemia, propionic acidemia, fatty acid oxidation defects, and respiratory chain defects

Ketosis

Organic acidemias, tyrosinemia, methylmalonic acidemia, maple syrup urine disease

Metabolic acidosis

Galactosemia, hereditary fructose intolerance, maple syrup urine disease, glycogen storage disease, organic acidemias

Hyperammonemia

Urea cycle defects, transient hyperammonemia of the neonate, organic acidurias, HMG-CoA lyase deficiency, fatty acid oxidation disorders

Neutropenia

Organic acidemias, especially methylmalonic acidemia and propionic acidemia; nonketotic hypoglycinemia, carbamyl phosphate synthetase deficiency

(Continued)

Table 100–2. SIGNS AND SYMPTOMS AND ASSOCIATED METABOLIC DISORDERS (CONTINUED)

Thrombocytopenia

Organic acidemias, lysinuric protein intolerance

Dysmorphic features

Glutaric aciduria type II, 3-hydroxyisobutyric aciduria, Smith-Lemli-Opitz syndrome, peroxisomal disorders, congenital disorders of glycosylation

Renal cysts

Glutaric aciduria type II, peroxisomal disorders

Abnormalities of the eye (eg, glaucoma, retinopathy)

Galactosemia, lysosomal storage disorders, peroxisomal disorders

Abnormal fat distribution/inverted nipples

Congenital disorders of glycosylation

Epiphyseal stippling in radiograph

Peroxisomal disorders (Zellweger syndrome, neonatal adrenoleukodystrophy, rhizomelic chondrodysplasia punctata)

CoA, coenzyme A; HMG, 3-hydroxy-3-methylglutaryl.

quite pronounced metabolic acidosis. The following tests (for details, see Section XII) should be performed as part of the **acute evaluation** of patients with encephalopathy:

a. Arterial or venous blood gas

- i. When interpreting the venous or arterial blood gas of a newborn, alterations in respiratory status,** which are frequent in this patient group, must be taken into consideration. An isolated respiratory acidosis is likely pulmonary or related to disturbed respiratory drive. A metabolic or mixed acidosis, especially shortly after delivery, may be related to perinatal events.

Table 100–3. MISDIAGNOSES OF METABOLIC DISEASE IN THE NEWBORN INFANT

Bacterial sepsis

Acute viral infection

Asphyxia

Gastrointestinal tract obstruction

Hepatic failure, hepatitis

Central nervous system catastrophe

Persistent pulmonary hypertension

Cardiomyopathy

Neuromuscular disorder

FIGURE 100-1. Algorithm for the diagnosis of metabolic disorders of acute onset in an ill infant (guideline only; for details, see text and references). CoA, coenzyme A; HMG, 3-hydroxy-3-methylglutaryl.

FIGURE 100-2. Algorithm for the differential diagnosis of hyperammonemia (guideline only; for details, see text and references). CoA, coenzyme A; HMG, 3-hydroxy-3-methylglutaryl.

of plasma amino acids and orotic acid is necessary to establish the exact diagnosis. Urine organic acids should also be examined.

- c. **Treatment.** Initial treatment is similar, independent of the final diagnosis (see Section XIII.A). Immediate transfer to a facility able to perform hemodialysis is strongly advised when hyperammonemia is detected. The use of medication such as sodium phenyl acetate and butyrate should be supervised by a biochemical geneticist. In some defects (eg, argininosuccinate lyase deficiency), substitution of arginine (intravenous arginine hydrochloride) may alleviate symptoms; arginine is a metabolite of the cycle and can be low if downstream from the deficient reaction. Long-term **protein restriction** is necessary (see Section XIII.B.1). Acute treatment of THAN is similar to that of inborn errors of the urea cycle, but deficiency of the metabolic pathway is temporary and normal protein intake is tolerated later in life.
 - d. **Outcome.** Outcome (especially in regard to CNS injury) depends on diagnosis and severity and duration of hyperammonemic episodes; outcome is more favorable for THAN compared with inherited urea cycle defects.
2. **Maple syrup urine disease.** Accumulation of **branched-chain amino acids (leucine, isoleucine, and valine)** is secondary to a defect in the decarboxylase involved in the catabolism of these amino acids. 2-Keto metabolites of the 3 amino acids also accumulate. Leucine is the amino acid that may be the most neurotoxic.
 - a. **Clinical presentation.** Symptoms typically develop after the second week of life but may manifest as early as at 24 hours of age and, therefore, may precede the report of the neonatal screening test result. **Typical symptoms** are feeding intolerance, lethargy, signs of encephalopathy such as hypotonia or posturing, abnormal movements, or frank seizures (late in the course). **Typical odor** (maple syrup or “burnt sugar”) may not be prominent; metabolic acidosis is a late presentation.
 - b. **Diagnosis.** Maple syrup urine disease (MSUD) is diagnosed by quantitative amino acid analysis (leucine, isoleucine, valine, and glycine are elevated) and detection of 2-keto metabolites in urine organic acid analysis. The 2,4-dinitrophenylhydrazine (2,4-DNPH) test detects 2-keto acids (usually offered by specialized laboratories only).
 - c. **Treatment.** Restrict protein intake acutely while providing high amounts of glucose and fluid (see Section XIII.A). Later, provide formula low in leucine, valine, and isoleucine with restriction of natural protein. **Dialysis** may be needed as acute therapy if severe encephalopathy has developed. Some patients may show response to thiamine (see Section XIII.B.3).
 3. **Nonketotic hyperglycinemia (glycine encephalopathy)**
 - a. **Clinical presentation.** A **typical presentation** for NKH is a patient suffering from a severe encephalopathy that is rapidly progressing and may eventually result in respiratory arrest. Standard evaluations for IEMs and other causes of this presentation do not reveal any abnormalities (no acidosis, hypoglycemia, or hyperammonemia and no other organ system affected). **Pronounced and sustained “hiccoughs”** in an encephalopathic infant have been associated with NKH.
 - b. **Diagnosis.** **Hyperglycinemia** in plasma is typical but may not be pronounced in young infants because of decreased renal reabsorption of this amino acid. In addition, other IEMs also result in increased blood glycine levels, such as MSUD (sometimes referred to as “ketotic hyperglycinemia”). Indications for **urine amino acids** are few, but in NKH, they can be of value because they detect the typical high renal glycine excretion. The diagnostic test for NKH is simultaneous measurement of CSF and plasma glycine levels to determine the **CSF-to-plasma glycine ratio**. Elevation of glycine in the

CSF is specific for NKH; a ratio of >0.08 is considered diagnostic (0.02 – 0.08 is equivocal; <0.02 is normal).

c. Treatment. Restoration of normal glycine levels in blood may be achieved through hydration or the use of sodium benzoate (see Section XIII.A.5), but the glycine accumulation in CSF remains unaffected. Several medications (eg, dextromethorphan) have been tried in attempts to favorably affect the CNS symptomatology but have achieved only limited success.

d. Outcome. Patients may survive because the respiratory depression has the potential to improve, but brain injury results in poor long-term outcome; patients with a rare transient form of NKH may do slightly better.

4. Peroxisomal disorders

a. Clinical presentation. Defects of peroxisome biogenesis (eg, Zellweger syndrome and neonatal adrenoleukodystrophy) and some of the peroxisomal single-enzyme defects (eg, multifunctional enzyme deficiency) present with encephalopathy in the neonatal period. Patients display **severe central hypotonia** (“floppy babies”) and develop **seizures** (usually within the first week of life). Hepatomegaly, renal and hepatic cysts, and skeletal or retinal abnormalities may also be found.

b. Diagnosis. Most peroxisomal defects can be detected by analysis of plasma **very-long-chain fatty acids (VLCFAs)** (with carbon chains of ≥ 24 carbons). Other peroxisome function tests (see Section XII.C.8) and DNA analysis help define the exact peroxisomal defect.

5. Organic aciduria/acidemias. This group of IEMs is complex; because clinicians often feel overwhelmed by biochemical details regarding these conditions, the focus will be on clinical characteristics:

a. Clinical presentations. Many organic aciduria/acidemias (OAs) present later in infancy. Three conditions commonly present in the neonatal period and are clinically nearly indistinguishable: **methylmalonic acidemia**, **propionic acidemia**, and **isovaleric acidemia**. Affected newborns typically develop encephalopathy with severe acidosis, hyperammonemia, and seizures; an unusual **odor** (most noticeable in urine [see Table 100–2]) may be noted; **neutropenia** and **thrombocytopenia** may occur. More OAs are listed in Table 100–1.

b. Diagnosis. Analysis of plasma amino acids and urine organic acids is essential to diagnose OAs. These tests are best interpreted by an experienced biochemical geneticist familiar with the clinical presentation of the patient.

c. Treatment. If OAs are suspected, enteral feedings should be withheld. In addition to hydration and glucose infusion (both at least 1.5 times the maintenance level), hyperammonemia should be treated (see Section XIII.A) and the metabolic acidosis corrected with bicarbonate while ensuring appropriate ventilation. Involvement of a metabolic geneticist in diagnostic workup and treatment is advisable. Some OAs may partially respond to vitamins (see Section XIII.B.3).

6. Congenital lactic acidosis. Some possible causes of lactic acidosis (LA) in a neonate are **pyruvate dehydrogenase (PDH) defect**, **pyruvate carboxylase defect**, and **mitochondrial respiratory chain defects** (most common are defects of complex I and/or IV).

a. Clinical presentation. Congenital LA may be difficult to differentiate clinically from hypoxic ischemic encephalopathy, sepsis, and other conditions that result in metabolic acidosis, poor perfusion, and shock. LA is more likely a genetic congenital LA if **severe** (especially if unexpected or more severe than clinical history explains) and in infants who are **growth restricted** or who have mild **dysmorphic features** and/or anatomic anomalies of the brain. **Multiorgan disease** unexplained by other causes (eg, hypertrophic cardiomyopathy or cataracts) may occur. **Hypoglycemia** is

common (but may also be a presentation of a glycogen storage disease; see Section VII.F).

- b. **Diagnosis.** Once an increase of lactic acid is found, determination of the **lactate-pyruvate ratio** further guides the diagnostic process (see Section XII.C.1). LA is a consequence of deficient energy production through aerobic metabolism, which depends on conversion of pyruvate to metabolites of the citrate cycle and an intact mitochondrial respiratory chain. In congenital LA, muscle and/or liver biopsies (Section XII.C.10) or sequencing of mitochondrial and/or genomic DNA (Section XII.C.11) may be needed to establish a diagnosis.
 - c. **Treatment.** Although hydration and glucose at 1.5 times maintenance is beneficial to most patients with suspected IEMs, PDH deficiency is a rare exception as the LA may worsen with high glucose infusion.
- 7. Other rare but relevant inborn errors of metabolism that can present with neonatal encephalopathy and/or seizures:**
- a. **Fatty acid oxidation disorders with dicarboxylic aciduria.** Although the most common fatty acid oxidation (FAO) defect (medium-chain acyl-CoA dehydrogenase [MCAD] deficiency) rarely causes illness in a neonate, short- and long-chain acyl-CoA dehydrogenase deficiencies (SCAD and LCAD, respectively) or other very rare FAO disorders may present in the neonatal period.
 - b. **Multiple carboxylase deficiency.**
 - c. **Holocarboxylase synthetase deficiency.**
 - d. **Glutaric acidemia type II.** A defect of the electron transport flavoprotein or its dehydrogenase.
 - e. **Pyroglutamic acidemia.** 5-Oxoprolinuria, a defect in glutathione synthetase.
 - f. **Molybdenum cofactor deficiency** (xanthine oxidase deficiency or sulfite oxidase deficiency). One diagnostic clue to xanthine oxidase deficiency may be a **low plasma uric acid level**. A commercial test is available to determine urine sulfite excretion in urine.
 - g. **3-Hydroxy-3-methylglutaryl-CoA lyase deficiency.**
 - h. **Pyridoxine-dependent seizures.** Patients present with seizures in the neonatal period or in early infancy that are refractory to treatment with anticonvulsants but resolve with administration of vitamin B6 (100 mg of pyridoxine intravenously). Note that diagnostic markers such as α -aminoadipic semialdehyde, piperidine-6-carboxylate, and pipercolic acid need to be obtained prior to administration of vitamin B6.
 - i. **Congenital disorders of glycosylation.** Although typically presenting later, congenital disorders of glycosylation (CDGs) may also present in neonates with acute encephalopathy, seizures, and stroke-like episodes. Many types of CDGs have been described in recent years. CDG type Ia is the most common, and if neonates are symptomatic, they are usually hypotonic. **Cerebellar atrophy** may be noted on pre- or postnatal imaging studies. Psychomotor development is delayed later in life; ataxia, dyskinesia, and muscle weakness become prominent. **Severe feeding problems and failure to thrive** are typical; intractable diarrhea in a neonate has been reported. **Unusual fat pads in the buttock area and inverted nipples** are believed to be quite characteristic findings.
 - j. **These autosomal recessive conditions are characterized by defects in the glycosylation of proteins (see Section XII.C.9 for diagnostic testing).** They are multisystem disorders. Other than neurologic involvement, hepatic dysfunction with abnormal liver enzymes, pericardial effusions, nephrotic syndrome, nonimmune hydrops, and facial dysmorphic features (broad nasal bridge, prominent jaw and forehead, large ears, strabismus) have been described in infants.

VII. Major clinical presentation: inborn errors of metabolism presenting with liver disease. Several IEMs result in neonatal liver disease that may present with **hepatomegaly, jaundice, hepatocellular dysfunction, and/or hypoglycemia**. In addition to routine diagnostic testing (eg, bilirubin levels, liver enzyme levels, and liver imaging), glucose, cholesterol, coagulation studies, total protein, and albumin levels can assess the synthetic function of the liver. Because the liver is a main organ of amino acid metabolism, analysis of plasma amino acid can be of interest but requires interpretation by a metabolic geneticist (who may also recommend further disease-specific testing as indicated). The following conditions are discussed because of either their frequency or clinical significance.

- A. Galactosemia.** Does not present in an affected newborn until the patient is receiving galactose. Breast milk and most formulas contain **lactose** (a disaccharide of glucose and galactose); most soy formulas do not. Typical symptoms are **hyperbilirubinemia** (which may be unconjugated initially but later becomes mainly conjugated) and then signs of **liver dysfunction** (which may include **coagulopathy, hypoglycemia, hypoalbuminemia, and ascites**) and **hepatomegaly**. If untreated, symptoms may worsen to encephalopathy with cerebral edema, metabolic acidosis (hyperchloremia and hypophosphatemia), and renal dysfunction. Patients with galactosemia may have **congenital cataracts** and have an increased risk of ***E coli* sepsis**. **Testing urine for reducing substances** is an initial screening test (see Section XII.B.7). If galactose has been discontinued, reducing substance testing may be falsely negative and blood tests are essential to make a diagnosis. Galactosemia is due to a defect in either **galactose-1-phosphate uridylyltransferase (GALT)** (classic galactosemia) or uridine 5'-diphosphate galactose 4-epimerase (rare variant). Red blood cells are used to measure GALT activity and/or accumulation of galactose-1-phosphate. Treatment consists of galactose restriction in the diet; the diet is relatively strict and difficult to follow. Even if compliance with the diet is good, many patients show **developmental delays**; females suffer **ovarian failure** later in life.
- B. Hepatorenal tyrosinemia.** Tyrosinemia type I, or hepatorenal tyrosinemia, usually presents in infancy, but some affected neonates may develop **severe liver dysfunction**, including hyperbilirubinemia, hypoglycemia, hyperammonemia, coagulopathy, hypoalbuminemia with ascites, and anasarca. This IEM also causes renal disease with mainly tubular dysfunction (amino aciduria or glucosuria) and results in hypophosphatemia and hyperchloremic metabolic acidosis. **Cardiomyopathy** can also develop; clinical presentation may thus overlap with disorders of fatty acid metabolism and respiratory chain defects. While tyrosine levels may be abnormal with liver dysfunction due to other causes, the presence of **succinylacetone** in urine is specific for tyrosinemia (see Section XII.C.4). Plasma cysteine might be low; plasma α -fetoprotein may be markedly increased. The only long-term treatment option is liver transplantation.
- C. α_1 -Antitrypsin deficiency.** This IEM may present in neonates and infants as **hyperbilirubinemia**, which is usually prolonged and conjugated (with signs of cholestasis) but may resolve spontaneously within the first 6 months of life. These children may then not present again clinically until **liver cirrhosis** with portal hypertension has developed. **Emphysema** is the adult manifestation and may develop as early as the third decade of life and is much accelerated by smoking. The destruction of pulmonary and hepatic tissue in α_1 -antitrypsin deficiency (AATD) is a consequence of a mutation in the *AATD* gene (designated as **Z mutation**), which, in homozygous carriers, results in deficiency of AAT, which is an inhibitor of an elastase, a degrading enzyme of neutrophils. Diagnosis is confirmed by **genotyping**, which is routinely available in most hospitals as a common test done in adults with emphysema. Although the symptoms during early life may resolve spontaneously and not all patients develop liver and lung manifestations, a diagnosis early in life allows patients to favorably affect their risk of serious adult disease through early behavior modification.

- D. Inborn errors of bilirubin metabolism.** Inherited defects in the metabolism of bilirubin include defects in conjugation (**Crigler-Najjar syndrome**) and uptake and excretion of bilirubin (**Dubin-Johnson and Rotor syndromes**). These conditions result in either indirect or direct hyperbilirubinemia. Dubin-Johnson and Rotor syndromes are rarely diagnosed in the newborn period.
- E. Fatty acid oxidation disorders.** FAO disorders may present with a combination of encephalopathy with cardiac and liver dysfunction; see Section VIII.A for more detailed information. The **liver dysfunction** may be milder than in other IEMs; **hyperammonemia** develops only with progression to significant liver dysfunction. The main clinical presentation may include generalized hypotonia and cardiomyopathy. Succinylacetone will be negative, whereas tyrosine metabolites may be present in urine organic acids. **Acylcarnitine profile** abnormalities may establish the diagnosis (see Section XII.C.5).
- F. Glycogen storage disease type I (von Gierke disease).** The clinical presentation of glycogen storage disorders in the newborn period may be limited to **hypoglycemia**, which can be severe and may be accompanied by LA. In von Gierke disease, the hypoglycemia is unresponsive to glucagon injection. **Liver enlargement and dysfunction** usually develop shortly thereafter (as soon as within 1–2 weeks). **Hyperlipidemia** may be present. Liver biopsy with enzyme analysis may be needed for diagnosis (see Section XII.C.10).
- G. Peroxisomal disorders.** Patients with disorders of peroxisomal biogenesis such as Zellweger syndrome and neonatal adrenoleukodystrophy develop **hepatomegaly** early in life which may progress to fibrosis and cirrhosis. The clinical presentation is usually dominated by **central hypotonia and seizures** (see Section VI. B.4.a). **Dysmorphic features** are present (Section IX.B). See Section XII.C.8 for specific diagnostic tests.
- H. Others.** Other inherited conditions that may present with hepatocellular dysfunction, sometimes as early as in the neonatal period, are as follows:
1. **Neonatal hemochromatosis.**
 2. **Hereditary fructose intolerance.**
 3. **Defects in carnitine metabolism.**
 4. **Other glycogen storage diseases.**
 5. **Lysosomal storage disorders.** Niemann-Pick disease may present with neonatal hepatitis.
 6. **Congenital disorders of glycosylation.** See Section VI.B.7.i.

VIII. Major clinical presentation: inborn errors of metabolism presenting with impairment of cardiac function

- A. Fatty acid oxidation disorders.** Suspect in any neonate with impairment of cardiac function without clear etiology; cardiac arrhythmias occur in some. Additional symptoms such as encephalopathy (see Section VI.B.7.a) or impaired liver function (see Section VII.E), rhabdomyolysis and muscle weakness, and/or retinopathy may be present. FAO disorders affecting the dehydrogenase steps of β -oxidation are subdivided according to the length of the carbon chain of the fatty acids that accumulate: SCAD, MCAD, and LCAD deficiency. In addition, deficiency of long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) or other enzymes of the trifunctional enzyme complex and defects resulting in an inability to metabolize fatty acids properly due to defects of the plasma membrane carnitine transporter or carnitine palmitoyl transferase I or II have been described. In addition to **cardiomyopathy** usually resulting in cardiac failure, **encephalopathy, myopathy, and hepatomegaly** also occur. With low glucose intake or intercurrent illnesses, patients characteristically develop **hypoketotic hypoglycemia**. Maternal fatty liver of pregnancy and HELLP (**hemolysis, elevated liver enzymes, and low platelets**) syndrome have been associated with FAO defects, especially LCHAD and SCAD.

Acylcarnitine profile analysis by mass spectrometry (see Sections XII.C.5 and XII.C.6) helps to establish the diagnosis, which is then confirmed by enzyme assays

in cultured fibroblasts. Newborn screening using the MS/MS will detect some FAO defects. Total and free **carnitine levels** should be determined (see Section XII.C.5). Treatment of FAO disorders consists of avoidance of prolonged periods without carbohydrate intake. Intravenous or oral carnitine may be indicated. Although medium-chain triglycerides (MCTs) are contraindicated in MCAD, they may be a good source of energy in the other conditions and can be given as commercially available MCT oil or through formulas with high levels of MCT oil as the predominant fat source.

- B. Pompe disease.** The cardiomyopathy of Pompe disease may (although not typically) present as early as in the neonatal period. Of diagnostic help are **electrocardiographic changes**, some of which are fairly characteristic: shortening of the PR interval, marked left-axis deviation, T-wave inversion, and enlarged QRS complexes. The diagnosis is confirmed by measurement of the deficient enzyme (α -glucosidase or acid maltase) in leukocytes or cultured fibroblasts (see Section XII.C.10).
- C. Hepatorenal tyrosinemia.** Type I tyrosinemia may present with cardiomyopathy in addition to liver and renal tubular dysfunction (see Section VII.B).
- D. Congenital disorders of glycosylation.** (See Section VI.B.7.i.) Pericardial effusions have been observed in affected patients.
- IX. Major clinical presentation: inborn errors of metabolism presenting as dysmorphic syndromes.** Several dysmorphic syndromes are now known to be IEMs. It is likely that more conditions initially described as syndromes will eventually be found to be IEMs or genetic conditions secondary to specific molecular mechanisms. Examples of disorders in this category include the following:
- A. Smith-Lemli-Opitz syndrome.** The metabolic basis of Smith-Lemli-Opitz syndrome is a defect in 7-dehydrocholesterol dehydrogenase, resulting in an **accumulation of 7-dehydrocholesterol** and typically low cholesterol levels in plasma. The main clinical signs of this relatively common syndrome (estimated frequency of 1 in 20,000) are as follows:
1. **Growth deficiency** (usually postnatal) and microcephaly.
 2. **Dysmorphic features** including a high forehead, ptosis, epicanthal folds, strabismus, rotated and low-set ears, a nose with a wide tip, and micrognathia.
 3. **Hypospadias** in males.
 4. **Syndactyly** of the second and third toes (typically Y-shaped).
 5. **Other common findings** include cataracts, hypotonia, and significant psychomotor developmental delay.
- B. Zellweger spectrum disorders.** Initially defined by clinical characteristics, **Zellweger syndrome**, **neonatal adrenoleukodystrophy**, and **infantile Refsum disease** are all clinical phenotypes of defects in peroxisomal biogenesis and function. The diagnosis is established by measurement of VLCFAs and other biochemical parameters affected by peroxisomal dysfunction (see Section XII.C.8). Typical findings are as follows:
1. **Dysmorphic features.** A high forehead, a wide and flat nasal bridge, epicanthal folds, and dysplastic ears; the fontanelles are wide open.
 2. **Severe hypotonia, seizures, and lack of psychomotor development.**
 3. **Hepatomegaly with fibrosis.**
 4. **Ocular abnormalities.** Corneal clouding, cataract, and retinal changes.
 5. **Punctate calcifications of the skeleton.**
 6. **Small renal cortical cysts.**
- C. Pyruvate dehydrogenase deficiency.** Patients with congenital LA (see Section VI.B.6) resulting from PDH deficiency often display dysmorphic features, including a high and prominent forehead, a widened nasal bridge, a small anteverted nose, and dysmorphic and enlarged ears.
- D. Congenital defects of glycosylation.** (See Section VI.B.7.i.) Dysmorphic features include broad nasal bridge, prominent jaw and forehead, large ears, and strabismus.

Unusual fat pads in the buttock area and inverted nipples are characteristic findings.

X. Major clinical presentation: inborn errors of metabolism presenting as nonimmune hydrops. The differential diagnosis of nonimmune hydrops is extensive. Although 3 groups of conditions are mentioned in the following sections, the list of possible genetic diagnoses is long; geneticists should be consulted and genome or exome sequencing should be considered.

A. In inherited hematologic conditions (eg, glucose-6-phosphate dehydrogenase deficiency and pyruvate kinase deficiency), the hydrops is due to anemia and heart failure.

B. Genetic conditions with disturbed lysosomal function. Cases of hydrops have been reported in **GM₁ gangliosidosis**, **Gaucher disease**, **Niemann-Pick disease**, and lysosomal disorders. The presence of **hepatomegaly**, **dysostosis multiplex**, and abnormal **vacuolated mononuclear cells** in the peripheral blood smear is a diagnostic clue.

C. Congenital disorders of glycosylation rarely present with nonimmune hydrops fetalis (based on a small number of case reports).

XI. An important inborn error of metabolism lacking neonatal symptoms: phenylketonuria. Untreated PKU **does not cause symptoms in the neonate**. Even though the patient is clinically well, **irreversible brain damage** occurs as a result of accumulating phenylalanine and its metabolites. Therefore, patients benefit enormously from detection by neonatal screening for PKU.

A. If neonatal screening shows elevation of phenylalanine, formula or breast milk must be discontinued and hydration provided (short-term enteral feedings with electrolyte solutions are feasible; intravenous therapy is usually not mandated). The patient should immediately (within hours) be referred to a geneticist for further evaluation (including differentiation between classic PKU and hyperphenylalaninemia), initiation of diet, and family education, training, and counseling.

B. A child of a mother with phenylketonuria is an obligate heterozygote for the disease, and the PKU allele is frequent in the general population (1:20); the child has a 1 in 80 risk of being affected. Thus, measurement of phenylalanine levels after enteral feedings are established is mandatory. Although institutional practices vary, many geneticists recommend early quantitative amino acid analysis rather than routine newborn screening in this scenario. Newborns of affected mothers with insufficient treatment may manifest with **microcephaly**, **congenital heart disease**, and **intellectual disability** (even if the infant is not homozygous for PKU).

XII. Diagnosis

A. Prenatal. Biochemical methods (eg, detection of metabolites in amniotic fluid and enzyme assays using cultured cells) and DNA analysis (specific mutation detection, genomics) are used for prenatal testing. Diagnostic procedures routinely available are **chorionic villus sampling** or **amniocentesis**. Newer methods such as **analysis of fetal cells in maternal circulation** or **preimplantation testing of the embryo with in vitro fertilization** may also be offered. Some in utero interventions may be available (eg, dietary control in maternal PKU or experimental fetal stem cell treatment); prenatal counseling is essential because, per local legislation, parents may be able to make an informed decision regarding continuation of pregnancy.

B. Postnatal. Emphasis is on the detection of a metabolic disorder with a quick turnaround time and targeted secondary testing; cost and limitation in the blood volume that can safely be obtained from a neonate are concerns. Although some of the laboratory tests have already been discussed earlier, details regarding the specifics of these tests and their interpretations are outlined here. Refer also to Table 100–4.

1. Complete blood count with differential, hemoglobin, and platelets. Note that neutropenia (often combined with metabolic acidosis) is not only typically found in sepsis and poor perfusion but may also be present in patients with organic acidopathy (especially propionic acidemia, methylmalonic acidemia,

Table 100-4. LABORATORY FINDINGS SUGGESTIVE OF METABOLIC DISEASE

Variable	Galactosemia	Glycogen Storage Disease	Maple Syrup Urine Disease	Nonketotic Hyperglycinemia	Glutaric Acidemia Type II	Organic Acidemia	Disorders of Pyruvate Metabolism	Disorders of the Urea Cycle	Transient Hyperammonemia of the Newborn
Hypoglycemia	+	+	±	-	±	±	+	-	-
Metabolic acidosis with or without elevated anion gap	+	±	+	-	±	+	±	±	±
Respiratory alkalosis	-	-	-	-	-	-	-	+	±
Hyperammonemia	-	-	-	-	-	+	-	+	+
Urine ketones	-	±	+	-	-	+	±	-	-
Urine abnormal odor or color	-	-	+	-	+	+	-	-	-
Neutropenia or thrombocytopenia	-	-	-	-	-	+	-	-	-

Note: Guidelines only; for details, see text and references.

and isovaleric acidemia). Thrombocytopenia may be present. Because patients are often typically also hyperammonemic, measurement of an ammonia level is essential in newborns with acidosis, leukopenia, or thrombocytopenia of unclear etiology.

2. **Blood gas.** Interpretation of the acid-base status is important (see Section VI.A.1.a). IEMs must be especially considered in the scenario of either a **severe metabolic acidosis** or a **respiratory alkalosis** (note that hyperventilation may be induced by a painful stimulus, such as blood sampling, but a pure respiratory alkalosis should not easily be dismissed as artifact). Ammonia measurement is indicated to rule out an organic aciduria with secondary hyperammonemia or a urea cycle defect causing a respiratory alkalosis as a result of hyperventilation due to direct stimulation of the respiratory center by ammonia. Be aware that excess heparin in a blood gas specimen may mimic a metabolic acidosis; specimens not instantly processed should be stored in ice water.
3. **Electrolyte determination.** In addition to the interpretation of the different electrolyte component levels, the **anion gap** should be calculated. The concentration of negatively and positively charged electrolytes is compared: Add the sodium and potassium levels (in mEq/L) and subtract the sum of the chloride and bicarbonate concentrations. An anion gap >17 mEq/L (consult with your local laboratory as cutoffs may vary depending on assays used) suggests an excess of negatively charged ions (eg, lactate or metabolites found in an organic acidopathy). If specimens are hemolyzed, potassium is released from cells that will distort the anion gap calculation (artificially increased). Disturbance of electrolytes is also found in other inherited conditions (eg, adrenogenital diseases).
4. **Ammonia level.** Measurement of ammonia levels can be of foremost importance in making the diagnosis of an IEM; unfortunately, the test is susceptible to artifacts, resulting in a false elevation of ammonia levels. Several precautions must be taken to avoid incorrect test results:
 - a. **The specimen must be placed on ice** at the bedside.
 - b. **Timely transfer to the laboratory** with instant preparation of the sample for analysis. If samples have to be stored, the blood must be separated and plasma frozen (at least -20°C). Without strict adherence to these precautionary measures, false elevation by as much as 60 to 100 mcg/dL may occur. Normal neonatal levels are up to 80 mcg/dL. IEMs typically result in levels in the hundreds and thousands. If a result is equivocal, a repeat measurement must be done; the hyperammonemia in IEM will most likely be worsening.
5. **Liver function tests.** Transaminases (aspartate aminotransferase and alanine aminotransferase) are released from hepatocytes with cell damage. γ -Glutamyl transferase (GGT) is produced in the liver cell but also is present in bile ducts. It is a very sensitive indicator of liver dysfunction and/or cholestasis; GGT may be elevated even with fairly minor exposures to medications/toxins. Raised **conjugated bilirubin** levels should always be considered abnormal (especially if $>5\%$ of total bilirubin) and can be due to a number of diseases including cholestasis. Cholesterol, albumin, and coagulation factor levels reflect the **synthetic function** of the liver. The **plasma amino acid pattern** is affected by IEMs and liver dysfunction. **Ammonia** levels are increased in IEMs and liver failure.
6. **Urine testing for ketones.** The presence of ketones in the urine of a neonate should always be considered abnormal. One of the IEMs that typically results in elevated urine ketones is MSUD.
7. **Urine testing for reducing substances.** Main indication in the neonate is suspected galactosemia. It is important that a nonenzymatic assay is done. A negative test does not rule out the diagnosis because even a few hours of galactose

restriction may result in a negative test. Consider which enteral nutrition the patient is receiving: soy formulas are often galactose free, whereas breast milk is not (lactose [“milk sugar”] is a disaccharide of glucose and galactose).

- 8. Lipid levels and profile.** Low cholesterol may be noted in patients with Smith-Lemli-Opitz syndrome. Hyperlipidemia may be present in some glycogen storage disorders.

C. Laboratory testing more specific for inborn errors of metabolism. Although many of the following tests might be available through routine laboratories or through reference laboratories, we consider them second-line testing for IEM; involvement of a genetics service in their interpretation is recommended. Select tests may be needed to further evaluate a specific clinical presentation, to evaluate abnormalities found on initial testing, or to confirm a clinically suspected diagnosis of an IEM.

- 1. Lactic acid level and lactate-to-pyruvate ratio.** Determination of lactate and pyruvate levels may be indicated in the evaluation of patients with severe metabolic acidosis. When excess lactate is present, the anion gap (see Section XII.B.3) is elevated. Blood to measure lactic acid is best obtained from a central line or as arterial specimen because even short stasis of blood (venous sampling using a tourniquet) increases lactate levels. The lactate-to-pyruvate ratio is normal (15–20) in PDH deficiency and defects of gluconeogenesis (glycogen storage diseases) and elevated to >25 in pyruvate decarboxylase deficiency and defects of the respiratory/electron transport chain.
- 2. Amino acid analysis.** Amino acid analysis must be quantitative to aid in the diagnosis of IEMs. Urine amino acid analysis is not indicated with 2 exceptions: suspected NKH with high glycine excretion (see Section VI.B.3) or to rule out cystinuria with renal calculi. **Plasma amino acid results** are best evaluated after a 3-hour fast. Usually patterns of abnormalities are diagnostic as single amino acid abnormalities may be nutritional or artifacts (eg, taurine is often increased with delayed analysis of samples). Discussion of the many diagnostic patterns of plasma amino acid abnormalities is beyond the scope of this manual. Interpretation of results by an experienced biochemical geneticist who is aware of the clinical presentation and nutritional status of the patient is strongly recommended.

Plasma amino acid analysis is not only indicated in classic IEMs of amino acid metabolism (eg, MSUD or PKU) but also helps evaluate urea cycle defects because several urea cycle metabolites are chemically amino acids (eg, citrulline, arginine, and ornithine; see Figure 100–2); in hyperammonemia, glutamine levels are often elevated as glutamine synthesis incorporates ammonia.

At least 1 to 2 mL of blood should be obtained. Laboratories usually request heparinized blood or samples without additives. Samples should be cooled; if analysis is deferred to a later time, serum or plasma should be separated and frozen.

- 3. Urine organic acid analysis.** This complex analytic test is usually performed by laboratories specializing in biochemical genetics. In expert hands, this test can provide an enormous amount of information. Urine organic acid analysis helps establish the diagnosis of organic acidemias. The most common of this large group of disorders are methylmalonic acidemia, propionic acidemia, and isovaleric acidemia (see Section VI.B.5). Most laboratories request at least 5 to 10 mL of fresh urine. As soon as the specimen is collected, it should be cooled or, preferably, frozen until analysis.
- 4. Succinylacetone in urine.** This test is specific for hepatorenal tyrosinemia. A sample is collected and used to wet a filter paper (as used for the routine neonatal screening tests). After air drying, the sample can be forwarded to the testing laboratory by mail or courier services.

5. **Acylcarnitine profile.** Fatty acids are conjugated with carnitine to facilitate their transport into the mitochondria. The acylcarnitine profiles allow for the recognition of diagnostic patterns of fatty acid metabolites typical for different FAO defects (note that VLCFAs with carbon chains of ≥ 24 carbons are metabolized in the peroxisome; see Section XII.C.8). Dried whole-blood samples placed on filter paper cards are used. As newborn screening by tandem mass spectrometry will assist in detection of FAO defects, an acylcarnitine profile should only be ordered after discussion with a biochemical geneticist; determination of **total and free carnitine plasma levels** (measured in heparinized blood) might also be indicated.
6. **Tandem mass spectrometry.** MS/MS detects a large number of disorders of amino and organic acid metabolism as well as FAO defects. This makes it a valuable tool for newborn screening, and MS/MS is **now used routinely by many neonatal metabolic screening programs**; many laboratories also accept samples obtained beyond the neonatal period from infants presenting with symptoms suggestive of an inborn error of metabolism. Samples are easy to obtain (blood spot samples mailed to laboratories), and testing is usually quite cost-effective. In symptomatic babies, the laboratory should be alerted to the possibility of an IEM as it might be possible to fast track selected samples.
7. **Galactosemia testing.** To measure galactose-1-phosphate levels and GALT activity, whole blood is usually requested by the laboratory because the metabolites and enzyme are localized in the erythrocytes. Blood must therefore be obtained before blood transfusions. An alternative in already transfused patients is testing of the parents as heterozygote detection is possible with the enzymatic assay.
8. **Peroxisomal function tests.** VLCFAs are measured by gas chromatography (GC) or GC/MS; normally, only trace amounts of fatty acids with carbon chains of ≥ 24 carbons are detectable. This test detects all peroxisomal disorders that affect the degradation of these compounds. Note that VLCFAs will be normal in a small subgroup of patients with peroxisomal defects (eg, rhizomelic chondrodysplasia punctata). Tests assessing other aspects of peroxisomal function (eg, plasmalogens, phytanic acid, or pipecolic acid measurements) may be necessary. Most of these analyses are done on plasma obtained from ethylenediaminetetraacetic acid (EDTA) blood. The red blood cell pellet of the sample should also be sent to the laboratory (separated) as plasmalogen levels are evaluated in red blood cells. Samples do not need to be frozen.
9. **Transferrin electrophoresis analysis.** A suspected diagnosis of carbohydrate-deficient glycoprotein syndromes (see Section VI.B.7.i) is initially evaluated by electrophoresis analysis of a glycoprotein, usually transferrin. The measurement of transferrin levels is inappropriate as a diagnostic test for these conditions (levels usually are normal). Involvement of a geneticist is essential as electrophoresis patterns are not abnormal in all patients and further specialized testing may be indicated. If electrophoresis of a patient of < 2 months of age is normal, repeat testing beyond 2 months of age is recommended.
10. **Muscle, liver, and skin biopsies.** In patients with LA, **skeletal muscle biopsies** may be needed to establish diagnosis of a mitochondrial respiratory chain defect. Examination by electron microscopy, special stains, and enzyme essays may also be needed. Certain IEMs may require determination of enzyme activities in **cultured skin fibroblasts**. Glycogen storage disorders may require **liver biopsies** to establish the exact diagnosis.
11. **DNA analysis and sequencing.** Molecular defects are known for many IEMs. Although diagnoses can usually be established through biochemical testing, sequencing of **genomic or mitochondrial DNA** may be indicated in certain scenarios. Considering the complexity of these tests and the associated cost, DNA testing should usually be initiated and supervised by a geneticist. As

genome and exome sequencing is becoming more cost effective, it is increasingly used as first-line genetic testing. Cytogenetic arrays can identify segments of the genome with duplications, deletions, or loss of heterozygosity (LOH); patients with LOH are at higher risk for recessive disorders located in these areas.

D. Postmortem evaluation when an inborn error of metabolism is suspected. If an IEM is suspected as a possible cause of death in a newborn or young infant, we recommend obtaining the following samples postmortem:

- 1. Blood.** Blood should be collected. If no central access was established, a postmortem cardiac puncture may be necessary to obtain a sufficient volume of blood. Serum and plasma should be frozen. In addition, keep the red blood cell pellets (not frozen). EDTA blood (nonseparated) and blood spots on filter paper should be kept to allow for later isolation and analysis of DNA.
- 2. Urine.** Collect urine, if possible, and freeze it at -20°C . If no urine can be obtained but urine organic acid analysis is indicated, swabs of the bladder surface can be obtained on autopsy to attempt urine organic acid analysis.
- 3. Skin.** A full-thickness sterile skin biopsy should be obtained (skin to be cleansed with alcohol, not iodine). Store in a sterile culture medium (if not available, store the sample in the patient's serum). Do not freeze the specimen, and transport it immediately to a tissue culture laboratory for fibroblast culture and storage.
- 4. Cerebrospinal fluid.** If a lumbar puncture was not performed before death, a lumbar or ventricular puncture can be obtained postmortem. This procedure may be indicated to rule out infection or an IEM. In addition to obtaining cultures, we recommend freezing a 1- to 2-mL CSF specimen at -20°C .
- 5. Percutaneous or open liver biopsy.** May be performed to obtain a specimen soon after death especially if the family did not consent to a full autopsy. Discuss the treatment of samples with the geneticist (frozen and/or formalin vs special solutions to preserve for assays and electron microscopy).
- 6. Full autopsy and consultation with a geneticist (even postmortem).** The geneticist may give special recommendations for postmortem specimens to be obtained on autopsy (eg, frozen or specially prepared samples rather than standard formalin processing); genetic counseling may be indicated.

XIII. Management. For most IEMs, therapy consists often of dietary measures and/or special medications and vitamin supplementation. In some metabolic disorders, **liver, bone marrow, or stem cell transplantation** may be an option.

A. Acute care while awaiting results of diagnostic studies

- 1. Supportive care.** Follow principles of neonatal and intensive care including provision of a secure **airway**, supporting **respiration** and **circulation**, and establishing **intravenous access**. General measures may also include correction of the acid-base balance, hypoglycemia, electrolyte abnormalities, and hydration status. Assisted ventilation may be required in severely affected neonates, and **antibiotic therapy** is frequently indicated because of the overlap in symptomatology with bacterial infection.
- 2. Nutritional measures.** An acutely ill newborn should be NPO. For almost all IEMs, a **supply of sufficient glucose** to avoid a catabolic state is strongly indicated. Try to achieve a caloric intake of 80 to 100 kcal/kg/d. **Eliminate protein** acutely (24–48 hours) but not over prolonged periods because breakdown of endogenous protein may otherwise occur and may worsen the patient's clinical status. **Intravenous lipids may be contraindicated** in certain FAO defects.
- 3. Hemodialysis or peritoneal dialysis.** May be needed to remove toxic metabolites. Exchange transfusions are not effective, and early transfer to a facility where hemodialysis is possible is mandatory in these situations (eg, hyperammonemia).

- 4. Vitamin treatment.** Several IEMs have vitamin-responsive forms. Often, a combination of vitamin cofactors (vitamin B12, biotin, riboflavin, thiamine, pyridoxine, and folate) is considered while specific test results are still outstanding. Give vitamins only after appropriate specimens have been obtained for metabolic investigations and after consultation with a geneticist. **Carnitine substitution** may be indicated in some patients (eg, FAO defects or OAs). Carnitine (L-carnitine) may be given intravenously (30–50 mg/kg/d, some recommend giving a loading dose followed by divided doses; some patients may need higher doses) or orally (usually at higher doses than intravenously).
- 5. Medications to treat hyperammonemia.** In patients with hyperammonemia, several medications can be used to provide an alternative pathway for ammonia excretion. These include **sodium phenyl acetate**, **sodium phenyl butyrate**, and **sodium benzoate**. A sodium phenyl acetate/sodium benzoate 10%/10% preparation is commercially available in the United States. Because of the intrinsic side effects, different indications, coordination with nutritional interventions, and frequent dosage adjustments necessary, the use of these medications should be initiated and supervised by an experienced biochemical geneticist.
- 6. Other medications.** In tyrosinemia, NTBC (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexanedione) may be used to prevent tyrosine degradation and production of succinylacetone.

B. Long-term therapy

- 1. Diet.** One of the classic principles for the treatment of IEMs is the restriction of the substance leading to the accumulation of a toxic metabolite (eg, phenylalanine in PKU). In some disorders (eg, urea cycle defects), the overall protein intake is restricted. Careful monitoring is necessary to avoid essential amino acid deficiencies.
- 2. Provision of a deficient substance** is effective when the deficient product is readily available and can reach the appropriate tissue (eg, cortisol and mineralocorticoid in 21-hydroxylase deficiency). Carnitine replacement may be needed in organic acidurias because carnitine is lost through renal excretion of metabolites bound to carnitine. Patients with urea cycle defects (with the exception of arginase deficiency) require arginine (and/or citrulline in some defects) replacement due to decreased synthesis.
- 3. Vitamin, cofactor, and other disease-specific therapy.** Large doses of specific cofactors may increase the activity of partially deficient enzymes: vitamin B6 (homocystinuria), vitamin B12 (methylmalonic acidemia), biotin (multiple carboxylase deficiency), thiamine (MSUD), and riboflavin (glutaric acidemia II). A subgroup of patients with PKU may respond to **sapropterin dihydrochloride** with a reduction of phenylalanine levels. For a number of lysosomal storage disorders, **enzyme replacement** therapies are available.
- 4. Supportive therapy** may help to reduce the morbidity associated with specific IEMs. **Splinting** may reduce deformities in mucopolysaccharidoses. **Splenectomy** may be indicated for thrombocytopenia associated with Gaucher disease.
- 5. Long-term therapy.** Genetic disorders require lifelong nutritional, medical, and laboratory monitoring by a team of specialists in these disorders. Intercurrent illnesses and stress often precipitate the recurrence of symptoms.
- 6. Early intervention and special education programs** may be beneficial in those disorders characterized by intellectual impairment. Families may find a forum for their concerns and stresses, and resources for valuable information can be found in **family support groups** such as the Genetic Alliance (www.geneticalliance.org; accessed September 18, 2018), the National Organization for Rare Disorders (NORD; www.rarediseases.org; accessed September 18, 2018), and numerous other disease- and syndrome-specific support groups.
- 7. Liver, bone marrow, or stem cell transplantation** may be a treatment option for selected IEMs.

Table 100–5. USEFUL RESOURCES FOR THE CLINICIAN IN THE EVALUATION, DIAGNOSIS, AND TREATMENT OF NEWBORNS WITH INBORN ERRORS OF METABOLISM

- **Genetics Home Reference** (ghr.nlm.nih.gov; accessed September 18, 2018) maintained by the National Library of Medicine of the United States.
- **Multiple databases at the National Center for Biotechnology Information (NCBI)** (www.ncbi.nlm.nih.gov; accessed September 18, 2018), which includes Online Mendelian Inheritance of Man (OMIM), GeneTests, and GeneReviews.
- **Information through support and family organizations:** Genetic Alliance (www.geneticalliance.org; accessed September 18, 2018), the National Organization for Rare Disorders (NORD; www.rarediseases.org; accessed September 18, 2018), and numerous other disease- and syndrome-specific support groups.
- **Laboratory resources:** GeneTests (available via the National Center for Biotechnology Information [NCBI] at www.ncbi.nlm.org; accessed September 18, 2018), a helpful resource to localize a laboratory for a specific genetic test. (*Note:* Published test catalogs or websites of major healthcare providers and/or regional referral laboratories are often also helpful resources.)

XIV. Prognosis. Due to the great number of IEMs, prognosis ranges from extremely favorable with normal development and life expectancy to severe physical and/or intellectual disability and death. In general, early diagnosis and, if available, treatment are associated with more favorable outcomes.

XV. Additional resources. In order to assist the clinician with the care of newborns with IEMs, Table 100–5 provides a listing of useful resources.

101 Infant of a Diabetic Mother

Diabetes in pregnancy can cause many complications starting with major congenital anomalies and fetal growth restriction in the first trimester and chronic hyperinsulinism in the second to third trimester causing multiple disorders/diseases presenting after delivery; it can then continue to cause transgenerational effects (increased risk of type 2 diabetes mellitus [T2DM], obesity, and kidney disease) later on in life. Because of an improved understanding of the pathophysiology of diabetic pregnancies, these complications can be recognized and treated. Data indicate that perinatal morbidity and mortality rates in **infants of diabetic mothers (IDM)** have improved with dietary management and insulin therapy.

I. Classification

A. Definitions. Any form of **diabetes mellitus (DM)** may require insulin. It is important to note, as stated by the American Diabetes Association, that “insulin use does not classify the patient.” Types of diabetes during pregnancy are:

1. **Pregestational diabetes mellitus (PGDM)** is diabetes that is diagnosed before pregnancy; 15% of pregnancies are complicated by PGDM.
 - a. **Type 1 diabetes (T1DM)** occurs due to autoimmune B-cell destruction, which causes an insulin deficiency.
 - b. **Type 2 diabetes (T2DM)** is caused by a progressive loss of B-cell insulin secretion with a background of insulin resistance.
2. **Preexisting pregestational diabetes** is diabetes diagnosed in women by standard diagnostic criteria in the first trimester. The diabetes is usually type 2; rarely is it type 1 or monogenic diabetes.

Table 101–1. WHITE'S MODIFIED CLASSIFICATION OF DIABETES IN PREGNANCY

Class	Description
A ₁	Gestational diabetes; diet controlled
A ₂	Gestational diabetes; insulin controlled
B	Onset after age 20 years; <10 years in duration
C	Onset between 10 and 19 years or 10 to 19 years in duration
D	Onset before 10 years or duration >20 years
F	Nephropathy
R	Retinopathy
H	Ischemic myocardial disease
T	Prior renal transplantation

Data from White P: Diabetes mellitus in pregnancy, *Clin Perinatol*. 1974 Sep;1(2):331-347.

3. Gestational diabetes (GDM) is diabetes diagnosed in the second or third trimester of pregnancy with no signs of preexisting T1DM or T2DM prior to the pregnancy. When present, GDM results in complications in 85% of pregnancies.

B. White classification. The White classification is a list of alphabetically assigned categories of diabetes and their severity in pregnancy. It is based on age of onset, duration of the disease, and presence or absence of vascular complications. The original White classification (1949) was most likely based on T1DM and was used to assess maternal and fetal risk. There have been multiple revisions, each adding more detail, with the latest 1980 revision including the addition of GDM as a separate class and hypertension risks. See Table 101–1.

C. American Diabetes Association classification (2014) presents 4 categories of diabetes. T1DM and T2DM are based on pathophysiology of the disease, and the other category is based on specific types of diabetes due to other causes. GDM is based on the time of diagnosis and the glucose tolerance results. See Table 101–2.

II. Incidence. Globally, the incidence of diabetes is increasing. The International Diabetic Federation estimated that approximately 16% of babies born in 2015 were exposed to hyperglycemia, approximately 85% due to GDM, approximately 7.5% due to PGDM (type 1 or type 2), and 7.4% due to other types of diabetes.

A. Gestational diabetes. The incidence of GDM varies greatly depending on population characteristics, diagnostic criteria, genetic factors, and screening methods. Globally, the incidence varies from 1% to 28%. The incidence has risen in the past 10 to 20 years and often reflects the underlying rate of T2DM in the population. Incidence of GDM made by various US organizations:

1. Centers for Disease Control and Prevention: 2% to 10% of pregnancies.

2. American Diabetes Association: Up to 9.2% of pregnancies.

3. US Preventive Services Task Force: 1% to 25% of pregnancies.

B. Type 1 and 2 diabetes. Incidence of pregnant women with T1DM or T2DM is approximately 1% to 2%.

III. Pathophysiology. Most of the problems with IDM are related to fetal hyperglycemia and the resulting increase in production of insulin by the fetal pancreas, which causes chronic hyperinsulinism.

A. Timing of poor diabetic control. Maternal diabetic control is a key factor in determining fetal outcome and can be related to key periods in pregnancy.

Table 101–2. AMERICAN DIABETES ASSOCIATION CLASSIFICATION SYSTEM

Classification	Description												
Type 1 diabetes (T1DM)	Due to β -cell destruction, usually leading to absolute insulin deficiency. It is either immune mediated or idiopathic.												
Type 2 diabetes (T2DM)	Range of predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance.												
Other specific types	Genetic defects of the β -cell function, genetic defects in insulin action, diseases of the exocrine pancreas, endocrinopathies, drug or chemical induced, infections, uncommon forms of immune-mediated diabetes, other genetic syndromes sometimes associated with diabetes (eg, Down, Klinefelter, Turner, Prader-Willi).												
Gestational diabetes mellitus (GDM)	<p>Diabetes diagnosed in the second or third trimester of pregnancy that was not clearly overt diabetes prior to gestation. Diagnosis depends on either the 1-step or 2-step strategy, both of which test women with no prior diagnosis of diabetes, and at 24–28 weeks' gestation.</p> <p>1-step strategy: Perform a fasting 75-g OGTT in a 24- to 28-week gestational woman. Diagnosis of GDM if any of the following plasma levels are met or exceeded: Fasting: 92 mg/dL; 1 hour: 180 mg/dL; 2 hour: 153 mg/dL</p> <p>2-step strategy: Diagnosis of GDM made if at least 2 of the following 4 plasma glucose levels are met or exceeded: Step 1: Perform a nonfasting 50-g GLT. If the plasma glucose measured 1 hour after the load is >130 mg/dL, 135 mg/dL, or 140 mg/dL: Step 2: Perform a fasting 100-g OGTT.</p> <p>Carpenter-Coustan or National Diabetes Data Group</p> <table border="0"> <tr> <td>Fasting:</td> <td>95 mg/dL</td> <td>105 mg/dL</td> </tr> <tr> <td>1 hour:</td> <td>180 mg/dL</td> <td>190 mg/dL</td> </tr> <tr> <td>2 hour:</td> <td>155 mg/dL</td> <td>165 mg/dL</td> </tr> <tr> <td>3 hour:</td> <td>140 mg/dL</td> <td>145 mg/dL</td> </tr> </table>	Fasting:	95 mg/dL	105 mg/dL	1 hour:	180 mg/dL	190 mg/dL	2 hour:	155 mg/dL	165 mg/dL	3 hour:	140 mg/dL	145 mg/dL
Fasting:	95 mg/dL	105 mg/dL											
1 hour:	180 mg/dL	190 mg/dL											
2 hour:	155 mg/dL	165 mg/dL											
3 hour:	140 mg/dL	145 mg/dL											

Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient.

GLT, glucose loading test; OGTT, oral glucose tolerance test.

Data from American Diabetes Association: 2. Classification and Diagnosis of Diabetes: Standards of Medical Care in Diabetes-2018, *Diabetes Care*. 2018 Jan;41(Suppl 1):S13-S27.

- Poor control prior to conception, at the time of conception, and in early first trimester.** Major congenital malformations, spontaneous early abortion, and fetal growth restriction.
- Poor control in the second trimester.** Hypertrophic cardiomyopathy with septal hypertrophy, polyhydramnios, preeclampsia, placental insufficiency, low intelligence quotient (IQ), pregnancy-induced hypertension, minor congenital anomalies, fetal loss, macrosomia.
- Poor control in the third trimester.** Macrosomia/large for gestational age (LGA) leading to cesarean delivery, birth trauma, fetal dystocia, neonatal hypoglycemia, respiratory distress syndrome, hypertrophic cardiomyopathy with septal hypertrophy, decreased oxygenation in the fetus, neonatal hypocalcemia, hypomagnesemia, hyperbilirubinemia, polycythemia/hyperviscosity, thrombocytopenia, intrauterine death.

4. **Maternal hyperglycemia in labor.** Hypoglycemia in the infant and poor Apgar scores.
 5. **Long-term transgenerational effects.** Obesity, diabetes, hypertension, and kidney disease in children born to mothers with diabetes in pregnancy.
- B. Examples of complications and their pathophysiology**
1. **Congenital anomalies.** Early in pregnancy during embryogenesis (before 7 weeks of gestation; **diabetic embryopathy**) with poorly controlled maternal insulin-dependent diabetes, some mechanism occurs to cause an increase in congenital anomalies. There are multiple factors in the diabetic mother that contribute to congenital anomalies, but the true teratogenic mechanism is not known. Hyperglycemia is thought to be the primary teratogen. It causes a deficiency of myoinositol, which is required in embryonic development. Other factors that have been suggested include hypoglycemia, insulin, vascular disease, oxygen free radicals, hypoxia, fetal zinc depletion, low maternal magnesium, hormone imbalances, amino acid/ketone abnormalities, protein glycosylation, and others.
 2. **Fetal growth restriction.** This has been attributed to maternal vascular disease causing uteroplacental insufficiency or lack of nutrients and oxygen required for growth. Ketosis and hypoglycemia may also contribute.
 3. **Perinatal asphyxia** is secondary to macrosomia and cardiomyopathy.
 4. **Prematurity.** Occurs secondary to maternal complications requiring early delivery (eg, hypertension, preeclampsia, intrauterine growth restriction) and a higher rate of preterm labor in diabetic mothers.
 5. **Macrosomia/large for gestational age.** It is the result of biochemical events along the maternal hyperglycemia–fetal hyperinsulinemia pathway, as described by Pedersen. This occurs because increased glucose and amino acids from the mother cross the placenta into the infant and the infant produces an increase in insulin to compensate. Insulin is actually a growth hormone and causes accelerated fetal growth in the infant. Other mechanisms contributing to macrosomia include maternal obesity, disturbances in lipid pathways in the placenta, and certain insulin-like growth factor hormones. Macrosomia causes birth trauma (fractured clavicle, brachial plexus injury).
 6. **Transient hypertrophic cardiomyopathy is hypertrophy of the left and/or right ventricle, and asymmetric septal hypertrophy** is thickening of the interventricular septum. Infants with hypertrophic cardiomyopathy associated with diabetes usually have asymmetric septal hypertrophy with a decrease in the ventricular chambers, which causes an obstruction of the left ventricular outflow tract. It is caused by hyperinsulinemia, which increases the fetal cardiac muscle mass by depositing glycogen and fat in the cells of the myocardium.
 7. **Respiratory distress syndrome.** Hyperinsulinemia causes a decrease in the production and secretion of surfactant by interfering with the glucocorticoid induction of the synthesis of surfactant. This increased risk even occurs in infants up to 38 weeks' gestation.
 8. **Hypocalcemia and hypomagnesemia.** Magnesium depletion occurs in mothers with diabetes secondary to increased renal loss and causes hypomagnesemia in the infant, which causes insufficient parathyroid to be released, resulting in hypocalcemia in the infant. Decreased parathyroid maturation/function may also contribute.
 9. **Hypoglycemia at delivery.** According to the Pedersen hypothesis, at birth, the transplacental glucose supply is terminated, and because of high concentrations of plasma insulin, blood glucose levels fall.
 10. **Polycythemia, hyperbilirubinemia, and thrombosis.** Chronic fetal hyperinsulinemia increases the metabolic rate and oxygen consumption. Relative hypoxemia occurs in utero, and the fetus produces more erythropoietin, which increases red blood cells (RBCs; polycythemia) to transport

oxygen. Hyperbilirubinemia occurs because of the increased breakdown of the increased RBCs. Increased RBCs mean sluggish blood flow and a prothrombotic state (renal vein thrombosis).

IV. Specific disorders frequently encountered in the infant of a diabetic mother. All of these disorders/diseases occur in GDM, T1DM, and T2DM, with the exception of congenital malformations (does not occur in GDM because it presents after the first trimester). Fetal risk is significantly higher in mothers with T1DM and T2DM than mothers with GDM.

A. Disorders of growth

- 1. Macrosomia.** Macrosomia is the classic presentation of the infant of a poorly controlled diabetic mother. After 20 weeks' gestation, maternal hyperglycemia leads to macrosomia. Macrosomia occurs in >25% of diabetic pregnancies and plays a role in birth injuries.
- 2. Fetal growth restriction.** Mothers with renal, retinal, or cardiac diseases are more likely to have small for gestational age (SGA) or premature infants, poor fetal outcome, fetal distress, or fetal death.

B. Birth injuries are increased in IDM because of macrosomia. They include the following:

- 1. More common:** Shoulder dystocia, brachial plexus injury, clavicle/humerus fracture, perinatal asphyxia (difficult delivery, intrauterine hypoxia).
- 2. Less common:** Facial palsy, subdural hemorrhage, cephalohematoma.

C. Metabolic disorders

- 1. Hypoglycemia.** Hypoglycemia is defined as a blood glucose level <45 mg/dL in a preterm or term infant. This value continues to be a debated topic in pediatric medicine. The most recent American Academy of Pediatrics (AAP) policy statement, published in 2011 and reaffirmed in 2015, supports this level in the first days of life. It is present in up to 40% of IDMs, most commonly in macrosomic infants. It usually presents within 1 to 2 hours after delivery. Mothers with well-controlled blood glucose levels have fewer infants with hypoglycemia. Hypoglycemia in SGA infants born to mothers with diabetic vascular disease is caused by decreased glycogen stores; it appears 6 to 12 hours after delivery.
- 2. Hypocalcemia.** Hypocalcemia has varying definitions, but serum levels of <7 mg/dL and ionized calcium levels <4 mg/dL are considered to be hypocalcemic. It is found in up to 50% of IDMs. The severity of hypocalcemia is usually related to the severity of maternal DM. Serum calcium levels are lowest at 24 to 72 hours of age.
- 3. Hypomagnesemia.** A serum magnesium level <1.52 mg/dL in any infant indicates hypomagnesemia. It is related to maternal hypomagnesemia and the severity of maternal DM.

D. Cardiorespiratory disorders

- 1. Perinatal asphyxia.** In a prospective study, 27% of IDMs, White class B-R-T, suffered asphyxia. Nephropathy appearing in pregnancy, maternal hyperglycemia before delivery, and prematurity were found to be significant risk factors.
- 2. Respiratory distress syndrome**
 - a. Incidence.** The incidence of respiratory distress syndrome (RDS) has decreased to only 3% of IDMs because of better management of diabetes during pregnancy. Most cases are the result of premature delivery, delayed maturation of pulmonary surfactant production, or delivery by elective cesarean section.
 - b. Fetal lung maturity.** Pulmonary surfactant production in the IDM is deficient or delayed principally in class A, B, and C diabetics. Fetal hyperinsulinism may adversely affect the lung maturation process in the IDM by interfering with the incorporation of choline into lecithin. More recent evidence suggests that a change in insulin signaling leads to a decrease in the amount of surfactant production.

- c. **Cesarean section.** Infants delivered by elective cesarean section are at risk for RDS because of lack of appropriate surfactant production, decreased prostaglandin production, and increased pulmonary vascular resistance.
 - 3. **Other causes of respiratory distress in infants of diabetic mothers**
 - a. **Transient tachypnea of the newborn (TTN)** is up to 3 times more common in IDM, especially after elective cesarean section. TTN may or may not require oxygen therapy and usually responds by 72 hours of age.
 - b. **Hypertrophic cardiomyopathy/asymmetric septal hypertrophy** occurs in up to 30% to 50% of IDMs, although most are without signs of disease. Infants with inadequate ventricular filling and decreased intraventricular volume can present with congestive heart failure, cyanosis, tachypnea, cardiomegaly, and tachycardia.
- E. **Hematologic disorders**
 - 1. **Hyperbilirubinemia.** Bilirubin production is increased in the IDM. The causes include prematurity, macrosomia, hypoglycemia, polycythemia, and delayed bilirubin clearance.
 - 2. **Polycythemia and hyperviscosity.** The cause of polycythemia is unclear but may be related to increased levels of erythropoietin in the IDM and increased RBC production secondary to chronic intrauterine hypoxia in mothers with vascular disease. Intrauterine placental transfusion resulting from acute hypoxia during labor and delivery may also contribute.
 - 3. **Renal venous thrombosis (RVT)** is a rare complication. The most likely causes include hyperviscosity, hypotension, or disseminated intravascular coagulation. RVT may present with hematuria and an abdominal mass and is usually diagnosed by ultrasonography.
- F. **Congenital malformations** occur more frequently in IDMs than in the general population. These malformations account for a significant portion of perinatal deaths. Risk of a major malformation is approximately 5% to 6% in mothers with hyperglycemia and 10% to 12% in mothers requiring insulin therapy. The majority of anomalies involve either the cardiovascular system (approximately 8.5 in 100 live births) or the central nervous system (5.3 in 100 live births). Caudal regression, although rare, is strongly associated with DM. A recent study noted the following malformations as the most common: anencephaly, transposition of the great vessels, bilateral renal agenesis/dysgenesis, and hemivertebrae.
 - 1. **Cardiac defects:** Transposition of the great vessels, ventricular septal defect, truncus arteriosus, aortic stenosis, double outlet right ventricle, tricuspid atresia, hypoplastic left heart syndrome, and patent ductus arteriosus.
 - 2. **Renal defects:** Renal agenesis, ureteral duplication, hydronephrosis.
 - 3. **Gastrointestinal tract defects:** Small left colon syndrome, duodenal atresia, imperforate anus, anorectal atresia, situs inversus.
 - 4. **Neurologic defects:** Anencephaly, microcephaly, neural tube defects.
 - 5. **Skeletal defects:** Hemivertebrae, flexion contractures, caudal regression syndrome, unusual facies.
 - 6. **Eye malformations:** Microphthalmos, optic nerve hypoplasia, tear duct obstruction, ocular lipomas, lens opacity.
- V. **Risk factors.** The following factors or conditions may be associated with an increased risk for problems in IDMs:
 - A. **Maternal class of diabetes**
 - 1. **In gestational diabetes and class A diabetes controlled by diet alone,** infants have few complications.
 - 2. **Women with class A diabetes controlled with insulin and class B, C, and D diabetes** are prone to deliver macrosomic infants if diabetes is inadequately controlled.
 - 3. **Diabetic women with renal, retinal, cardiac, and vascular disease** have the most severe fetal problems.

- B. Hemoglobin A1c.** To decrease perinatal morbidity and mortality, the diabetic woman should attempt to achieve good metabolic control before conception. Elevated hemoglobin A1c (normal <5.7%) levels during the first trimester appear to be associated with a higher incidence of congenital malformations. For example, with a hemoglobin A1c level of >11%, the risk of having an infant with a congenital malformation is 25%.
 - C. Diabetic ketoacidosis.** Pregnant women requiring insulin are apt to develop diabetic ketoacidosis. The onset of this complication may be life threatening for the mother and fetus or may lead to preterm delivery.
 - D. Preterm labor.** Preterm delivery occurs more frequently in diabetic pregnancies. Premature onset of labor in a diabetic woman is a serious problem because of the increased likelihood of RDS in the fetus. Furthermore, sympathomimetic agents used to prevent preterm delivery may be associated with maternal hyperglycemia, hyperinsulinemia, and acidosis.
 - E. Immature fetal lung profile.** Fetal lung maturity tests are not recommended to guide the timing of delivery. Medical indications for late preterm and early term deliveries include PGDM with vascular disease and PGDM or GDM that is poorly controlled. Infants delivered during the late preterm and early term have an increased rate of respiratory morbidity. A course of antenatal steroids if indicated in the mother is associated with a decrease in RDS and respiratory support. In diabetic mothers who receive steroids, it is important that they are followed more closely and have frequent blood glucose levels. Supplementary insulin may be necessary.
- VI. Clinical presentation of the infant of a diabetic mother**
- A. During birth,** the infant may be LGA or, if the mother has vascular disease, SGA. The size of most infants is appropriate for gestational age; however, if macrosomia is present, birth trauma may occur. Any signs of respiratory distress in the delivery room need to be addressed immediately.
 - B. After birth,** hypoglycemia can present as lethargy, poor feeding, apnea, or jitteriness in the first 6 to 12 hour after birth. Jitteriness that occurs after 24 hours of age may be the result of hypocalcemia or hypomagnesemia. Signs of respiratory distress secondary to immature lungs can be noted on examination. Cardiac disease may be present as an enlarged cardiothymic shadow on a chest x-ray film or by physical evidence of heart failure. Gross congenital anomalies may be noted on physical examination. Check for abdominal distension and passage of meconium (small left colon syndrome).
- VII. Diagnostic testing of the infant of a diabetic mother**
- A. Laboratory studies.** The following tests must be closely monitored in the IDM:
 - 1. Serum glucose levels** should be checked at delivery and may be needed frequently over the first 48 hours. Often values are checked hourly initially and then spaced out thereafter. Glucose levels should be checked with bedside measurement tools. Readings <45 mg/dL at the bedside should be verified by serum glucose measurements.
 - 2. Serum calcium levels** are often checked in the first day of life, and subsequent values are obtained as needed. If serum calcium levels are low, **serum magnesium levels** should be obtained because they may also be low.
 - 3. The hematocrit** is often checked at birth and again at 24 hours of life.
 - 4. Serum bilirubin levels** should be checked as indicated by physical examination.
 - 5. Other tests.** Arterial blood gas levels, complete blood cell counts, cultures, and Gram stains should be obtained as clinically indicated.
 - B. Radiologic studies** are not necessary unless there is evidence of cardiac, respiratory, gastrointestinal, or skeletal problems. Any IDM with respiratory symptoms should undergo a chest x-ray. If there is abdominal distension and suspicion of small left colon syndrome, a contrast enema should be done. It will show a small left colon and abrupt transition zone at the splenic flexure.

C. **Electrocardiography and echocardiography** should be performed if hypertrophic cardiomyopathy or a cardiac malformation is suspected. Echocardiography shows a hypercontractile thickened myocardium with septal hypertrophy.

VIII. Management of the infant of a diabetic mother

A. **Initial evaluation.** Upon delivery, the infant should be closely evaluated by a trained provider as soon as possible, with close attention to specific complications due to birth trauma and major malformations the infant. In the nursery, blood glucose levels and a hematocrit may be obtained. The infant should be observed for jitteriness, tremors, convulsions, apnea, weak cry, and poor sucking. A physical examination should be performed, paying particular attention to the heart, kidneys, lungs, and extremities. Look for any evidence of birth trauma and closely look for any major or minor malformations.

B. **Continuing evaluation.** Over the first several hours after delivery, the infant should be screened for hypoglycemia and assessed for signs of respiratory distress. During the first 48 hours, observe for signs of jaundice and for renal, cardiac, neurologic, and gastrointestinal tract abnormalities.

C. Metabolic management

1. **Hypoglycemia.** AAP recommends screening for late preterm and term IDM/LGA infants and has specific guidelines for management of hypoglycemia in those groups. The Pediatric Endocrine Society has published new recommendations for hypoglycemia in neonates. See Chapter 67 for the specific recommendations.

2. Hypocalcemia

a. **Calcium therapy.** Symptomatic infants should receive 10% calcium gluconate intravenously. The infusion should be given slowly to prevent cardiac arrhythmias, and the infant should be monitored for signs of extravasation. After the initial dose, a maintenance dose is given by continuous intravenous infusion. The hypocalcemia should respond in 3 to 4 days; until then, serum calcium levels should be monitored every 12 to 24 hours. Management is discussed in Chapter 91.

b. **Magnesium maintenance therapy.** Magnesium is usually added to intravenous fluids or given orally as magnesium sulfate. See dose in Chapter 155.

D. Management of cardiorespiratory problems

1. **Perinatal asphyxia.** Close observation for fetal distress should continue throughout labor and delivery. See Chapter 110.

2. **Respiratory distress.** Management of respiratory distress depends on the etiology. RDS, TTN, and other conditions are more common in the IDM. However, other causes should also be considered (eg, pneumonia or spontaneous pneumothorax). Provide oxygen and ventilator support as needed initially. Treatment depends on the etiology and is discussed further in Chapter 117.

3. **Hypertrophic cardiomyopathy** associated with DM is self-limited and usually resolves within 6 months. Therapy includes possible mechanical ventilation, maintenance fluids, and correction of hypoglycemia and hypomagnesemia; if medication is necessary, the treatment of choice is short-acting β -blockers (esmolol, propranolol). Digoxin or other positive inotropic agents are contraindicated and can make the infant worse because of possible ventricular outflow obstruction and are only indicated if there is a decrease in cardiac contractility. Diuretics are not necessary unless there is fluid overload. If pulmonary hypertension is present, inhaled nitric oxide should be considered.

E. Hematologic management

1. **Hyperbilirubinemia.** Frequent monitoring of serum bilirubin levels may be necessary. Phototherapy and exchange transfusion for infants with hyperbilirubinemia are discussed in Chapters 63 and 99.

2. **Polycythemia.** Observation and/or fluids and/or partial exchange transfusion depending on the hematocrit and clinical symptoms. See Chapters 76 and 116.

3. **Renal venous thrombosis.** Treatment consists of appropriate fluid management and close monitoring of electrolytes and renal status. Supportive therapy is indicated to ensure adequate blood circulation. Both anticoagulation and antithrombotic therapies are considered, and in unilateral disease, nephrectomy is usually only a last resort.

F. Management of morphologic and functional problems

1. Macrosomia and birth injury

a. **Fractures of the extremities** should be treated with immobilization.

b. **Brachial plexus injuries** are usually treated with physical therapy involving range-of-motion and strengthening exercises or possible reconstruction surgery if not resolved.

2. **Congenital malformations.** If a gross malformation is discovered, a specialist should be consulted.

IX. Prognosis. Less morbidity and mortality occur with adequate control during the diabetic pregnancy. Preconceptual counseling is used as an adjunct to preventive health-care of the diabetic patient. The known pregnant diabetic woman is currently receiving better healthcare than before, but the challenge is early identification of women with biochemical abnormalities of GDM. The increased risk of subsequent diabetes in the infants of these women is at least 10 times greater than in the general population, suggesting the need for lifelong follow-up.

102 Infant of a Mother with Substance Use Disorder

Existing studies on the neonatal effects of drug exposure in utero are subject to many confounding factors. Many studies have relied on the history obtained from the mother, which is notoriously inaccurate. In addition to recall bias, there is a considerable incentive to withhold information. Testing of urine for drugs of abuse does not reflect drug exposure throughout pregnancy and does not provide quantitative information. Many women who abuse drugs are multiple drug abusers and also drink alcohol and smoke cigarettes. It is thus difficult to isolate the effects of any 1 drug. Social and economic deprivation is common among drug abusers, and this factor not only confounds perinatal data but also has a major effect on long-term studies of infant outcome.

- I. Definition.** An **infant of mother with substance use disorder** (formerly referred to as infant of substance-abusing mother) is one whose mother has taken drugs that may potentially cause neonatal withdrawal symptoms. The **constellation of signs and symptoms associated with withdrawal**, often polysubstance exposure that includes opioids, is called the **neonatal abstinence syndrome (NAS)**. Table 102-1 lists the drugs associated with this syndrome.
- II. Incidence.** Maternal substance abuse has increased over the past decade. In the United States, the incidence of NAS increased nearly 5-fold between 2000 and 2012 and is continuing to increase, with the incidence of NAS being approximately 6 per 1000 hospital births. The incidence is subject to wide geographic variation.
- III. Pathophysiology.** Drugs of abuse are of low molecular weight and usually water soluble and lipophilic. These features facilitate their transfer across the placenta and accumulation in the fetus and amniotic fluid. The half-life of drugs is usually prolonged in the fetus compared with an adult. Most drugs of abuse either bind to

Table 102–1. DRUGS CAUSING NEONATAL WITHDRAWAL SYNDROME

Opiates	Barbiturates	Miscellaneous
Codeine	Butalbital	Alcohol
Heroin	Phenobarbital	Amphetamine
Meperidine	Secobarbital	Chlordiazepoxide
Methadone		Clomipramine
Morphine		Cocaine
Pentazocine		Desmethylimipramine
Propoxyphene		Diazepam
		Diphenhydramine
		Ethchlorvynol
		Fluphenazine
		Glutethimide
		Hydroxyzine
		Imipramine
		Meprobamate
		Phencyclidine
		Selective serotonin reuptake inhibitors (SSRIs)

various central nervous system (CNS) receptors or affect the release and reuptake of various neurotransmitters. This may have a long-lasting trophic effect on developing dendritic structures. Drugs of abuse have also been suggested to alter in utero or perinatal programming through either epigenetic or other factors. In addition, some drugs are directly toxic to fetal cells. The developing fetus may also be affected by the direct physiologic effects of a drug. Many of the fetal effects of cocaine, including its putative teratogenic effects, are thought to be due to its potent vasoconstrictive property.

Some drugs appear to have a partially beneficial effect. The incidence of respiratory distress syndrome (RDS) is decreased after maternal use of heroin and possibly also with cocaine use. These effects are probably a reflection of fetal stress rather than a direct maturational effect of these drugs. Particularly in the case of cocaine, the decreased incidence of RDS is more than offset by the considerable increase in pre-term deliveries after its use. The major concern in these drug-exposed infants is the long-term outcome. The importance of direct and indirect effects of drugs on the developing CNS predominates, and the risks of drug abuse far outweigh the benefits. Pathophysiology of specific drugs is noted in the following text.

- A. Opiates.** Opiates bind to opiate receptors in the CNS; part of the clinical manifestations of narcotic withdrawal result from α_2 -adrenergic supersensitivity (particularly in the locus coeruleus).
- B. Cocaine.** Cocaine prevents the reuptake of neurotransmitters (epinephrine, norepinephrine, dopamine, and serotonin) at nerve endings and causes a supersensitivity or exaggerated response to neurotransmitters at the effector organs. Cocaine is a CNS stimulant and a sympathetic activator with potent vasoconstrictive properties. It causes a decrease in uterine and placental blood flow with consequent fetal

hypoxemia. It causes hypertension in the mother and the fetus with a reduction in fetal cerebral blood flow.

- C. **Alcohol.** Ethanol is an anxiolytic-analgesic with a depressant effect on the CNS. Both ethanol and its metabolite, acetaldehyde, are toxic. Alcohol crosses the placenta and also impairs its function. The risk of affecting the fetus is related to alcohol dose, but there is a continuum of effects and no known safe limit.
- IV. **Risk factors.** Associated with an increased incidence of maternal drug abuse are the following:
- A. **Maternal history**
1. **Poor social and economic circumstances.**
 2. **Poor antenatal care.**
 3. **Teenage or unwed mothers.**
 4. **Poor education.**
 5. **Associated conditions include infectious diseases** (hepatitis B, syphilis, and other sexually transmitted diseases/sexually transmitted infections), human immunodeficiency virus (HIV)-positive serology, multiple drug abuse, poor nutritional status, and anemia.
- B. **Obstetric complications**
1. **Premature delivery.**
 2. **Premature rupture of membranes.**
 3. **Chorioamnionitis.**
 4. **Fetal distress.**
 5. **Intrauterine growth restriction.**
 6. **With cocaine use,** the following may be present (in addition to the conditions just noted):
 - a. **Hypertension.**
 - b. **Abruptio placentae.**
 - c. **Cardiac.** Arrhythmias, myocardial ischemia, and infarction.
 - d. **Cerebrovascular accident.**
 - e. **Respiratory arrest.**
 - f. **Fetal demise.**
- V. **Clinical presentation.** Signs and symptoms of drug withdrawal are listed in Table 102–2. These signs essentially reflect CNS “irritability,” altered neurobehavioral organization, and abnormal sympathetic activation. Although each drug may have its own effects, these signs and symptoms must be noted for every mother who may have polydrug use; conversely, drug abuse should be suspected in infants exhibiting these signs and symptoms. Signs and symptoms for specific drugs are as follows:
- A. **Opiates.** Infants born to opiate-addicted mothers show an increased incidence of fetal growth restriction (FGR) and perinatal distress. Even when these infants are not small for gestational age, they have lower weight and a smaller head circumference compared with drug-free infants.
1. **Signs and symptoms of withdrawal occur in 60% to 90% of exposed infants.** The onset of symptoms may be minutes after delivery up to 1 to 2 weeks of age, but most infants exhibit signs by 2 to 3 days of life. The onset of withdrawal may be delayed beyond 2 weeks in infants exposed to methadone (parents should be appropriately informed).
 2. **The clinical course is variable, ranging from mild symptoms of brief duration to severe symptoms.** The clinical course may be protracted, with exacerbations or recurrence of symptoms after discharge. Restlessness, agitation, tremors, wakefulness, and feeding problems may persist for 3 to 6 months. There is a reduced incidence of both RDS and hyperbilirubinemia.
- B. **Cocaine**
1. **Symptoms seen in neonates exposed to cocaine in utero.** Irritability, tremors, hypertonia, a high-pitched cry, hyperreflexia, frantic fist sucking, feeding

Table 102–2. SIGNS AND SYMPTOMS OF NEONATAL ABSTINENCE

Hyperirritability
Increased deep-tendon and primitive reflexes
Hypertonus, hyperacusis
Tremors
High-pitched cry
Seizures
Wakefulness
Increased rooting reflex
Uncoordinated or ineffectual sucking and swallowing
Regurgitation and vomiting
Loose stools and diarrhea
Tachypnea, apnea
Yawning, hiccups
Sneezing, stuffy nose
Mottling
Fever
Failure to gain weight
Lacrimation

problems, sneezing, tachypnea, and abnormal sleep patterns. A specific cocaine withdrawal syndrome has not been described. The symptoms just mentioned may be a reflection of cocaine intoxication rather than withdrawal, and after an initial period of irritability and overactivity, a period of lethargy and decreased tone has been described.

2. *Controversial cocaine associations*

a. In the neonate, the following have been described. Necrotizing enterocolitis, transient hypertension, reduced cardiac output (on the first day of life), intracranial hemorrhages and infarcts, seizures, apneic spells, periodic breathing, abnormal electroencephalogram, abnormal brainstem auditory evoked potentials, abnormal response to hypoxia and carbon dioxide, and ileal perforation. These reports were mostly case reports or insufficiently controlled case series with numerous confounding factors and large case-control studies that have found no association between cocaine exposure and intraventricular hemorrhage. Despite earlier concerns, there does not appear to be an increased risk of sudden infant death syndrome (SIDS).

b. Cocaine has been suggested as a teratogen. Its teratogenic potential is presumed to be due to its vascular effects, although direct toxicity on various cell lines may also play a role. Numerous CNS anomalies, as well as cardiovascular abnormalities, limb reduction defects, intestinal atresias, and other malformations, have been attributed to cocaine. However, most of these associations were derived from case reports, case series, or poorly controlled studies, and a detailed examination of the data does not substantiate most of these teratogenic associations. An exception appears to

be an increased risk of genitourinary tract defects associated with cocaine exposure during gestation. Moreover, there does not appear to be a dysmorphism recognizable as a “cocaine syndrome.” Cocaine is associated with an increased incidence of spontaneous abortion, stillbirth, abruptio placentae, premature labor, and FGR.

C. Alcohol. Probably the foremost drug of abuse today. **The risk that an alcoholic woman will have a child with fetal alcohol syndrome (FAS) is approximately 35% to 40%.** However, even in the absence of FAS, and also with lower alcohol intake, there is an increased risk of congenital anomalies and impaired intellect. It is estimated that alcohol is the major cause of congenital intellectual disability today. **FAS consists of the following:**

- 1. Prenatal or postnatal growth retardation**, CNS involvement such as irritability in infancy or hyperactivity in childhood, developmental delay, hypotonia, or intellectual impairment.
- 2. Facial dysmorphism.** Microcephaly, microphthalmos, or short palpebral fissures; a poorly developed philtrum; a thin upper lip (vermilion border); and hypoplastic maxilla.
- 3. Other congenital anomalies.** These have been described after exposure to alcohol in utero both with and without full-blown FAS. CNS symptoms may appear within 24 hours after delivery and include tremors, irritability, hyper-tonicity, twitching, hyperventilation, hyperacusis, opisthotonos, and seizures. Symptoms may be severe but are usually of short duration. Abdominal distention and vomiting are less frequent than with most other drugs of abuse. In premature infants of women who were heavy alcohol users (>7 drinks/wk), there is an increased risk of both intracranial hemorrhage and white matter CNS damage. (See also Chapter 93.)

D. Barbiturates. Symptoms and signs of withdrawal are similar to those observed in narcotic-exposed infants, but symptoms usually appear later. Most infants become symptomatic toward the end of the first week of life, although onset may be delayed up to 2 weeks. The duration of symptoms is usually 2 to 6 weeks.

E. Benzodiazepines. Symptoms are indistinguishable from those of narcotic withdrawal, including seizures. The onset of symptoms may be shortly after birth.

F. Phencyclidine. Symptoms usually begin within 24 hours of birth, and the infant may show signs of CNS “hyperirritability” as in narcotic withdrawal. Gastrointestinal symptoms of withdrawal are less common.

G. Marijuana. Studies have suggested a slightly shorter duration of gestation and somewhat reduced birthweight, but the extent of these differences does not seem to be clinically important. Marijuana may have some mild effect on a variety of newborn neurobehavioral traits.

H. Selective serotonin reuptake inhibitors. Selective serotonin reuptake inhibitors (SSRIs) are typically used as antidepressants, with symptoms occurring in up to 30% of exposed infants. Symptoms may include irritability, seizures, myoclonus, hyperreflexia, jitteriness, persistent crying, shivering, increased tone, feeding difficulties, tachypnea, and temperature instability. It may be difficult to make a clinical distinction between symptoms of withdrawal and those of a neonatal variant of the serotonin syndrome.

I. Buprenorphine. This drug, a partial μ -receptor opiate agonist, is being increasingly used as an alternative to methadone in the treatment of pregnant opiate users. Its short-term effects on the neonate are similar to that of methadone, although duration of symptoms appears to be decreased. Symptoms of withdrawal usually occur within the first 3 days of life.

VI. Diagnosis

A. History. Many, if not most, drug abusers withhold this information. Details of the extent, quantity, and duration of abuse are unreliable. However, the history is the simplest and most convenient means of diagnosis.

B. Laboratory tests. The most commonly used tests to detect drugs of abuse are immunoassays (enzymatic assays or radioimmunoassays). However, they are subject to a low rate of false-negative results and, because of cross-reactivity, false-positive testing. Thus, they are viewed as screening tests. When it is either medically or legally important, these tests should be supplemented by the more sensitive and specific chromatographic or mass spectrometric tests.

1. Urine. Easily obtained and is the most common substance used for drug testing. It reflects intake only in the last few days before delivery. Urine may be obtained from both the mother and the infant (in whom the substance may persist for a longer time).

a. False-negative immunoassays. May be due to dilution (low specific gravity) or high sodium chloride content (detected by high specific gravity). Various adulterants may also affect detection; this is unlikely in the neonate but may occur in maternal urine.

b. False-positive immunoassays. Although these depend on the specific assay used, the following have been reported:

i. Detected as morphine. Codeine (found in many cold and cough medications and in analgesics). About 10% of codeine is metabolized to morphine in the liver. The consumption of baked goods containing poppy seeds (eg, bagels) can result in detectable amounts of morphine in the urine. These are “physiologic” false-positive results, but chromatography or mass spectrometry may determine the source by quantitative assays of other metabolites.

ii. Detected as amphetamines. Ranitidine, chlorpromazine, ritodrine, phenylpropanolamine, ephedrine, pseudoephedrine, phenylephrine, phentermine, and phenmetrazine. Some of these (eg, pseudoephedrine) are found in many over-the-counter preparations.

2. Meconium. Easily obtained, and drugs may be detected up to 3 days after delivery. It reflects drug use after the first trimester, has a lower rate of false negatives, is a more sensitive test than urine for detecting drug abuse, and reflects usage over a longer period than is detectable by urine testing. Its main disadvantage is that the specimen requires processing before testing and hence places an additional burden on the laboratory. The ability to detect drugs is reduced after formation of fed stools.

3. Hair. This is by far the **most sensitive test** available for detection of drug abuse. Hair grows at 1 to 2 cm/mo; hence, maternal hair can be segmented and each segment analyzed for drugs. Thus, details of drug abuse throughout pregnancy may be obtained. There is a quantitative relationship between amounts of drug used and amounts incorporated in growing hair. Hair may be obtained from the mother or the infant (in whom it will reflect usage only during the last trimester). Hair may also be obtained from the infant a long time after delivery should symptoms occur that suggest in utero drug exposure that was previously unsuspected. The test requires processing before assay, is more expensive, and is currently not as widely available as other test methods.

4. Routine laboratory testing. Routine laboratory tests are usually not required in infants of mothers with substance use disorder (other than tests to confirm the diagnosis). Laboratory tests are required to rule out other causes of particular signs and symptoms (eg, calcium and glucose for cases of jerky movements) or to follow up and manage some particular complication of drug abuse appropriately.

C. Other studies. A **scoring system** has been devised for assessment of withdrawal signs. Commonly called the **Finnegan score**, after its originator, the score was devised for neonates exposed to opiates in utero. Its usefulness for assessing

Table 102–3. MODIFIED FINNEGAN’S SCORING SYSTEM FOR NEONATAL WITHDRAWAL**Signs and symptoms are scored between feedings.**

Cry:	High-pitched	2
	Continuous	3
Sleep hours after feed:	1 h	3
	2 h	2
	3 h	1
Moro reflex:	Hyperactive	2
	Marked	3
Tremors when disturbed:	Mild	2
	Marked	3
Tremors when undisturbed:	Mild	3
	Marked	4
Muscle tone increased:	Mild	3
	Marked	6
Convulsions:		8
Feedings:	Frantic sucking of fists	1
	Poor feeding ability	1
	Regurgitation	1
	Projectile vomiting	1
Stools:	Loose	2
	Watery	3
Fever:	100–101°F	2
	>101°F	2
Respiratory rate:	>60/min	1
	Retractions	2
Excoriations:	Nose	1
	Knees	1
	Toes	1
Frequent yawning:		1
Sneezing:		1
Nasal stuffiness:		1
Sweating:		1
Total scores per day		()

Once an objective score has been attained, a dose for treatment can be decided on.

Reproduced with permission from Morselli PL, Garattini S, Sereni F: *Basic and Therapeutic Aspects of Perinatal Pharmacology*. New York, NY: Raven Press; 1975.

signs after exposure to other drugs or for guiding management in these cases has not been established, but it can be used as a guide. The scoring system is shown in Table 102–3. Other tools for assessing neonatal abstinence are the **Lipsitz tool**, **Neonatal Narcotic Withdrawal Index**, and the **Neonatal Withdrawal Inventory**, but these are less commonly used.

VII. Management. Manifestations of drug withdrawal in many infants resolve within a few days, and drug therapy is not required. Supportive care suffices in many, if not most, infants. It is not appropriate to treat prophylactically infants of drug-dependent mothers. The infant's withdrawal score should be assessed to monitor the progression of symptoms and the adequacy of treatment.

A. Supportive care

1. **Minimal stimulation.** Attempt to keep the infant in a darkened, quiet environment. Reduce other noxious stimuli.
2. **Swaddling and positioning.** Use gentle swaddling with positioning that encourages flexion rather than extension.
3. **Prevent excessive crying with a pacifier, cuddling, and so on.** Feedings should be on demand if possible, and treatment should be individualized based on the infant's level of tolerance.

B. General drug treatment. Warning: Naloxone (Narcan) may precipitate acute drug withdrawal in infants exposed to narcotics. It should not be used in infants born to mothers suspected of abusing opiates.

The general aim of treatment is to allow sleep and feeding patterns to be as close to normal as possible. When supportive care is insufficient to do this, or if symptoms are particularly severe, drugs are used. Indications for drug treatment are progressive irritability, continued feeding difficulty, and significant weight loss. A score >7 on the Finnegan score for 3 consecutive scorings (done every 4 hours during the first 2 days) may also be regarded as an indication for treatment. However, the Finnegan score should not be followed slavishly and treated as a definitive laboratory value. Many centers use the Finnegan score only every 12 hours and increase the frequency of its application if the infant's scores rapidly escalate. Drugs used for withdrawal are discussed next. Additional treatment may be required for some symptoms (eg, dehydration or convulsions). There have been very few clinical trials in this area, and drug therapy is based largely on anecdotal evidence and hence is variable. Cumulative reports suggest that drugs that act on the relevant receptors are superior to sedatives. When compared with opiates, phenobarbital, at doses required to suppress symptoms of withdrawal, may impair sucking in infants withdrawing from maternal opiates and may require a more protracted duration of treatment.

1. **Morphine.** A recent randomized trial comparing morphine with tincture of opium showed that infants treated with morphine required a somewhat longer duration of treatment but had better weight gain. An appropriate schedule of treatment would be to start at a morphine dose of 0.04 mg/kg every 3 to 4 hours. Dosage may be increased every 4 hours at increments of 0.04 mg/kg until symptoms are under control (absent side effects) or a (recommended) total maximum of 1.3 mg/kg/d is reached. If the baby is still symptomatic after a maximal dose is given, an additional adjunct drug is used (see Section VII.B.10). Once the symptoms are under control (eg, Finnegan score <8), treatment is maintained at that dosage for 72 hours and then weaning is commenced. Weaning is done by decreasing the daily dose by 10% every day, as long as symptoms do not relapse. If the infant becomes symptomatic during weaning, the dose is increased back to the last previous dose that had controlled the symptoms. There are no reports of any maximal dose of morphine used for withdrawal, but prudence suggests that infants be closely watched for side effects, and some centers recommend cardiorespiratory monitoring if morphine dosage exceeds 0.8 mg/kg/d. As mentioned, there is a paucity of controlled trials on this topic, and treatment schedules are highly variable between institutions. The schedule just suggested is within the range of common practice but is not carved in stone.
2. **Methadone.** This has the advantage of a longer half-life and hence requires less frequent administration. However, there is large individual pharmacokinetic

variability and response in NAS patients. Many formulations also contain ethanol. There is no overall consensus as to the relative superiority of morphine and methadone as primary drug treatments for NAS. Typical dosage is 0.2 mg/kg/d divided into 2 to 6 doses.

3. **Paregoric (camphorated opium tincture).** This has 0.4 mg/mL morphine equivalents and is thought to be more “physiologic” than nonnarcotic agents but is no longer recommended due to other constituents present in the preparation (eg, camphor, alcohol, benzoic acid).
4. **Opium tincture, also called tincture of opium.** This is similar to paregoric and has the advantage of fewer additives. It has 10 mg/mL morphine equivalents and should be diluted to provide the same morphine dosage as in Section VII.B.1.
5. **Phenobarbital.** An adequate drug for controlling withdrawal from narcotics, especially signs of irritability, fussiness, and hyperexcitability. It is not as effective as morphine for control of gastrointestinal symptoms. It is not suitable for dose titration because of its long half-life. It is mainly useful for treatment of withdrawal from nonnarcotic agents. Anecdotally, phenobarbital is reportedly useful in the management of NAS following polydrug exposure. The dosage is a 10- to 20-mg/kg loading dose, followed by 2 to 4 mg/kg/d maintenance. Once symptoms have been controlled for 1 week, decrease the daily dose by 25% every week.
6. **Chlorpromazine** is quite effective in controlling symptoms of withdrawal from both narcotics and nonnarcotics. It has multiple untoward side effects (it reduces seizure threshold and can cause cerebellar dysfunction and hematologic problems) that make it **potentially undesirable** for use in neonates when alternatives can be used. The dosage is 3 mg/kg/d, divided into 3 to 6 doses per day.
7. **Clonidine.** This has been used for withdrawal from both narcotic and nonnarcotic agents. The dosage is 3 to 4 mcg/kg/d, divided into 4 doses per day.
8. **Diazepam.** This has been used to treat withdrawal from narcotics. One study showed a greater incidence of seizures after methadone withdrawal when infants were treated with diazepam rather than paregoric. When used to treat methadone withdrawal, it also impairs nutritive sucking more than methadone does alone. It may produce apnea when used with phenobarbital. It may be used for treatment of withdrawal from benzodiazepines and possibly also for the hyperexcitable phase after cocaine exposure. The dosage is 0.5 to 2 mg every 6 to 8 hours.
9. **Buprenorphine.** In a randomized trial, sublingual buprenorphine was found to reduce the duration of pharmacotherapy and length of stay in NAS when compared to morphine. Results are promising, but further trials are required before its widespread use. Also of concern is that the drug contains ethanol. Initial dosage is 4 to 5 mcg/kg/dose given every 8 hours, with doses increased up to a maximum of 60 mcg/kg/d.
10. **Combination therapy (failure of monotherapy).** When maximal dosage of a drug of choice has been reached and symptoms of NAS are still of concern, an adjunct drug is used. When morphine has been the initial first-line medication, either phenobarbital or clonidine is often used as an adjunct medication. Results of several studies yield contradictory results; however, a 2010 Cochrane review concluded that the addition of either phenobarbital or clonidine may reduce duration of treatment for NAS.

C. Long-term management. If the infant is discharged after 4 days, an early appointment with the pediatrician should be arranged and the parents should be informed as to possible signs of delayed-onset withdrawal. Minor signs and symptoms of drug withdrawal may continue for a few months after discharge. This places a difficult infant in a difficult home situation. There are a

few reports of an increased incidence of child abuse in these circumstances. Thus, frequent follow-up visits and close involvement of social services may be required.

- D. Breast feeding.** The various drugs of abuse may be presumed to enter breast milk, and there have been case reports of intoxication in breast-fed infants whose mothers had continued to abuse drugs. Mothers on low-dose methadone have been allowed to breast feed, but this required close supervision, and there was a constant concern that unsupervised weaning would precipitate withdrawal. A recent study demonstrated that concentration of methadone in breast milk, even at peak maternal plasma levels, was low in the perinatal period. The mothers had been receiving methadone doses of 76 ± 22 mg. The data support recommendations of breast feeding for women on methadone maintenance. However, methadone-dependent women require special considerations and support and should also be counseled as to the unknown CNS effects of long-term exposure to small amounts of methadone present in breast milk. Similarly, there is no evidence that breast feeding should not be discouraged in mothers who are receiving treatment with SSRIs. However, pending definitive evidence, caution suggests that breast feeding might be discouraged in the particular case of fluoxetine use due to its long elimination half-life and risk of accumulation.

VIII. Prognosis. During the first few years of life, infants exposed to drugs in utero may have various neurobehavioral problems. Prognosis is largely dependent on the drug used.

- A. Opiates.** There are increased risks of SIDS and strabismus. A substantial proportion of children demonstrate good catch-up growth by 1 to 2 years of age, although they may still be below the mean. There are limited data on long-term follow-up, but at 5 to 6 years of age, these children appear to function within the normal range of mental and motor development. Some differences have been found in various behavioral, adaptive, and perceptual skills. At 9 years of age, there is a trend, in opiate-exposed children, to score lower than controls in some measures of language processing. Some children require special education classes. A positive and reinforcing environment can improve infant outcome significantly.
- B. Cocaine.** No major deficits in motor development have been found after gestational exposure to cocaine. By 1 to 6 years of age, there are no significant differences in weight, height, and head circumference between cocaine-exposed and nonexposed children. Gestational cocaine exposure may, however, be associated with long-term effects on behavior. Cocaine-exposed children exhibited more behavioral problems (both internalizing and externalizing) on follow-up to age 7 years, and these issues were related to degree of cocaine exposure during gestation. A long-term study found a 4.4-point decrease in intelligence quotient (IQ) at 4.5 to 7 years of age after gestational exposure to cocaine. In addition, cocaine-exposed children are more likely to be referred for special education services at school when compared with unexposed children.
- C. Phencyclidine.** Very few studies have been done, but at 2 years of age, these infants appear to have lower scores in fine motor, adaptive, and language areas of development. Although weight, length, and head circumference are somewhat reduced at birth, most children demonstrate adequate catch-up growth.
- D. Marijuana.** There is no definitive evidence of long-term dysfunction. Some scientific studies have found that infants born to women who used marijuana during their pregnancy display altered responses to visual stimulation, increased tremors, and a high-pitched cry, which may indicate problems with nervous system development. During preschool and early school years, marijuana-exposed children have been reported to have more behavioral problems and difficulties with sustained attention and memory than unexposed children.

103 Intracranial Hemorrhage

An **intracranial hemorrhage (ICH)** can occur in term and preterm infants and is the most common central nervous system (CNS) acute complication of a preterm birth. Types of ICH include subdural hemorrhage, epidural hemorrhage, subarachnoid hemorrhage, intracerebral intraparenchymal hemorrhage, intracerebellar parenchymal hemorrhage, and germinal matrix and intraventricular hemorrhage. An **ICH in term infants** tends to be extra-axial (subdural, subarachnoid, or subtentorial) and is most related to birth trauma, hypoxic ischemic events, and coagulopathies (eg, thrombophilias or thrombocytopenia). The **most common ICH in preterm infants** is bleeding from the subependymal germinal matrix and may result in intraventricular or periventricular hemorrhage, either of which can potentially cause hemorrhagic infarctions of the cerebral white matter. With the spread of improved neuroimaging techniques, cerebellar hemorrhage has been detected with increasing frequency, in particular among very immature preterm infants.

SUBDURAL HEMORRHAGE

- I. Definition.** A **subdural hemorrhage (SDH)** is an accumulation of blood between the dura and the arachnoid membrane and involves tears of bridging veins of the subdural compartment (see Figure 7–3). The vascular structures most affected are superficial cerebral veins, infratentorial posterior fossa venous sinuses, the inferior sagittal sinus, and tentorial sinuses and veins (eg, vein of Galen). Blood from an infratentorial hemorrhage in the posterior fossa may accumulate and cause acute symptoms of increased intracranial pressure (ICP) or reside as a hematoma that slowly evolves as a chronic subdural hematoma with increasing fluid accumulation and increasing ICP.
- II. Incidence.** Up to 45% of term newborns may have asymptomatic SDH. Symptomatic SDH usually follows a traumatic delivery of a late preterm or term infant. Only on rare occasions does SDH become clinically critical. Symptomatic SDH occurred in 2.9 per 10,000 spontaneous deliveries, as compared with 8.0 and 9.8 per 10,000 vacuum-assisted and forceps-assisted deliveries, respectively. When both vacuum and forceps are used in delivery, the rate goes up to 21.3 per 10,000.
- III. Pathophysiology.** An SDH is typically related to traumatic birth events involving labor and delivery. Undue pressure on the skull and torsion may produce shear forces resulting in rupture of superficial cerebral bridging veins (carrying blood through the dura mater to the arachnoid mater of the meninges) or tears in the dura or dural reflections (eg, either the falx cerebri or tentorium and associated venous sinuses), causing blood to collect below the dura and superior to the subarachnoid villi. These events are usually found over the cerebrum or within the posterior fossa. Occasionally, skull fractures accompany these findings. Timing of the onset of SDH and clinical findings may be acute or delayed. Clinical signs may be minimal to none, with the SDH self-resolving, or subtle findings of slight irritability or a seemingly hyperalert state may foretell an underlying accumulating SDH with delayed onset of more serious neuropathic circumstances. Latent SDH can lead to a subdural hematoma and subdural effusion with increasing ICP.
- IV. Risk factors.** Include precipitous labor and delivery, instrumented deliveries using forceps or vacuum-assist devices, a large for gestational age infant with cephalopelvic disproportion, abusive head trauma, blunt prenatal trauma, glutaric aciduria type 1, and coagulopathies including familial thrombophilias, vitamin K deficiency, and maternal ingestion of hydroxycoumarin derivatives (eg, warfarin).
- V. Clinical presentation.** Neonates with SDH may present similarly to those with hypoxic ischemic encephalopathy. Signs include lethargy alternating with irritability or asymmetric hypotonia of upper and lower extremities on the contralateral side of the SDH.

More specific to SDH is impaired third cranial nerve function ipsilateral to the SDH. Focal seizures may present at any time and are much more likely to occur in low birth-weight infants. Signs of increasing ICP may include a bulging fontanel, deviations of eye movements, and increasing occipital-frontal head circumference. Additional clinical signs can be poor feeding, intermittent vomiting, and failure to thrive, all of which are more often related to late post-SDH neuropathic events.

VI. Diagnosis

A. Laboratory

1. **Serial hematocrit.** Unexplained anemia.
2. **Total serum bilirubin.** Persistent newborn jaundice.
3. **Cerebrospinal fluid studies** are indicative but not diagnostic of SDH. Suggestive of an ICH hemorrhage is the cerebrospinal fluid (CSF) analysis combination of a large numbers of red blood cells (especially if crenated), xanthochromia, elevated protein content, and hypoglycorrachia (ie, CSF glucose <50% of concomitant blood glucose).

B. Imaging studies

1. **Computed tomography (CT)** readily identifies most SDH.
2. **Magnetic resonance imaging (MRI)** is superior and currently recommended. It is best for detailing posterior fossa lesions and accumulations of blood or effusion. Routine use of MRI has shown that small asymptomatic SDHs are common.
3. **Ultrasound (US)** does not readily lend itself to SDH identification, except for possible midline shifts.

VII. Management. Documentation of risk factors and appropriate cogent observation are the most important first clinical steps. Careful and repeated neurologic examinations will reveal neurologic signs that should be followed by laboratory and imaging studies. In most cases, blood collections will gradually resorb over the weeks and months following the initial hemorrhage. Rarely, in the case of a large SDH causing increased ICP or mass effect, neurosurgical drainage may be required.

VIII. Prognosis. The outcome of SDH ranges from early death to minimal or no disabling conditions. Much of the neurologic outcome of SDH depends on accompanying conditions soon after birth (eg, prematurity, birth asphyxia, shock, hypoxic ischemic encephalopathy, or infection). Up to 80% of infants with SDH show no disability. Massive tentorial tears and hemorrhage can result in death or severe and long-term handicap. Infants with major SDH can have mortality rates upward of 45%. Conversely, in most cases, SDH can be limited, produce few clinical signs, and have a good outcome. More than 50% of infants with minimal early clinical findings and later good outcomes have been largely found to have had small cerebral convexity SDH hemorrhages.

EPIDURAL HEMORRHAGE

An **epidural hemorrhage**, blood between the inner skull and dura, is extremely rare in newborns. It is usually caused by injury to the middle meningeal artery, which is less susceptible to injury because it moves freely (see Figure 7-3). Trauma is the most likely etiology, including birth trauma, an infant being dropped at delivery, or abusive head trauma. Diagnosis is typically by CT or MRI. Affected infants may also have a skull fracture and cephalohematoma, and treatment is supportive with possible surgical/needle aspiration.

SUBARACHNOID HEMORRHAGE

1. **Definition.** A **subarachnoid hemorrhage (SAH)** is an accumulation of blood between the arachnoid mater and the pia mater. The arachnoid mater is an avascular membrane situated below the dura mater and, together with the pia mater, constitutes what is known as the leptomeninges. Unlike adult SAH, which is arterial, infant SAH is venous in origin, coming from bridging veins within the subarachnoid space; however, on rare

occasions, it may be arterial, coming from leptomeningeal arteries of the subarachnoid space. SAH may be primary, coming from the vessels of the subarachnoid space, or secondary, occurring when the blood extends from existing intraventricular, cerebral, or cerebellar hemorrhages.

- II. **Incidence.** A small asymptomatic SAH is commonly seen in preterm and term newborn infants. It is of limited significance unless other conditions are present, such as prematurity, coagulopathies, birth trauma, or asphyxia. Primary bleeding within the subarachnoid space is usually self-limited, and it is the second most common ICH seen in newborns.
- III. **Pathophysiology.** Rupture of the small vessels of the subarachnoid space can be associated with trauma in term infants or birth asphyxia in preterm infants and is most often idiopathic and insignificant.
- IV. **Risk factors.** See Pathophysiology.
- V. **Clinical presentation.** In term infants, an SAH is mostly asymptomatic. Mild to intermittent irritability or lethargy may herald the onset of seizures on the second to third day of life.
- VI. **Diagnosis**
 - A. **Laboratory.** CSF findings in SAH mirror those already discussed for SDH.
 - B. **Imaging studies.** CT and MRI studies establish the existence of primary SAH or identify other lesions that may be the source of secondary SAH.
- VII. **Management.** Close observation and repeated neurologic examinations suffice for those infants at risk but without signs of SAH. Anticonvulsant medication and intravenous fluid therapy are needed if the infant has lethargy and/or seizure activity. Serum electrolyte and urine output monitoring for possible syndrome of inappropriate antidiuretic secretion is recommended if a significant amount of SAH has been identified. Regular sequential head circumference measurements and, in some cases, serial head US will identify suspected cases of posthemorrhagic hydrocephalus. The latter is due to obliteration of CSF resorption sites by the organizing blood. Follow-up cranial imaging studies will also be needed.
- VIII. **Prognosis.** The location and extent of the hemorrhage may play a role. A primary isolated SAH is mostly uncomplicated. Infants who have seizures that resolve before discharge from the hospital have an expected 90% uncomplicated outcome. Infants who develop long-term complications are mostly those who had coexisting problems associated with birth trauma or perinatal asphyxia. SAH in the frontal lobe is associated with higher rates of disability.

INTRACEREBRAL INTRAPARENCHYMAL HEMORRHAGE/ PERIVENTRICULAR HEMORRHAGIC INFARCTION

- I. **Definition.** An **intracerebral parenchymal hemorrhage** occurs deep within the brain tissue after venous infarction and is commonly referred to as **periventricular hemorrhagic infarction (PVHI)**. Porencephalic cysts and periventricular necrotic cystic lesions are not uncommon complications of PVHI.
- II. **Incidence.** The occurrence of PVHI may be as high as 10% to 15% among infants with ICH.
- III. **Pathophysiology.** It is postulated that venous thrombosis and/or venous congestion causes PVHI through increased intravascular pressure that leads to rupture of parenchymal vessels and ischemic necrosis secondary to impaired arterial perfusion. Affected preterm infants have hemorrhagic venous infarction of subcortical and periventricular white matter, whereas affected term infants develop subcortical hemorrhage with infarction of overlying cortex.
- IV. **Risk factors.** PVHI is seen most often after a perinatal hypoxic ischemic event.
- V. **Clinical presentation.** Clinical signs of PVHI follow those of severe neonatal encephalopathy and overlap with clinical signs as seen with SDH, SAH, or intraventricular hemorrhage (IVH).

- VI. Diagnosis**
- A. Computed tomography** can be useful for detecting recent hemorrhage.
 - B. Magnetic resonance imaging** findings of hypodensities suggest evolving areas of brain injury.
 - C. Cranial ultrasound** is particularly useful in identifying PVHI. An echodense lesion of periventricular white matter with an associated germinal matrix (GM) hemorrhage or IVH usually identifies coexisting PVHI.
- VII. Management.** PVHI requires observational and supportive care, such as severe SDH or SAH. If imaging studies suggest a midline shift, neurosurgical consultation should follow. Subsequent posthemorrhagic hydrocephalus is always a threat, which also requires neurosurgical consultation.
- VIII. Prognosis.** Developmental studies of preterm infants with PVHI have shown that significant cognitive and/or motor delays complicate overall recovery in at least two-thirds of survivors. Careful follow-up is thus indicated in every case of PVHI.

INTRACEREBELLAR PARENCHYMAL HEMORRHAGE

- I. Definition.** An **intracerebellar parenchymal hemorrhage (ICPH)** is a cerebellar hemorrhage that is increasingly detected and is more common in premature infants compared with term newborns. Cerebellar hemorrhage is now recognized as an important complication of preterm birth. Cerebellar hemorrhage can occur in isolation but more commonly occurs in combination with supratentorial brain injury and can range from small punctate hemorrhagic lesions to very large cerebellar hemorrhages.
- II. Incidence.** Reports vary by gestational age and by the method of detection. By cranial US that includes an additional mastoid view, an incidence of 9% was reported among infants <33 weeks' gestation, of whom 60% weighed <750 g. Using brain MRI with specific MRI sequences (eg, susceptibility-weighted imaging), the incidence was reported to be 37% among a similar-age population.
- III. Risk factors.** Traumatic delivery.
- IV. Pathogenesis.** Four mechanisms for intracerebellar parenchymal hemorrhage are possible:
- A. Primary hemorrhage into either cerebellar hemisphere or into the vermis.**
 - B. Venous infarction.**
 - C. Supratentorial intraventricular hemorrhage and subarachnoid hemorrhage** are associated with reduction of preterm cerebellar growth, which may reflect concurrent cerebellar injury or direct effect of the blood on cerebellar development.
 - D. Direct trauma to the posterior fossa with rupture of cerebellar bridging veins or the occipital sinuses.** This is seen primarily in term infants. Most ICPH is unilateral and focal with a predilection to the right cerebellar hemisphere.
- V. Clinical presentation.** An ICPH is unique in causing unexplained motor agitation, in addition to respiratory compromise, apnea, and breathing irregularities. Otherwise, the general symptoms of ICH are present as well.
- VI. Diagnosis.** CT and MRI have superior ability over US in diagnosing ICPH. However, US done via the mastoid fontanel can provide additional information.
- VII. Management.** All management modalities presented for other ICH patients apply to infants with confirmed or suspected ICPH. For infants at risk for ICPH, the added combination of shock and acidosis is closely related and warrants diagnostic efforts specific for ICPH.
- VIII. Prognosis.** Infants with ICPH usually require longer periods of mechanical ventilation. They will need close neurodevelopmental assessment, much as required with other types of ICH. In general, cerebellar hemorrhages seen only on MRI have much better prognosis than those detectable by US.

GERMINAL MATRIX AND INTRAVENTRICULAR HEMORRHAGE

- I. Definition.** IVH is the most common CNS acute complication of a preterm birth. The occurrence is greatly associated with the persistent presence of the GM. Chorioamnionitis, acidosis, birth asphyxia, shock, blood pressure fluctuations, and respiratory distress associated with hypocapnia, hypercapnia, hypoxemia, or mechanical ventilation are common related problems.

The GM, located between the caudate nucleus and the ependymal lining of the lateral ventricle, is normally not seen on cranial US. When GM hemorrhage occurs, it becomes readily identified by US and is seen as subependymal bleeding originating between the groove of the thalamus and the head of the caudate nucleus. Bleeding may be confined to the GM, or it may rupture into either lateral ventricle and thereby become a unilateral or bilateral GM/IVH.

By 36 weeks' postconceptional age, the GM has involuted for most infants. If IVH occurs in term infants, it originates most often in the choroid plexus; however, residual subependymal GM may also be a point of origin. Following IVH, further insult by venous thromboses may result in thalamic infarction.

- II. Incidence.** The overall occurrence of IVH in preterm infants <1500 g is about 18% to 25%. Rates vary by gestation, with the greatest risk of GM/IVH in preterm infants with birthweights <750 g. Because IVH is rarely seen in term infants, their incidence rates are exceptionally low and associated with birth-related injury or asphyxia. Curiously, 2% to 3% of seemingly normal term infants, when studied prospectively, have been noted to have asymptomatic IVH.

- III. Pathophysiology.** The GM is a highly vascularized area. The GM vessels exhibit a variety of characteristics that underlie the fragility and propensity to hemorrhage such as absence of a complete basal lamina, a fenestrated lining, and high morphometric ratio of diameter to wall thickness. The GM begins to involute after 34 weeks' postconceptional age, and thus, the peculiar vulnerability and predilection for GM/IVH for preterm infants lessens but is not totally removed. Late preterm infants (34–37 weeks' gestation) may have IVH that reflects those of early preterm infants. **Fluctuations in cerebral blood flow (CBF)** play an important role in the pathogenesis of GM/IVH because sick premature infants have **pressure-passive cerebral circulation**. A sudden rise or fall in systemic blood pressure can result in an increase in CBF with subsequent rupture of the GM vessels. Decreases in CBF can also result in ischemic injury to the GM vessels and surrounding tissues, making them prone to secondary rupture following reperfusion.

The unique deep venous anatomy at the level of the foramen of Monroe and the open communication between the GM vessels and the venous circulation contribute to the danger of abrupt or sharp fluctuations in cerebral venous pressure. Given this anatomic proximity, rupture through the GM subependymal layer results in entrance of blood into the lateral ventricles in nearly 80% of affected infants.

A. Neuropathologic consequences of intraventricular hemorrhage

- 1. Germinal matrix ventricular-subventricular zone contains the migrating cells of origin for the cerebral cortex.** It is the site of production of neurons and glial cells of the cerebral cortex and basal ganglia. GM destruction may result in impairment of myelination, brain growth, and subsequent cortical development. Moreover, in preterm infants, GM/IVH leads to reduction of cerebral perfusion in the first 2 weeks after the hemorrhage. The reduction was found to be most severe around day 5 and was irrespective of the IVH grade.
- 2. Periventricular hemorrhagic infarction** is venous in origin, associated with severe and usually asymmetric IVH, and invariably occurs on the side with the larger amount of intraventricular blood. It is a distinct pathologic event following venous stasis; it is often mistakenly described as an "extension" of IVH, of which it is not. Moreover, PVHI is neuropathologically distinct from periventricular leukomalacia (PVL). See preceding discussion under PVHI.

3. **Posthemorrhagic hydrocephalus** is more common in infants with the highest grade of hemorrhage. It is most frequently attributable to obliterative arachnoiditis either over the convexities of the cerebral hemispheres with occlusion of the arachnoid villi or in the posterior fossa with obstruction of outflow of the fourth ventricle. Rarely, aqueductal stenosis is caused by an acute clot or reactive gliosis.
4. **Periventricular leukomalacia** is a frequent accompaniment of IVH but is not directly caused by IVH. PVL is an ischemic brain injury followed by necrosis of periventricular white matter adjacent to the lateral ventricles. It is usually a nonhemorrhagic event resulting from hypotension, apnea, and other hypoxic ischemic events known to decrease CBF. Most PVL lesions are symmetrical in distribution.

IV. Risk factors. Prematurity and respiratory distress syndrome have remained as the most closely related clinical circumstances to GM/IVH. Other risk factors associated with the development of IVH include small for gestational age, male sex, and hypercarbia. As mentioned earlier, the immature cerebrovascular structures of preterm infants are extremely vulnerable to volume and pressure changes and to hypoxic and acidotic changes. Secondly, respiratory distress and its attendant limitations for oxygenation further attenuate the immature vasculature of the preterm brain. The possible “overzealous” ventilatory maneuver performed to correct for the respiratory failure may adversely affect cerebral perfusion leading to GM venous congestion. Birth asphyxia, pneumothorax, shock/hypotension, acidosis, hypothermia, and therapeutic volume and/or osmolar overloads all serve to multiply the risk for GM/IVH. Even procedures that we perceive as routine in the care of premature infants may also be contributory, such as tracheal suctioning, abdominal examination, and handling to reposition or to instill mydriatics for an eye examination.

Of growing importance for the understanding of preterm GM/IVH is the possible role of fetal and neonatal inflammatory responses. Chorioamnionitis and funisitis may be harbingers of postnatal cerebral vascular events leading up to GM/IVH. Fetal inflammatory responses and subsequent neonatal hypotension and sepsis are closely related processes to IVH. Mediators of an inflammatory response, such as cytokines, have vasoactive properties that may be the source of exaggerated blood pressure changes that overwhelm the pressure-passive state of the GM.

V. Clinical presentation. The clinical presentation is diverse, and diagnosis requires neuroimaging for confirmation. The clinical symptoms may mimic those of other ICH or common neonatal disorders such as metabolic disturbances, asphyxia, sepsis, or meningitis. IVH may be totally asymptomatic, or there may be subtle symptoms, for example, a bulging fontanel, a sudden drop in hematocrit, apnea, bradycardia, acidosis, seizures, changes in muscle tone, or changes in level of consciousness. A catastrophic syndrome may accompany an extensive IVH. It is characterized by a precipitous decrease in hematocrit, a rapid onset of stupor or coma, respiratory failure, seizures, decerebrate posturing or a profound flaccid quadriparesis, and fixed pupils.

VI. Diagnosis

A. Cranial ultrasound. Cranial US (see Chapter 12 for imaging examples) is the procedure of choice for screening and diagnosis. CT and MRI are acceptable alternatives but are more expensive and require transport to the imaging service. They are valuable for a more definitive diagnosis or documentation of static brain injury before discharge from the hospital. Two systems for classifying GM/IVH have been advanced for clinical use. The older and most time honored has been that of Papile, based originally on CT but adapted for interpretation of cranial US. The second is the classification promulgated by Volpe, based also on cranial US. The utility of classification schema resides in the ability of clinicians to communicate degrees of severity and to have a source of information for comparison of lesions as well as having a means to follow progression or regression and recovery of the initial insult of IVH. **The GM/IVH classification by Papile** (updated in 2002) gives grades I to IV. Grades I and II are small hemorrhages. **Grade I** is hemorrhage

only seen in the GM (~40% of all IVHs). **Grade II** shows hemorrhage from the GM extending into the lateral ventricles but without ventricular dilation (~25% of all IVHs). **Grade III** shows hemorrhage filling >50% of the lateral ventricles that are consequently enlarged (~20% of all IVHs). **Grade IV** is marked by extension of the hemorrhage into the surrounding brain white matter parenchyma (~15% of all IVHs).

A cranial US is indicated for screening sick preterm infants for IVH from the first day of life and throughout the hospitalization. Typically, a cranial US is done between day 1 and day 7, depending on the clinical presentation and institutional protocols, keeping in mind that 50% of GM/IVH may occur on day 1, but 90% have occurred by day 4 of life. Of all GM/IVH identified by day 4 of life, 20% to 40% will progress to more extensive hemorrhage during the first 7 to 10 days of life. Most clinicians obtain a final cranial US, CT, or MRI before discharge, or at 36 weeks' postconceptional age.

- B. Near-infrared spectroscopy** is a bedside monitor that measures real-time brain tissue oxygenation, which can reflect CBF and loss of autoregulation. Studies have correlated changes on the near-infrared spectroscopy monitor with increased IVH in preterm neonates.
- C. Amplitude electroencephalogram** may be associated with a depression in the background activity as well as dissimilarity between right and left waves in the case of unilateral IVH.
- D. Laboratory studies.** CSF initially shows elevated red and white blood cells, with elevated protein concentration. The degree of elevation of CSF protein correlates approximately with the severity of the hemorrhage. It is frequently difficult to distinguish IVH from a "traumatic tap." Within a few days after hemorrhage, the CSF becomes xanthochromic, with a decreased glucose concentration as in other forms of ICH. Often, the CSF shows a persistent increase in white blood cells and protein and a decreased glucose level, making it difficult to rule out meningitis.

VII. Management

A. Prenatal prevention

- 1. Avoidance of premature delivery.**
- 2. Transportation in utero.**
- 3. Data suggest that active preterm labor may be a risk factor for early intraventricular hemorrhage and there may be a protective role for cesarean delivery.** However, Anderson et al showed that cesarean birth before the active phase of labor resulted in a lower frequency of severe IVH and less progression to severe IVH, although it did not affect the overall incidence of IVH. In a study by Durie et al, there was no correlation between mode of delivery and the incidence of IVH in very low birthweight infants who are presenting by the vertex.
- 4. Antenatal steroid therapy.** Several large multicenter trials have shown a clear efficacy of antenatal steroids in reducing IVH. In 1 study, the incidence of GM/IVH was 2- to 3-fold lower in infants whose mothers received a complete course of antenatal steroids compared with those whose mothers received no steroids or an incomplete course (<48 hours). Moreover, this beneficial effect appears to be independent of the improvement in respiratory status. The prevention of IVH may be a composite effect of enhanced vascular integrity, decreased respiratory distress, and possibly altered cytokine production. Blickstein and coworkers have reported that antenatal steroids (given between 24 and 32 weeks' gestation) as a completed course (48 hours) resulted in a 2.5 times lower incidence of GM/IVH (7.7% vs 19.4%) for singleton and multiple births.

B. Postnatal prevention

- 1. Avoid birth asphyxia.**
- 2. Avoid large fluctuations in blood pressure.**
- 3. Avoid rapid infusion of volume expanders or hypertonic solutions.**

4. **Use prompt but cautious cardiovascular support to prevent hypotension.**
5. **Correct acid-base abnormalities.**
6. **Correct abnormalities of coagulation.**
7. **Avoid poorly synchronized mechanical ventilation.** Consider sedation and, in difficult situations, pharmacologic paralysis.
8. **Maintaining a midline head position** for premature neonates can be beneficial because it allows for unobstructed drainage of the jugular veins, which prevents cerebral venous congestion that may make neonates prone to IVH.
9. **Postnatal pharmacologic intervention with indomethacin.** Ment et al reported in 1994 that low-dose prophylactic indomethacin significantly lowered the incidence and severity of IVH but did not appear to be of benefit in the prevention or extension of early IVH. Subsequent reports over the ensuing years have confirmed that on balance, in the total experience with indomethacin, a generally favorable preventive effect of the drug on IVH seems apparent, particularly in male patients. The use of “prophylactic” indomethacin remains *controversial because the IVH protective effect does not translate generally into a better neurodevelopment.* However, on long-term follow-up of school-age preterm infants when male and female patients are analyzed separately, a clear cognitive benefit is apparent in male but not female patients. Much of the controversy today surrounding low-dose prophylactic indomethacin therapy for the prevention or amelioration of GM/IVH involves the continuing concerns for indomethacin-related complications of necrotizing enterocolitis, spontaneous intestinal perforation, and decreased renal function (albeit transient in most cases). The use of other prostaglandins inhibitors, such as ibuprofen, for patent ductus arteriosus closure is not associated with a likewise neuroprotective action.

C. Management of acute hemorrhage

1. **General supportive care** to maintain a normal blood volume and a stable acid-base status.
2. **Avoid fluctuations** of arterial and venous blood pressures.
3. **Follow-up serial imaging** (cranial US or CT) to detect progressive hydrocephalus (see Chapter 97).

VIII. Prognosis

- A. **Short-term outcome** of GM/IVH is directly related to birthweight, gestational age, and the ensuing severity of the hemorrhagic insult to the immature brain. The early mortality rates (first 14 days) are 12%, 24%, 32%, and 45% for grade I, II, III, and IV hemorrhages, respectively, among infants whose birthweight is <750 g. Posthemorrhagic ventricular dilation is mostly observed among infants with grade III (75% and 77%) and grade IV (83% and 66%) hemorrhage whose birthweight is below or above 750 g, respectively.
- B. **Long-term major neurologic sequelae** of GM/IVH depend primarily on the extent of associated parenchymal injury, laterality, and any added effects of the short-term complications. The incidence of major neurologic sequelae (spastic motor deficits, major cognitive deficits) after minor degrees of hemorrhage is slightly higher than that in infants without hemorrhage and increases to approximately 50% in infants with severe hemorrhage; a higher incidence occurs in infants with IVH complicated by periventricular hemorrhagic infarction or cystic PVL, or both.

The rate of disability rises with immaturity. As an illustration, in the multicenter EPIPAGE study that enrolled 1954 infants, it was reported that <32 weeks' gestation cerebral palsy rates with isolated grade I to III IVH increased with immaturity, from 5% in infants born at 31 to 32 weeks to 10% to 15% in those born at 27 to 30 weeks and 33% in those born at 24 to 26 weeks.

The major determinant of outcome is the presence and severity of associated periventricular hemorrhagic infarction. In a recent study, the mortality rate for

such infants was 59%, whereas it was only 8% for infants with the IVH grade III. Among the survivors, 87% exhibited major motor deficits, and 68% had cognitive function <80% of normal. The motor deficits correlated with the topography of the parenchymal lesions and thus consisted of either spastic hemiparesis or asymmetrical spastic quadriplegia. In more recent reports, the incidence of major motor deficits has been lower (ie, ~50% in 36 surviving infants <32 weeks of gestational age and 60% in 30 surviving infants <2500 g birthweight).

104 Intrauterine (Fetal) Growth Restriction

- I. Definitions.** Fetal growth restriction (FGR)/intrauterine growth restriction (IUGR) and small for gestational age (SGA) are sometimes used interchangeably but are not synonymous. **FGR and IUGR are the same conditions** where intrinsic fetal pathology exists or when placental support for the fetus is compromised, resulting in fetal hypoxia and undernourishment, and a pathologic restriction of the fetal genetic potential for growth. **SGA** describes an infant whose weight is lower than the population norms or a predetermined cutoff weight. Most commonly, **SGA infants** are defined as having a birthweight below the 10th percentile for gestational age and gender, or >2 standard deviations below the mean for gestational age. It can occur following a pathological process (FGR/IUGR) or just represent a small infant based on constitutional factors (maternal weight, height, ethnicity, parity), known as **constitutional SGA**. FGR/IUGR infants are not all SGA, and SGA infants are not all FGR. It has been proposed that “SGA should be based on growth percentiles, and FGR be based on evidence of pathologic growth.” This distinction between constitutional SGA and pathologic FGR has important implications for fetal monitoring, risks of perinatal morbidity and mortality, and the optimal timing of delivery. FGR increases the risk of fetal mortality 10- to 20-fold compared to an appropriately grown fetus. Constitutionally small infants are not at an increased risk of perinatal mortality or morbidity.

FGR (as opposed to IUGR) is used more often recently, especially in the obstetric literature. **The American College of Obstetrics and Gynecology defines FGR as** a fetus with an estimated fetal weight (EFW) <10% of gestational age. It is the condition where infants have not achieved their optimal intrauterine growth potential. FGR infants are further classified as **symmetric or asymmetric** based on anthropometric measurements and by **onset as early or late onset**.

A. Symmetric or asymmetric FGR

- 1. Symmetric fetal growth restriction** (head circumference, height, and weight all <10th percentile). The head circumference, length, and weight are all proportionately reduced for gestational age. Symmetric FGR is due to either decreased growth potential of the fetus (congenital infection or genetic disorder) or extrinsic conditions that are active very early in pregnancy. Features include: earlier insult in gestation, less common than asymmetric, accounts for approximately 30% of FGR cases, ponderal index (see Section VI.E.4 for definition) normal, malnutrition less pronounced, normal cell size with reduced cell number, and poor prognosis.
- 2. Asymmetric fetal growth restriction (more common).** Fetal weight is reduced out of proportion to the length and head circumference. The head circumference and length are closer to the expected percentiles for gestational age than is the weight. In these infants, brain growth is usually spared. Common etiologies

include uteroplacental insufficiency, maternal malnutrition, and extrinsic conditions appearing late in pregnancy. Features include: occurs later in gestation, more common than symmetric growth restriction (70%–80% of cases), normal cell number but cell size is reduced, low ponderal index, more pronounced malnutrition, and good prognosis.

B. Early or late onset FGR. Early detection of FGR identifies infants at risk of mortality in utero, but is difficult based on fetal anthropometry (by measuring crown-rump length) alone. Estimation of fetal growth velocity with serial measurements may be useful to identify FGR. For example, a fetus with weight >10th percentile may be growth restricted if fetal growth velocity declines.

1. Early onset FGR (<32 weeks' gestation). Early onset is associated with sequential changes in Doppler studies that parallel worsening placental function. Typically, umbilical artery Doppler changes precede biophysical profile parameters. Early FGR is associated with more severe placental disease, fetal hypoxia and undernutrition, systemic cardiovascular adaptation, increased risks of pre-eclampsia in the mother, and increased risks of fetal mortality and neonatal morbidity.

2. Late onset (>32 weeks' gestation). Late FGR is more difficult to identify and has less characteristic Doppler changes (see further discussion later in the chapter).

II. Incidence. About 3% to 10% (up to 15% in some studies) of all pregnancies are associated with FGR, and 20% of stillborn infants are growth restricted. The prevalence of early FGR is 1% to 2%, and that of late FGR is 3% to 5%. The perinatal mortality rate is 5 to 20 times higher for growth-restricted fetuses, and serious short- and long-term morbidities are noted in half of the affected surviving infants. FGR is estimated to be the predominant cause for low birthweight in developing countries. It is estimated that a third of infants with birthweights <2500 g are in fact growth restricted and not premature. Term infants with birthweights less than the third percentile have a 10 times higher mortality than appropriate for gestational age (AGA) infants. In the United States, uteroplacental insufficiency is the leading cause of FGR. An estimated 5% to 10% of cases are secondary to congenital infection. Chromosomal and other genetic disorders are reported in 5% to 20% of FGR infants.

III. Pathophysiology. Fetal growth is influenced by fetal, maternal, and placental factors.

A. Fetal factors

1. Fetal genotype. Approximately 20% of birthweight variability in a given population is determined by fetal genotype. Genetic determinants of fetal growth have their greatest impact in early gestation during the period of rapid cell development. Racial and ethnic backgrounds influence size at birth irrespective of socioeconomic status. Males weigh an average of 150 to 200 g more than females at birth. This weight increase occurs late in gestation. Birth order affects fetal size; infants born to primiparous women weigh less than subsequent siblings.

2. Genetic causes. Five to twenty percent of FGR is caused by genetic factors which include chromosomal anomalies, single gene disorders, and other genetic factors. **Chromosome anomalies** include: Aneuploidy (like Trisomy 21, 18, 13, and 16), uniparental disomy (of chromosomes 6, 14, 16), partial deletions or duplications (Cri du chat syndrome, Wolf Hirschhorn syndrome), ring chromosome, and aberrant genomic imprinting. The finding of symmetric FGR prior to 20 weeks of gestation suggests aneuploidy as the cause, most commonly trisomy 18. **Single gene disorders** such as Russell Silver syndrome, Bloom syndrome, Cornelia de Lange syndrome, and Fanconi anemia have been associated with FGR.

3. Congenital malformations. Congenital diaphragmatic hernia, abdominal wall defects (omphalocele and gastroschisis), renal agenesis or dysplasia, anencephaly, tracheoesophageal fistula, single umbilical artery, gastrointestinal atresia, Potter syndrome, anorectal malformation, and pancreatic agenesis are examples of

congenital anomalies associated with FGR. The frequency of FGR increases as the number of congenital defects increases.

4. **Cardiovascular anomalies may lead to abnormal fetal growth** (with the possible exception of transposition of the great vessels and tetralogy of Fallot). Greatest risk is in fetuses with major CHD (FGR is found in one-fifth of infants with major CHD). Abnormal hemodynamics are thought to be the basis of some cases of FGR.
5. **Congenital infection.** TORCHZ infections (*toxoplasmosis, other* [syphilis, HIV, malaria], *rubella, cytomegalovirus, herpes simplex virus, and Zika virus*) are often associated with FGR and account for 5% to 10% of FGR fetuses. The incidence of FGR is highest when infection occurs in the first trimester. The clinical findings in different congenital infections are nonspecific and overlap considerably. Cytomegalovirus and rubella are associated with severe FGR. The most common infectious etiology of FGR in developed countries is CMV. Rubella causes damage during organogenesis and results in a decreased number of cells, whereas cytomegalovirus infection results in cytolysis and localized necrosis within the fetus. Zika virus is associated with severe microcephaly.
6. **Inborn errors of metabolism.** Transient neonatal diabetes, galactosemia, and phenylketonuria are other disorders associated with FGR. Single-gene defects affecting insulin-like growth factors or their receptors, or associated with impaired insulin secretion or action are often associated with impaired fetal growth (see Chapter 100).

B. Maternal factors (Table 104–1)

1. **Reduced uteroplacental blood flow.** Maternal disorders such as preeclampsia-eclampsia, chronic renal vascular disease, and chronic hypertensive vascular disease often result in decreased uteroplacental blood flow and result in FGR. Impaired delivery of oxygen and other essential nutrients is thought to limit organ growth and musculoskeletal maturation. Risk of placental thrombi is increased in conditions of inherited thrombophilias.
2. **Maternal malnutrition.** Small maternal size (height and prepregnancy weight) and minimal maternal weight gain during pregnancy increase the risk of FGR. Low maternal body mass index, defined as $(\text{weight [kg]}/\text{height [m]}^2)/100$, and maternal malnutrition (particularly decreased intake) influence fetal growth and birthweight. A balanced protein energy supplementation during pregnancy decreases the risk of FGR.
3. **Multiple pregnancies.** Impaired growth results from failure to provide optimal nutrition for >1 fetus in utero. In total, 15% to 30% of multiple pregnancies develop FGR; the condition is more common in monochorionic twins affected by twin-to-twin transfusion syndrome. Up until the 28th to 30th week of pregnancy, fetuses in multiple pregnancies have growth rates similar to singletons; however, after this period, there is a 15% to 20% decrease in the growth rate. The degree of FGR increases with increasing number of fetuses.
4. **Maternal substance use.** See also Chapter 102.
 - a. **Cigarettes and alcohol.** Chronic abuse of cigarettes or alcohol is demonstrably associated with FGR. The effects of alcohol and tobacco seem to be dose dependent, with FGR becoming more serious and predictable with heavy abuse.
 - b. **Heroin and cocaine.** Maternal heroin and cocaine addictions are associated with FGR mediated by placental insufficiency or direct toxic effect on the fetus.
 - c. **Others.** Other drugs and chemical agents causing FGR include known teratogens, antimetabolites, and therapeutic agents such as trimethadione, warfarin, valproic acid, and phenytoin. Each of these agents causes characteristic malformation syndromes. Repeated use of antenatal steroids and lithium use are also associated with low birthweight.

Table 104–1. MATERNAL FACTORS IN FETAL GROWTH RESTRICTION

Pregnancy-induced hypertension (>140/90 mm Hg)
Weight gain (<0.9 kg every 4 weeks)
Uterus fundus growth lag (<4 cm for gestational age)
Cyanotic heart disease
Heavy smoking
Residing at high altitude
Substance abuse and drugs
Maternal medication (warfarin, steroids, anticonvulsants)
Short stature
Low socioeconomic class
Anemia (hematocrit <30%)
Asthma
Prepregnancy weight and height (<50 kg, body mass index <20 kg/m ²)
Prior history of FGR
Chronic hypertension, diabetes mellitus
Collagen vascular disorders such as lupus
Renal disease
Severe maternal malnutrition
Multiple pregnancy
Low or advanced maternal age (<16 years, >35 years)
Preeclampsia
Inherited thrombophilias
Maternal infections (TORCHZ, malaria, tuberculosis)

FGR, fetal growth restriction; TORCHZ, toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus, and Zika virus.

- 5. Maternal hypoxemia.** Hypoxemia is seen in mothers with hemoglobinopathies, especially sickle cell disease, and they often have growth-restricted births. Chronic hypertension, preeclampsia, chronic renal insufficiency, SLE, and pregestational diabetes (classes C, D, R, F) can decrease fetal perfusion and lead to hypoxia. Infants born at high altitudes tend to have lower mean birthweights for gestational age.
- 6. Other maternal factors.** Young maternal age, advanced maternal age, short interpregnancy interval, uterine anomalies, maternal race, lower socioeconomic status, living in a developing country, primiparous, grand multiparous, low prepregnancy weight, and poor weight gain during pregnancy are associated with subnormal birthweight. Maternal hyperhomocysteinemia is also associated with low birthweight.
- 7. DNA damage** measured by micronucleus (MN) formation may play a role in FGR. MNs are formed by the lagging chromosomal fragments during anaphase in both mitosis and meiosis. Increased MN count in maternal

lymphocytes at 20 weeks' gestation is associated with increased risks of FGR and preeclampsia.

C. Placental factors

- 1. Placental insufficiency.** In the first and second trimesters, fetal growth is determined mostly by inherent fetal growth potential. By the third trimester, placental factors (ie, an adequate supply of nutrients) assume major importance for fetal growth. When the duration of pregnancy exceeds the nurturing capacity of the placenta, placental insufficiency results with subsequent impaired fetal growth. This phenomenon occurs mostly in postterm gestations but may occur at any time during gestation. Presence of asymmetrically grown fetus, low amniotic fluid index, and umbilical artery abnormalities (abnormal waveforms, absent or reversed end-diastolic flows) together suggests placental insufficiency.
 - 2. Uteroplacental insufficiency.** It is the most common reason for FGR and occurs in almost 70% of infants with FGR. Impaired oxygen extraction and nutrient delivery (glucose and amino acids) leads to fetal hypoglycemia and hypoxia. The latter is associated with decrease in cell size and number, lighter brain weight, and lower DNA content. Small placental volume and a reduction in terminal villi are seen in FGR placentas.
 - 3. Placenta structural abnormalities.** Various anatomic factors, such as multiple infarcts, velamentous umbilical cord insertion, marginal cord insertion, bilobate placenta, circumvallate placenta, umbilical vascular thrombosis, and hemangiomas, are described in FGR placentas. FGR is twice as common with a 2-vessel-cord pregnancy as compared with 3-vessel-cord pregnancies. Premature placental separation may reduce the surface area exchange, resulting in impaired fetal growth. An adverse intrauterine environment is apt to affect placental and fetal development; hence, FGR infants usually have small placentas. One study noted that those with abnormal umbilical artery waveform abnormalities but normal uterine artery waveforms were more likely to deliver at higher gestational age, have higher risks of aneuploidy, and have chronic intervillitis and perivillous fibrin deposition, both of which carry high recurrence risks.
 - 4. Placental metabolic derangements.** FGR is associated with downregulation of placental amino acid and lipoprotein lipase transporter expression and activity at birth. These derangements lead to lower plasma amino acid levels and decreased fatty acid transfer. It is unknown whether these changes are a cause or a consequence of FGR. Placental genetic imprinting may also play a role in some cases of FGR (eg, alterations of the placenta-specific *IGF-2* gene in knockout mice have produced FGR).
 - 5. Fetal endocrine responses.** Include alterations in the hypothalamic-pituitary axis, resulting in elevated corticotropin-releasing hormone, adrenocorticotropic hormone, and cortisol with a decrease in insulin-like growth factor-1 (IGF-1). Thyroid-stimulating hormone is high, but thyroxine and triiodothyronine are low, as are serum vitamin D and osteocalcin. High cortisol levels are associated with decreased postnatal catch-up growth and delayed neurodevelopmental outcomes.
 - 6. Confined placental mosaicism.** Confined placental mosaicism (CPM) refers to chromosomal mosaicism in the placenta, but not in the fetus. It usually involves a trisomy and is strongly associated with FGR. CPM has been identified in about 10% of otherwise idiopathic FGR cases and in one-third of FGR cases associated with placental infarction and decidual vasculopathy. The severity of CPM-associated FGR depends on the chromosomes involved, the proportion of mosaic cells, and the presence of uniparental disomy.
- IV. Risk factors.** Related to fetal, maternal, or placental pathophysiologic factors (see previous text) (Table 104–2).
- V. Clinical presentation.** The maternal history may raise the index of suspicion regarding suboptimal fetal growth. The infant will have a reduced birthweight for gestational

Table 104–2. PLACENTAL FACTORS IN FETAL GROWTH RESTRICTION

Two-vessel cord (single umbilical artery)
Abruption placentae, placental hematoma, placenta previa, chronic abruption
Hemangioma
Placental weight (weight <350 g)
Infarction
Aberrant cord insertion (velamentous cord)
Umbilical vessel thrombosis
Circumvallate placentation
Confined placental mosaicism
Massive perivillous fibrin deposition (immune mediated)
Chronic villitis of unknown etiology
Placental mesenchymal dysplasia
Placental infections (tuberculosis, malaria)

age. Using growth charts and the Ballard score can help assess gestational age and intrauterine and postnatal growth. See Figures 6–2 through 6–6.

VI. Diagnosis

A. Establishing gestational age. Determining the correct gestational age is imperative. The last menstrual period, size of the uterus, time of quickening, and early ultrasound measurements are used to determine gestational age. (See Chapter 6.)

B. Fetal assessment. FGR evolves from a preclinical phase to clinically apparent growth delay and fetal compromise before the onset of labor. Liver size (hence a decrease in abdominal circumference) is affected before head and body growth are affected. Abnormalities in placental perfusion in the maternal compartment increase uterine artery flow resistance. When fetal villi are affected, umbilical artery end-diastolic flow patterns get altered (see below). Finally, when fetal arterial partial pressure of oxygen is compromised, middle cerebral artery (MCA) Doppler flow velocities are affected. When FGR develops early, there is a greater degree of vascular abnormality in the maternal and fetal compartments of the placenta and a 40% to 70% rate of associated preeclampsia. Umbilical artery pulsatility index is elevated. When FGR develops late, cerebral and umbilical Doppler abnormalities may occur independently of each other. Failure of diagnosis or surveillance in late-onset FGR increases risks of stillbirth.

1. Clinical diagnosis. Manual estimations of weight, serial measurements for uterine fundus height, and maternal estimates of fetal activity are simple clinical measures.

2. Ultrasonography. Because of its reliability to date pregnancy and to detect impaired fetal growth by anthropomorphic measurements and fetal anomalies, ultrasonography currently offers the greatest promise for diagnosis. The following anthropomorphic measurements are used in combination to predict growth impairment with a high degree of accuracy.

a. Estimated fetal weight. To assess for FGR, 4 biometric measures are commonly used: biparietal diameter, head circumference, abdominal circumference, and femur length. The biometric measurements can be combined to generate an EFW. The estimate may deviate from the birthweight by up to 20%. The liver is the first organ to suffer the effects of growth restriction due

to redistribution of ductus venosus blood flow to the heart and a decrease in glycogen deposition in the liver. Reduced growth of the abdominal circumference (<5 mm/wk) is the earliest sign of asymmetric growth restriction and diminished glycogen storage. A recent study noted a >17-fold higher risk of morbidity if the fetus was growth restricted (<10th percentile for age) and the abdominal circumference growth velocity was in the lowest decile.

Nomograms exist to monitor fetal growth using EFW. An EFW <10th percentile can identify FGR but may not distinguish it from a constitutionally SGA fetus. An EFW less than the third percentile and the abdominal circumference growth rate together are more likely to identify true FGR, and EFW estimates with abnormal Doppler studies can identify the fetus at increased risk of adverse outcomes (see later discussion). The World Health Organization (WHO) fetal growth charts for EFW and ultrasound biometric measurements are based on data from low-risk healthy pregnancies in 10 countries. Individualized growth charts taking into account maternal physiologic characteristics such as race, ethnicity, parity, and height, and fetal characteristics such as gender are also now available (INTERGROWTH-21st Project).

Term optimal weight (TOW) is defined as the optimal weight based on fetal weight curves of healthy infants born at term. For an individual pregnancy, fetal growth can be combined with TOW to show the **gestation-related optimal growth (GROW)** curve. GROW charts adjusted for maternal height, weight, parity, and ethnicity are available at www.gestation.net (accessed September 14, 2018).

- b. Ratio of head circumference to abdominal circumference.** This ratio normally changes as pregnancy progresses. In the second trimester, the head circumference is greater than the abdominal circumference. At about 32 to 36 weeks' gestation, the ratio is 1:1, and after 36 weeks, the abdominal measurements become larger. Persistence of a head-to-abdomen ratio <1 late in gestation is predictive of late-onset FGR.
 - c. Femur length.** Femur length appears to correlate well with crown-heel length and provides an early and reproducible measurement of length. Serial measurements of femur length are as effective as head measurements for detecting early-onset FGR.
 - d. Placental morphology and amniotic fluid assessment** may help in distinguishing a constitutionally small fetus from a growth-restricted fetus. For example, placental aging with oligohydramnios suggests FGR and fetal jeopardy, whereas normal placental morphology with a normal amount of amniotic fluid suggests a constitutionally small fetus.
 - e. Placental volume measurements** may be helpful in predicting subsequent fetal growth. Placental weight and/or volume is decreased before fetal growth decreases. FGR with decreased placental size is more likely to be associated with fetal acidosis. Placental volume correlates with placental flow indices.
- 3. Doppler measurements** in both maternal and various fetal vascular beds are increasingly used to detect, monitor, and optimize time of delivery in FGR infants. Doppler studies are more helpful in diagnosing moderate to severe FGR than mild FGR. The various groups of vessels used are as follows:
- a. Uterine artery flow abnormalities.** Used to predict FGR as early as 12 to 14 weeks. A persistent abnormality at 23 to 24 weeks has an approximate 75% sensitivity in predicting early FGR.
 - b. Umbilical artery flow abnormalities.** Used to evaluate placental insufficiency, particularly in high-risk pregnancies. Normally, the umbilical artery (UA) resistance declines with pregnancy. Increased pulsatility index (PI), decreased end-diastolic velocity (EDV), and absent EDV (AEDV) or reversed EDV (REDV) occur with worsening fetal compromise. AEDV and REDV are associated with 20% to 68% mortality. Decreased EDV is seen when 30% of

placental flow is attenuated, and AEDV/REDV is noted when 60% to 70% of placental flow is affected. AEDV and REDV are associated with a 4.0- and 10.6-fold increased risk of mortality, respectively, compared to those with normal Doppler.

- c. **Fetal cerebral arterial flow.** Usually studied in the MCA as a PI (MCA PI) and MCA peak systolic velocity (MCA PSV). With worsening FGR, MCA PSV increases. Abnormal MCA PI precedes MCA PSV changes. Changes in MCA PI are not as consistent in predicting mortality, although decreased MCA resistance is associated with worse perinatal outcomes. MCA Doppler changes better identify late-onset FGR when the predictive ability of cerebroplacental ratio (CPR) decreases (see Section VI.B.3.e).
- d. **Doppler venous flow studies** of the vena cava, umbilical vein (UV), and ductus venosus (DV) provide information about fetal cardiovascular and respiratory responses. Decreased venous blood flow in the UV and an abnormal deep or retrograde “a” wave in DV are suggestive of ventricular decompensation. Changes in venous flow are usually late and represent more severe decompensation. Absent or reversed DV flow correlates with acidosis and is associated with 63% to 100% mortality.
- e. **Cerebroplacental ratio .** The CPR quantifies the redistribution of cardiac output by dividing the Doppler PI of the MCA with that of the UA: $CPR = \text{MCA PI}/\text{UA PI}$. Adverse outcomes have been associated with a CPR ratio of <1 or <1.08 . CPR can be affected in about 25% of term SGA fetuses. The CPR seems to be more sensitive to hypoxia than its individual components. Gestational age-specific CPR nomograms are available and can accurately identify brain sparing in late FGR and those at risk of adverse outcomes. Adverse outcomes with FGR are rare when UA Doppler flows are normal, whereas abnormal CPR regardless of fetal size or the time of onset of FGR (early vs late onset) increases the need for operative delivery, admissions to the neonatal intensive care unit, perinatal mortality, and postnatal neurologic deficits. CPR abnormalities precede abnormalities in biophysical profile and UA or MCA abnormalities. An online CPR calculator is also available at <https://fetalmedicine.org/research/thirdTrimesterDoppler> (accessed September 18, 2018). A decrease in expected CPR measurement after 28 weeks’ gestation is highly sensitive in diagnosing late-onset FGR.

Doppler study abnormalities outlined earlier correlate with fetal acid-base status and need for intervention. The frequencies of monitoring are shown in Table 104–3.

- 4. **Biophysical profile score.** Used for noninvasive fetal monitoring. The 5 components biophysical profile (BPP) scoring show a reliable and reproducible relationship with fetal pH irrespective of gestational age. A BPP <4 is associated with pH <7.20 , and BPP <2 is 100% sensitive to detect fetal acidemia. However, BPP is less sensitive to detect longitudinal deterioration.
 - 5. **Cardiotocography.** Used more commonly in Europe to assess the timing of delivery for situations wherein significant fetal acidosis is suspected. It is a component of BPP and is limited when used alone. In an FGR fetus, a short-term variability of <3.5 milliseconds predicts UA pH <7.20 .
 - 6. **Placental magnetic resonance imaging.** This can assess the severity of FGR on the basis of decreased placental volume and changes in placental thickness-to-volume ratio. Fetal demise can also be predicted by abnormal signal intensity.
- C. **Diagnosing compensated versus decompensated fetus.** Persistence of uteroplacental insufficiency results in fetal adaptation to maintain adequate cerebral oxygenation and growth.
- 1. **Uteroplacental insufficiency results in increased placental vascular resistance and fetal hypoxemia by reducing umbilical blood flow.** The fetus responds by redistribution of blood to the brain (brain sparing) through cerebral

Table 104–3. FREQUENCY OF MONITORING IN EARLY AND LATE FGR

	Doppler Studies	Frequency of Monitoring
Early-onset FGR	Elevated UA Doppler indices (>2 SD for age)	Biweekly Weekly BPP
	Low MCA PI or CPR	Weekly Doppler + BPP
	UA absent EDV (AEDV)	Doppler 2×/week + BPP
	UA reversed EDV (REDV), increased Doppler indices, and/or oligohydramnios	3×/week Doppler + BPP, daily CTG
	Absent/reversed DV a-wave	Daily monitoring + BPP
Late-onset FGR	Elevated Doppler	Weekly Doppler + BPP
	Low MCA PI or CPR	2–3×/week Doppler + BPP

BPP, biophysical profile; CPR, cerebroplacental ratio; CTG, cardiotocography; DV, ductus venosus; EDV, end-diastolic flow; FGR, fetal growth restriction; FHR, fetal heart rate; MCA, middle cerebral artery; PI, pulsatility index; SD, standard deviation.

vasodilatation, mesenteric vasoconstriction, preferential shunting through the foramen ovale, increased fractional extraction of oxygen, polycythemia, and a relative decrease in fetal oxygen consumption. Fetal growth velocity and weight gain are decreased. Nonstress test (NST), BPP, and cardiotocography are normal. Decreased diastolic flow in the UA and increased diastolic component in the MCA may be seen. The fetus is hypoxemic but does not have cerebral hypoxemia at this stage.

- 2. With worsening placental dysfunction**, fetal compromise may occur with cerebral hypoxemia and acidemia associated with no fetal weight gain, oligohydramnios, decreased fetal heart rate variability, and abnormal NST, cardiotocography, and BPP. UAs show AEDV followed by REDV. Deep “a” wave is seen in the DV, suggestive of ventricular dysfunction. With severe acidosis, MCA PI and MCA PSV decrease, suggesting the imminent collapse of the fetus.

- 3. Acute fetal decompensation.** AEDV/REDV in UAs in early-onset FGR babies can be present up to 1 week before acute decompensation. Approximately 40% of fetuses with acidosis have AEDV/REDV pattern. MCA vasodilation with abnormal PI may be present for up to 2 weeks before acute deterioration in 50% to 80% of infants. MCA vasodilation may be independently associated with abnormal outcomes in late-onset FGR. Oligohydramnios develops in 20% to 30% of FGR infants about 1 week before acute deterioration (Table 104–4).

- D. Staging of fetal growth restriction and optimal timing of delivery.** No treatment has been shown to improve FGR. The assessment of fetal well-being and timely delivery are the major goals of management. Early delivery versus expectant management showed more disabilities in survivors delivered early. In term SGA infants as well, early delivery does not improve outcomes compared to expectant management. The optimal timing of delivery with FGR is determined by the severity of fetal compromise and the risk of stillbirth. Some have stratified FGR into stages as provided below to help determine the optimal time of delivery, whereas others have used Doppler studies for monitoring of fetal well-being (Table 104–3):

- 1. Stage I (mild placental insufficiency):** Abnormal Doppler studies including CPR ratios.
- 2. Stage II (severe uteroplacental insufficiency):** There is absent EDV in the UA. Delivery should be after 34 weeks with twice-a-week monitoring.

Table 104–4. SEQUENTIAL CHANGES OF DOPPLER STUDIES IN DECOMPENSATING FETAL GROWTH RESTRICTION

Initial changes	Decreased amniotic fluid index Increased uterine artery resistance with EDV
Early changes (in 50% 2–3 weeks before nonreactive FHR)	Decreased MCA resistance (brain sparing) Absent uterine artery EDV
Late changes (~6 days before nonreactive FHR)	Increased resistance in DV-reversed EDV in uterine artery
Very late changes (in 70%, 24 hours before changes in BPP)	Reversed flow in DV (absent or reversed a-wave in DV) and pulsatile flow in umbilical vein

BPP, biophysical profile; DV, ductus venosus; EDV, end-diastolic flow; FHR, fetal heart rate; MCA, middle cerebral artery.

- 3. Stage III (fetal deterioration, low suspicion of fetal acidosis):** There is a reversal of EDV in the UA or DV PI >95th percentile. Risks of stillbirth and neurologic handicap are increased. Delivery should be around 32 weeks.
- 4. Stage IV (fetal acidosis):** Spontaneous fetal decelerations, reduced variability or reversal of atrial flow on DV. Imminent risk of fetal demise. Deliver immediately.

E. Neonatal assessment

- 1. Reduced birthweight for gestational age.** This is the simplest method of diagnosing FGR. However, this method tends to misdiagnose constitutionally small infants.
- 2. Physical appearance.** When infants with congenital malformation syndromes and infections are excluded, the remaining groups of FGR infants have a characteristic physical appearance. These infants, in general, are thin with loose, peeling skin because of loss of subcutaneous tissue, a scaphoid abdomen, and a disproportionately large head.
- 3. Appropriate growth charts should be used.** Several standardized growth charts are available to assess intrauterine and postnatal growth. Fetal growth charts are now available (Chapter 6). Additional postnatal growth charts based on Centers for Disease Control and Prevention (CDC) and WHO data from birth to 36 months can be found at the CDC website: <http://www.cdc.gov/growthcharts/> (accessed September 18, 2018).
- 4. Ponderal index.** The **ponderal index** is one of the anthropometric methods used to diagnose impaired fetal growth, especially to assess asymmetrical fetal growth restriction. It can be used to identify infants whose soft tissue mass is below normal for the stage of skeletal development. The higher the score, the higher the level of body fat. Ponderal index is recorded as a number in g/cm^3 , but there are also percentile curves for ponderal index. Normal ponderal index is GA dependent, but is generally 2.2 to 3.0 g/cm^3 . A ponderal index of <2 or <10% is abnormal and suggests asymmetrical FGR. Infants with constitutional or symmetric FGR typically have a normal ponderal index. Infants with asymmetric FGR have a low ponderal index. The formula for ponderal index is:

$$\text{Ponderal index in } \text{g}/\text{cm}^3 = [\text{weight (in g)} \times 100] \div [\text{length (in cm)}]^3$$

- 5. Ballard score.** Gestational age can also be assessed by means of the Ballard scoring system. This examination is accurate within 2 weeks of gestation in infants weighing <999 g at birth and is most accurate at 30 to 42 hours of age. (See Chapter 6.)

F. Neonatal complications of fetal growth restriction

1. Hypoxia

- a. **Perinatal asphyxia.** FGR fetuses are at risk of hypoxia-ischemia at birth because they tolerate the stress of labor poorly. A large proportion of still-born infants had FGR in utero.
- b. **Persistent pulmonary hypertension.** Many FGR infants are subjected to chronic intrauterine hypoxia, which results in abnormal thickening of the smooth muscles of the small pulmonary arterioles. This, in turn, reduces pulmonary blood flow and results in varying degrees of pulmonary artery hypertension. FGR infants are particularly at risk for persistent pulmonary hypertension.
- c. **Respiratory distress syndrome.** It is controversial whether FGR results in accelerated fetal pulmonary maturation due to chronic intrauterine stress. Respiratory distress syndrome may be seen less frequently in FGR infants; however, these infants are at higher risk of pulmonary morbidities such as bronchopulmonary dysplasia compared to appropriately grown infants.
- d. **Meconium aspiration.** Postterm FGR infants are particularly at risk for meconium aspiration.
- e. **Patent ductus arteriosus.** Conflicting data suggest that hemodynamically significant patent ductus arteriosus (PDA) may be bigger and occur earlier in FGR infants compared to AGA infants; nevertheless, spontaneous closure of PDA is more frequent in FGR infants with <1000 g birthweight. FGR infants with PDA are at greater risk for pulmonary hemorrhage, intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), and renal failure.

2. **Hypothermia.** Thermoregulation is compromised in FGR infants because of diminished subcutaneous fat insulation. Infants with FGR secondary to fetal malnutrition late in gestation tend to be thin as a result of the loss of subcutaneous fat.

3. Metabolic

- a. **Hypoglycemia.** Carbohydrate metabolism is seriously disturbed, and FGR infants are highly susceptible to hypoglycemia as a consequence of diminished glycogen reserves and decreased capacity for gluconeogenesis. Oxidation of free fatty acids and triglycerides is reduced in FGR infants, which limits alternate fuel sources. Hyperinsulinism, excess sensitivity to insulin, and deficient catecholamine release during hypoglycemia suggest abnormalities of counterregulatory hormonal mechanisms during periods of hypoglycemia in FGR infants. Hypothermia may potentiate the problem of hypoglycemia as well.

- b. **Hyperglycemia.** FGR infants may have low insulin secretion, resulting in hyperglycemia.

- c. **Hypocalcemia.** Hypocalcemia may occur in asphyxiated FGR infants.

- d. **Liver disease.** FGR infants are at greater risk for developing cholestasis associated with parenteral nutrition. There is also an increased risk of non-fatty liver disease in children born SGA.

- e. **Other.** Hypertriglyceridemia, increased sympathetic tone, and reduced concentrations of IGF-1 have been associated with increased aortic intimal thickness in FGR infants.

4. **Hematologic disorders.** Hyperviscosity and polycythemia may result from increased erythropoietin levels secondary to fetal hypoxia associated with FGR. Thrombocytopenia, neutropenia, and altered coagulation profile are also seen. Polycythemia may also contribute to hypoglycemia and lead to cerebral injury. There is an increased number of nucleated red cells secondary to extramedullary hematopoiesis. Persistent elevation of nucleated red cell counts is associated with worse prognosis.

5. **Altered immunity.** FGR infants have decreased immunoglobulin G levels. In addition, the thymus is reduced in size by 50%, and peripheral blood

lymphocytes are decreased. Reduction in total white cell count, neutrophils, monocyte and lymphocyte subpopulations, and thrombocytopenia may occur, and selective suppression of helper and cytotoxic T cells can be seen.

- 6. Others.** FGR infants are at increased risk of developing NEC, particularly when associated with an absent or reversed end-diastolic flow in UA Doppler. Preterm FGR infants are also at increased risk of pulmonary hemorrhage, chronic lung disease, more severe IVH, and renal failure.

VII. Management. Optimal management of the FGR fetus requires accurate identification of the fetus at risk of adverse outcome, prevention of stillbirth, and appropriate timing of delivery. Antenatal diagnosis is the key to proper management of FGR that allows for appropriate surveillance until delivery.

A. History of risk factors. The presence of maternal risk factors should alert the obstetrician to the likelihood of fetal growth retardation. Ultrasonography confirms the diagnosis. Correctable causes of impaired fetal growth warrant immediate attention.

B. Delivery and resuscitation. The optimal timing for delivery of FGR infants is still debated, but Doppler measurements provide an important tool for monitoring fetal well-being. Staging of FGR helps in both monitoring and optimizing the time of delivery (see Section VI.D and Table 104–3). FGR infants have a 2- to 3-fold increased risk of preterm delivery when fetal growth standards are used for diagnosis, and preterm delivery increases risks of mortality when delivered before 30 weeks. Outcomes are more favorable with cesarean delivery because the FGR fetus tolerates the stress of labor poorly. Skilled resuscitation should be available because perinatal depression is common.

C. Prevention of heat loss. Meticulous care should be taken to conserve body heat (see Chapter 8).

D. Hypoglycemia. Close monitoring of blood glucose levels is essential for all FGR infants. Hypoglycemia should be treated promptly with parenteral dextrose and early feeding (see Chapter 67).

E. Hematologic disorders. A central hematocrit reading should be obtained to detect polycythemia.

F. Congenital infection. FGR infants should be examined for congenital malformations or signs of congenital infections. Many intrauterine infections are clinically silent, and screening for these should be done routinely in FGR infants. At our institution, we consider evaluation for cytomegalovirus in FGR neonates without an underlying etiology. The placenta should be sent for histologic examination, and CPM should be sought.

G. Genetic anomalies. Screening for genetic anomalies should be done as indicated by the physical examination.

VIII. Prognosis. Mortality increases with decreasing gestational age when FGR is also present. Mortality decreases by 48% for each week that the fetus remains in utero before 30 weeks' gestation. At 24 to 26 weeks' gestation, survival is around 50% (EFW 500 g or –26 weeks) and intact survival is approximately 20%. Survival improves by approximately 2% per day spent in utero. Intact survival between 26 and 28 weeks only improves to around 30%; survival improves to >90% by 32 weeks. Neonatal morbidities can be minimized by delivering at 38 weeks in late-onset FGR. Neurodevelopmental morbidities are seen 5 to 10 times more often in FGR infants compared with AGA infants and depend not only on the cause of FGR but also on the adverse events in the neonatal course (eg, perinatal depression or hypoglycemia). Many studies reveal evidence of minimal brain dysfunction, including hyperactivity, short attention span, and learning problems. Preterm FGR infants also show alterations in early neurobehavioral functions, such as attention-interaction capacity and cognitive and memory dysfunction, that persist. Increased risk of cerebral palsy, a wide spectrum of learning disabilities, mental retardation, pervasive developmental disorders, and neuropsychiatric disorders are seen in later years. The risk of morbidities is higher in term FGR

infants. FGR infants who have normal Doppler studies have better outcomes than those with abnormal antenatal Doppler studies. Even mild FGR increases the risk of mortality and long-term development.

- A. Symmetric versus asymmetric fetal growth restriction.** Infants with symmetric FGR caused by decreased growth potential generally have a poor outcome. The recent PORTO study evaluated 1200 consecutive ultrasound-dated singleton pregnancies with gestational age between 24 0/7 and 36 6/7 weeks and an EFW <10th percentile (fetuses with major structural and/or chromosomal abnormalities were excluded) and used abnormal CPR as a proxy for brain sparing. The study found an almost 11-fold higher risk of adverse outcomes (a composite of IVH, periventricular leukomalacia, hypoxic ischemic encephalopathy, NEC, bronchopulmonary dysplasia, sepsis, and death) in those with asymmetric FGR. Conversely, smaller head circumference is also associated with cognitive, psychomotor, and behavioral delays that persist into adolescence.
- B. Preterm fetal growth-restricted** infants have a higher incidence of abnormalities than the general population because they are subjected to the risks of prematurity in addition to the risks of FGR. Outcomes are significantly worse for children whose brain growth failure occurred before 26 weeks' gestation. Gestational age may be a more important predictor of developmental outcomes than FGR, particularly before 32 to 34 weeks. Moreover, neuroimaging studies using magnetic resonance imaging show that preterm FGR infants have a high incidence of white matter loss, reduced myelination in the internal capsule, and decreased cortical gray matter volume by as much as 28%. The total brain volume is also reduced by 10% when compared with AGA infants, particularly in the hippocampal, parietal, and parietooccipital areas. Preterm FGR infants exhibit an increased prevalence of elevated fasting glucose and metabolic syndrome in childhood and adolescence.
- C. Chromosomal disorders.** FGR infants with major chromosomal disorders have a 100% incidence of disability.
- D. Congenital infections.** Infants with congenital rubella or cytomegalovirus infection with microcephaly have a poor outcome, with a disability rate >50%.
- E. Learning ability.** The school performance of FGR infants is significantly influenced by social class; children from higher social classes score better on achievement tests.
- F. Catch-up growth.** Most children who were born SGA have adequate catch-up growth without pharmacologic intervention. However, for a minority, **growth hormone** therapy (started before 8 years of age and continued for >7 years) can augment growth parameters.
- G. Metabolic syndrome in adulthood.** Epidemiologic evidence indicates that obesity, type 2 diabetes, hypertension, and cardiovascular diseases are more common among adults who were FGR at birth.
- H. Risk for recurrence of fetal growth restriction in subsequent pregnancies** depends on the underlying etiology for FGR. Previous history of FGR, preeclampsia, placental abruption or infarction, and acquired or inherited thrombophilias increase the risk of FGR in the subsequent pregnancies. The placental pathologic examination should be attempted in all FGR infants because the risk of FGR in subsequent pregnancies is very high (eg, the risk of recurrence is 50%–100% with fibrin deposition). In selected cases, folic acid, aspirin, and supplementation with L-arginine to improve placental blood flow may improve outcomes. Aspirin supplementation started before 16 weeks decreases FGR and preeclampsia, preferably taken in the evening due to concerns for effect on maternal circadian rhythm and renin activity. Benefits have, however, not been noted with use of low molecular weight heparin. Ongoing studies for preventing FGR include phosphodiesterase-5 inhibitors (eg, sildenafil), melatonin, N-acetylcysteine, statins, and nitric oxide donors.
- I. Fetal growth restriction and stillbirth.** FGR is an important predictor of unexplained stillbirths. Greater than 50% of stillborn fetuses without congenital anomalies are FGR. Maternal obesity increases the risk of concomitant FGR and stillbirth.

105 Magnesium Disorders

(Hypomagnesemia, Hypermagnesemia)

Abnormalities of magnesium (Mg^{2+}) and calcium (Ca^{2+}) metabolism are commonly seen in the neonatal intensive care unit. Calcium disturbances may be mirrored by magnesium, as seen in hypocalcemia with hypomagnesemia or hypercalcemia with hypermagnesemia. Infants of diabetic mothers and infants with fetal growth restriction may present with hypocalcemia, hypomagnesemia, or both. Abnormalities in serum values for Ca^{2+} and Mg^{2+} are of concern in any infant and warrant further investigation.

I. Hypomagnesemia

A. Definition. Normal serum levels for Mg^{2+} are typically 0.6 to 1.0 mmol/L (1.6–2.4 mg/dL). Hypomagnesemia is usually seen as any value <0.66 mmol/L (1.6 mg/dL); however, clinical signs do not manifest until levels drop below 0.5 mmol/L (1.2 mg/dL).

B. Incidence. True overall incidence in neonates is not well documented and remains to be determined; however, neonates appear to be more predisposed than other groups of patients, and the most frequent occurrence tends to follow that of those infants with hypocalcemia.

C. Pathophysiology. Mg^{2+} is a key trace element for maintaining skeletal integrity, and it acts as a catalyst for intracellular enzymes for adenosine triphosphate (ATP) activation in skeletal and myocardial contractility. It has an important role in different processes related to cell physiology, hormonal and metabolic pathways, nerve conduction, and blood coagulation. It is also integral to protein synthesis, vitamin D metabolism, parathyroid function, and calcium homeostasis.

D. Risk factors

1. Hypocalcemia

2. Preterm and late-preterm infants

3. Inadequate intake of magnesium

4. **Infant of diabetic mother**, reflecting maternal Mg^{2+} deficiency secondary to gestational diabetes

5. **Fetal growth restriction**, especially if mother had preeclampsia

6. **Inherited renal wasting** (eg, Gitelman syndrome, Na^+/K -ATPase mutation)

7. Hypoparathyroidism

8. Associated hypocalciuria and nephrocalcinosis

9. Magnesuria secondary to furosemide or gentamicin administration

10. Citrated blood exchange transfusions

E. Clinical presentation

1. **Similar to hypocalcemia** (see Chapter 91) (eg, jitteriness, apnea, feeding intolerance) and may also present as seizures.

2. **Clinical signs may be masked as hypocalcemia.** If symptoms persist after adequate calcium gluconate therapy, hypomagnesemia should be considered.

F. Diagnosis.

Laboratory testing to establish serum levels.

1. **Serum magnesium level.** Normal values are 0.6 to 1.0 mmol/L (1.6–2.4 mg/dL), although it may vary minimally with gestational age. Twin gestation, multiple births, or vaginal delivery may result in lower levels of Mg^{2+} . It is important to note that most methods to assess Mg^{2+} levels measure total Mg^{2+} concentration, whereas only free Mg^{2+} is biologically active and almost 30% is inactive and bound to albumin.

2. **Total and ionized calcium levels.** Usually hypomagnesemia is associated with hypocalcemia, but hypercalcemia may inhibit magnesium reabsorption in the distal loop of Henle and can cause hypomagnesemia as well.

- G. Prevention.** Adequate intake of magnesium should be assured in parenteral and enteral nutrition to prevent hypomagnesemia (recommend 8–15 mg/kg/d).
- H. Management. Acute hypomagnesemia should be treated with intravenous magnesium sulfate** (see Chapter 155 for specific dosing guidelines). Infusion must be monitored closely for cardiac arrhythmias and hypotension. Maintenance Mg^{2+} can be administered by parenteral nutrition solutions or by oral feeds with a 5-fold dilution of Mg^{2+} salt solution. Mg^{2+} infusion should be used cautiously if the infant has impaired renal function due to its accumulated toxicity.
- I. Prognosis.** Hypomagnesemia generally has a good outcome if diagnosed promptly and treated adequately. The exception is a clinical presentation that includes seizures associated with hypomagnesemia and asphyxia.

II. Hypermagnesemia

- A. Definition.** Reference levels of serum magnesium signifying hypermagnesemia vary from >1.15 mmol/L (2.3 mg/dL) to >1.5 mmol/L (3.0 mg/dL).
- B. Incidence.** Largely unknown; however, it occurs more frequently in infants whose mothers have been treated with magnesium sulfate. Otherwise, it occurs rarely in healthy newborns. Randomized trials and 2 meta-analyses performed during the past decade concluded that there is enough evidence to support the use of maternal magnesium sulfate for reducing cerebral palsy in preterm infants. The American College of Obstetricians and Gynecologists and Australian national guidelines have recommended the prenatal administration of magnesium sulfate as neuroprotection for <32 weeks' gestational age preterm infants. **This new trend of magnesium sulfate use may increase the incidence of hypermagnesemia in preterm infants being admitted to neonatal units and may need to be monitored.**
- C. Pathophysiology.** Increased serum Mg^{2+} levels depress the central nervous system, impair electrical conduction, and decrease skeletal muscle contractility. Antenatal magnesium sulfate administration to mothers before preterm delivery is associated with a decreased incidence of cerebral palsy in preterm infants. The precise mechanism by which magnesium sulfate exerts a neuroprotective benefit is not known, but it is speculated that it possesses anti-inflammatory and anti-excitotoxic effects while also improving cerebral blood flow and stabilizing fluctuations in blood pressure in the newborn. Magnesium may serve as an *N*-methyl-D-aspartate receptor antagonist, membrane stabilizer, and vasodilator.
- D. Risk factors**
- 1. Increased maternal serum levels** following magnesium sulfate therapy for pregnancy-related hypertension, preeclampsia, and neonatal neuroprotection before preterm delivery.
 - 2. Excessive magnesium sulfate administration** to an infant with hypomagnesemia (iatrogenic medication error) or following administration of Mg^{2+} -containing antacids, especially if dehydrated. Excess magnesium in total parenteral nutrition (TPN) is a common cause.
- E. Clinical presentation.** Severity of symptoms and signs of hypermagnesemia may not correlate with serum Mg^{2+} levels. Symptoms may mimic hypercalcemia.
- 1. Hypotonia, hypotension, hyporeflexia, seizures**
 - 2. Respiratory depression, hypoventilation, apnea**
 - 3. Bradycardia, hypotension, cardiac arrest with toxic Mg^{2+} levels** (ie, >7.5 mmol/L)
 - 4. Poor suck, feeding intolerance, decreased gastrointestinal motility, increased gastric aspirates**, abdominal distention, and delayed meconium passage
 - 5. Meconium plug syndrome, intestinal perforation**
 - 6. Urinary retention**
- F. Diagnosis**
- 1. Laboratory studies**
 - a. Serum magnesium.** Normal levels are 0.6 to 1.0 mmol/L (1.6–2.4 mg/dL).
 - b. Serum calcium.** Always determine both total and ionized calcium levels with Mg^{2+} abnormalities.

2. **Electrocardiogram** may reveal a prolonged PR interval, increased QRS interval, prolonged QT interval, and atrioventricular block.

G. Management

1. **Identify and remove the source of excess magnesium** (eg, TPN, antacids).
 2. **Urinary excretion** is the only mechanism for decreasing serum Mg^{2+} levels.
 3. **Maintain intravenous hydration** if the patient is symptomatic.
 4. **Furosemide diuresis** may facilitate magnesium excretion, but close monitoring of electrolytes is needed, and its effect is not well studied.
 5. **Monitor serum electrolytes**, urine output, and acid-base status.
 6. **With acute signs such as seizures or electrocardiogram changes**, give intravenous calcium gluconate in doses as for hypocalcemia.
 7. **Avoid aminoglycosides** because they may potentiate the neuromuscular manifestations of hypermagnesemia.
 8. **Respiratory support** may be needed in severely affected infants (hypoventilation, apnea).
 9. **Exchange transfusion** has been used. Dialysis is uncommon in neonates.
- H. Prognosis is good following treatment**, especially if normal renal function has been preserved. In general, antenatal use of magnesium sulfate is safe for preterm infants during the postnatal period, but it needs to be further studied and monitored.

106 Meconium Aspiration

- I. **Definition.** Meconium is the first intestinal discharge of the newborn infant. In addition to epithelial cells, fetal hair, mucus, and bile, meconium also contains a number of proinflammatory components. With the passage of meconium in utero, the **meconium-stained amniotic fluid (MSAF)** may be aspirated. The presence of MSAF in the trachea can cause airway obstruction. With aspiration below the vocal cords, further obstruction, air trapping, and an inflammatory response can result in severe respiratory distress. Hallmarks include early onset of respiratory distress in an infant with MSAF who presents with poor lung compliance, hypoxemia, and a characteristic lung radiograph.
- II. **Incidence.** The incidence of **MSAF** varies from 8% to 20% of all deliveries. With improved perinatal care, the incidence has decreased. The incidence of MSAF increases from 1.6% at 34 to 37 weeks to 30% at ≥ 42 weeks. Of infants born through MSAF, approximately 5% go on to develop meconium aspiration syndrome (**MAS**). MAS primarily affects **term and postmature infants**. The intrauterine passage of meconium by infants < 34 weeks' gestation is very unusual and may represent bilious reflux secondary to intestinal obstruction, not MAS.
- III. **Pathophysiology**
 - A. **In utero passage of meconium** depends on hormonal and parasympathetic neural maturation. The exact mechanisms for in utero passage of meconium remain unclear, but fetal distress, vagal stimulation, and placental dysfunction are probable factors.
 - B. **Aspiration of meconium.** After intrauterine passage of meconium, deep irregular respiration or gasping, associated with fetal hypoxia, can cause aspiration of the MSAF. Early consequences of meconium aspiration include airway obstruction, decreased lung compliance, and increased expiratory large airway resistance.
 1. **Airway obstruction.** Thick MSAF can result in acute upper airway obstruction. As the aspirated meconium progresses distally, total and partial airway obstruction may occur. Partial airway obstruction can result in a ball-valve phenomenon

leading to air trapping and alveolar hyperexpansion with a subsequent 20% to 50% risk of air leak. Total obstruction may lead to asymmetric areas of atelectasis, resulting in hypoxia and increased pulmonary vascular resistance (PVR).

2. **Chemical pneumonitis.** With distal progression of meconium, chemical pneumonitis develops, which causes bronchiolar edema and narrowing of the small airways, all leading to increased hypercarbia and hypoxemia.
 3. **Inflammatory mediators.** Intrapulmonary meconium triggers the release of a number of proinflammatory cytokines that lead to further airway edema, apoptosis, hypoxia, and increased PVR. Endogenous production of phospholipase A₂, identified in the lungs of infants with MAS, is associated with upregulation of inflammatory mediators, direct injury to the alveolar cell membrane, airway constriction, and surfactant catabolism.
 4. **Surfactant dysfunction.** The free fatty acids in meconium can strip surfactant from the surface of the alveoli. Meconium also impacts surfactant production and clearance by affecting phosphatidylcholine metabolism.
 5. **Persistent pulmonary hypertension.** A third of infants with meconium aspiration develop **persistent pulmonary hypertension of the newborn (PPHN)**. Meconium aspiration alone may result in a delay of the normal decline in PVR. Additional increases in PVR are multifactorial. PVR increases as a direct result of alveolar hypoxia, acidosis, and lung hyperinflation. PVR increases in areas of obstruction with alveolar hypoxia. The increase in PVR may lead to atrial and ductal right-to-left shunting and further hypoxemia.
- IV. Risk factors.** A number of factors have been associated with the development of MAS. Risk factors that have held statistical significance across a number of trials include thick MSAF, low 5-minute Apgar scores, and evidence of fetal distress. Ethnic groups including African Americans, Africans, Pacific Islanders, and indigenous Australians have an increased risk.
- V. Clinical presentation.** The presentation of an infant who has aspirated MSAF is variable, ranging from mild to profound respiratory distress.
- A. General features**
1. **Infant.** Infants with MAS often exhibit signs of postmaturity. Respiratory distress is evident at birth or in the transition period. Respiratory depression, poor respiratory effort, and decreased tone are often accompanied by perinatal asphyxia. Meconium-stained skin is proportional to the length of exposure and meconium concentration. Fifteen minutes of exposure to thick MSAF or 1 hour to lightly stained fluid will begin to stain the umbilical cord. Yellow staining of the newborn's nails requires 4 to 6 hours; staining of the vernix caseosa takes approximately 12 hours.
 2. **Amniotic fluid.** The meconium present in amniotic fluid varies in appearance and viscosity, ranging from a thin green-stained fluid to a thick "pea soup" consistency. The majority of infants who develop MAS have a history of thick MSAF.
- B. Airway obstruction.** Large amounts of thick MSAF, if not removed, can result in an acute large airway obstruction. These infants may be apneic or have gasping respirations, cyanosis, and poor air exchange. As the meconium is driven down to more distal airways, the smaller airways are affected, resulting in air trapping and scattered atelectasis.
- C. Respiratory distress.** The infant who has aspirated meconium into the distal airways but does not have total airway obstruction manifests signs of respiratory distress secondary to increased airway resistance, decreased compliance, and air trapping (ie, **tachypnea, nasal flaring, intercostal retractions, increased anteroposterior diameter of the chest, and cyanosis**). Air trapping can lead to air leak syndromes. Some infants **may have a delayed presentation**, with only mild initial respiratory distress that worsens hours after delivery as atelectasis, surfactant inactivation, and chemical pneumonitis develop. **Note:** Most infants with MSAF appear normal at birth with no signs of respiratory distress.

VI. Diagnosis

- A. Laboratory studies.** **Arterial blood gas results** characteristically reveal hypoxemia. In mild cases, hyperventilation may result in respiratory alkalosis. Infants with severe disease usually have a respiratory acidosis due to airway obstruction, atelectasis, and pneumonitis. With concomitant perinatal asphyxia, combined respiratory and metabolic acidosis is present.
- B. Imaging studies**
- 1. Chest radiographs** typically reveal hyperinflation of the lung fields and flattened diaphragms. There are coarse, irregular patchy infiltrates. A pneumothorax or pneumomediastinum may be present. The severity of radiographic findings does not always correlate with the clinical disease. (See Figure 12–18.)
 - 2. Point-of-care lung ultrasonography** can be used to diagnose MAS. The most specific finding in MAS was a large consolidation area with irregular edges with air bronchograms (100% of cases). Other findings include pleural line anomalies and disappearance of A lines (100% of cases), alveolar-interstitial syndrome or B line in the nonconsolidation area (100%), atelectasis (16%), and pleural effusion (~14%).
- C. Cardiac echocardiogram.** Pulmonary hypertension and subsequent hypoxemia from right-to-left atrial and ductal shunt are frequently associated findings in infants with meconium aspiration pneumonia.
- D. Placental evaluation.** Funisitis (inflammation of the connective tissue of the umbilical cord) occurs prenatally in MAS, and the stage of funisitis and chorionic vascular muscle necrosis may be a marker for MAS and predict the severity of MAS.

VII. Management

- A. Prenatal management.** The key to management of meconium aspiration lies in prevention of fetal distress during the prenatal period.
- 1. Identification of high-risk pregnancies.** The approach to prevention begins with recognition of predisposing maternal factors that may result in fetal hypoxia during labor. Risk of MAS is highest in infants with gestational ages >41 weeks. Thus, induction as early as 41 weeks may help prevent meconium aspiration.
 - 2. Monitoring.** During labor, any sign of fetal distress (eg, appearance of meconium-stained fluid, loss of beat-to-beat variability, fetal tachycardia, or deceleration patterns) warrants assessment of fetal well-being. If the assessment identifies a compromised fetus, corrective measures should be undertaken or the infant should be delivered in a timely manner.
 - 3. Amnioinfusion.** The efficiency of amnioinfusion (instilling isotonic fluid into the amniotic cavity) in altering the risk or severity of meconium aspiration has not been demonstrated except in settings with limited perinatal surveillance. In this setting, amnioinfusion is associated with substantial improvements in perinatal outcomes. A Cochrane 2014 review notes that amnioinfusion for MSAF is associated with substantive improvements in perinatal outcome only in settings where perinatal surveillance is limited. The American Congress of Obstetricians and Gynecologists (2016) states that “routine prophylactic amnioinfusion is not recommended for dilution of meconium-stained amniotic fluid. It should only be done in the setting of additional clinical trials.” It is recommended in the treatment of repetitive variable decelerations, whether or not there is MSAF.
- B. Delivery room management.** As outlined in Chapter 3, a skilled resuscitation team must be present in all deliveries of infants with MSAF. Management depends on whether the infant is vigorous or nonvigorous.
- 1. Vigorous infants.** The appropriate intervention for **vigorous infants** (spontaneous respirations and movements, a heart rate >100 beats/min, flexed extremities) with MSAF of any consistency should be limited to routine care. The infant can stay with the mother to receive the initial steps of newborn care. Use a bulb syringe to clear meconium-stained secretions from the mouth and then the nose.

- 2. Nonvigorous infants.** Those **nonvigorous infants** who have depressed/inadequate respirations or poor muscle tone should be brought to the radiant warmer. Use a bulb syringe to clear meconium-stained secretions from the mouth and then the nose, and perform the initial steps of newborn care. If the infant is not breathing or the heart rate is <100 beats/min, proceed with positive-pressure ventilation. If the infant does not improve, chest movement does not occur, and the endotracheal tube (ETT) has been verified as properly placed, then meconium may be obstructing the airway. At this time, use a suction catheter through the ETT (see Table 33-1). If this does not work, clear the airway by connecting the ETT to a meconium trap aspirator attached to wall suction at a pressure of 80 to 100 mm Hg. Repeat the suctioning until the airway is cleared. Positive-pressure ventilation should be avoided, if possible, until tracheal suctioning is accomplished.
- C. Management of the newborn with meconium aspiration.** Infants with meconium below the vocal cords are at risk for pulmonary hypertension, air leak syndromes, and pneumonitis and must be observed closely for signs of respiratory distress. Observation in the special care nursery or neonatal intensive care unit for infants with MSAF who have any signs of respiratory distress in the delivery room is recommended for a minimum of 4 to 6 hours.
- 1. General management.** Infants who have aspirated meconium and require resuscitation often develop metabolic abnormalities such as hypoxia, acidosis, hypoglycemia, and hypocalcemia. Because these patients may have suffered perinatal asphyxia, surveillance for any end-organ damage is essential.
- Maintain a neutral thermal environment.**
 - Minimal handling protocol to avoid agitation.**
 - Maintain adequate blood pressure and perfusion.** Volume expansion may be necessary with normal saline or packed red blood as well as vasopressor support such as dopamine. Maintaining a hematocrit $>40\%$ to 45% will optimize tissue oxygen delivery.
 - Correct any metabolic abnormalities** such as hypoglycemia, hypocalcemia, or metabolic acidosis.
 - Sedation may be needed in infants on mechanical ventilation.** Intravenous morphine (loading dose 100–150 mcg/kg over 1 hour, continuous infusion of 10–20 mcg/kg/h) and fentanyl (1–5 mcg/kg/h) can be used. A neuromuscular blocker (eg, pancuronium, 0.1 mg/kg push per dose) can be used.
- 2. Respiratory management**
- Pulmonary toilet.** If suctioning the trachea does not result in clearing of secretions, it may be advisable to leave an ETT in place in symptomatic infants for pulmonary toilet. Chest physiotherapy every 30 minutes to 1 hour, as tolerated, will aid in clearing the airway (**controversial**). Chest physiotherapy is contraindicated in labile infants when associated PPHN is suspected. Some neonatologists avoid chest physiotherapy in all infants because of possible PPHN.
 - Arterial blood gas levels.** On admission to the neonatal intensive care unit, obtain blood gas measurements to assess ventilatory compromise and supplemental oxygen requirements. If the patient requires >0.4 FiO_2 or demonstrates pronounced labiality, an arterial catheter for frequent sampling should be inserted.
 - Oxygen monitoring.** A pulse oximeter provides information regarding the severity of the infant's respiratory status. Comparing oxygen saturation values from a pulse oximeter on the right arm to those placed on the lower extremities may help identify infants with right-to-left ductal shunting secondary to MAS-associated pulmonary hypertension.
 - A chest radiograph** should be obtained after delivery if the infant is in distress. It may also help determine which patients will experience respiratory distress. However, radiographs often poorly correlate with the clinical presentation.

- e. **Antibiotic coverage.** MAS alone is not an indication for antibiotic therapy. However, meconium does inhibit the normally bacteriostatic quality of amniotic fluid. Due to the difficulty of radiographically differentiating MAS from pneumonia, infants with infiltrates on a chest radiograph should be started on broad-spectrum antibiotics (ampicillin and gentamicin; for dosages, see Chapter 155) after appropriate cultures have been obtained. A Cochrane review (2017) found no differences in infection rates (sepsis risk) following antibiotic treatment among neonates exposed to meconium (with MAS and those born through meconium-stained fluid). Another study stated that antibiotics did not show any benefits in infants with MAS with no evidence of sepsis.
- f. **Supplemental oxygen.** A major goal is to prevent episodes of alveolar hypoxia leading to hypoxic pulmonary vasoconstriction and the development of PPHN. Supplemental oxygen is provided “generously” to maintain the arterial oxygen tension at least in the range of 80 to 90 mm Hg. Some clinicians may elect to maintain PaO_2 at a higher level (95%–98%) because the risk of retinopathy should be negligible among full-term infants. The same goal of preventing alveolar hypoxia requires cautious weaning from oxygen therapy. Many of the patients are very labile. Weaning from oxygen should be done slowly, sometimes at a pace of 1% at a time. The prevention of alveolar hypoxia includes a high index of suspicion for the diagnosis of air leak as well as efforts to minimize handling of the infant.
- g. **Continuous positive airway pressure (CPAP)** can be used to improve oxygenation if the FiO_2 exceeds 40%. If hyperinflation is present, use CPAP cautiously since it can make air trapping worse.
- h. **Mechanical ventilation.** Patients with severe disease who are in impending respiratory failure with hypercapnia and persistent hypoxemia require mechanical ventilation. Infants with severe hypoxemia ($\text{PaO}_2 < 50$ mm Hg), hypercarbia ($\text{PaCO}_2 > 60$ mm Hg), or acidosis ($\text{pH} < 7.25$) with $\text{FiO}_2 > 0.6$ should be intubated and ventilated.
 - i. **Specific ventilatory strategies.** Ventilation must be tailored to the individual patient and depends on the presence or absence of PPHN. Volume-targeted ventilation may decrease lung overdistension. The use of a relatively short inspiratory time may further limit potential air trapping. Modes of ventilation that allow the infant to regulate the frequency and degree of mechanical assistance (assist/control or pressure support ventilation) may be preferable. Infants with MAS typically require higher tidal volumes and overall higher minute ventilation than those with respiratory distress syndrome.
 - ii. **Pulmonary complications.** For any unexplained deterioration of clinical status, the possibility of a **pneumothorax** or **pneumomediastinum** should be considered and appropriate evaluation undertaken. The need to use high mean airway pressures to maintain adequate oxygenation and ventilation with concomitant atelectasis and air trapping furthers the risk of air leak. The approach to ventilation must be directed at preventing hypoxemia and providing adequate ventilation at the lowest mean airway pressure possible to reduce the risk of catastrophic air leak.
 - iii. **High-frequency ventilation.** Randomized controlled trials supporting the use of high-frequency ventilation (HFV) specifically for MAS are lacking. Other prospective studies have demonstrated that HFV can be an effective modality. HFV at 10 Hz may provide improved ventilation and lower the risk of air trapping. Both high-frequency jet ventilation and high-frequency oscillatory ventilation are efficacious in infants in whom adequate ventilation cannot be maintained on conventional ventilation without using excessive ventilatory pressures. HFV has also

been used to maximize the beneficial effects of inhaled nitric oxide (see Chapter 9).

- iv. Heliox ventilation.** In a limited study, the use of heliox was associated with improved oxygenation but failed to demonstrate significant improvement in other outcomes, including oxygenation index, survival, or degree of respiratory support, beyond the reduction in FiO_2 .
 - i. Surfactant.** A number of randomized controlled trials have shown that infants with severe MAS who require mechanical ventilation and have radiologic evidence of parenchymal lung disease are likely to benefit from early surfactant therapy via bolus or lavage. Doses may exceed those used for preterm infants with respiratory distress syndrome. Because of the potential for concomitant pulmonary hypertension, close observation is required to prevent the consequences of transient airway obstruction that may develop during the tracheal instillation of surfactant. Analysis of clinical trials has failed to show an impact on survival but has shown a reduction in the duration of mechanical ventilation and hospital stay. Surfactant lavage has also been shown to decrease systemic proinflammatory cytokines that normally accompany MAS. A Cochrane review (2014) reports that in term and late preterm infants with MAS, surfactant administration may decrease the severity of respiratory illness and decrease the number of infants with progressive respiratory failure requiring support with extracorporeal life support (ECLS). The Committee on Fetus and Newborn of the American Academy of Pediatrics recommends that rescue surfactant can be considered in infants with hypoxic respiratory failure caused by surfactant deficiency from meconium aspiration, with recent data supporting that surfactant, either as lavage or bolus, decreased the duration of mechanical ventilation and hospital stay and that surfactant as a bolus decreased the need for ECLS.
 - j. Inhaled nitric oxide.** Pulmonary hypertension commonly affects infants with severe MAS. This can be effectively treated by inhaled nitric oxide (see Chapter 115). In an update of an earlier Cochrane System Review, data suggest that in settings without access to nitric oxide or HFV, **sildenafil** has been shown to be effective in reducing PVR, improving oxygenation, and decreasing mortality. In infants who do not respond to inhaled nitric oxide therapy, sildenafil, milrinone, and dipyridamole may be tried.
 - k. Extracorporeal life support (ECLS).** The use of inhaled nitric oxide and surfactant therapy has decreased the number of infants who go on to require ECLS. Compared with other population subsets that require ECLS, infants with meconium aspiration have a high survival rate (93%–100%). (See Chapter 20.) Venovenous ECLS is as reliable as venoarterial ECLS in infants with MAS with refractory respiratory failure who require ECLS.
 - l. Steroids.** Limited human trials are conflicting in regard to the potential benefit, and there are not sufficient data to warrant the use of steroids. Some human trials suggest that steroid therapy for MAS may be harmful. Until sufficient data are available, steroids should not be employed for MAS.
 - m. New therapies being studied.** Antioxidants such as *N*-acetylcysteine given intravenously improved lung functions and decreased meconium-induced inflammation and oxidative lung injury in the animal model of MAS and may enhance the therapeutic outcome of MAS. *N*-acetylcysteine with surfactant worked better than either treatment alone. Protease inhibitors (fetal pancreatic enzymes) may be useful in the treatment or prophylaxis of MAS.
- 3. Persistent pulmonary hypertension.** Meconium aspiration is the most common respiratory disorder associated with PPHN and occurs in approximately 40% of cases. (See Chapter 115.)

D. Prognosis. Complications are common. New modalities of therapy such as exogenous surfactant, HFV, inhaled nitric oxide, and ECLS have reduced the mortality to <5%. In patients surviving severe meconium aspiration, bronchopulmonary dysplasia/chronic lung disease may result from prolonged mechanical ventilation. MAS is associated with neurodevelopmental sequelae, including global developmental delay, cerebral palsy, and autism, and therefore warrants long-term follow-up. Infants with a high aspartate aminotransferase levels have a poorer neurodevelopmental outcome.

107 Multiple Gestation

- I. Definition.** A multiple gestation occurs when >1 fetus is carried during a pregnancy.
- II. Incidence.** As of 2017, the overall rate of twin births was 33.3 in 1000 live births, and the rate of triplet or other higher order multiple births was 101.6 in 100,000 live births in the United States. Between 1980 and 2009, the twinning rate climbed 76% (18.9–32.2 per 100 live births) and has slowly increased since. The rate of triplet births escalated more rapidly, increasing 400% during the 1980s and 1990s, with a peak in 1998. The rate of triplets and higher order multiple births has dropped 46% from the 1998 peak to present. The incidence of multiple gestation pregnancies is probably underestimated. Fewer than half of twin pregnancies diagnosed by ultrasonography during the first trimester are delivered as twins, a phenomenon that has been termed *vanishing twin*. Two gestational sacs can be identified with ultrasonography by 6 weeks' gestation. In addition, routine screening for maternal α -fetoprotein (AFP) may identify pregnancies with multiple gestations at an early gestational age. About a third of twins in the United States are monozygotic. The incidence of monozygotic twinning is constant at 3 to 5 per 1000 pregnancies, whereas the rate for dizygotic twinning varies from 4 to 50 per 1000 pregnancies.
- III. Pathophysiology.** Placental classification and determination of zygosity are important in the pathophysiology of twins.
 - A. Classification.** Placental examination affords a unique opportunity to identify two-thirds to three-fourths of monozygotic twins at birth.
 - 1. Twin placentation is classified according to the placental disk** (single, fused, or separate), number of chorions (monochorionic or dichorionic), and number of amnions (monoamniotic or diamniotic) (Figure 107–1).
 - 2. Heterosexual (assuredly dizygotic) twins** always have a dichorionic placenta.
 - 3. Monochorionic twins** are always of the same sex. All monochorionic twins are believed to be monozygotic. In 70% of monozygotic twin pregnancies, the placentas are monochorionic, and the possibility exists for commingling of the fetal circulations. Less than 1% of twin pregnancies are monoamniotic.
 - B. Placental complications.** Twin gestations are associated with an increased frequency of anomalies of the placenta and adnexa, for example, a single umbilical artery or velamentous or marginal cord insertion (6–9 times more common with twin gestation). The cord is more susceptible to trauma from twisting. The vessels near the insertion are often unprotected by Wharton jelly and are especially prone to thrombosis when compression or twisting occurs. Intrapartum fetal distress from cord compression and fetal hemorrhage from associated vasa previa are potential problems with velamentous insertion of the cord.

FIGURE 107-1. Percentage distribution of twins according to placental type. Mono, monoamniotic; Di, diamniotic.

- C. Determination of zygosity.** The most efficient way to identify zygosity is as follows:
- 1. Gender examination.** Male-female pairs are dizygotic. The dichorionic placenta may be separate or fused.
 - 2. Placental examination.** Twins with a monochorionic placenta (monoamniotic or diamniotic) are monozygotic. Care should be taken not to confuse apposed fused placentas for a single chorion. If doubt exists on a gross inspection of the dividing membranes, a transverse section should be studied. The zygosity of twins of the same sex with dichorionic membranes cannot be immediately known. Genetic studies are needed (eg, blood typing, human leukocyte antigen typing, DNA markers, and chromosome marking) to determine zygosity.
- IV. Risk factors.** Use of assisted reproductive technology is a risk factor for multiple births, but the risk of higher order multiple gestation pregnancies associated with assisted reproductive technology has dropped steadily over the past decade. The incidence of dizygotic twinning increases with a family history of twins, maternal age (peak at 35–39 years), previous twin gestation, increasing parity, maternal height, fecundity, social class, frequency of coitus, and exposure to exogenous gonadotropins, clomiphene, or in vitro fertilization. The risk of twinning decreases with undernourishment. Ethnic background (African Americans > Caucasians > Asians) is a preconception risk factor for naturally conceived multiple gestation births.
- V. Clinical presentation.** Twins are more likely to have prematurity, fetal growth restriction, congenital anomalies, and twin-twin transfusion.
- A. Prematurity and uteroplacental insufficiency** are the major contributors to perinatal complications. In 2015, 1% of singletons, 10% of twins, and 36% of triplets had birthweights of <1500 g.
 - B. Fetal growth restriction (intrauterine growth restriction).** The incidence of low birthweight in twins is approximately 50% to 60%, a figure that is 5 to 7 times higher than the incidence of low birthweight in singletons. In general, the more fetuses in a gestation, the smaller is their weight for gestational age (Figure 107-2). Twins tend to grow at normal rates up to about 30 to 34 weeks' gestation when they reach a combined weight of 4 kg. Thereafter, they grow more slowly. Two-thirds of twins show some signs of growth restriction at birth.

FIGURE 107-2. Growth curve showing the mean weights of infants from single and multiple pregnancies by gestational age. (Modified with permission from McKeown T, Record RG: *Observations on foetal growth in multiple pregnancy in man*, J Endocrinol. 1952 Oct;8(4):386-401.)

C. Uteroplacental insufficiency. The incidence of acute and chronic uteroplacental insufficiency is increased in multiple gestations. Five-minute Apgar scores of 0 to 3 are reported for 5% to 10% of twin gestations. These low scores may relate to acute stresses of labor, cord prolapse (1%–5%), or trauma during delivery superimposed on chronic uteroplacental insufficiency.

D. Congenital anomalies. Birth defects are 2 to 3 times more common in monozygotic twins than in singletons or dizygotic twins, who have a 2% to 3% incidence of major defects diagnosed at birth. Three mechanisms are postulated for the increased frequency of structural defects in monozygotic twins: deformations caused by intrauterine space constraint, disruption of normal blood flow secondary to placental vascular anastomoses, and defects in morphogenesis. Such defects are usually discordant in monozygotic twins; however, in purely genetic conditions (eg, chromosomal abnormalities or single-gene defects), concordance would be the rule. Twins conceived by in vitro fertilization have twice the risk of major congenital anomalies compared with twins conceived naturally.

- 1. Anomalies unique to multiple pregnancies.** Certain anomalies, such as conjoined twins and acardia, are unique to multiple pregnancies.
- 2. Deformations.** Twins are more likely to suffer from intrauterine crowding and restriction of movement, leading to synostosis, torticollis, facial palsy, positional foot defects, and other defects.

3. **Vascular disruptions.** Disruptions related to monozygotic vascular shunts may result in birth defects. Acardia occurs from an artery-to-artery placental shunt, in which reverse flow leads to the development of an amorphous recipient twin. In utero death of a co-twin may result in a thromboembolic phenomenon, including disseminated intravascular coagulation, cutis aplasia, porencephaly or hydranencephaly, limb reduction defects, intestinal atresias, or gastroschisis.

E. Twin-twin transfusion syndrome

1. **Vascular anastomoses.** Almost all monochorionic placentas demonstrate vascular anastomoses, whereas dichorionic placentas rarely do. Vascular anastomoses may be superficial direct communications easily visible on inspection between arteries (most common) or veins (uncommon), deep connections from arteries to veins via villi, or combinations of superficial and deep connections.

2. **Incidence.** Despite the high frequency of vascular anastomosis in monochorionic placentation, the twin-twin transfusion syndrome is relatively uncommon (~15% of monochorionic gestations).

3. **Clinical manifestations.** Clinically, the twin-twin transfusion syndrome is diagnosed when twins have a hemoglobin difference of >5 g/dL and is due to artery-to-vein anastomoses.

a. **The donor twin** tends to be pale and have a low birthweight, oligohydramnios, anemia, hypoglycemia, decreased organ mass, hypovolemia, and amnion nodosum. Donor twins often require volume expansion, red blood cell transfusion, or both.

b. **The recipient twin** is frequently plethoric and has a high birthweight, polyhydramnios, polycythemia or hyperviscosity, increased organ mass, hypervolemia, and hyperbilirubinemia. Recipient twins often require partial exchange transfusion.

c. **Infants born with twin-twin transfusion syndrome** have an increased risk of being diagnosed with antenatally acquired severe cerebral lesions and are at an increased risk of neurodevelopmental sequelae, even when treatment is initiated antenatally. Antenatal treatment with fetoscopic selective laser coagulation may reduce the risk of death or long-term impairment.

d. **Very low birthweight infants** who are multiple births may have an increased risk of mortality and intraventricular hemorrhage compared with singletons.

VI. Diagnosis. Multiple gestation is usually diagnosed prenatally by ultrasound as early as 5 weeks (can see gestational sacs) and by an increased AFP (in twin pregnancies, the average AFP is double that found in a singleton pregnancy).

VII. Management

A. Site of delivery. When a complicated twin gestation has been identified, delivery should ideally be conducted at a high-risk perinatal center with experienced pediatric delivery teams in attendance.

B. Physical examination. Infants should be examined for evidence of fetal growth restriction, congenital anomalies, and twin-twin transfusion syndrome. Central hematocrits should be obtained in both infants. When 1 of the infants has a congenital anomaly, the other twin is at increased risk for complications. In particular, death of 1 fetus puts the others at risk for fetal disseminated intravascular coagulation.

C. Complications in newborn period. The second-born twin is more likely to develop respiratory distress syndrome and bronchopulmonary dysplasia and to die.

D. Co-bedding of multiples. Although co-bedding multiples was once common practice, the safety or the benefit of this practice has not been established, and the practice is discouraged.

E. Risks beyond the neonatal period

1. **Catch-up growth.** In monozygotic twins, birthweight differences may be as much as 20%, but the lighter twin has a remarkable ability to make up intra-uterine growth deficits.
2. **Social problems.** Parents of multiple births may have an increased level of stress and may respond differently to their children compared with singletons. Counseling for parents of twins may be invaluable.

VIII. Prognosis

- A. **Twins.** The perinatal death rate for twins may be higher in the second twin, especially if the second twin is smaller. Delivery may be considered at 37 weeks to minimize the risk of stillbirth in dichorionic twins. Between 2005 and 2013, survival improved in periviable twins (23–24 weeks), whereas composite morbidity in surviving twins increased in this population.
 1. **Monoamniotic twins.** Monoamniotic twins have the highest mortality rate among the different types of twins, largely because of cord entanglement.
 2. **Monozygotic twins.** Monozygotic twins have a perinatal mortality and morbidity rate that is 2 to 3 times that of dizygotic twins. There is insufficient evidence, however, to recommend elective delivery prior to 36 weeks.
 3. **Fetal death in twins.** When the cause of death is intrinsic to 1 dichorionic fetus and does not threaten the other fetus, complications are rare. Hazardous intra-uterine environments threaten both twins, whether monochorionic or dichorionic. With monochorionic placentas, the incidence of major complications or death in the surviving twin is approximately 50%.
- B. **Triplets.** The neonatal mortality rate for triplets is 18.8%, and the perinatal mortality rate is 25.5%. The risk of death or neurodevelopmental impairment has been shown to be increased in extremely low birthweight triplets and other higher order multiples compared to singletons (adjusted odds, 1.7; 95% confidence interval, 1.3–2.2).

108 Myasthenia Gravis (Transient Neonatal)

- I. **Definition.** **Myasthenia gravis (MG)** is an autoimmune disease where antibodies attack and destroy nerve muscle connections that affect neuromuscular function. MG presents with skeletal muscle weakness and progressive fatigability that increases with activity and improves with rest. MG has multiple subgroups, but 3 distinct forms are seen in children: **transient neonatal MG (TNMG)**, **juvenile MG**, and **congenital MG** (now known as congenital myasthenic syndromes).
 - A. **Transient neonatal myasthenia gravis** is the **most common form of MG in the neonate** and will be discussed here. It is seen in neonates born to mothers with active MG (most common), but it can occur in infants of mothers who are in remission. This occurs when maternal AChR antibodies passively cross from the mother through the placenta into the fetus, resulting in destruction of fetal AChRs. Only some infants born to mothers with MG develop TNMG. It is transient, and the condition only lasts a few weeks.
 - B. **Juvenile myasthenia gravis** is rare and presents in late infancy and adolescence, typically in female, usually before 19 years of age, is not transient, has no genetic component, and has a clear autoimmune component.
 - C. **Congenital myasthenic syndromes** are very rare causes of neuromuscular junction failure in neonates (reported incidence of approximately 600 families with affected

individuals) that are not related to maternal disease. Common examples include primary AChR deficiency (MC), RAPSN mutations, DOK7 mutations, and COLQ mutations. It is almost always a permanent disorder without remission. Characteristics include a positive family history, inherited in an autosomal recessive pattern, usually manifest in infancy or early childhood with variable degrees of weakness that fluctuates, are caused by genetic defects (specific mutations) in components of the neuromuscular junction (presynaptic, synaptic, and postsynaptic), and has no autoimmune component. Weakness in the ocular and bulbar muscles typically occurs in these infants. Ptosis is more common in these infants than in infants with TNMG. Infants can have feeding difficulties, delay in crawling and walking. Note that life-threatening episodes of apnea can occur in these infants.

- II. Incidence.** The annual incidence of MG is 8 to 10 cases per million; the prevalence is 150 to 250 cases per million. **TNMG occurs in 10% to 20% of infants born to mothers with MG.** There is no race or sex preference and no correlation between maternal disease severity or maternal antibody level and risk of TNMG in the neonate. Occasionally an infant with TNMG is born to a mother with asymptotically elevated AChR antibody levels. The risk of recurrence in subsequent pregnancies is 75%.
- III. Pathophysiology.** MG is an autoimmune disease that affects acetylcholine neurotransmission at the neuromuscular junction. Immunoglobulin G autoantibodies bind to the AChR (75%–85%), muscle-specific kinase (1%–10%), or lipoprotein receptor–related peptide 4 (1%–3%), preventing the nerve impulse from activating the muscle. Other autoantibodies may also play a role in disease severity. Antibody binding to these proteins directly blocks acetylcholine, accelerates receptor degradation, and induces the lysis of the postsynaptic membrane through induction of the complement system. **TNMG is caused by transplacental passage of maternal antibodies to the fetus.** Antibodies can be directed against the fetal AChR (present until 30 weeks' gestation) or the adult receptor. Higher maternal antibody titers directed against the fetal AChR have been shown to increase the risk and severity of TNMG and may lead to fetal AChR inactivation syndrome. α -Fetoprotein inhibits this binding and may be partly responsible for the unpredictable nature of maternal disease and development of TNMG.
- IV. Risk factors.** Mother with MG, mothers who have already had a child affected by TNMG (75% risk of recurrence in second child), higher levels of maternal autoantibodies. Infants of mothers with MG who had their thymus gland surgically removed are at a lower risk of developing TNMG.
- V. Clinical presentation.** Two clinical presentations exist, typical and atypical. Infants with **typical TNMG** will have **poor sucking, swallowing and respiratory difficulties, lethargy, generalized weakness, and hypotonia.** They present within a few hours of birth (usually 3–72 hours). If the diaphragm or intercostals are affected, they may have mild respiratory distress. In severe cases, mechanical ventilation may be necessary. Other signs include weak cry, facial diplegia or paresis, ptosis, ophthalmoparesis, and swallowing difficulties. Deep tendon reflexes will be present. **Atypical presentations** can include arthrogryposis, pulmonary hypoplasia, and fetal or neonatal death if not adequately supported. Severe cases can present with fetal manifestations of arthrogryposis multiplex congenita and polyhydramnios. Infants can also present with hypertrophic pyloric stenosis. Prematurity is seen in one-third of cases, and mothers may report decreased fetal movement and polyhydramnios. Symptoms begin within 24 hours of life in 75% of patients with TNMG, and nearly all present by 3 days of age. Infants whose mothers have been taking anticholinesterase agents tend to present later than infants whose mothers have not been treated. Infants born to mothers with seronegative maternal ocular MG also tend to present later.
- VI. Diagnosis.** A symptomatic infant born to a mother with MG is classic for TNMG. Antibody titers and pharmacologic challenge tests confirm the diagnosis. **Other disorders of the neuromuscular junction that present with similar symptoms include congenital myasthenic syndromes, hypermagnesemia, aminoglycoside toxicity, and infant botulism.**

A. Antibody titers. Commercial assays are available to test for autoantibodies of the AChR, muscle-specific kinase, or lipoprotein receptor–related peptide 4. Required blood volume for testing should be considered. If mother's status is unknown, she should be tested first. There have been antibody-negative cases, but these are less common with the evolution of cell-based assays for antibody detection.

B. Anticholinesterase agents. Symptomatic improvement after the administration of an anticholinesterase agent confirms the diagnosis. Improvement is defined as the reversal of definite neurologic impairments (usually sucking or swallowing difficulties) or a decrease in ventilatory requirements. Observing for changes in hypotonia or spontaneous motor activity is not as accurate, particularly in premature infants, infants with hypoxic ischemic encephalopathy, or those with intraventricular hemorrhage. Atropine may be required to help manage the muscarinic side effects (ie, diarrhea and salivation) of the drug.

1. Neostigmine methylsulfate. A single 0.15 mg/kg dose administered intramuscularly (IM) or subcutaneously. In a positive test, neurologic improvement is seen 10 to 15 minutes after administration and persists for 1 to 3 hours. Muscarinic side effects, in particular tracheal secretions, can be problematic. False-negative results have been reported. Intravenous (IV) administration in the neonate can cause fatal ventricular fibrillation and should not be done.

2. Edrophonium chloride. A single 0.15 mg/kg dose IM or subcutaneously or 0.1 mg/kg IV. Positive effects are seen within 3 minutes (IV) or 3 to 5 minutes (IM or subcutaneously) and last for 10 to 15 minutes. Muscarinic side effects are not as severe as with neostigmine. Edrophonium can rarely cause respiratory arrest (especially in larger doses). False-negative results are reported particularly in premature infants.

C. Electromyography. Repetitive nerve stimulation can be used for diagnosis when pharmacologic testing has yielded equivocal results. May be useful in patients with prematurity or intrapartum asphyxia where the response to an anticholinesterase inhibitor is questionable and also provides a quantitative assessment of neuromuscular function. The amplitude of the fifth evoked muscle action potential is compared with the first before and after an anticholinesterase agent is administered. The test is considered positive when the fifth action potential has decreased by at least 10% and is restored to normal after anticholinesterase treatment.

VII. Management. Due to the unpredictable nature of TNMG, delivery should always occur at a tertiary center. Asymptomatic infants born to mothers with MG should be observed in the hospital for 1 week.

A. Supportive care. The primary TNMG strategy is to provide supportive care as antibody levels gradually decline and the symptoms resolve. In 20% of patients, symptoms are mild, requiring only small, frequent oral feedings and close observation. In 80% of patients, greater support is required, including gavage feeds, respiratory support, and/or anticholinesterase medications.

B. Anticholinesterase treatment. Neostigmine methylsulfate, 0.05 to 0.15 mg/kg (up to 0.1 mg) IM or subcutaneously every 4 to 6 hours administered 30 minutes before feeding, or neostigmine bromide, 0.5 mg/kg (up to 1 mg) orally or nasogastrically every 4 to 6 hours administered 1 to 2 hours before feeding, is the treatment of choice. Doses may be titrated gradually until sucking and swallowing are reestablished. As the dose is increased, careful monitoring for side effects (eg, diarrhea, increased secretions, muscle fasciculations) must occur. As symptoms improve, the dose can be decreased. When symptoms are no longer present and/or when repetitive nerve stimulation is normal, the medication can slowly be discontinued. For patients presenting with moderate or severe symptoms, 50% will require anticholinesterase treatment for 1 to 2 weeks, 30% will require treatment for 3 to 4 weeks, and 20% will need >5 weeks of therapy.

C. Ephedrine. Treatment with ephedrine has been used when other medications have failed. Ephedrine may improve muscle weakness and fatigue, but more studies are

needed. A Cochrane review found no randomized controlled trials on ephedrine in the treatment of neonatal MG.

D. Other. Exchange transfusion and IV immunoglobulin have been used with some benefit in the few infants who are resistant to anticholinesterase therapy. Adults with MG (including pregnant women) are currently being managed with a variety of other treatments including steroids, immunosuppressants, immunomodulators, chemotherapeutics, thymectomy, and plasmapheresis, and their potential effects on the fetus and neonate should be considered.

E. Caution with medications. Many medications interfere with the neuromuscular junction and may worsen MG or be associated with an exacerbation. Medications that should be avoided include antibiotics (aminoglycosides, tobramycin, macrolides, clindamycin, ampicillin [safe but some cases of respiratory depression reported]), high-dose steroids, β -blockers, neuromuscular blocking agents, antiarrhythmic medications, some anticonvulsants, and ophthalmologic medications (Timolol).

VIII. Prognosis. TNMG can be life-threatening if not identified and treated promptly, but for the majority of infants, it is a transient illness with no lasting effects. Symptoms last for an average of 18 days (5 days to 4 weeks), and full recovery is seen in 90% of patients by 2 months of age. The remaining 10% of patients recover by 4 months. In rare cases, symptoms persist and can lead to permanent disability including persistent myopathy, multiple joint contractures, dysarthria, velopharyngeal incompetence, mild learning disabilities, and hearing impairment. Rarely, persistent myopathic sequelae (usually facial and bulbar myopathy) have been reported following TNMG and can be caused by maternal antibodies against the AChR- γ subunit. **Fetal AChR inactivation syndrome (FARIS)** should be considered in this group of infants, especially those with marked dysarthria and velopharyngeal incompetence. Treatment with albuterol was beneficial in 1 child with this disorder. Infants with TNMG should be followed up for subtle myopathic signs and potential complications.

109 Necrotizing Enterocolitis

- I. Definition.** **Necrotizing enterocolitis (NEC)** is an ischemic and inflammatory necrosis of the bowel primarily affecting premature neonates after the initiation of enteral feeding.
- II. Incidence.** NEC develops in 4% to 10% of infants weighing <1500 g, with the highest incidence in the most premature infants. About 10% of NEC cases occur in term infants, many of whom have preexisting medical conditions.
- III. Pathophysiology.** Multifactorial theory has been suggested in which several risk factors, including prematurity, formula feeds, ischemia, and altered intestinal microbiota, interact to initiate mucosal damage via a final common pathway involving activation of the inflammatory cascade. A recently proposed unifying hypothesis suggests that the premature intestine exists in a hyperreactive state with higher expression of toll-like receptor-4 (TLR-4). Activation of TLR-4 by lipopolysaccharide from colonizing gram-negative bacteria leads to inflammation, impaired healing (impaired crypt stem cell function), and apoptosis of enterocytes. Translocation of bacteria leads to TLR-4 activation on the endothelium of the bowel mesentery, leading to intestinal ischemia via decreased production of endothelial nitric oxide. This and other described pathways (eg, those involving platelet-activating factor [PAF]) may lead to intestinal necrosis. The process can be exacerbated by an upregulation of proinflammatory T-helper cells and activation of intestinal macrophages.

IV. Risk factors

- A. Prematurity.** There is an inverse relationship between gestational age (GA), birth weight, and risk for developing NEC. Although most preterm infants develop NEC at postmenstrual age (PMA) of 30 to 32 weeks, various factors resulting from premature birth places them at increased risk for NEC. These may involve immature mucosal (mucin) barrier, mucosal enzymes, and various gastrointestinal (GI) hormones, as well as immature bowel motility and function. Premature infants have immature local host defenses and may have an imbalance between pro- and anti-inflammatory factors, and thus have increased activation of inflammatory mediators and decreased inactivation of specific mediators such as PAF, which have been linked to NEC. Abnormal TLR-4 signaling in the premature intestine and increased activation of nuclear factor- κ B (NF κ B) may play a role in the pathogenesis of NEC. An inability to effectively regulate the intestinal microcirculation and differences in bacterial colonization may also make preterm infants more susceptible to NEC.
- B. Abnormal intestinal microbiome.** Microbial colonization of the intestine starts in utero and is dependent on the mode of delivery, level of maturity, and exposure to antibiotics. During the first week of life in healthy infants, the intestinal microbiome changes to a preponderance of organisms (eg, *Bifidobacterium longum* subspecies *infantis* and lactobacilli) capable of consuming human milk oligosaccharides (HMO). These normal microbiota play a symbiotic role with the intestine through toll-like receptors by regulating the expression of genes involved in intestinal physiology, postnatal maturation and function (eg, barrier, digestion, angiogenesis, and production of immunoglobulin A [IgA]), and protection against more pathologic organisms. Exposure to prolonged antibiotic courses (>5 days) or increased use of H₂ blockers can lead to colonization with gram-negative bacteria (intestinal dysbiosis), which promotes inflammation and apoptosis by signaling pathways such as NF κ B. Abundance of proteobacteria (gram-negative facultative bacteria such as *Escherichia coli* and *Klebsiella*) and underrepresentation of obligate anaerobic bacteria such as Firmicutes and Bacteroidetes in infants' intestines has been noted before NEC develops. Although several bacteria and viruses have been implicated in NEC, blood cultures are positive in only 20% to 30% of cases.
- C. Enteral feedings.** NEC is rare in unfed infants, and 90% to 95% of infants with NEC have received at least 1 enteral feed. Enteral feeding provides necessary substrate for proliferation of enteric pathogens. Hyperosmolar formulas/medications may alter mucosal permeability and cause mucosal damage. Short-chain fatty acids, produced as a result of colonic fermentation, may add to the damage.
- Breast milk significantly lowers risk of NEC.** Mammalian breast milk is a biologic fluid that has been highly conserved for millions of years to provide survival advantage to the newborn. It contains immune cells, growth factors (eg, epidermal growth factor), anti-inflammatory factors (eg, interleukin [IL]-10), secretory IgA, lactoferrin, and live bacteria. It also contains HMOs that have no nutritive value for the infant but can be consumed by bacteria such as *B infantis* and help protect and develop the neonatal GI tract. Additionally, breast milk inactivates PAF as well as inhibits TLR-4 signaling. In 1 study, receiving a diet of >50% breast milk in the first 14 days of life resulted in an 83% reduction in the incidence of NEC.
- D. Intestinal ischemia.** During periods of hypoxia/ischemia, blood is diverted away from the splanchnic circulation (diving reflex). This is usually followed by reperfusion, which may lead to oxidant damage and bowel injury. Imbalance between vascular dilator (eg, endothelial nitric oxide) and constrictor (eg, endothelin-1) molecules leads to defective splanchnic blood flow autoregulation and may contribute to injury. Infants who subsequently develop NEC have been shown (by Doppler flow) to have higher flow resistance in the superior mesenteric artery on the first day of life. Infants with a symptomatic patent ductus arteriosus are at higher risk for NEC possibly due to intestinal ischemia associated with aortopulmonary shunt and diastolic steal. A diminished blood supply to the gut in infants exposed to

maternal cocaine (and other vasoconstrictive drugs) may also increase the risk for NEC. Most term infants who develop NEC have predisposing conditions associated with hypoxia/ischemia including congenital heart disease (eg, hypoplastic left heart syndrome), polycythemia/hyperviscosity, and birth asphyxia.

- E. Other factors.** A recent study has found an association between **maternal cigarette smoking** during pregnancy and development of NEC in the newborn infant. The underlying mechanism may be the effect of nicotine on blood vessel development in the fetal GI tract. A significant association between **red blood cell transfusion** and NEC has been reported in some retrospective studies, with about 25% to 35% of NEC cases occurring within 48 hours of packed red blood cell (PRBC) transfusions. However, 3 randomized controlled trials performed to date comparing liberal versus restrictive blood transfusion parameters have not shown a causative relationship. A recent prospective, multicenter observational cohort study found that, among very low birthweight infants, severe anemia, but not PRBC transfusion, was associated with an increased risk of NEC. It is possible that anemia may place significant stress on the intestine, leading to reperfusion-type injury following transfusion. **H₂-receptor antagonists**, which are inhibitors of gastric acid production, increase the gastric pH, which may enhance pathogenic bacterial growth and increase the risk of NEC. Finally, a **genetic predisposition**, through variation in pattern recognition receptors such as TLR-4 and NFκB, can lead to unregulated inflammation and NEC. In addition, immune-modulating single nucleotide polymorphisms involving certain cytokines (eg, IL-6) and growth factors (eg, transforming growth factor-β1) have been associated with severe NEC. Similarly, alterations in antioxidants, vascular endothelial growth factor, arginine, and nitric oxide may also increase the risk for developing NEC.
- V. Clinical presentation.** Although term infants who develop NEC are often diagnosed in the first week of life, most premature infants who develop NEC are older than 14 days or at 30 to 32 weeks' PMA. Most of them are healthy, feeding well, and growing. The early clinical presentation may include feeding intolerance, increased gastric residuals, and blood in stools. Specific abdominal signs include abdominal distention, tenderness, abdominal skin discoloration, and bilious drainage from nasogastric tube. Systemic symptoms are nonspecific (similar to those of neonatal sepsis) and include increased apnea/bradycardia episodes, temperature instability, hypotension, and circulatory shock. The clinical course of NEC is variable. Although about 30% may have a mild presentation that responds to medical treatment, about 7% may have a fulminant course with rapid progression to NEC totalis, septic shock, severe metabolic acidosis, and death. The **modified Bell's staging criteria** are often used to classify NEC according to clinical and radiographic presentations and are broken down into 3 stages.
- A. Stage I: Suspected necrotizing enterocolitis.** Characterized by nonspecific systemic signs, such as temperature instability, apnea, and lethargy. Abdominal signs include increased gastric residuals, abdominal distention, emesis, and heme-positive stool. Abdominal radiographs may be normal or show dilation of the bowel loops consistent with mild ileus. There is disagreement among experts in the field regarding whether or not the entity described as Bell stage I is actually NEC.
- B. Stage II: Proven necrotizing enterocolitis.** Includes symptoms and signs of stage I plus absent bowel sounds with abdominal tenderness. Some infants have cellulitis of the abdominal wall or a mass in the right lower quadrant. Other findings include mild metabolic acidosis and thrombocytopenia (stage IIb). Radiographic signs include pneumatosis intestinalis with or without portal venous gas (PVG). (See Figures 12-27 and 12-28.)
- C. Stage III: Advanced necrotizing enterocolitis.** Findings include severe respiratory and metabolic acidosis, respiratory failure, hypotension, oliguria, shock, neutropenia, and disseminated intravascular coagulation (DIC). The abdomen is tense and discolored with spreading erythema, edema, and induration (signs of peritonitis). The hallmark radiographic sign is pneumoperitoneum (free air; see Figure 12-26).

- VI. Diagnosis.** NEC is a tentative diagnosis in any infant presenting with the triad of feeding intolerance, abdominal distension, and grossly bloody stools.
- A. Laboratory studies.** These tests should be performed and repeated as necessary:
- 1. Complete blood count with differential.** The white blood cell count is frequently either elevated with increased left shift or depressed with low neutrophil count (neutropenia). Thrombocytopenia is often seen.
 - 2. C-reactive protein (CRP)** correlates with the inflammatory response. Because initial CRP may be normal, serial CRP levels done at 12- to 24-hour intervals are more useful. Markers of inflammation, such as tumor necrosis factor- α , IL-6, IL-8, fecal calprotectin levels, and urine intestinal fatty acid-binding proteins, have been suggested as screening tools but have not gained widespread use.
 - 3. Blood culture** for aerobes, anaerobes, and fungi (*Candida* species) is indicated.
 - 4. Stool cultures** for rotavirus and enteroviruses may be useful when there is clustering of cases within a single unit.
 - 5. Electrolyte panel** may show hyponatremia and hyperkalemia.
 - 6. Arterial blood gas measurements** often show metabolic or combined acidosis.
 - 7. Coagulation studies** include prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, and fibrin degradation products (FDP and D-dimer). An elevated PT, PTT, and FDP indicate DIC, a frequent complication of severe NEC.
- B. Imaging and other studies**
- 1. Radiographs of the abdomen (supine with left lateral decubitus or cross-table views)**
 - a. Suspicious for necrotizing enterocolitis.** Abnormal bowel gas pattern, ileus, dilated or thickened bowel loops.
 - b. Confirmatory for necrotizing enterocolitis.** Pneumatosis intestinalis, PVG (in the absence of umbilical venous catheter (see Figures 12–27 and 12–28), and free air (pneumoperitoneum). Left lateral decubitus or cross-table views are very helpful in confirming free peritoneal air. Serial radiographic studies of the abdomen should be obtained every 6 to 8 hours in the presence of pneumatosis intestinalis or PVG to look for pneumoperitoneum because these infants are at risk for bowel perforation within 48 to 72 hours of disease onset.
 - 2. Abdominal ultrasound.** May be useful in the presence of nonspecific clinical and radiologic findings (gasless abdomen) or in infants with NEC not responding to medical management. Ultrasound (US) can detect intramural intestinal gas (pneumatosis) and intermittent gas bubbles in the liver parenchyma and the portal venous system. In addition, focal fluid collections, bowel wall thickness, and bowel motility can be viewed in real time. Color Doppler US is useful in detecting bowel necrosis and mesenteric flow. Point-of-care US is currently being evaluated and offers some promise for the future. See Chapter 44.
 - 3. Mesenteric oxygen saturation.** Recent studies have shown the possibility of using near-infrared spectroscopy to detect mesenteric oxygen saturations. This provides hope of early detection and real-time noninvasive monitoring for mesenteric bowel perfusion in infants at risk for NEC. This technique is still experimental.
- VII. Differential diagnosis.** The differential diagnosis of NEC includes other conditions that cause rectal bleeding, abdominal distension, gastric retention, or intestinal perforation. These include infectious enteritis, spontaneous intestinal perforation (see Chapter 121), anal fissure, neonatal appendicitis, neonatal sepsis (presents similar to stage I NEC), and cow's milk protein allergy.
- VIII. Management.** The goal is to provide bowel rest and prevent progression of disease to intestinal perforation, septic peritonitis, and shock.
- A. Medical management**
- 1. Nil per os (NPO)** to allow GI rest for 7 to 14 days (shorter course for stage I NEC). Total parenteral nutrition (TPN) to provide basic nutritional needs.

2. **Gastric decompression** with large-bore orogastric tube (Replogle) at low intermittent or continuous suctioning.
 3. **Close monitoring** of vital signs and abdominal circumference. Check all gastric aspirates and stools for blood.
 4. **Respiratory support.** Provide optimal respiratory support to maintain acceptable blood gas parameters. Progressive abdominal distension causing loss of lung volume may increase need for positive-pressure ventilation.
 5. **Circulatory support.** There may be excessive third spacing of fluid, which requires effective volume replacement. Inotropic support may be needed to maintain normal blood pressure. Maintain urine output of 1 to 3 mL/kg/h. Remove potassium from intravenous fluids in the presence of hyperkalemia or anuria.
 6. **Laboratory monitoring.** Check complete blood count and electrolyte panel every 12 to 24 hours until stable. Obtain blood and urine culture prior to starting antibiotics.
 7. **Antibiotic therapy.** Treat with parenteral antibiotics for 10 to 14 days. Antibiotic regimen should cover pathogens that cause late-onset sepsis in premature infants. Add anaerobic coverage if bowel necrosis or perforation is suspected. Reasonable antibiotic regimens include the following:
 - a. **Ampicillin (or vancomycin, in the presence of central line),** gentamicin, and clindamycin (or metronidazole).
 - b. **Vancomycin (in the presence of central line)** and piperacillin/tazobactam.
 8. **Monitoring for bleeding and disseminated intravascular coagulation.** Infants in stage II and III may develop DIC and require fresh frozen plasma and cryoprecipitate. PRBC and platelet transfusions may also be needed.
 9. **Surgical consultation** is needed for confirmed stage II and III NEC, especially when the condition is rapidly progressing or there is evidence of GI perforation.
- B. Surgical management.** Goal is to prevent enteric spillage and resect necrotic intestine while preserving as much of viable intestine as possible. A pneumoperitoneum is the only absolute indication for surgical intervention but is present in only half of the infants with intestinal perforation and necrosis at time of surgery. Relative indications for surgery include PVG, abdominal wall edema and cellulitis (indicating peritonitis), fixed dilated intestinal segment by x-ray (sentinel loop), tender abdominal mass, and clinical deterioration refractory to medical management. Biochemical markers such as thrombocytopenia, elevated CRP, fecal calprotectin, intestinal fatty acid binding protein, and elevated IL-6 and IL-8 levels have been suggested as markers to predict surgical NEC, but their practical clinical application remains questionable.
1. **Exploratory laparotomy.** This involves examining the bowel and resecting the necrotic segments. A portion of viable bowel is used to create an enterostomy and mucous fistula. Reanastomosis takes place after 8 to 12 weeks. If NEC only involves a short segment of bowel with limited resection, primary anastomosis is used by some surgeons; this avoids complications associated with ileostomy and need for second reanastomosis surgery. In situations of widespread intestinal necrosis, the abdomen may be closed after placement of a drain and reexplored later. A poor prognosis is associated with severe short bowel syndrome, and foregoing further treatment may be considered.
 2. **Peritoneal drain placement.** A small transverse incision is made at McBurney's point. Abdominal layers are bluntly dissected, and a Penrose drain is threaded into the abdomen and secured.

Two multicenter trials have shown that use of a peritoneal drain (PD) and laparotomy in infants with bowel perforation have similar mortality, need for TPN, and length of hospital stay. Secondary laparotomy after PD has varied from 38% in the study by Moss et al to 74% in that by Rees et al, without affecting survival. PD is a relatively simple procedure and can be done with local anesthesia

at the bedside. Hence, it is often used as a temporizing procedure in critically sick infants. However, PD has been questioned by Rees et al because they have shown lack of improvement in physiologic measurements following PD and the majority of infants required definitive laparotomy later. Currently, the optimal surgical management for infants with bowel perforation remains **controversial**. The Necrotizing Enterocolitis Surgery Trial (NEST), which is evaluating survival without neurodevelopmental impairment at 18 to 22 months for infants undergoing laparotomy or PD for NEC or intestinal perforation, is currently underway (ClinicalTrials.gov identifier: NCT01029353).

IX. Prevention

- A. **Human milk has been shown to prevent NEC.** Although a mother's own milk is ideal, a meta-analysis of 9 randomized clinical trials of donor human milk versus formula suggests that human milk was beneficial; infants randomized to formula had a 2.8 times increased risk of NEC. The rate of NEC was also shown to be lower in infants receiving human milk fortifier compared to those receiving bovine milk-based fortifier.
- B. **Use of standardized feeding regimens with initial period of trophic feeds** has been shown to decrease the incidence of NEC. A cautious approach to feeding in high-risk infants with circulatory compromise or congenital heart disease or those receiving PRBC transfusions is recommended.
- C. **Probiotics.** Probiotics are live nonpathogenic microbial preparations that colonize the healthy intestine. They have the potential to prevent NEC by promoting colonization of the gut with beneficial organisms, preventing colonization by pathogens and improving the maturity and function of gut mucosal barrier and modulation of the immune system. Probiotics have been studied extensively to prevent NEC; the largest clinical trial to date of 1315 preterm infants (GA 23–30 weeks) demonstrated no difference in the incidence of Bell stage II or III NEC between patients randomly assigned to receive the probiotic *Bifidobacterium breve* BBG-001 compared with the placebo group (9% vs 10%). A recent meta-analysis, which included 38 trials (total of 10,520 preterm infants), showed a significant reduction of NEC (relative risk [RR], 0.43; confidence interval [CI], 33–0.56) and mortality (RR, 0.79; CI, 0.68–0.93) with no significant change in incidence of culture-proven sepsis (RR, 0.88; CI, 0.77–1). However, this benefit was not seen in the most premature infants with birthweight <1 kg. Because probiotics are considered nutritional supplements and not “drugs,” they are not controlled by the US Food and Drug Administration. As such, there are no established regimens of optimal strain and dosing and no quality control regulations to ensure consistency and safety of these products; therefore, they cannot be recommended at this time. In addition, there have been some case reports of bacteremia from the probiotic strain used and 1 case of fatal mucormycosis in a preterm infant exposed to probiotics.
- D. **Probiotics, or nutrients that enhance the growth of beneficial microbes,** have been proposed as a preventive strategy. These include oligosaccharides, inulin, galactose, fructose, lactose, and others. Although prebiotics enhance the proliferation of endogenous flora, their efficacy in prevention of NEC is unclear.
- E. **Avoidance of prolonged empiric antibiotic use.** Antibiotics alter the gut flora, promoting growth of pathogens, and should be avoided in premature infants. This is supported by a retrospective study that showed that extremely low birthweight infants receiving an initial antibiotic course of >5 days had an increased risk of NEC or death. The association was confirmed in a recent systematic review and meta-analysis.
- F. **Avoidance of H₂ blockers.** Innate GI immunity provided by gastric acid may be important in preventing the cascade of infectious and inflammatory events leading to NEC. A large retrospective study from the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network showed that infants with NEC were more likely to have received H₂ blockers compared to matched

controls (odds ratio, 1.71; CI, 1.34–2.19). Therefore, routine use of H₂ blockers in premature infants should be avoided.

X. Complications

- A. **Recurrence of NEC** may occur in about 5% to 10% of cases.
- B. **Colonic strictures** may occur in 10% to 20% cases and present with recurrent abdominal distension and persisting feeding intolerance. Contrast radiographic studies are usually diagnostic. The most common site for stricture formation is the colonic splenic flexure.
- C. **Short bowel syndrome** may develop in infants undergoing extensive resection of bowel (occurs in 9% of surgical NEC cases). The traditional limits of intestinal length for successful survival (at least 20 cm of viable small bowel remaining with an intact ileocecal valve, or 40 cm viable remaining small bowel with loss of ileocecal valve) are now being challenged with improvements in short bowel management by multidisciplinary teams. Fewer infants are now being referred for intestinal transplant after the use of intestinal lengthening procedures such as serial transverse enteroplasty and improved TPN and infection prevention strategies. Intestinal (with or without liver) transplant remains an option for some of these infants.
- D. **Total parenteral nutrition–associated liver disease** occurs more frequently in infants with surgical therapy for NEC.

- XI. **Prognosis.** Risk of mortality is 20% to 30%; the mortality is higher with lower GA and surgical interventions. Infants with surgical NEC have been shown to have significant growth and neurodevelopmental impairment. They are at risk for developing periventricular leukomalacia, cerebral palsy, deafness, and blindness. In a report from NICHD, only half the infants with surgical NEC survived. Among the survivors, 56.7% had neurodevelopmental impairment (cerebral palsy, mental development index <70, physical development index <70, blindness, or deafness). Overall, mortality or neurodevelopmental impairment was present in 82.3% of infants in this high-risk group.

110 Neonatal Encephalopathy

I. Definition

- A. **Neonatal encephalopathy (NE)** is a clinically defined syndrome of disturbed neurologic function in the earliest days of life in infants born ≥ 35 weeks' gestation, demonstrated by an altered level of consciousness or seizures and frequently associated with depressed respiratory drive, hypotonia, and depressed or absent reflexes. NE may result from a metabolic disorder, infection, drug exposure, **hypoxic ischemic encephalopathy (HIE)**, or neonatal stroke. NE is the preferred terminology to describe a depressed newborn from any cause at the time of birth.
- B. **Perinatal asphyxia** is a condition of impaired blood gas exchange that, if it persists, leads to progressive hypoxemia and hypercapnia. HIE, which is a subset of NE, can result from perinatal asphyxia whereby inadequate oxygen delivery to the brain leads to compromised brain metabolism
- C. **The likelihood that acute intrapartum or peripartum hypoxia-ischemia (HI)** may have contributed to NE is based on the following factors identified by the American College of Obstetricians and Gynecologists (ACOG) task force on NE:
 - 1. **Neonatal signs**
 - a. **Apgar score <5 at 5 minutes and 10 minutes.**
 - b. **Fetal umbilical artery acidemia** pH <7 and base deficit >12 mmol/L or both.

- c. **Neuroimaging evidence of acute brain injury** seen on brain magnetic resonance imaging (MRI) or magnetic resonance spectroscopy consistent with HI.
 - d. **Presence of multisystem organ failure** consistent with HIE.
 - 2. **Type and timing of contributing factors**
 - a. **A sentinel hypoxic or ischemic event** occurring immediately before or during labor and delivery.
 - b. **Fetal heart rate monitor patterns** consistent with an acute peripartum or intrapartum event.
 - c. **Timing and type of brain injury patterns** based on imaging studies consistent with an etiology of an acute peripartum or intrapartum event.
 - d. **No evidence of other proximal or distal factors** that could be contributing factors.
 - 3. **Developmental outcome**
 - a. **Developmental outcome is spastic quadriplegia or dyskinetic cerebral palsy.** Other subtypes of cerebral palsy (CP) and other developmental abnormalities are not specific to acute intrapartum HIE.
- II. **Incidence.** NE occurs in 3.0 per 1000 live term births and leads to death in 15% to 20% of cases and permanent neurologic deficits in 25% of infants. It is estimated that 70% of cases of NE are due to events that arise before onset of labor, 20% are due to intrapartum events, and 10% are due to postnatal complications. Several case-control studies suggest that a combination of antepartum and intrapartum events is involved in moderate to severe NE. HIE has an incidence of 1.5 per 1000 live births. The worldwide prevalence of CP is 2 to 3 per 1000 live births. Intrapartum hypoxia-acidemia accounts for only approximately 10% to 20% of CP cases.
- III. **Pathophysiology**
 - A. **Hypoxic ischemic injury.** A reduction in oxygen delivery precipitates an immediate drop in cellular high-energy phosphate levels, which is termed a **primary energy failure**. Lactic acid accumulation leads to cellular swelling via failure of membrane ion pump. Calcium influx releases glutamate and ultimately leads to an excitotoxic cycle resulting in free radical and nitric oxide production, lipid peroxidation of cell membranes, and necrotic cell death. If cerebral blood flow is restored with resuscitation, partial restoration of energy sources can occur during the **reperfusion period**. A **latent phase** follows with varying duration based on the severity of the insult. Within 6 to 48 hours after the initial insult, the latent phase can progress to a **secondary energy failure**, which is characterized by inflammation, oxidative and free radical damage, and neuronal death via **apoptosis**. The severity of the insult determines the extent of brain injury. Current neuroprotective therapies are designed to intervene within the latent phase before the onset of secondary energy failure.
 - B. **Adaptive responses of the fetus or newborn to asphyxia.** The fetus and neonate are much more resistant to asphyxia than adults. In response to asphyxia, the mature fetus uses the “diving reflex” physiology to redistribute cardiac output to the heart, brain, and adrenals to ensure adequate oxygen and substrate delivery to these vital organs. Autoregulation of cerebral blood flow becomes disrupted and the cerebral circulation becomes pressure passive; this increases the risk for cerebral ischemia with systemic hypotension and cerebral hemorrhage with systemic hypertension. Cerebrovascular hemorrhage may occur upon reperfusion of the ischemic areas of the brain. However, when there has been prolonged and severe asphyxia, local tissue recirculation may not be restored because of collapsed capillaries in the presence of severe cytotoxic edema.
 - C. **Neuropathology.** Neuropathologic injury from HIE includes the following classic patterns. Different combinations of injury can result based on duration and severity of the injury.
 - 1. **Selective neuronal necrosis** is the most common type of brain injury and can present in 3 patterns: diffuse, cortical–deep nuclear, and deep nuclear–brainstem.

2. **Parasagittal cerebral injury** occurs in the end-arterial watershed area of the parieto-occipital cortex and subcortical white matter.
 3. **Periventricular leukomalacia (PVL)** is necrosis and gliosis of periventricular white matter. Although more common in preterm infants, it can be seen in term infants with HIE. PVL involving the pyramidal tracts usually results in spastic diplegic or quadriplegic CP.
 4. **Focal ischemic necrosis** refers to arterial stroke along the vascular distribution of cerebral arteries.
 5. **Porencephaly, hydrocephalus, hydranencephaly, and multicystic encephalomalacia** may follow focal and multifocal ischemic cortical necrosis, PVL, or intraparenchymal hemorrhage.
 6. **Brainstem damage** is seen in the most severe cases of HI brain injury and results in permanent respiratory impairment.
- IV. **Risk factors.** The following risk factors have been established for HIE, but the timing of fetal hypoxia may be difficult to establish.
- A. **Preconception risk factors** include maternal age ≥ 35 years, family history of seizures or neurologic disease, and infertility treatment.
 - B. **Antepartum risk factors** include maternal thyroid disease, diabetes, severe preeclampsia, multiple gestation, genetic abnormalities, fetal growth restriction, maternal trauma, and antepartum hemorrhage.
 - C. **Intrapartum risk factors** include sentinel events such as placental abruption, umbilical cord prolapse, uterine rupture, fetomaternal hemorrhage, and shoulder dystocia, as well as other intrapartum risk factors such as maternal fever with or without chorioamnionitis. Case-control studies have suggested an interaction between brain injury due to inflammation and HI.
 - D. **Postnatal risk factors** include postnatal injury secondary to cardiorespiratory failure, congenital heart disease, and neurologic abnormalities.
- V. **Clinical presentation.** HIE can result in central nervous system (CNS) injury alone, CNS and other end-organ damage, isolated non-CNS organ injury, or no end-organ damage.
- A. **Central nervous system injury in severe cases of hypoxic ischemic encephalopathy manifest with variable clinical signs that evolve over time:**
 1. **Birth to 12 hours.** Deep stupor or coma, respiratory failure or periodic breathing, diffuse hypotonia with minimal movement, intact pupillary and oculomotor responses. Term infants may have subtle or focal clonic seizures by 6 to 12 hours, whereas preterm infants can present with generalized tonic seizures and posturing.
 2. **12 to 24 hours.** The level of alertness can appear to improve in less critical cases of brain injury, but severe seizures, marked jitteriness, and apnea can also emerge. Term infants can present with weakness of the proximal upper limbs, whereas preterm infants have lower extremity weakness.
 3. **24 to 72 hours.** The consciousness level worsens, leading to deep stupor or coma and respiratory arrest. Pupillary and oculomotor disturbances are now present due to brainstem involvement. Death due to HIE most often occurs at a median age of 2 days.
 4. **After 72 hours.** Mild to moderate stupor may persist, but the overall level of alertness improves. Diffuse hypotonia may persist, or hypertonia can become evident. Feeding difficulties become obvious due to abnormal sucking, swallowing, and tongue movements.
 - B. **Non-central nervous system multiorgan dysfunction can present as follows:**
 1. **Renal.** Acute tubular necrosis (ATN) and syndrome of inappropriate antidiuretic hormone (SIADH) are common.
 2. **Pulmonary.** Respiratory failure may result from poor central drive, persistent pulmonary hypertension, and meconium aspiration.
 3. **Cardiac.** Myocardial dysfunction and congestive heart failure may result in arrhythmias and hypotension.

4. **Hepatic dysfunction** may manifest as transaminitis, coagulopathy, and hypoglycemia.
5. **Hematologic.** Thrombocytopenia and leukopenia may occur due to hypoxic marrow suppression. An increased release of nucleated red blood cells may occur as well.
6. **Gastrointestinal.** Paralytic ileus or necrotizing enterocolitis may occur due to mesenteric hypoperfusion.
7. **Metabolic.** Acidosis (elevated lactate), hypoglycemia, hypocalcemia, and hyponatremia may be seen.

VI. Diagnosis

A. Maternal data

1. **History.** A thorough maternal history (prior pregnancy loss, thyroid disease, fever, drug use, infection) and family history (thromboembolic disorders, seizure disorder) can help identify causes of NE other than HIE.
2. **Fetal heart rate patterns.** Per ACOG guidelines, a fetal heart rate (FHR) pattern suggestive of previous fetal injury is a category II tracing lasting 60 minutes \geq that is identified on initial presentation with persistently minimal or absent variability and lacking accelerations. A category I tracing on presentation that converts to a category III tracing is **suggestive** of an HI event. Additional FHR patterns that **may suggest** intrapartum timing of an HI event include a category I tracing that evolves into tachycardia with recurrent decelerations or persistent minimal variability with recurrent decelerations. (FHR categories are discussed in Chapter 1.)
3. **Umbilical cord blood gases.** Per ACOG guidelines, the probability but not the timing of an intrapartum hypoxic event leading to NE may be suggested by metabolic acidosis in umbilical cord gases. Fetal umbilical artery pH ≤ 7.0 , base deficit ≥ 12 mmol/L, or both increase the probability of NE having an intrapartum hypoxic component. For cord arterial pH > 7.20 , NE is unlikely to be a result of intrapartum hypoxia.
4. **Placental pathology.** Important information regarding the etiology of NE may be gleaned from abnormalities seen on the maternal or fetal side of the placenta. Pathologic umbilical cord lesions, such as velamentous or marginal cord insertion or cord hematoma or tears, may indicate a disruption in the fetal vascular supply. Chorioamnionitis and funisitis may indicate an infectious etiology of NE, whereas fetal thrombotic vasculopathy can point to a genetic coagulopathic disorder. While placental findings should be taken in context of the clinical scenario, findings favoring acute in utero compromise include acute villous edema, acute intravillous hemorrhage, acute retroplacental hemorrhage, and acute meconium staining.

B. Neonatal data

1. **Apgar scores.** Although most infants with a low Apgar score will not develop CP, a low Apgar score at 5 minutes and 10 minutes confers an increased relative risk of CP. Per ACOG, if the 5-minute Apgar score is ≥ 7 , peripartum HI is unlikely to be a major contributor to NE.
2. **Physical examination.** The classification of HIE into clinical stages based on severity is determined by the **Sarnat scale and its modified versions**.
 - a. **Stage 1 (mild).** Hyperalert, normal activity, normal muscle tone, weak suck, strong Moro, mydriasis, tachycardia, and absence of seizures.
 - b. **Stage 2 (moderate).** Lethargic or obtunded, decreased activity, hypotonia, strong distal flexion, weak or absent suck, weak Moro, miosis, bradycardia, and focal or multifocal seizures are common.
 - c. **Stage 3 (severe).** Stupor or coma, absent activity, flaccid muscle tone, intermittent decerebration, absent suck, absent Moro, poor pupillary light response with fixed, dilated pupils, variable heart rate, and frequent prolonged seizures.

3. **Laboratory studies.** Complete blood count with differential, blood culture, serum electrolytes, glucose, lactate, blood urea nitrogen, creatinine, cardiac enzymes, liver enzymes, a coagulation panel, and blood gases should be obtained at time of admission and serially monitored as indicated. Further metabolic workup including ammonia, urine ketones, plasma amino acids, urine amino acids, urine organic acids, and acylcarnitine profile may be indicated in the workup of NE not consistent with HIE.
4. **Imaging other than cranium.** An echocardiogram can be obtained to evaluate cardiac ventricular function, presence of tricuspid regurgitation, and right to left shunting via foramen ovale and patent ductus arteriosus. Renal and hepatic ultrasounds may provide further information regarding end-organ damage.
5. **Conventional electroencephalogram.** Along with evaluation of seizure burden, interpretation of electroencephalography (EEG) background includes the following variables.
 - a. **Amplitude.** Refers to the voltage measured from peak to peak of the waveform. Amplitude decreases with increasing gestational age. Abnormalities can include an isoelectric EEG (maximally depressed or flat) or low voltage.
 - b. **Symmetry.** Refers to the symmetry of activity arising from both hemispheres. Asymmetry can indicate a stroke or structural lesion.
 - c. **Continuity.** Refers to a tracing with relatively constant and consistent amplitude. Discontinuity refers to high-amplitude bursts that alternate with periods of low amplitude. Continuity increases with increasing gestational age.
 - d. **Sleep-wake state.** Refers to the pattern of EEG alterations among different behavioral states. The presence of sleep-wake cycling (SWC), as expected in a normal EEG, may be poorly defined or absent in a neonate affected by HIE. SWC is also gestational age dependent.
6. **Amplitude-integrated EEG.** This mode of monitoring uses a bedside cerebral function monitor, which records and amplitude integrates a single- or double-channel EEG from biparietal electrodes. Amplitude-integrated EEG (aEEG) has the advantage over conventional EEG of not requiring extensive formal training for interpretation. Studies have shown aEEG to be useful in predicting long-term neurodevelopmental outcomes in infants with HIE. The following is 1 classification scheme suggested to describe aEEG findings.
 - a. **Continuous normal voltage.** Continuous activity with lower margin (minimum amplitude) above $5 \mu\text{V}$ and upper margin (maximum amplitude) above $10 \mu\text{V}$.
 - b. **Discontinuous normal voltage.** Discontinuous background with lower margin below $5 \mu\text{V}$ and upper margin above $10 \mu\text{V}$.
 - c. **Burst suppression.** Discontinuous background with lower margins below $10 \mu\text{V}$ with occasional bursts with amplitude $>25 \mu\text{V}$.
 - d. **Continuous extremely low voltage.** Continuous background pattern of very low voltage (around or below $5 \mu\text{V}$). Occasional spikes are seen over $10 \mu\text{V}$.
 - e. **Isoelectric or flat tracing.** Primarily inactive (isoelectric) background below $5 \mu\text{V}$; prominent spikes are likely due to patient movements/artifacts.Computer-based automated quantitative EEG power analysis is an emerging field that may play a role in identifying and managing seizures and predicting outcome in neonate with HIE.
7. **Magnetic resonance imaging of the brain.** The pattern of brain involvement, rather than the severity of injury, determines neurodevelopment outcomes of infants with HIE.
 - a. **Watershed predominant pattern.** Results from partial prolonged HIE injury and affects the vascular watershed area in the white matter.

- b. Basal ganglia/thalamus predominant pattern.** Results from acute profound HIE and affects deep gray nuclei and perirolandic cortex. The total cortex can be involved in severe HIE. This pattern is associated with severe cognitive and motor deficiencies, including CP.
- c. Additional injuries.** Involvement of the cortical gray matter can be seen in severe HIE. This pattern is associated with cognitive impairment. Hemorrhages, focal-multifocal white matter injury, and global brain injury can also occur.
- 8. Magnetic resonance spectroscopy.** Magnetic resonance spectroscopy is used to evaluate cerebral metabolic abnormalities after HIE. The best predictors of neurodevelopmental outcomes are the ratio of lactate to *N*-acetyl aspartate (NAA) and the absolute concentration of NAA.
- 9. Diffusion-weighted imaging and diffusion tensor imaging.** Diffusion-weighted imaging (DWI) relies on water molecule diffusion in the brain to provide image contrast. DWI allows quantification of lesions by measuring the apparent diffusion coefficient and fractional anisotropy. Diffusion tensor imaging (DTI) measures the magnitude and directionality of water molecule diffusion. The time-dependent nature of apparent diffusion coefficient contributes to its poor predictive value for neurodevelopment. Fractional anisotropy calculated from DTI data has been associated with neurodevelopment outcomes in infants with HIE.
- 10. Near-infrared spectroscopy (NIRS)** provides a noninvasive method of monitoring cerebral hemodynamics and oxygenation. Measurement of cerebral perfusion by NIRS has been correlated with brain MRI findings in HIE infants.
- 11. Biomarkers.** Early biochemical markers of perinatal brain damage include the following: absolute nucleated red blood cells, S100B (cytosolic calcium-binding protein), adrenomedullin, erythropoietin (EPO), activin A (growth and differentiation factor), neuron-specific enolase, oxidative stress markers, glial fibrillary acidic protein, and creatine kinase BB, among others.

VII. Management. The management of infants with HIE begins with the identification of perinatal patients at a high risk for asphyxia and optimal resuscitation in the delivery room. Because many cases of HIE are unanticipated and unpreventable, clinical care mostly focuses on providing supportive care to prevent further exacerbation of injury and specific neuroprotective therapies targeted at the therapeutic window prior to the onset of irreversible secondary energy failure. The ethical and medicolegal aspects of care also need to be considered.

A. Supportive care

- 1. Resuscitation.** The 2015 Neonatal Resuscitation Program guidelines recommend initiating resuscitation of newborn ≥ 35 weeks with 21% oxygen with a targeted preductal saturation of 60% to 65% by 1 minute of life and 80% to 85% by 5 minutes of life. When chest compressions are indicated, after optimal ventilation has been established, oxygen concentration should be increased to 100% and weaned as soon as the heart rate recovers.
- 2. Ventilation.** Assisted ventilation may be required to maintain P_{CO_2} within the physiologic range. While hypercarbia exacerbates cerebral intracellular acidosis and impairs cerebrovascular autoregulation, hypocarbia decreases cerebral blood flow and is associated with poor outcomes in neonates with HIE. It is unclear whether hypocarbia is a risk factor or an early marker for poor neurodevelopmental outcome.
- 3. Perfusion.** Mean arterial blood pressure should be maintained in the normotensive range. Due to the loss of cerebrovascular autoregulation, volume expanders and inotropic support should be used cautiously to avoid rapid shifts between systemic hypotension and hypertension. Blood pressure management needs to be individualized based on the presence of comorbidities such as pulmonary hypertension and myocardial dysfunction.

4. **Acid-base status.** The base deficit is thought to increase in the first 30 minutes of life due to an initial washout effect secondary to improved perfusion and transient increase in lactic acid levels. In most infants, acidosis normalizes by 4 hours of life regardless of bicarbonate therapy. The rate of recovery from acidosis is reflective of HIE severity but not duration and is not predictive of outcomes. **Sodium bicarbonate therapy is not recommended** as it causes a concomitant rise in intracellular PCO_2 levels, negating any changes in pH, and is associated with increased rates of intraventricular hemorrhage and mortality. An inborn error of metabolism must be considered if the degree and duration of acidosis seem out of proportion to the history and presentation.
5. **Fluid status.** Initial fluid restriction is recommended as HIE infants are predisposed to a fluid overload state from renal failure secondary to ATN and SIADH. The avoidance of volume overload helps avert cerebral edema. Subsequent fluid management is based on clinical status including renal function, urine output, and electrolytes.
6. **Blood glucose.** The maintenance of normoglycemia plays a vital role in determining neurologic outcome after an HI event. Both hypoglycemia and hyperglycemia in infants with moderate to severe HIE are independently associated with unfavorable outcome.
7. **Temperature.** Hyperthermia for infants with HIE has been associated with adverse outcomes and should be avoided in the delivery room.
8. **Infection.** Evaluate for sepsis with use of antibiotics (not gentamicin) as NE may be the result of infection.
9. **Seizures.** Seizure activity is both a consequence and determinant of brain injury regardless of the primary neurologic insult. Seizures are frequently unrecognized or subclinical (electrographic). Jitteriness, tremors, and benign sleep myoclonus may be misdiagnosed as seizures. Continuous monitoring of EEG allows for timely treatment of subclinical seizures. Phenobarbital is the main antiepileptic drug (AED) used. A 2016 Cochrane review showed prophylactic barbiturate therapy to result in a reduction in seizure burden but no reduction in mortality; insufficient data regarding long-term outcome were provided. Other AEDs used include levetiracetam, phenytoin (and fosphenytoin), benzodiazepines, and lidocaine. AED levels in asphyxiated infants should be carefully monitored due to impaired hepatic and renal clearance.

B. Neuroprotective strategies

1. **Hypothermia.** Therapeutic hypothermia attenuates secondary energy failure by decreasing cerebral metabolism, inflammation, excitotoxicity, oxidative damage, and cellular apoptosis. A 2013 Cochrane review of 11 trials of both whole-body and selective cooling showed that hypothermia therapy within 6 hours of birth for infants with moderate or severe encephalopathy reduced mortality and neurodevelopmental disability. **Hypothermia therapy is the standard of care for newborns with moderate to severe HIE**, and timely identification and referral to cooling centers is crucial. Whole-body cooling can be safely and effectively done during neonatal transport. Hypothermia protocols and recommended temperature regulation prior to admission (eg, passive cooling or active cooling on transport) are institution specific and must be clarified with the accepting facility at the time of referral. A recent trial looking at longer (120 hours vs 72 hours) and/or deeper (32°C vs 33.5°C) cooling, either alone or combined, did not reduce neonatal deaths, and the trial was closed early for safety concerns. The time to initiate cooling has been correlated with outcomes. A multicenter National Institute of Child Health and Human Development (NICHD) trial evaluating the effectiveness of whole-body cooling initiated between 6 and 24 hours of age and continued for 96 hours in infants with HIE was recently published; it showed the primary outcome (death or disability) at 18 to 22 months to be present in 19 (24.4%) of 78 hypothermic

infants and 22 (27.9%) of 79 noncooled infants (absolute difference, 3.5%; 95% confidence interval, -1% to 17%). Using Bayesian analysis, the authors concluded that hypothermia initiated at 6 to 24 hours after birth may have benefit, but there is uncertainty in its effectiveness. An NICHD trial to assess the safety and effectiveness of whole-body hypothermia for preterm infants 33 to 35 weeks' gestation is currently underway. Therapeutic hypothermia is currently not recommended for infants with mild encephalopathy, but some studies are investigating this area as well.

2. Pharmacotherapy. Multiple drugs are currently being studied to augment neuroprotection in infants with HIE. Demand for combination therapies stems from the realization that 45% of infants with HIE treated with hypothermia alone have adverse outcome. EPO provides neuroprotection via its anti-inflammatory and antiapoptotic effect on neural cells and promotion of neural regeneration. A phase II clinical trial showed that high doses of EPO given with hypothermia for HIE reduced MRI brain injury and improved 1-year motor function. An upcoming large phase III trial is underway to determine if EPO and hypothermia can improve long-term outcome. Trials using darbepoetin as an adjunctive therapy to hypothermia are also in process. Allopurinol, a free radical scavenger, has been shown to provide long-term neuroprotection in some studies. Melatonin has antioxidant and anti-inflammatory properties and has been shown to be neuroprotective in a pilot study. Xenon is an inhaled anesthetic that inhibits excitatory amino acid release. A trial of total-body hypothermia plus xenon did not demonstrate an enhanced neuroprotective effect. Agents such as deferoxamine and *N*-acetyl-L-cysteine have been studied in animal models but not human trials. Stem cell therapy is also an area of interest.

C. Ethics. Families are often unprepared to deal with the complexities of HIE. Direct and timely communication between the medical team and the neonate's family is therefore essential to foster shared decision making with difficult medical and emotional decisions such as discontinuation of artificial life support. A multidisciplinary team approach is essential, as severely depressed infants may have multiple complex medical needs. A neurology consult is helpful to provide parents with important prognostic information based on the infant's neurologic assessment. A palliative care consult may offer families support while optimizing the quality of the life for the infant. Therapeutic hypothermia has been shown to significantly reduce death without an increase in survivors with disability. Withdrawal of artificial support and allowing natural death can be addressed with families during hypothermia in profoundly affected infants.

D. Medicolegal aspects

1. Obstetric care. Fetal status must be assessed with electronic fetal monitoring at the time of maternal admission to identify and categorize risk for intrapartum fetal distress. A reactive FHR pattern is a reliable sign of fetal well-being, whereas a nonreactive pattern indicates a higher probability of intrapartum fetal distress and adverse fetal outcome. The early recognition of FHR patterns that are associated with fetal academia and HI with timely intervention may potentially alleviate brain injury. However, FHR patterns may reflect preexisting or underlying neurologic impairment originating prior to the perinatal period. Caution must be used in identifying a specific event as the cause for an adverse outcome, as the baseline fetal brain status is often unknown.

2. Neonatal care. Many cases of NE are unanticipated, and an experienced resuscitation team may not always be readily available. In an anticipated high-risk birth, clear communication between members of the obstetric and neonatal teams prior to delivery is imperative. The resuscitation team must be thoroughly prepared for the potential for vigorous resuscitation per current Neonatal Resuscitation Program guidelines. Careful attention must be paid to avoiding hyperthermia, hypoglycemia, hypotension, and hypocarbia in the

postresuscitation stabilization period. Early referral for evaluation for hypothermia therapy is crucial, as transport and admission to the tertiary center is ideally achieved within 6 hours after birth. Documentation of the resuscitation and stabilization process as well as informed consent for transport are important parts of the medical record.

- VIII. Prognosis.** The presence of NE is considered an essential etiologic link between perinatal events and permanent brain damage. Mild cases of neonatal HIE have a favorable outcome, whereas severe cases have a high rate of mortality and neurodevelopmental disability. Despite the use of therapeutic hypothermia, the mortality rate and the composite outcome of death or major disability remain high. Findings of persistent severe HIE at 72 hours and an abnormal neurologic exam at discharge are associated with a greater risk of death or disability. The discharge exam also improves the predictive ability of the initial stage of encephalopathy at <6 hours for death or disability. Other findings associated with an increased risk of death or disability include hypertonia, fisted hand, abnormal movements, absent gag reflex, asymmetric tonic neck reflex, and need for gavage tube/gastrostomy feeds at time of discharge. EEG and aEEG play an important part in predicting outcomes. A persistently abnormal aEEG at 48 hours or more is associated with an adverse neurodevelopmental outcome. Infants with high seizure burden and moderate to severe injury on MRI (basal ganglia, thalamus, and posterior limb of the internal capsule) are at greatest risk of abnormal outcome. Diffusion-weighted MRI in the first week of life has the highest specificity, whereas T1/T2-weighted MRI in the first 2 weeks of life has the highest sensitivity. Basal ganglia or thalamic lactate/NAA ratio is a predictor for adverse neurodevelopmental outcome. Visual evoked potentials may also provide prognostic information. Reassuring prognostic factors include early return of SWC with normalization of background EEG, normal MRI, oral feeding, and normal neurologic examination at discharge.

111 Neural Tube Defects

- I. Definitions.** Neural tube defects (NTDs) are malformations of the developing brain and spinal cord. In normal development, the closure of the neural tube occurs over a 4- to 6-day period with completion around the 29th day postconception, often before a woman has realized that she is pregnant. Most current hypotheses consider NTDs to be defects from failure of a neural tube closure rather than the reopening of a previously closed tube. The nomenclature for NTDs is not standardized; frequently used terms are as follows:
- A. Anencephaly.** The defective closure of the upper or rostral end of the anterior neural tube. Hemorrhagic and degenerated neural tissue is exposed through an uncovered cranial opening extending from the lamina terminalis to the foramen magnum. Infants with anencephaly have a typical appearance with prominent eyes when viewed face on. **Craniorachischisis totalis** (a neural platelike structure without skeletal or dermal covering resulting from complete failure of neural tube closure) and **myeloschisis** or **rachischisis** (in which the spinal cord is exposed posteriorly without skeletal or dermal covering because of failure of posterior neural tube closure) are other, less frequent open lesions.
 - B. Encephalocele.** Herniation of brain tissue outside the cranial cavity resulting from a mesodermal defect occurring at or shortly after anterior neural tube closure; usually a closed lesion. Approximately 80% of encephaloceles occur in the occipital region.

- C. Myelomeningocele.** Often also referred to as **spina bifida** (protrusion of the spinal cord into a sac on the back through a deficient axial skeleton with variable dermal covering). Considering that, strictly speaking, “spina bifida” only describes the bony defect, the term **spinal dysraphism** is considered more accurate by some. More than 80% of defects in this category occur in the lumbar region, and approximately 80% are not covered by skin. In contrast to myelomeningoceles, **meningoceles** (closed lesions involving the meninges only) usually do not result in neurologic deficits.
- D. Spina bifida occulta and occult spinal dysraphism.** Disorders of the caudal neural tube that are covered by skin (skin dimples or only very small skin lesions are present). These dysraphic disturbances range from cystic dilation of the central canal (**myelocystocele**), over bifida spinal cords with or without a separating bony, cartilaginous, or fibrous septum (**diastematomyelia** or **diplomylelia**), to a **tethered cord with a dermal sinus** or other visible changes such as hair tufts, lipomas, or hemangiomas. The term *spina bifida occulta* is used incorrectly when it is applied to an incomplete ossification of the posterior vertebral arch, a frequent and insignificant finding that is neither clinically nor developmentally related to NTDs.
- II. Incidence.** Ninety-five percent of children with NTDs are born to couples with no family history of such defects.
- A. Statistics related to neural tube defects are to be interpreted with caution** and in the context of population, location, and time because occurrence of NTDs is affected by many epidemiologic and medical factors (see later sections).
- B. The overall worldwide incidence** has been quoted as approximately 1 in 1000 live births. Folic acid supplementation and clinical practice (eg, termination of pregnancy) have affected the incidence at birth; differences between countries are significant (see Section II.H).
- C. Spina bifida occulta, myelomeningocele, and anencephaly** are the more frequently encountered NTDs.
- D. At early embryonic stages, the incidence of neural tube defects is as high as 2.5%**; many abort spontaneously.
- E. The Centers for Disease Control and Prevention report that approximately 1500 infants with spina bifida are born in the United States per year.** The prevalence has decreased with folic acid food fortification (initiated in 1998) from 7.92 per 10,000 in 1996 (year of birth) to 4.61 per 10,000 in 2006. In 2016, it was estimated that in the United States alone, 600 to 700 babies are born without spina bifida per year as a result of folic acid fortification.
- F. Medical costs are significant.** Lifetime cost of NTDs are significant. In 2017, lifetime cost (for a US patient) was estimated at \$791,900, or \$577,000 excluding caregiving cost.
- G. Countries that have implemented mandatory fortification programs have reported a 20% to 50% reduction in incidence and subsequent decreases in prevalence of neural tube defects.** In the United States, a 19% reduction in the birth prevalence of NTDs was reported after fortification of the food supply.
- H. Geographic variation, sex, race, and social class**
- 1. The incidence is higher in females versus males.**
 - 2. The risk is higher in Eastern Europeans, Hispanics, and in those from parts of Asia (northern China).** The risk is lower in Africans Americans, Africans, those from other regions of Asia, Pacific Islanders, and Ashkenazi Jews (compared to whites of European descent).
 - 3. Some populations with frequent consanguineous matings have an increased risk.**
 - 4. The risk is increased in infants of particularly young or particularly older mothers of lower socioeconomic class.** This increase may be related to nutritional factors.

- III. Pathophysiology.** The causes of NTDs seem to be multifactorial in most cases of anencephaly, encephalocele, myelomeningocele, and meningocele. Interactions between genetic and environmental factors result in disturbance of normal development. Recognized causes or contributing factors include the following:
- A. Nutritional and vitamin deficiencies.** Main concern: folate deficiency; other deficiencies linked to NTDs: vitamin B12 and zinc. **Note:** Folate occurs naturally; folic acid is the synthesized supplement.
 - B. Chromosome abnormalities.** Include trisomies 13 and 18, triploidy, unbalanced translocations, and ring chromosomes.
 - C. Genetic syndromes.** NTDs have been observed as part of a variety of syndromes, some with Mendelian inheritance patterns. A typical example is **Meckel-Gruber syndrome** (autosomal recessive), which presents with encephalocele, microcephaly, polydactyly, cystic dysplastic kidneys, and other anomalies of the urogenital system. Genetic references and databases list >50 syndromes associated with NTDs in the differential diagnosis. Recent advances into the understanding of neurodevelopment emphasize the importance of intact folate metabolism, primary cilia function and intact signaling pathways for normal development.
 - D. Teratogens.** **Nitrates** (cured meat, blighted potatoes, salicylates, and hard water), **antifolates** (aminopterin, methotrexate, phenytoin, phenobarbital, primidone, carbamazepine, and valproic acid), **thalidomide**, and **abnormal glucose homeostasis in diabetic mothers** have all been implicated to contribute to the occurrence of NTDs. The role of other potential causes of NTD remains **controversial**; a potential interference with normal neurodevelopment has been discussed for a variety of exposures, including (but not limited to) **lead, glycol, clomiphene, hazardous waste, and maternal hyperthermia.**
 - E. Other causes.** An overall increase in birth defects has been reported in infants of teenage mothers (<20 years old) compared with those mothers in the 25- to 29-year age range. The relative risk of nervous system defects in infants of teen mothers is 3.4 times that for children of 25- to 29-year-old mothers. Although a low body mass index does not increase the risk for NTDs, obesity does. The parents' ages are not related to the occurrence of NTDs per se; the risk for twins maybe higher.
- IV. Risk factors**
- A. Considering pathophysiology and introduction of folic acid food fortification,** the main clinically relevant risk groups are currently the following:
 - 1. Women with insulin-dependent diabetes mellitus** (the risk appears to be influenced by the level of control).
 - 2. Women with seizure disorders** who are being treated with valproic acid or carbamazepine.
 - 3. Women with a family history of neural tube defects.**
 - B. The recurrence risk is as follows:**
 - 1. Two to three percent with 1 affected sibling.** Some types of NTDs may be folic acid resistant, and even with folic acid treatment, a residual risk of approximately 1% remains.
 - 2. Approximately 4% to 6% with 2 affected siblings.** Higher if other associated findings suggest a syndrome/condition with possible Mendelian inheritance.
 - V. Clinical presentation.** Clinical presentations of the most severe NTDs are the obvious cranial defect in anencephaly and open spinal defects of the thoracic and/or lumbar spine with open spinal NTDs, both with exposure of neural tissue. NTDs with an intact skin cover may show an obvious mass (eg, an occipital encephalocele) or be more subtle. Subtle findings include bulging of the skin cover over the occipital or spinal defect, small openings sometimes missed on initial examination, dimples, or hair patches. See Section I for definitions and description of the different NTDs.

VI. Diagnosis

- A. Prenatal screen using maternal serum α -fetoprotein at 14 to 16 weeks' gestation.** Elevated levels (>2.5 multiples of the mean, which are adjusted to gestational age) are indicative of open NTDs at a sensitivity of 90% to 100%, a specificity of 96%, and a negative predictive value of 99% to 100% but a low positive predictive value.
- B. Prenatal diagnosis.** Documentation of an elevated maternal serum α -fetoprotein (AFP) is followed by:
- 1. Genetic counseling.** The patient should receive counseling regarding the risk of NTDs and other conditions with elevated AFP (gastroschisis or other conditions leading to fetal skin defects) in her fetus. The possibility of false-positive results (imprecise dates or twin pregnancies) should be considered; further evaluation (see following text) should be discussed, and nondirective counseling regarding treatment options should be provided.
 - 2. Detailed fetal ultrasonography with anomaly screening.** In skilled hands, a detailed ultrasonogram (now often enhanced by 3-dimensional images) is extremely sensitive and specific for detection of NTDs. Sonographic determination of the level of the lesion is useful in predicting the ambulatory potential of fetuses with NTDs. Ultrasonography is also done to rule out other major congenital defects and is now often aided by fetal magnetic resonance imaging (MRI).
 - 3. Measurement of the amniotic fluid α -fetoprotein and acetylcholinesterase.** Amniocentesis is usually done between 16 and 18 weeks' gestation. The detection rate for anencephaly and open spina bifida is 100% when results of amniotic fluid acetylcholinesterase and AFP are combined, with a false-positive rate of only 0.04%. If indicated, cells for a karyotype or microarray analysis can also be obtained.
- C. Postnatal diagnosis.** Physical examination, imaging (as discussed for each NTD), and, if not done prenatally, genetic testing (karyotype, microarray or genome sequencing) as indicated.

VII. Management

A. Prevention of neural tube defections

- 1. The British Medical Research Council** demonstrated in 1991 that high-dose folic acid (4 mg/d) reduced the recurrence risk of NTDs by 72%.
- 2. Multiple guidelines addressing supplementation have been published by a number of public health agencies and professional organizations.** Most address folic acid and/or prenatal vitamin supplementation for women capable of becoming pregnant and higher dose folic acid for women with a history of NTDs:
 - a. All women of childbearing age who are capable of becoming pregnant should consume a daily supplement containing 0.4 to 0.8 mg of folic acid.** This recommendation was most recently reaffirmed by the US Preventative Services Task Force (2017).
 - b. Women with a previous pregnancy resulting in a fetus affected by a neural tube defect should consume 4 mg of folic acid daily.** This was most recently affirmed in a policy statement by the American College of Medical Genetics (2011).
 - c. Ideally, folic acid should be taken before conception and at least through the first few months of gestation.**
- 3. Sources of folate and folic acid**
 - a. Dietary.** The average US diet used to contain about 0.2 mg of folate, which is less bioavailable than folic acid. Folate intake of 0.4 mg/d can be achieved through careful selection of folate-rich foods (spinach and other leafy green vegetables, dried beans, peas, liver, and citrus fruits). **Since January 1998, enriched grains (including flour, bread, rolls, cornmeal, pasta, and rice) in**

the United States are fortified with folic acid by order of the US Food and Drug Administration. Some countries have opted against food fortification due to concerns about adverse effects (masking of vitamin B12 deficiency, potential promotion of tumor growth) and issues relating to freedom of choice.

b. Supplementation. Folic acid is available over the counter and by prescription. Prenatal vitamins also contain folic acid. Multiple sources are available to provide educational material: March of Dimes (www.marchofdimes.com; accessed September 20, 2018), Centers for Disease Control and Prevention (www.cdc.gov; accessed September 20, 2018), American Academy of Pediatrics via their Healthy Children Website (www.healthchildren.org; accessed September 20, 2018), and American College of Obstetrics and Gynecology (www.acog.org; accessed September 20, 2018).

4. Current epidemiologic, biochemical, and genetic evidence suggests that some NTDs are not primarily due to folate insufficiency but rather arise from changes in the metabolism of folate and possibly vitamin B12 in predisposed women. The mechanisms may also involve homocysteine metabolism. Polymorphisms of methylene tetrahydrofolate reductase and other genes encoding proteins involved in folate metabolism may be associated with an increased frequency of NTDs. Due to the homocysteine-lowering effect of folic acid, **supplementation may also reduce the risk for cardiovascular disease.** Some studies suggest that **folate and vitamin supplementation may also reduce the risk for other birth defects** (including congenital heart defects, orofacial clefts, urinary tract and limb defects, or even occurrence of trisomy 21). Other reports suggest an inverse association between folate intake and breast cancer, childhood neuroblastoma, and acute lymphoblastic leukemia. Promotion of tumor growth and the obscuring of vitamin B12 deficiency have been discussed as **potential adverse effects** of folate supplementation.

B. Specific management

1. Anencephaly

a. Approximately 75% of anencephalic infants are stillborn. Live-born infants die within the first 2 weeks after birth.

b. Considering the lethality of anencephaly, palliative care is given. Support services for the family, including social work and genetic and general counseling, are essential. Ethically *controversial* issues regarding the extent of care and other issues (eg, organ donation) may require involvement of other support systems (eg, ethics committees, support groups, or religious guidance—if desired by the family).

2. Encephalocele

a. Physical examination and initial management. In addition to the general principles of neonatal resuscitation, an especially careful physical examination is indicated to assess the NTD and detect any **associated malformations.** We recommend that the child be given nothing by mouth until the **consultations** by subspecialties such as neurosurgery are obtained and a treatment plan has been formulated. **Imaging studies** (ultrasonography and MRI) should be arranged as indicated. If not done prenatally, genetic evaluation and testing (karyotype, microarray, and/or genome sequencing) should be initiated if indicated.

b. Neurosurgical intervention. May be indicated to prevent ulceration and infection, except in cases with massive lesions and marked microcephaly where the decision might be for comfort care only. The encephalocele and its contents are often excised because the brain tissue within is frequently infarcted and distorted. Surgery may be deferred, depending on the size, skin coverage, and location. **Ventriculoperitoneal (VP) shunt** placement may be required because as many as 50% of cases have secondary hydrocephalus.

c. Counseling and long-term outcome. A multidisciplinary approach is necessary to counsel the family regarding recurrence risk, long-term outcome, and

follow-up. For family support and other resources, see Section VII.B.3.j. The degree of **deficits** is determined mainly by the extent of herniation and location; 1 or both cerebral hemispheres, the cerebellum, and even the brainstem can be involved. **Visual deficits** are common with occipital encephaloceles.

Motor and intellectual deficits are found in approximately 50% of patients.

3. **Myelomeningocele.** Traditionally, postnatal surgery and management by a multidisciplinary team are the treatment for myelomeningocele. A multidisciplinary team approach, including a neonatologist, neurosurgeon, geneticist, genetic counselor, urologist, orthopedic surgeon, social worker, physiotherapist, and primary care physician, is necessary. The Management of Myelomeningocele Study (MOMS) was published in 2011 and found that prenatal surgery for myelomeningocele reduced the need for placement of a cerebrospinal fluid shunt and improved motor outcomes at 30 months but was associated with maternal and fetal risks. A Cochrane review in 2014 assessed evidence to be insufficient to recommend in utero repair for unborn babies with spina bifida; several centers in the United States continue to perform fetal surgery, and the MOMS study is ongoing.
 - a. **Physical examination.** Initial care as per Section VII.B.2.a; physical examination should include careful evaluation for other malformations (see Section III.C). See Table 111–1 for correlations between the level of a

Table 111–1. CORRELATION OF THE LEVEL OF MYELOMENINGOCELE WITH LEVELS OF CUTANEOUS SENSATION, SPHINCTER FUNCTION, REFLEXES, AND POTENTIAL FOR AMBULATION

Level of Lesion	Innervation	Cutaneous Sensation (Pinprick)	Sphincter Function	Reflexes	Ambulation Potential
Thoracolumbar	T12–L2	Groin (L1) Anterior upper thigh (L2)	—	—	Nonfunctional ambulation: Wheelchair, standing frame, full-leg orthosis
Lumbar	L3–L4	Anterior lower thigh and knee (L3) Medial leg (L4)	—	Knee jerk	Mainly household ambulation: May ambulate with orthosis and crutches
Lumbosacral	L5–S1	Lateral leg and medial foot (L5) Sole of foot (S1)	—	Ankle jerk	Usually household and community ambulation: May ambulate with or without short leg orthosis
Sacral	S2–S4	Posterior leg and thigh (S2) Medial buttock (S4) Middle of buttock (S3)	Bladder and rectal function	Anal wink	Community ambulation without orthosis

myelomeningocele and cutaneous sensation, sphincter function, reflexes, and potential for ambulation. Voluntary muscle movements may be difficult to elicit in newborns with myelomeningocele, and examination may be distorted initially by reversible spinal cord dysfunction above the level of the actual defect induced by exposure of the open cord.

- i. **Extent of neurologic dysfunction** tends to correlate with the level of the spinal cord lesion.
 - ii. **Paraplegia** typically below the level of the defect.
 - iii. **The presence of the anal wink and anal sphincter tone** suggests functioning sacral spinal segments and is prognostically important. In one study, 90% of patients with a positive anocutaneous reflex were determined to be “dry” on a regimen of intermittent catheterization as opposed to 50% of those with a negative reflex.
- b. Initial management of the spinal lesion.**
- i. **There are institutional differences on how to cover the lesion**, and provision of a **sterile cover** can be achieved by several means. Some surgeons request that the infant be placed in a sterile plastic bag; others prefer application of plastic wrap to cover the lesion. Contact with gauze or other material that could adhere to the tissue and result in mechanical damage when removed is to be avoided. It is advisable to try to keep the defective area moist while avoiding bacterial contamination. If tolerated, the patient should be positioned on the side; fecal contamination should be avoided as much as possible.
 - ii. **Be aware that a high rate of latex allergies** is reported in patients with NTDs. All patients with myelodysplasia should be considered at risk for anaphylaxis and other allergic complications. **Latex avoidance** is practiced as a preventive protocol. One study showed that after 6 years of a latex-free environment, the prevalence of latex sensitization fell from 26.7% to 4.5% of children with spina bifida. For information about latex allergy see American Latex Allergy Association (<https://www.allergyhome.org/blogger/the-american-latex-allergy-association-and-latex-allergy/>).
 - iii. **In most centers, patients are started on antibiotics and given nothing by mouth.**
- c. Surgical management.** Usually closure of the back lesion is done within 48 to 72 hours to prevent infection and further loss of function.
- d. Hydrocephalus.** Common and often **noncommunicative** secondary to associated **Arnold-Chiari malformation** of the foramen magnum and upper cervical canal (usually type II) with resultant downward displacement of the medulla, pons, and cerebellum and obstruction of cerebrospinal fluid flow.
- i. **The risk of hydrocephalus** is 95% for infants with thoracolumbar, lumbar, and lumbosacral lesions and 63% for those with occipital, cervical, thoracic, or sacral lesions.
 - ii. **In some cases, hydrocephalus may not be evident** until after closure of the myelomeningocele, and placement of a **VP shunt** may be required at a later date.
 - iii. **Aggressive treatment with early ventriculoperitoneal shunt placement may improve cognitive function**, but cognitive function may also be affected by developmental abnormalities of the brain.
 - iv. **Serial ultrasound scans are necessary to monitor the degree of hydrocephalus** because ventricular dilation may occur without rapid head growth or signs of increased intracranial pressure. The hydrocephalus often becomes clinically overt 2 to 3 weeks after birth.

- e. **Urinary tract dysfunction.** One of the major causes of morbidity and mortality after the first year of life.
- i. **More than 85% of myelomeningoceles located above S2 are associated with neurogenic bladder dysfunction, urinary incontinence, and ureteral reflux.** Poor bladder emptying immediately after NTD closure may be temporary (“spinal shock”), and improvement of bladder function may be observed up to 6 weeks after repair.
 - ii. **Without proper management, hydronephrosis** may develop, with progressive scarring and destruction of the kidneys.
 - iii. **Renal ultrasonography and a voiding cystourethrogram** may identify patients who may benefit from anticholinergic medication, clean and intermittent catheterization, prophylactic antibiotics, or early surgical intervention.
 - iv. **Other associated renal anomalies** may be present in patients with NTDs, including renal agenesis, horseshoe kidneys, and ureteral duplications.
- f. **Bowel dysfunction.** A high percentage (>90% reported) of spina bifida patients have a neurogenic bowel that may result in fecal incontinence requiring diet modification, stool softeners, laxatives, or even surgical interventions.
- g. **Orthopedic issues**
- i. **With impairment of lower extremity innervation,** the risk of atrophy is high.
 - ii. **Deformities of the foot, knee, hip, and spine** are common as a result of muscle imbalance, abnormal in utero positioning, or teratologic factors.
 - iii. **Hip dislocation or subluxation** may occur and is usually evident within the first year of life; common in patients with midlumbar myelomeningocele.
 - iv. **Treatment of orthopedic abnormalities** should be instituted as soon as there is sufficient healing of the back wound.
 - v. **Physical therapists** assist with proper positioning of the extremities to minimize contractures and to maximize function.
- h. **Endocrine dysfunction.** NTDs can adversely affect the hypothalamic-pituitary axis. Precocious puberty and growth hormone deficiency (30%–70%) have been noted in children with NTDs.
- i. **Outcome of aggressive therapy**
- i. **The overall mortality rate** is now <15% by 3 to 7 years of age; 1-year survival of infants with spina bifida has been reported as high as 87.2%. Factors associated with increased mortality are low birthweight and high lesions.
 - ii. **Infants with sacral lesions** have essentially no mortality.
 - iii. **The outcome in regard to the highest potential for ambulation** depends largely on the level of the original lesion (see Table 111–1) and is modified by the orthopedic treatment and potential complications.
 - iv. **Children with lumbar myelomeningocele score within the normal range on intelligence and achievement tests,** but deficits, possibly progressive, for performance intelligence quotient (IQ), arithmetic achievement, and visuomotor integration have been reported; reading and spelling may be less affected.
 - v. **An intelligence quotient >80** is found in essentially all patients with lesions below S1; approximately 50% of survivors with thoracolumbar lesions have an IQ >80.
 - vi. **Cognitive function** is improved in the presence of favorable socioeconomic and environmental factors.
- j. **Family support groups, educational material, and other resources.** Educational material and further information may be found at the following sites: March of Dimes (www.marchofdimes.com); Spina Bifida Association of America (www.spinabifidaassociation.org); International

Federation for Spina Bifida and Hydrocephalus (based in Europe; www.ifglobal.org). For information about latex allergy see American Latex Allergy Association (<https://www.allergyhome.org/blogger/the-american-latex-allergy-association-and-latex-allergy/>).

4. Spina bifida occulta

- a. **Neonatal features.** The presence of spina bifida occulta is suggested by overlying abnormal collections of hair, hemangiomas, pigmented macules, aplasia cutis congenita, skin tags, subcutaneous masses, and cutaneous tracts, usually in the lumbosacral area. Shallow sacral dimples are common and less of a concern.
- b. **If undetected in the neonatal period,** clinical presentation later in infancy may include delayed development of sphincter control, delayed walking, foot deformities, and/or recurrent meningitis. Sudden symptoms may represent vascular insufficiency produced by tension on a **tethered cord**, angulation of the cord around fibrous or related structures, or cord compression from a mass or cyst.
- c. **Diagnosis**
 - i. **Ultrasonography is useful for screening.** Note that the acoustic window used to diagnose a tethered cord closes at 3 to 6 months.
 - ii. **Magnetic resonance imaging** provides superior anatomic details; contrast is usually not needed.
- d. **Early surgical correction of a tethered cord** may be necessary to avoid the onset of symptoms. A timely surgical release and spinal cord decompression in patients developing symptoms may completely or partially reverse recently acquired deficits.

VIII. Prognosis. See individual topics in management section.

112 Orthopedic and Musculoskeletal Problems

Orthopedic problems are common in neonates. The problems can be isolated deformities or part of a generalized disorder. Usually these deformities are obvious, but a comprehensive musculoskeletal examination is the key for diagnosis of associated generalized disorders. This chapter provides an overview of the common problems encountered in the neonatal intensive care unit. **Many images of these neonatal orthopedic and musculoskeletal conditions, designated by [✎], can be found online** by visiting our website www.neonatologybook.com and clicking on the image tab.

I. Spine problems

A. Scoliosis

1. **Definition.** Scoliosis is a lateral deviation of the spine that is >10 degrees and typically includes the rotation and sagittal deformity. Scoliosis is classified into several types including idiopathic, congenital, and neuromuscular.
 - a. **Infantile idiopathic scoliosis** is more common in boys and in Europe than North America. It is an uncommon scoliosis and thought to be related to infant positioning. Most children are diagnosed within the first 6 months of life and have left-sided thoracic curves. Plagiocephaly is a common association. The natural history is *controversial*, but these curves can improve

spontaneously. Radiographic measures described by Mehta have been used to predict the likelihood of progression. Neuro-axis abnormalities have been noted in >20% of these children, and a magnetic resonance image (MRI) of the spine is recommended for children with curves measuring 20 degrees or more. Casting and bracing have been successful treatment modalities in this condition. Occasionally surgical treatment is required, and the instrumentation is typically a growing rod.

- b. Congenital scoliosis** is caused by anomalies in the growing vertebra. The etiology is unknown, but studies have indicated that carbon monoxide exposure may be a factor, and recent genetic studies suggest a possible congenital basis.

The neuro-axis, vertebral column, and organ systems develop at similar periods in utero. Neuro-axis abnormalities can occur in up to a third of these children, 20% will have a genitourinary abnormality, and 20% will have a cardiac abnormality. The classification consists of 2 basic abnormalities: defects of vertebral formation and defects of vertebral segmentation. The hemivertebrae is an example of a defect in formation, while defects of segmentation include block vertebra and unilateral bars (this is where 1 side of 2 vertebrae are connected, leading to a growth tether).

Progression of the deformity is typically due to an unbalanced growth and can be highly variable. A hemivertebrae with normal growth caudally and cranially can progress significantly. The unilateral bar is the most common cause of congenital scoliosis and can result in significant deformity, particularly if there are hemivertebrae associated.

- 2. Treatment.** Bracing is usually not a successful treatment regimen. Surgical management may be indicated for progressive curves. It may consist of a vertebral resection and spine realignment or a fusion to prevent further progression.

B. Spina bifida. [☼] See also Chapter 111.

- 1. Definition.** This group of disorders is characterized by congenital malformation of the spinal cord and vertebral column. Whereas the etiology of spina bifida is unknown, inadequate maternal intake of folic acid, gestational diabetes, and history of previously affected siblings with the same partner are contributory factors. There are 2 types:

a. Spina bifida occulta is a defective formation of the posterior elements with intact skin and normal meninges and spinal cord.

b. Spina bifida cystica is open skin with abnormal meninges and spinal cord. Spina bifida cystica is further subdivided into 3 types:

i. Meningocele. The meningeal cyst herniates through a defect of the posterior elements of the spine but without the spinal cord or roots.

ii. Myelocele. All the neural tissues are exposed without overlying tissues.

iii. Myelomeningocele. This is the most common type (90%). The spinal cord and the nerve roots protrude outside the spinal canal through a defect in the posterior arch along with the meninges (dura, arachnoid). Other abnormalities of the spinal cord often occur with the myelomeningocele, including duplication of the cord (**diplomelia**) and vertebral bony anomalies, such as defects in segmentation and failure of fusion of vertebral bodies, which cause congenital scoliosis, kyphosis, and kyphoscoliosis.

- 2. Diagnosis.** The diagnosis can be made prenatally by elevated maternal serum α -fetoprotein or by ultrasound, or postnatally by the presence of the lesion in the neonate's back. **A tuft of hair over the neonate's lumbosacral spine or skin dimple may be a sign of underlying anomalies.** Associated conditions are hydrocephalus, Arnold-Chiari malformation, congenital spinal deformity, and tethered cord syndrome. Ambulation is usually lost in upper thoracic or high lumbar lesions and is often preserved in lower lumbar and sacral lesions.

3. **Treatment.** Surgical repair is usually indicated within 48 hours after birth. If hydrocephalus is present, a shunt is required.

C. Torticollis

1. **Definition.** A lateral tilt of the neck and head typically due to a tight sternocleidomastoid muscle. The head and neck tilt toward the involved side, and the chin is turned toward the contralateral side. The most common causes are:
 - a. **Congenital muscular torticollis.** [☼] Fibrosis of the sternomastoid muscle, which may be due to a localized compartment syndrome or uterine packing problems.
 - b. **Vertebral anomalies.** Klippel-Feil syndrome (congenital anomalies of the cervical spine) or congenital occipitocervical anomalies.
2. **Diagnosis.** The diagnosis can be made with the observation of the typical deformity as well as palpation of a tight sternocleidomastoid muscle. A palpable mass in the muscle may appear in the postnatal period and resolve later on. Examination of the neonate for other congenital anomalies (developmental dysplasia of hip [DDH], metatarsus adductus) is essential. Radiographs of the cervical spine should be done to rule out any vertebral anomalies when there is no response to stretching exercises of the sternomastoid. Complications include plagiocephaly with facial asymmetry and restriction of neck movement.
3. **Treatment.** Stretching exercises are successful in 90% of the cases. Surgical correction may be considered in resistant cases after 1 year of age.

II. Upper limb and hand anomalies

A. Radial club hand

1. **Definition.** Radial club hand is a longitudinal partial or complete deficiency of the radius. The typical deformity is radial deviation of the wrist and hand with or without thumb hypoplasia. The ulna is usually short and deformed. It may be associated with thrombocytopenia (TAR [thrombocytopenia with absent radius] syndrome), Fanconi anemia, Holt-Oram syndrome, Nager syndrome, VATER/VACTERL (vertebral defects, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia/vertebral defects, anal atresia, cardiac malformations, tracheoesophageal fistula, renal dysplasia, and limb abnormalities) association, and other skeletal and cardiac abnormalities.
2. **Treatment.** Splinting, stretching, physical therapy, and surgery.

B. Below-elbow amputation (congenital amputation)

1. **Definition.** Below-elbow amputation is a transverse deficiency resulting in the complete absence of the forearm just below the elbow. It is the most common form of congenital amputation (1 in 20,000 newborns has a transverse forearm deficiency). The hand or its remnants can be attached to the proximal forearm. Commonly, it is unilateral with no genetic basis or known cause.
2. **Treatment.** There is no treatment required, although prosthesis fitting may be useful.

C. Polydactyly

1. **Definition.** Polydactyly is duplication of 1 or more fingers. It is most common among African Americans. It may be associated with Ellis-van Creveld syndrome or chromosomal anomalies.
 - a. **Ulnar polydactyly, postaxial type.** [☼] It may affect the little finger. It has an autosomal dominant inheritance with variable penetration.
 - b. **Central polydactyly.** It affects the central 3 fingers (central polydactyly). It typically has autosomal dominant inheritance.
 - c. **Thumb polydactyly, preaxial type.** [☼] It affects the thumb.
2. **Treatment.** Surgical reconstruction is often indicated.

D. Macroductyly

1. **Definition.** Macroductyly is an abnormal enlargement of the digits due to an osseous and/or soft tissue enlargement. Generalized enlargement may be due to a complex vascular malformation or neurofibromatosis. Klippel-Trenaunay-Weber

syndrome (triad of port-wine stain, varicose veins, and bony and soft tissue hypertrophy involving an extremity) and Proteus syndrome are rare syndromes associated with macrodactyly. There are 2 varieties of macrodactyly: 1 presents as a large digit at birth, which grows at a normal growth rate, and in the other, the digit is normal at birth and then grows at a faster rate subsequently.

2. **Treatment.** Surgical reconstruction is usually indicated.

E. Syndactyly

1. **Definition.** Syndactyly [✪] is congenital webbing between the fingers. The fusion may be complete if it extends to the fingertips or complex if it involves the bony elements of the adjacent digits. It may be an isolated anomaly or associated with chromosomal or genetic disorders (eg, trisomies 21, 13, 18; Silver syndrome; Prader-Willi syndrome; or focal dermal hypoplasia). It is more common in boys, often with bilateral involvement. Also, it is more common in the ring and middle fingers than the index finger and thumb.

2. **Treatment.** Surgical reconstruction is often indicated in the first year of life to allow for development of hand function.

III. Hip disorders

A. **Developmental dysplasia of the hip.** [✪] (See also Chapter 7.) A wide spectrum of hip abnormalities ranging from hip instability to frank dislocation. In certain cultures, newborn cradling may be an etiologic factor in DDH (eg, American Indians' use of the cradleboard with the hip extended and adducted). Hip examinations usually demonstrate hip instability. The following tests are used for clinical screening of the neonates:

1. **Ortolani test** (reduction test for the dislocated hip). [✪] The child should be positioned supine with both the knees and hips flexed 90 degrees. The test is then performed with 1 hand stabilizing the pelvis and the other hand with the thumb over the hip adductors and the index finger over the greater trochanter. The hip is slowly abducted, so the dislocated femoral head slips toward the acetabulum, creating reduction (audible and palpable). The positive Ortolani test is a sign of dislocated hip.

2. **Barlow test** (provocative test for the dislocatable hip). [✪] The child is positioned as for the **Ortolani test**. The hip is mildly adducted and pressure is applied posteriorly. If the femoral head slips over the posterior rim of the acetabulum and slides back again into the acetabulum when the pressure is released, this is considered Barlow positive, which means the hip is dislocatable.

3. **Hip ultrasound examination** is indicated for screening of high-risk neonates (Table 112-1), although some clinical communities do ultrasound screening of all children. **Pavlik harness** is the treatment of choice for neonates with dislocated hips (positive Ortolani test). In the majority of Barlow-positive neonates, the hips stabilize in the postnatal period. Neonates with a positive Barlow test should have a repeat clinical and ultrasound examination after 4 weeks. If the hip is not stable at that time, a Pavlik harness should be used. Surgical treatment is rarely indicated in the postnatal period [✪].

B. **Surveillance versus screening.** Surveillance is suggested to replace the term *screening* because it means "close monitoring of someone or something to avoid adverse outcome." In clinical practice, this means periodic physical examinations during the well-child visits. Surveillance should be done until the age of 6 to 9 months. These exams should be supplemented with ultrasound or pelvis x-rays according to the child's age.

C. **Treatment.** Evidence supports screening and treatment of a hip dislocation (positive Ortolani test). It also supports observing instability (positive Barlow test) and mild early forms of dysplasia. The goal is to diagnose hip dislocation/subluxation by 6 months of age by doing periodic physical examinations and selective ultrasonography or radiography, with consultation with pediatric radiology and/or orthopedics.

Table 112–1. RISK FACTORS FOR DEVELOPMENTAL DYSPLASIA OF THE HIP (THE RISK FACTORS HAVE ADDITIVE EFFECT)

Important risk factors:

- Breech presentation
- Female gender
- Incorrect lower extremity swaddling
- Family history of DDH
- Second infant of identical twin if the other had DDH (40% risk), nonidentical twin (3% risk)

Other suggested factors (not found to increase the risk of nonsyndromic DDH):

- First-born infant
- Torticollis
- Foot abnormalities
- Oligohydramnios

DDH, developmental dysplasia of the hip.

1. **Observation** for early milder forms of dysplasia and instability (as seen in positive Barlow test). Observation involves periodic reexamination and possible repeat imaging by a pediatrician or orthopedist. If those infants with a positive Barlow test continue to show clinical instability, they need to be referred to an orthopedist. The majority of hip anomalies seen on ultrasound at 6 weeks to 4 months of age will resolve without treatment. There are no specific recommendations on whether to observe or treat these minor ultrasound findings (minor variations in the alpha and beta angles and subluxation with stress maneuvers).
2. **Treatment for hip dislocation (positive Ortolani test)** is recommended, and it is not an emergency. These infants can follow up with an orthopedist within several weeks of discharge. Hip-abduction braces are usually recommended and do not have to be initiated in the hospital. Use of “triple diapers” (theoretically prevents hip adduction) is not recommended with presumed DDH.
3. **Practice safe swaddling. Avoid traditional/tight swaddling.** Safe swaddling is hip-healthy swaddling (allows for hip motion, hip flexion and abduction, and knee flexion), avoids the forced position of hip extension and adduction, and decreases the risk of DDH.

IV. Lower extremity disorders

A. Proximal focal femoral deficiency [☼]

1. **Definition.** Proximal focal femoral deficiency (PFFD) is a congenital anomaly of the proximal femur and pelvis resulting in a short femur and hip deformity. There is no known genetic etiology. The femoral segment is short, abducted, flexed, and externally rotated. There may be genu valgum and anterior cruciate ligament deficiency of the knee joint. The deformity is bilateral in 15% of cases. Fibular hemimelia may be associated with PFFD.
2. **Treatment.** Either reconstruction (limb lengthening and realignment) or amputation.

B. Fibular hemimelia [☼]

1. **Definition.** This is characterized by congenital complete or partial absence of the fibula. There is no known genetic etiology. The tibia is short with a valgus and procurvatum deformity. There is often a skin dimple at the apex of the deformity. Fibular hemimelia is frequently associated with foot deformities with or without deletion of the lateral foot rays. Equinovalgus foot deformity is the most common associated foot deformity.
2. **Treatment.** Depends on the foot deformity and degree of limb length discrepancy (LLD). The surgical options are limb reconstruction (lengthening and realignment) or amputation of the deformed foot and fitting of a prosthesis.

C. Tibial hemimelia [✧]

1. **Definition.** This is a congenital partial or complete absence of the tibia. The infant usually presents with a short extremity with a rigid equinovarus, supinated foot deformity. [✧] Preaxial polydactyly is a relatively common associated anomaly. Other congenital anomalies may be associated with tibial hemimelia, such as congenital cardiac anomalies and/or spine deformities. It is one of the few congenital limb deformities that have a genetic etiology and is seen with syndromes associated with ectrodactyly (cleft hand and foot deformity).
2. **Treatment.** The surgical options are either reconstruction or knee disarticulation.

D. Posteromedial bowing of the tibia

1. **Definition.** This is a benign condition characterized by a posteromedial bowing of the tibia. It is associated with a calcaneovalgus foot deformity and LLD. The condition should be differentiated from anterolateral bowing of the tibia (associated with congenital pseudarthrosis of the tibia and neurofibromatosis) and from fibular hemimelia.
2. **Treatment.** The natural history is complete resolution of the tibial deformity, although LLD may be significant.

E. Hyperextension deformity of the knee (congenital knee dislocation)

1. **Definition.** It is a rare deformity and varies from a simple hyperextension of the knee to a frank anterior dislocation of the tibia on the femur. It is seen as an isolated deformity and may be associated with other conditions (eg, Larsen syndrome). There is a loss of ability to flex the knee actively or passively. Radiographs are helpful to make the diagnosis and to differentiate simple hyperextension deformities from congenital knee dislocation.
2. **Treatment.** Mild cases respond to serial manipulation and casting. Surgery may be required in severe cases.

V. Foot disorders. Foot disorders are common and require careful assessment for proper diagnosis. Examples of common foot disorders are noted in the following text and in Table 112–2.**A. Syndactyly**

1. **Definition.** Syndactyly is congenital webbing between toes. There are usually no functional problems associated with foot syndactyly. The fusion may be complete if it extends to the toenails or complex if it involves the bony elements of the adjacent digits. It may be associated with polydactyly.
2. **Treatment.** Surgical release is rarely indicated for foot syndactyly.

B. Cleft foot [✧]

1. **Definition.** Cleft foot is due to an absence of the central 2 or 3 rays of the foot. The cone-shaped cleft of the forefoot tapers proximally. Autosomal inheritance is common in bilateral cases and uncommon in unilateral cases. In bilateral cases, the hand may be affected as well.
2. **Treatment.** Surgery may be indicated to improve shoe fitting.

C. Macroductyly [✧]

1. **Definition.** This is an uncommon deformity due to an enlargement of both soft tissue and osseous elements of the toes; it may affect the great toes or lesser toes. The hand may be affected as well.
2. **Treatment.** Debulking (excision of bone and soft tissues) procedures are usually indicated.

D. Constriction band (amniotic band) syndrome

1. **Definition.** This syndrome is due to a tight band around the extremity. It can present in different forms: congenital amputations, acrosyndactyly, clubfoot, and craniofacial defects such as cleft palate (see Figure 93–1).
2. **Treatment.** A surgical release of the tight band. The band may cause acute vascular compromise, and emergency surgical release of the band may be indicated to preserve the neonate's limb.

Table 112-2. DIFFERENTIAL DIAGNOSIS OF COMMON NEONATAL AND NEWBORN FOOT DISORDERS

Foot Deformity	HF	FF	Missing Rays	Flexibility	Treatment	Comments
FH (fibular hemimelia) [☼]	Equinovalgus	Normal or adductus	Lateral rays may be missing	Flexible or rigid	Amputation vs reconstruction	Tibia is short and deformed
CF (clubfoot) [☼]	Equinovarus	1. Adductus, cavus, supination				May be associated with DDH or spine anomalies
	Posterior crease	2. Transverse crease of the midfoot crossing longitudinal arch	No	Rigid	Serial casting	Genetic factors may have role Prenatal diagnosis at 16–20 weeks
VT (vertical talus) [☼]	Equinovalgus	Adductus	No	Very rigid	Serial casting and surgery	Isolated deformity 50% Spina bifida 50% bilateral
MA (metatarsus adductus) [☼]	Normal	Adductus	No	Flexible	No treatment vs serial casting	Associated with DDH or spine anomalies Related to intrauterine packing
CV (calcaneovalgus foot) [☼]	Equinovalgus	Normal	No	Flexible	No treatment vs stretching	May be associated with posteromedial bowing tibia

[☼] Images can be found at www.neonatologybook.com.

Adductus, medial deviation of metatarsus; cavus, increased medial longitudinal arch of the foot; DDH, developmental dysplasia of the hip; equinus, limited ankle dorsiflexion; FF, forefoot; HF, hindfoot; valgus, eversion deformity; varus, inversion deformity.

E. Polydactyly [☼]

1. Definition. Polydactyly is characterized by duplication of 1 or more toes. Preaxial polydactyly refers to a duplication of the great toe; postaxial is a duplication of the fifth toe (the most common type—80%). It is less common in central toes. It is more common in African American children. Fifty percent are bilateral, and 30% of patients have a positive family history. There is an autosomal dominant inheritance with variable expressivity. Foot polydactyly is commonly an isolated deformity but may be associated with other syndromes such as **Ellis-van Creveld syndrome** or trisomy 13. The diagnosis is usually obvious, and radiographs are essential to detect the type of polydactyly (which bony structures are duplicated). Preaxial polydactyly may be associated with tibial hemimelia.

2. Treatment. Amputation of the extra digit is the treatment of choice.

VI. Arthrogryposis multiplex congenita [☼]

A. Definition. It is a syndrome characterized by multiple (at least 2 or more) joint contractures in multiple body areas (literally the word means “curved joints”). The specific etiology is still unknown. Reduced fetal movement is an etiologic factor. The typical newborn has all the extremities affected. The typical joint contractures are internally rotated shoulders, elbow extension, a pronated forearm, and flexion contractures of the wrist and fingers. Lower extremity contractures include flexion and external contracture of the hip, or the hip may be extended and dislocated. The knee may be extended or flexed, and severe foot deformities are common.

1. Treatment. Stretching and splinting are the treatments of choice in early life to avoid fixed deformities.

VII. Birth trauma. Orthopedic injuries or fractures that occur during birth (Table 112–3). Recent reports suggested the use of ultrasound for fracture diagnosis to minimize the risk of radiation exposure. Ultrasound is comparable to x-ray for the detection of fractures and should be used first. It is simple, readily available, and not expensive for detection of birth-related injuries, especially around unossified epiphysis.

A. Clavicular fractures

1. Definition. Clavicular fractures are the most common birth fractures in neonates. These typically occur during delivery with shoulder dystocia or complete extension of the arm in breech presentations or in large infants. The neonate may have minimal symptoms or signs, and the diagnosis may be retrospective with palpation of the callus in the second week of life. The neonate may be irritable with tenderness over the clavicle; there may also be loss of motion of the affected arm, an asymmetric Moro reflex, and pseudo-paralysis. **The radiograph is diagnostic with the fracture at the junction between the middle and outer thirds.** The condition should be differentiated from a humerus fracture or brachial plexus injury. Prognosis is very benign.

2. Treatment. Treatment is immobilization with pinning of the sleeve of the shirt to the chest of the neonate’s clothes for 7 to 10 days.

Table 112–3. RISK FACTORS FOR ORTHOPEDIC-RELATED BIRTH INJURIES^a

Oversized infants >4 kg

Premature infants <37 weeks (due to their fragile bones, which can be easily fractured)

Shoulder dystocia with difficult labor

Cephalopelvic disproportions

Prolonged labor

^aBirth fractures rarely occur below the elbow or below the knee.

B. Humeral and femoral fractures

- 1. Definition.** These fractures are less common than the clavicle fracture. **Both are associated with prolonged labor, extension of the injured extremity during breech presentation, rapid extraction of the infant during fetal distress, and forceps delivery.** The fracture usually occurs through the diaphysis (femur; less commonly the humerus) or through the growth plate (proximal or distal humerus, distal femur). The neonate usually has pain, limitation of movements, pseudo-paralysis, tenderness, and crepitus at the fractured ends. Periarticular fractures can be easily overlooked. The diagnosis is made by radiograph.
- 2. Treatment.** Immobilization of the limb with splints for 3 weeks is satisfactory, and the prognosis is excellent. There is a remarkable remodeling potential and rarely residual shortening or angulation.

C. Brachial plexus injuries

- 1. Definition.** Stretching of the cervical nerve roots during delivery results in brachial plexus injuries. **The condition is usually associated with oversized neonates with a vertex presentation and shoulder dystocia, or after a breech presentation.** The fifth and sixth cervical nerve roots are commonly affected and result in **Erb palsy**. The arm is adducted and internally rotated with elbow extension and forearm pronation with normal hand function. The extremity sensation is intact, and the Moro reflex and biceps reflex are usually absent in the affected limb. If the lower cervical and first thoracic roots are affected, it is called **Klumpke paralysis**. There is a loss of the grasp response of the hand with forearm paralysis, and both are poor prognostic signs. Examination of the other extremities is essential to exclude neonatal quadriplegia. Occasionally, it may be bilateral, especially with breech deliveries. Full muscle testing is essential 48 hours after delivery. **Horner syndrome (eg, decreased pupil size, a drooping eyelid) is usually present on the affected side.** Recovery may occur within 48 hours or it can take up to 6 months. Imaging studies include plain radiograph, computed tomographic myelography, and MRI. Nerve conduction studies may be helpful to differentiate between root avulsion versus neurapraxia. For upper plexus injuries, the biceps function is a marker of spontaneous recovery. A preserved biceps function has a better prognosis. The prognosis depends on the type of injury to nerve roots (neurapraxia, axonotmesis, or neurotmesis) and the extent of nerve involvement and degree of recovery after initial palsy.
- 2. Treatment.** Surgery is rarely indicated in neonates. Surgical options include a microsurgical repair, tendon transfers to replace the weak muscles, or humeral osteotomy to correct the residual deformities in untreated cases.

VIII. Orthopedic infections (osteomyelitis). [☆] Prematurity, skin infections, and a complicated delivery are known risk factors for osteomyelitis. Hematogenous spread is the most common route of spread. The organisms may gain access to the circulation through venous or umbilical catheters, intravenous feeding lines, or invasive monitoring. The infection usually starts in the metaphysis of long bones. Because the nutrient vessels cross the growth plate to supply the epiphysis, septic thrombophlebitis of these vessels can lead to a growth plate injury and growth disturbances later in life. The thin cortex and periosteum of the neonate's bones are poor barriers for infection spread, allowing an infection to be easily spread to the adjacent tissues. When the metaphysis of long tubular bones is intracapsular, these infections usually result in septic arthritis (hip joint, shoulder joints). The osteomyelitis in premature infants or severely ill full-term infants tends to be multifocal with or without septic arthritis (usually 2 or 3 sites). **The most common organism is *Staphylococcus aureus*; the least common organism is group B streptococci, although other organisms may be isolated.** Diagnosis may be difficult due to a lack of symptoms and signs, especially in mild cases, but limitation of movements or pseudo-paralysis and/or local swelling should be taken seriously. Less common presentations are pain on passive motion and abnormal posture of the limb. Once the sepsis is suspected, joint or bone aspiration is indicated to confirm the

diagnosis. Laboratory tests include a complete blood count, erythrocyte sedimentation rate, C-reactive protein, and blood culture. Other diagnostic tools include a plain radiograph (usually normal or might only show a soft tissue swelling), ultrasound, bone scan, or MRI. Surgical drainage is indicated when an abscess is formed. The common sites are hip, shoulder, and knee joints. It is considered a surgical emergency to avoid the long-term results of infection.

113 Osteopenia of Prematurity (Metabolic Bone Disease)

- I. **Definition.** Prematurity affects bone mineralization and bone mineral content (BMC). **Metabolic bone disease (MBD)** of prematurity is a term currently used more often compared with osteopenia of prematurity. MBD is best defined as a decrease in BMC relative to expected level of mineralization for gestational age (GA) with **biochemical** and **radiologic** features. Normal bone is formed by the deposition of minerals, predominantly calcium (Ca^{2+}) and phosphorus (P), onto an organic matrix (osteoid) secreted by the osteoblasts. Osteoclasts play an important role in bone resorption and remodeling. Although osteopenia and rickets result in decreased bone mineralization and may have similar clinical findings, they are not identical processes and thus the term *rickets of prematurity* is not used in this chapter. Osteopenia or MBD is principally a result of inadequate Ca^{2+} and P intake to meet bone growth demands. Rickets, however, is principally due to vitamin D deficiency; vitamin D supplementation alone will not resolve either osteopenia or rickets. Both disease processes involve the utilization of Ca^{2+} , P, and vitamin D.
 - A. **Osteopenia** refers to a decrease in the amount of organic bone matrix (osteoid) due to a decrease in the thickness or number of trabeculae and/or decreased thickness of the bone cortex. These can be due to either insufficient deposition or increased resorption of the organic bone matrix. Bone mineral density is the amount of minerals per square centimeter of bone (measured as T-scores [the number of standard deviations (SDs) above or below the mean of a healthy adult of the same sex] or Z-scores [the number of SDs above or below the mean compared with someone with the same age, gender, weight, and ethnicity]). Osteopenia is defined as bone density with as a score of -1 to -2.5 .
 - B. **Osteomalacia** refers to the lack of *mineralization* of the organic bone matrix resulting in accumulation of nonmineralized osteoid and softening of bones. *When involving the growth plate*, it results in **rickets**. Bone density and BMC are both decreased.
 - C. **Osteoporosis**. Refers to a decrease in bone mineral density (T-scores) <2.5 standard deviations from the norm (adults). There is no accepted definition of osteoporosis in infants.
- II. **Incidence.** The current incidence of MBD in very low birthweight (VLBW; <1500 g) infants is unknown because there is no universal consensus on its definition and no large population-based or network-based studies have addressed this issue. However, due to improvements in nutritional management such as initiation of early feedings, changes in nutritional formulas, and initiation of early parenteral nutrition, the current incidence of MBD may be decreasing. MBD is now more commonly seen in extremely low birthweight (ELBW; <1000 g) infants and those with chronic illnesses such as bronchopulmonary dysplasia/chronic lung disease and necrotizing enterocolitis.

Previous studies have reported osteopenia to occur in 23% of VLBW infants and in 55% to 60% of ELBW infants. A more recent prospective study found mild MBD (alkaline phosphatase [ALP] >500 IU/L and P \geq 4.5 mg/dL) in 13.7% and severe MBD (ALP >500 IU/L and P <4.5 mg/dL) in 3.3% of VLBW infants. Fractures have been reported previously in up to 10% of VLBW infants but are likely to be less common now. A recent multicenter retrospective study from England found evidence of rib fractures in approximately 2% of ex-preterm infants (median GA at birth, 26 weeks; median corrected GA at time of chest radiograph, 39 weeks).

III. Pathophysiology. Intrauterine bone formation occurs either as endochondral ossification (axial and appendicular skeleton) with the deposition of an osteoid matrix with a cartilaginous core or as membranous matrix without the cartilaginous precursors (skull, maxilla, mandible). Several vitamins (A, C, D), cytokines, minerals (Ca²⁺, P), and hormones (thyroid hormone, estrogen, calcitonin, growth hormone, parathyroid hormone [PTH]-related peptide) play important roles in fetal bone growth. The placenta is essential to fetal nutrient and mineral accretion. Conditions that affect placental sufficiency directly impact fetal mineral accretion.

A. An increase in trabecular thickness and bone volume occurs faster in utero compared with ex utero. After birth, bone growth is secondary to cyclical bone formation and resorption. In the first year, bone growth occurs by increases in length and diameter but with a decrease in cortical thickness; however, there is an overall 3-fold increase in bone strength. This adaptation occurs earlier in preterm infants than in term infants. Mineral retention is affected more than linear growth, contributing to a reduction in bone density following preterm birth. In preterm infants, the BMC remains lower at term-equivalent than for full-term infants.

B. Approximately 99% of body calcium and 80% of phosphorus is in the skeleton at a term birth, and nearly 80% of this transfer occurs between 25 weeks' gestation and term. Fetal accretion rate for Ca²⁺ (120 mg/k/d) and P cannot be met ex utero. Further, inadequate intake (Ca²⁺ and P) in the face of increased growth demands results in nutrient deficiency.

C. Genetics and bone disease. In adults and in VLBW infants, osteoporosis is associated with polymorphisms involving *VDR*, *ER*, and *COL1A1* genes. In VLBW infants, homozygous allelic variants of ER α genotype with a low number of thymidine-adenine repeats [(TA)*n*] were correlated with high urinary pyridinoline crosslink levels (indicating increased bone resorption) and with the development of MBD. The locus interaction between *VDR* and *COL1A1* was found to be protective in the development of bone disease.

IV. Risk factors

A. Fetal and neonatal causes

1. Prematurity and low birthweight. Preterm birth interrupts placental transfer of minerals to the newborn resulting in Ca²⁺ and P deficiency. Physiologic adaptation following preterm birth also increases bone reabsorption. **The frequency of MBD is inversely related to GA and birthweight.** Both conditions predispose these infants to mineral deficiencies in the face of increased nutritional and growth requirements.

2. Feeding practices. Delayed enteral feeding, prolonged use of parenteral nutrition, use of unfortified human milk, enteral feeding restrictions, and malabsorption states can result in mineral deficiencies. Chronic metabolic acidosis increases bone reabsorption. A recent multicenter study found that **widespread hypophosphatemia and MBD were associated with elemental formula (Neocate)** use in infants; presumably due to impaired bioavailability of formula P.

3. Human milk is low in P, and donor milk content is even lower compared with preterm maternal milk. Prolonged use can result in low serum P levels and decreased incorporation into the organic bone matrix. Unfortified human milk cannot match the mineral accretion that can be achieved across the placenta.

4. **Drugs.** Corticosteroids, furosemide, and methylxanthines are commonly used in preterm infants and cause mobilization of Ca^{2+} from the bone, resulting in decreased BMC.
 5. **Lack of mechanical stimulation.** Bone growth requires mechanical stimulation that is interrupted by preterm birth, illness, sedation, and paralysis. Neurologically impaired infants with spina bifida or arthrogryposis with limited mobility have poor bone growth.
 6. **Vitamin D.** Preterm infants can absorb vitamin D and convert 25-OH to 1,25-dihydroxy vitamin D. Vitamin D is also converted to 1,25-dihydroxycholecalciferol in the placenta, which is important in the transfer of P to the fetus. Generally, **MBD of prematurity is not secondary to vitamin D deficiency.** Postnatal vitamin D deficiency may occur in breast-fed infants without fortification due to low levels (25–50 IU/L) in breast milk. Other causes of vitamin D deficiency in preterm infants include the following:
 - a. **Renal (osteodystrophy) disorders.**
 - b. **Drugs such as phenytoin and phenobarbital** increase vitamin D metabolism.
 - c. **Pseudo-vitamin D deficiency** (absence of 1- α hydroxylase enzyme that converts 25-OH to 1,25-dihydroxy vitamin D [type I] or tissue resistance to 1,25-dihydroxy vitamin D [type II]).
 7. **Aluminum contamination of parenteral nutrition.**
 8. **Malabsorption of vitamin D and calcium** can occur in infants with prolonged cholestasis and short gut syndrome.
- B. Maternal factors**
1. **Maternal deficiency of vitamin D results in low fetal levels.** Maternal vitamin D deficiency in Europe, particularly in the winter, is associated with a low total BMC and a decreased intrauterine long bone growth. Maternal vitamin D status may also influence head circumference (at 3–6 months) and BMC at 9 years of age.
 2. **Maternal smoking, thin body habitus,** low Ca^{2+} intake, and increased physical activity in the third trimester result in a decreased BMC in the fetus.
 3. **Exposure to high doses of magnesium** in utero, preeclampsia, chorioamnionitis, and placental infections are associated with osteopenia.
 4. **Higher incidence of postnatal rickets** is seen in infants with **fetal growth restriction** (chronic damage to the placenta may alter P transport).
 5. **Placental hormones including estrogen** and PTH and PTH-related protein also play a role.
- V. Clinical presentation.** Clinically, osteopenia manifests between 6 and 12 weeks of age and is usually asymptomatic; however, signs may include the following:
- A. Severe manifestations**
1. **Poor weight gain and growth failure.**
 2. **Rickets-like findings** may include growth retardation, frontal bossing, craniotables, prominence of the costochondral junction (rachitic rosary), and epiphyseal widening.
 3. **Fractures** may manifest as pain on handling.
 4. **Respiratory difficulties** or failure to wean off ventilator support due to poor chest wall compliance.
- B. Consequences of osteopenia.** Osteopenia can result in myopia of prematurity due to alterations in the shape of the skull. In childhood, infants remain thinner and shorter with a decreased total BMC and density. Increased urinary Ca^{2+} excretion has also been reported.
- VI. Diagnosis**
- A. Radiographs.** Osteopenia may be seen subjectively on radiographs obtained for other indications. Objective changes are not seen until a 20% to 40% decrease in bone mineralization occurs. Thin “washed-out” bones, cupping, fraying, and rarefaction of the end of long bones may occur. Subperiosteal new bone formation

and fractures may also be visible. Serial radiographs in 3 to 4 weeks may be useful for follow-up. A radiologic scoring system has also been developed but is not well validated.

- B. Screening.** The American Academy of Pediatrics Committee on Nutrition (AAP-CON) recommends screening all VLBW infants for MBD with serum P and ALP starting at 4 to 5 weeks of age and biweekly thereafter until stable and down trending ALP. Other high-risk infants (eg, prolonged total parenteral nutrition use [>4 weeks], cholestasis, exposure to chronic steroids or diuretics, unable to reach full fortified enteral feeds by 4 weeks, elemental formula feeding) should be screened as well.

C. Biochemical markers of bone turnover

1. Markers of bone activity

- a. Calcium levels** usually remain normal until late in the course.
- b. Phosphorous.** Serum P levels are low (<4 mg/dL) in this disease. Low P levels have low sensitivity but high specificity. Low levels of inorganic phosphate <1.8 mmol/L with elevated ALP may be more specific for diagnosing inadequate intake. Phosphate deficiency may be the earliest sign of poor mineralization. Some experts also recommend measuring urine P and calculating tubular reabsorption of phosphate, which is elevated ($>95\%$) in MBD.
- c. Alkaline phosphatase.** Serum ALP is the sum of 3 isoforms (liver, intestine, and bone). The bone isoform contributes to the largest proportion (90%). ALP in infants can be up to 5 times the normal adult values. Elevated levels can be due to both osteoblastic and osteoclastic activity. The use of bone-specific isoform has not been found to improve sensitivity for predicting the development of osteopenia. Serial monitoring of ALP may be helpful in diagnosing osteopenia, with levels >500 IU/L suggestive in ELBW infants. ALP is also negatively correlated with P levels in MBD.
- i. Elevated levels of alkaline phosphatase** can be seen with normal growth, healing rickets, fractures, or copper deficiency.
- ii. Low levels of alkaline phosphatase are seen with zinc deficiency,** severe malnutrition, and congenital hypophosphatasia.
- iii. Isolated elevation in alkaline phosphatase** without Ca^{2+} and P derangements may occur with transient hyperphosphatasemia of infancy.
- iv. Elevated alkaline phosphatase >900 IU/L and low phosphorous (<4.6 mg/dL)** have high sensitivity (100%) but low specificity (70%) for diagnosing low bone density. **Very high levels (>1200 IU/L) have been associated with short stature in childhood.**
- d. Parathyroid hormone** may be an early marker with better sensitivity than ALP in screening for MBD. In 1 study, at 3 weeks of chronologic age, a PTH level >180 mg/dL $^{-1}$ or a P level <4.6 pg/mL $^{-1}$ yielded a sensitivity of 100% and specificity of 94% for severe MBD.
- e. 1,25-Dihydroxy vitamin D levels** are elevated with osteopenia. Routine measurement of vitamin D or its metabolites is not recommended.
- f. Osteocalcin (marker for osteoblastic activity)** may be elevated.

2. Markers of bone resorption

- a. Urinary calcium and phosphorous.** Extreme prematurity is associated with a low P threshold and an increased excretion even with low serum P levels. High tubular resorption of P suggests inadequate intake. Urinary Ca^{2+} excretion >1.2 mmol/L and inorganic phosphate at >0.4 mmol/L suggest a high bone mineral accretion.
- b. Crosslinked carboxy-terminal telopeptide of type I collagen,** urinary pyridinium crosslink products, crosslinked N-telopeptides of type I collagen, and pyridinoline crosslinks of collagen are markers for bone resorption but are in limited clinical use.

3. **Bone mineral density.** Reference values for bone mineral densities in healthy preterm infants with normal ALP levels have been developed that correlate with dual-energy x-ray absorptiometry (DEXA). A normal bone mineral density >0.068 g/cm² has a high negative predictive value for developing MBD.
- D. **Ultrasound.** A quantitative ultrasound, using a broadband ultrasound measurement, speed of sound (SOS), or bone transmission time, has been used. However, SOS cannot be used as surrogate for DEXA.
 1. **Advantages.** Ultrasound offers several advantages, including easy accessibility and lack of exposure to ionizing radiation. It uses peripheral sites such as the calcaneus and tibia. It measures both qualitative and quantitative bone properties, such as bone mineralization and cortical thickness, respectively, in addition to bone mass (osteopenia), elasticity, and microarchitecture.
 2. **Speed of sound is most commonly used.** The SOS decreases in preterm infants from birth to term (corrected age) and is suggestive of decreased BMC. Inverse correlation between tibial SOS at birth and serum ALP has also been noted. Higher Ca²⁺ intake may inversely affect the decline in SOS noted after preterm birth.
- E. **Dual-energy x-ray absorptiometry.** It is the gold standard used to assess both bone size and bone mineral status and can predict risk of fractures in newborn infants. Normative data and guidelines for use in infants are lacking, making interpretation of results difficult. Disadvantages also include expense, radiation, and possible need for sedation.

VII. Management

- A. **Feeding and nutritional practices.** Establishment of early enteral feeding, decreasing length of parenteral nutrition, fortification of human milk, and using specialized preterm formula can limit osteopenia. Postdischarge use of specially designed preterm or transitional formulas (see also Chapter 11 on nutrition) and human milk fortification promotes mineralization. AAP-CON recommends Ca²⁺ (150–220 mg/kg/d) and P (75–140 mg/kg/d) supplementation to achieve adequate *retention* levels. This is usually achieved by feeding preterm formula/fortified human milk at 160 mL/kg/d. Calcium gluconate and sodium or potassium phosphate supplements are suitable choices for infants who require intravenous administration. Occasionally, additional enteral supplements are needed based on P and ALP level. Care should be taken to avoid adding them directly to milk to prevent precipitation. Adequate vitamin D intake is also essential.
- B. **Vitamin D.** Vitamin D sufficiency in mothers is important to prevent deficiency in the fetus. Requirements have been reported to vary between 150 and 1000 IU/d of vitamin D. AAP-CON recommends that infants should receive 200 to 400 IU/d of vitamin D.
- C. **Physical activity/stimulation.** Mechanical stimulation by passive exercises to improve bone mineralization has yielded conflicting outcomes. Improved weight gain and length but not head circumference have been reported with some improvements in BMC, bone length, and bone area in individual studies. A recent Cochrane review concluded that current evidence does not justify the standard use of physical activity programs in preterm infants.
- D. **Minimize use of furosemide and corticosteroids.** The use of thiazide diuretics, although of theoretical advantage, has not been shown to prevent osteopenia.
- E. **Malabsorption.** Infants at risk of cholestasis and malabsorption may benefit from additional supplementation with fat-soluble vitamins and use of a specialized formula to facilitate fat absorption.

- VIII. **Prognosis.** MBD appears to be decreasing with improved prevention and treatment practices. BMC remains 25% to 70% lower at term in the extremely premature infants. Catch-up mineralization occurs by 6 months of age. Long-term follow-up suggests that bone growth and adult height may also be impacted in these infants.

114 Patent Ductus Arteriosus

- I. Definition.** The ductus arteriosus is a large vessel that connects the main pulmonary trunk (or proximal left pulmonary artery) with the descending aorta, some 5 to 10 mm distal to the origin of the left subclavian artery. In the fetus, it serves to shunt blood away from the lungs and is essential (closure in utero may lead to fetal demise or pulmonary hypertension). In full-term healthy newborns, functional closure of the ductus occurs rapidly after birth. Final functional closure occurs in almost half of full-term infants by 24 hours of age, in 90% by 48 hours, and in all by 96 hours after birth. **Patent ductus arteriosus (PDA) refers to the failure of the closure process and continued patency of this fetal channel.**
- II. Incidence.** The incidence varies according to means of diagnosis (eg, clinical signs vs echocardiography).
- A. Factors associated with increased incidence of patent ductus arteriosus**
- 1. Prematurity.** The incidence is inversely related to gestational age. PDA is found in approximately 45% of infants <1750 g; in infants weighing <1000 g, the incidence is closer to 80%.
 - 2. Respiratory distress syndrome and surfactant treatment.** The presence of respiratory distress syndrome (RDS) is associated with an increased incidence of a PDA, and this is correlated with the severity of RDS. After surfactant treatment, there is an increased risk of a clinically symptomatic PDA; moreover, surfactant may lead to an earlier clinical presentation of a PDA.
 - 3. Fluid administration.** An increased intravenous fluid load in the first few days of life is associated with an increased incidence of PDA.
 - 4. Asphyxia.**
 - 5. Congenital syndromes.** PDA is present in 60% to 70% of infants with congenital rubella syndrome. Trisomy 13, trisomy 18, Rubinstein-Taybi syndrome, and XXXXX (penta-X) syndrome are associated with an increased incidence of PDA.
 - 6. High altitude.** Infants born at a high altitude have an increased incidence of PDA.
 - 7. Congenital heart disease.** A PDA may occur as part of a congenital heart disease (eg, coarctation, pulmonary atresia with intact septum, transposition of the great vessels, or total anomalous pulmonary venous return).
- B. Factors associated with a decreased incidence of patent ductus arteriosus**
- 1. Antenatal steroid administration**
 - 2. Fetal growth restriction**
 - 3. Prolonged rupture of membranes**
- III. Pathophysiology.** In the fetus, the ductus is essential to divert blood flow from the high-resistance pulmonary circulation to the descending aorta. After birth, functional closure of the ductus occurs within hours (but up to 3–4 days). The patency of the ductus depends on the balance between the various constricting effects (eg, of oxygen) and the relaxing effects of various substances (most importantly, the prostaglandin E family). The effects of oxygen and prostaglandins vary at different gestational ages. Oxygen has less of a constricting effect with decreasing gestational age. However, the sensitivity of the ductus to the relaxing effects of prostaglandin E₂ is greatest in immature animals (and decreases with advancing gestational age). In term infants, responsiveness is lost shortly after birth, but this does not occur in the immature ductus. Indomethacin constricts the immature ductus more than it does in the close-to-term ductus.
- The magnitude and direction of the ductus shunt are related to the vessel size (diameter and length), the pressure difference between the aorta and the pulmonary artery, and the ratio between the systemic and pulmonary vascular resistances. The clinical features associated with a left-to-right ductal shunt depend on the magnitude of the shunt and the

ability of the infant to handle the extra volume load. Left ventricular output is increased by the extra volume return. The increase in pulmonary venous return causes an increase in ventricular diastolic volume (preload). Left ventricular dilation will result, with an increase in left ventricular end-diastolic pressure and a secondary increase in left atrial pressure. This may eventually result in left heart failure with pulmonary edema. Eventually, these changes may lead to right ventricular failure. With a PDA, there is also a redistribution of systemic blood flow secondary to retrograde aortic flow (ductal steal, or “run off”). Renal and mesenteric blood flows are thus reduced, as is cerebral blood flow.

IV. Risk factors. See Section II.

V. Clinical presentation. The initial presentation may be at birth but is usually on days 1 to 4 of life. The cardiopulmonary signs and symptoms are as follows:

- A. Heart murmur.** The murmur is usually systolic and heard best in the second or third intercostal space at the left sternal border. The murmur may also be continuous and sometimes heard only intermittently. Frequently, it may be necessary to disconnect the infant from mechanical ventilation to appreciate the murmur.
- B. Hyperactive precordium.** The increased left ventricular stroke volume may result in a hyperactive precordium.
- C. Bounding peripheral pulses and increased pulse pressure.** The increased stroke volume with diastolic runoff through the PDA may lead to these signs.
- D. Hypotension.** A PDA is associated with a decreased mean arterial blood pressure. In some infants (particularly those of extremely low birthweight), hypotension may be the earliest clinical manifestation of a PDA, sometimes without a murmur (ie, the “silent” PDA).
- E. Respiratory deterioration.** Respiratory deterioration after an initial improvement in a small premature infant with RDS should arouse suspicion of a PDA. The deterioration may be gradual (days) or brisk (hours) but is usually not sudden (as in pneumothorax). PDA may similarly complicate the respiratory course of chronic lung disease.
- F. Other signs.** These may include tachypnea, crackles, or apneic spells. If the PDA is untreated, the left-to-right shunt may lead to heart failure with frank pulmonary edema and hepatomegaly.

VI. Diagnosis

- A. Echocardiography.** Two-dimensional echocardiography combined with Doppler ultrasonography is by far the most sensitive means of diagnosing a PDA. The ductus can be directly visualized, and the direction of flow may be demonstrated. In addition, echocardiography can assess the secondary effects of the PDA (eg, left atrial and ventricular size) and contractility. The echocardiogram will also rule out alternative or additional cardiac diagnoses.
- B. Imaging studies.** On initial presentation, the chest film may be unremarkable, especially if the PDA has occurred against a background of preexisting RDS. Later, pulmonary plethora and increased interstitial fluid may be noted with subsequent florid pulmonary edema. True cardiomegaly is usually a later sign.

VII. Management

- A. Ventilatory support.** Respiratory distress secondary to a PDA may require intubation and mechanical ventilation. If the infant is already ventilated, the PDA may lead to increased ventilatory requirements. These should be determined by blood gases. Increasing positive end-expiratory pressure is helpful in controlling pulmonary edema.
- B. Fluid restriction.** Decreasing fluid intake as far as possible decreases the PDA shunt as well as the accumulation of fluid in the lungs. Increased fluid intake in the first few weeks of life is associated with an increased risk of patency of the ductus in premature infants with RDS.
- C. Increasing hematocrit.** Increasing the hematocrit (Hct) above 40% to 45% will decrease the left-to-right shunt. Frequently, an increase in Hct abates some of the signs of the PDA (eg, the murmur may disappear).

D. Indomethacin. A prostaglandin synthetase inhibitor that has proved to be effective in promoting ductal closure. Its effectiveness is limited to premature infants and also decreases with increasing postnatal age; thus, it has limited efficacy beyond 3 to 4 weeks of age, even in premature infants. There are essentially 3 approaches to administering indomethacin for ductal closure in premature infants: **prophylactic, early symptomatic, and late symptomatic.** **Note:** There are minor variations in dosage regimens, and what follows are guidelines. Pharmacologic information on indomethacin can be found in Chapter 155.

1. **Prophylactic indomethacin.** A dose of 0.1 mg/kg/dose is given intravenously (infused over 20 minutes) every 24 hours from the first day of life for 6 days. In this regimen, indomethacin is given prophylactically to all infants <1250 g birthweight who have received surfactant for RDS (before any clinical signs suggestive of PDA). It would also be appropriate to limit this regimen to infants with RDS who are <1000 g birthweight. Clinical trials have shown that this treatment is safe and effective in reducing the incidence of symptomatic PDA in these infants. The major drawback is that up to 40% of these infants probably would never have had a symptomatic PDA and hence did not require treatment.
2. **Early symptomatic indomethacin.** Infants are given indomethacin, 0.2 mg/kg intravenously (infused over 20 minutes). Second and third doses are given 12 and 36 hours after the first dose. The second and third doses are 0.1 mg/kg/dose if the infant is <1250 g birthweight and <7 days old. If the infant is either >7 days old or >1250 g, the second and third doses are also 0.2 mg/kg/dose. Indomethacin is given if there is any clinical sign of a PDA (eg, a murmur) and before there are signs of overt failure. This is usually on days 2 to 4 of life.
3. **Late symptomatic indomethacin.** Infants are given indomethacin when signs of congestive failure appear (usually at 7–10 days). Dosage is as described in Section VII.D.2. The problem with this approach is that if indomethacin fails to constrict the ductus significantly, there is less opportunity for a second trial of indomethacin, and the infant is more likely to require surgery.
4. **Ductus reopening and indomethacin failure.** In 20% to 30% of infants, the ductus reopens after the first course of indomethacin. In such cases, a second course of indomethacin may be worthwhile because a significant proportion of these infants have their PDA closed with this course. The ductus is more likely to reopen in infants of very low gestational age and in those who had received a greater amount of fluids previously. Infection and necrotizing enterocolitis (NEC) are also risk factors for ductus reopening (and may be contraindications for indomethacin).
5. **Complications of indomethacin**
 - a. **Renal effects.** Indomethacin causes a transient decrease in the glomerular filtration rate and urine output. In such cases, fluid intake should be reduced to correct for the decreased urine output, which should improve with time (usually within 24 hours).
 - b. **Gastrointestinal bleeding.** Stools may be heme positive after indomethacin. This is transient and usually of no clinical significance. Indomethacin is a mesenteric vasoconstrictor, but the PDA itself also decreases mesenteric blood flow. In most trials of indomethacin, there was no increased incidence of NEC.
 - c. **Spontaneous intestinal perforation.** Indomethacin exposure has been associated with spontaneous intestinal perforation, especially when the drug was given early or when given together with postnatal corticosteroids. Caution is warranted, although none of the randomized trials comparing indomethacin with placebo have shown this finding.

d. Platelet function. Indomethacin impairs platelet function for 7 to 9 days regardless of platelet number. In the various trials of indomethacin, there is no increased incidence of intraventricular hemorrhage (IVH) associated with the drug, and there is no evidence that it extends the degree of preexisting IVH. Nevertheless, it may be unwise to impose additional platelet dysfunction in infants who are also significantly thrombocytopenic.

6. Indomethacin contraindications

a. Serum creatinine >1.7 mg/dL.

b. Frank renal or gastrointestinal bleeding or generalized coagulopathy.

c. Necrotizing enterocolitis.

d. Sepsis. All anti-inflammatory drugs should be withheld if there is sepsis. Indomethacin may be given once sepsis is controlled.

E. Ibuprofen. Another nonselective cyclooxygenase inhibitor that closes the ductus in animals. Clinical studies have shown that ibuprofen is as effective as indomethacin for the treatment of PDA in preterm infants. It has an advantage in that it does not reduce mesenteric and renal blood flow as much as indomethacin and is associated with fewer renal side effects. Urine output is higher and serum creatinine is lower in infants treated with ibuprofen compared with those treated with indomethacin. However, in trials comparing indomethacin with ibuprofen, no differences were found in incidence of significant clinical side effects (eg, NEC, renal failure, IVH). Choice of 1 drug over the other is largely a matter of institutional preference and may be often based on physiologic rather than clinical considerations. The dose used is an initial dose of 10 mg/kg followed by 2 doses of 5 mg/kg each after 24 and 48 hours if treatment is given in the first week of life. Due to change in pharmacokinetics, dosages of 18 mg/kg, 9 mg/kg, and 9 mg/kg at 24-hour intervals have been recommended when given in the second week of life.

F. Acetaminophen (Paracetamol) acts by inhibiting prostaglandin synthetase at its peroxidase segment, thereby reducing the production of prostaglandin E_2 . It is unknown whether this is the only mechanism whereby acetaminophen affects the PDA. However, a number of recent studies, both observational and randomized controlled, have shown that acetaminophen has a success rate comparable to that of ibuprofen in closing the PDA. Although the optimal dosage has yet to be ascertained, a common protocol for intravenous acetaminophen is a loading dose of 20 mg/kg followed by doses of 10 mg/kg every 6 hours for a duration of 3 days. Dosage may be continued for a further 3 days if the PDA remains open. For extremely premature babies (<28 weeks), it may be prudent to increase the interval between doses to 8 to 12 hours. For older neonates, dosages of 15 mg/kg have also been suggested. Acetaminophen can also be given orally, and in that form, dosage of 15 mg/kg/dose given every 6 to 8 hours has been used. Case series have suggested that acetaminophen may be useful in some cases where the postnatal age may mitigate against the success rate of indomethacin or ibuprofen or in cases where there is contraindication to their use. The primary concern in using acetaminophen in premature neonates is the potential for hepatic dysfunction. Although current data suggest that the drug is safe, there are still insufficient data, especially in extremely low birthweight neonates, and it may be prudent to monitor liver enzymes.

G. Surgery. Surgery should be performed in patients with a hemodynamically significant PDA in whom medical treatment has failed or in whom there is a contraindication to the use of indomethacin. Surgical mortality is low (<1%). However, some observational studies have suggested that surgical ligation is associated with an increased risk of chronic lung disease and neurodevelopmental/neurosensory impairment in extremely premature infants. It is not clear whether this association is causal or whether the need for ligation served as a marker for a higher risk subgroup of patients. However, a recent large observational study has suggested that surgical ligation of the PDA does not carry an additional burden of mortality or morbidity.

H. Patent ductus arteriosus in the full-term infant. PDA accounts for approximately 10% of all congenital heart disease in full-term infants. The PDA in a full-term infant is structurally different, which may explain why it does not respond appropriately to the various stimuli for closure. Indomethacin is usually ineffective. The infant should be monitored carefully, and surgical ligation should be considered at the earliest signs of significant congestion. Even without signs of failure, the PDA should be ligated before 1 year of age to prevent endocarditis and pulmonary hypertension.

I. Should the ductus be treated? (*Controversial*) The issues of when and whether to treat the PDA in the preterm infant are matters of ongoing controversy. There is no doubt that there is an association between the PDA and various morbidities of the premature infant. However, there is a debate about whether this relationship is a causal one and hence whether treatment is likely to be of benefit. Numerous controlled trials have failed to show clinical benefit to the pharmacologic closure of the symptomatic PDA in terms of duration of mechanical ventilation, incidence of bronchopulmonary dysplasia/chronic lung disease, NEC, retinopathy of prematurity, or length of hospitalization. Early pharmacologic closure is, unsurprisingly, associated with a decreased need for later surgical ligation (and hence surgical morbidities). Meta-analyses have confirmed these findings. The only beneficial effect of very early prophylactic treatment with indomethacin appears to be a reduction in the incidence of severe pulmonary hemorrhage and of severe IVH, and even this does not necessarily translate into improved long-term neurodevelopmental outcome. Hence, there has been an increasing trend, over the past few years, to leave many cases of PDA untreated in the neonatal period and during the neonatal intensive care unit stay. However, a differing overview and analysis of the clinical trials carried out to date and controlled observational data have suggested that prolonged exposure to a large PDA is associated with a prolonged need for supplemental oxygen or mechanical ventilation. In addition, studies in premature baboons have shown diminished alveolar development and impaired pulmonary mechanics in animals exposed to a moderate PDA for 14 days. The impaired alveolarization and pulmonary mechanics were attenuated by pharmacologic closure of the PDA (but not by surgical ligation). It is thus possible that the adverse effects of the ductus would be primarily seen in those infants destined to have either a PDA with a sizable shunt and/or prolonged exposure to significant ductal patency. Thus, only a subgroup of neonates may require treatment. Various attempts to identify such a select subgroup of high-risk neonates who might benefit from treatment have been made using a variety of clinical and echocardiographic criteria or biochemical ones (eg, B-type natriuretic peptide). However, no outcomes-based randomized controlled trials have been done to demonstrate improved outcomes with selective treatment based on these criteria.

J. Feeding infants with patent ductus arteriosus (or on treatment) (*controversial*). Given the physiologic effects of the PDA, and medications used to treat it, on intestinal blood flow, there is no consensus regarding whether feedings should be withheld or continued in the presence of a PDA or during its treatment. Data are lacking, and there is wide variability in clinical practice.

VIII. Prognosis. Prognosis is excellent in infants who only have a PDA. Studies show that premature infants <30 weeks have a spontaneous closure of the PDA 72% of the time. Conservative treatment (with medication) has a closure rate of approximately 94%.

115 Persistent Pulmonary Hypertension of the Newborn

- I. **Definition.** Persistent pulmonary hypertension of the newborn (PPHN) is a condition characterized by marked pulmonary hypertension resulting from elevated pulmonary vascular resistance (PVR) and altered pulmonary vasoreactivity, leading to right-to-left extrapulmonary shunting of blood across the foramen ovale and the ductus arteriosus, if it is patent. It is associated with a wide array of cardiopulmonary disorders that may also cause intrapulmonary shunting. When this disorder is of unknown cause and is the primary cause of cardiopulmonary distress, it is often called idiopathic PPHN or persistent fetal circulation.
- II. **Incidence:** 2 to 6 per 1000 live births.
- III. **Pathophysiology.** PPHN may be the result of underdevelopment of the lung together with its vascular bed (eg, congenital diaphragmatic hernia and hypoplastic lungs), maladaptation of the pulmonary vascular bed to the transition occurring around the time of birth (eg, various conditions of perinatal stress, hemorrhage, aspiration, hypoxia, and hypoglycemia), and maldevelopment of the pulmonary vascular bed in utero from a known or unknown cause. It is convenient to think in terms of this basic pathologic classification. However, the clinical manifestations of PPHN are often not attributable to a single physiologic or structural entity, and many disorders exhibit >1 underlying pathology. Often, even when there is evidence of perinatal or postnatal stress (eg, meconium aspiration), the underlying cause of PPHN had been secondary to an in utero process of some duration.

Preacinar arteries are already present in the lungs by 16 weeks' gestation; thereafter, respiratory units are added with further growth of the appropriate arteries. Muscularization, differentiation, and growth of the peripheral pulmonary arteries are influenced by numerous trophic factors (eg, fibroblast growth factors) and by changes that occur in the connective tissue matrix. The lungs of infants with PPHN contain many undilated precapillary arteries, and pulmonary arterial medial thickness is increased. There may be extension of muscle in small and peripheral arteries that are normally nonmuscular. After a few days, there is already evidence of structural remodeling with connective tissue deposition.

In the fetus, PVR is high, and only 5% to 10% of the combined cardiac output flows into the lungs, with most of the right ventricular output crossing the ductus arteriosus to the aorta. After birth, with expansion of the lungs, there is a sharp drop in PVR, and pulmonary blood flow increases approximately 10-fold. The factors responsible for maintaining high PVR in the fetus and for effecting the acute reduction in PVR that occurs after birth are incompletely understood. Fetal and neonatal pulmonary vascular tone is modulated through a balance between vasoconstrictive and vasodilatory stimuli. Vasoconstrictive stimuli include various products of arachidonic acid metabolism (eg, thromboxane) and the endothelins (ETs). The hemodynamic effects of the ETs are mediated by at least 2 receptors: ET-A and ET-B. The fetal lung also produces a number of cyclooxygenase-dependent metabolites that function as pulmonary vasodilators (eg, prostaglandin [PG] I₂, PGE₁, and PGE₂). It has also become clear that the endothelium (and its interaction with vascular smooth muscle cells) plays a crucial role in regulating pulmonary vascular tone. Nitric oxide (NO), a potent vasodilator, is synthesized from L-arginine by endothelial NO synthase. NO stimulates soluble guanylate cyclase, which produces cyclic guanosine monophosphate (cGMP) and causes vasodilation. cGMP, in turn, is hydrolyzed by cyclic nucleotide phosphodiesterases (PDEs), and manipulation of these controls the intensity and duration of cGMP action. Various isoenzymes of

PDE have been identified, and inhibition of PDE type 5 (PDE5; by, eg, sildenafil) causes pulmonary vasodilation.

In summary, for successful pulmonary circulatory transition to occur, various mechanical, physiologic, and biochemical factors, which maintain high fetal PVR, must be eliminated or reversed. Major events are the replacement of the fluid-filled lung of the fetus with the air-filled postnatal lung, the increase in oxygen tension, and the increase in pulmonary blood flow (which increases shear stress and thereby increases NO). At the same time, changes occur in the synthesis and release of various biochemical modulators of vascular tone, and there are interactions between the mechanical and biochemical events surrounding birth. Disturbances in this cascade of events may lead to PPHN. At the same time, manipulation of these pathways enables us to treat it.

IV. Risk factors. The following factors or conditions may be associated with PPHN:

- A. Lung disease.** Meconium aspiration, respiratory distress syndrome (RDS), pneumonia, pulmonary hypoplasia, cystic lung disease (including congenital cystic adenomatoid malformation and congenital lobar emphysema), diaphragmatic hernia, and congenital alveolar capillary dysplasia.
- B. Systemic disorders.** Polycythemia, hypoglycemia, hypoxia, acidosis, hypocalcemia, hypothermia, and sepsis.
- C. Congenital heart disease.** Particularly, total anomalous venous return, hypoplastic left heart syndrome, transient tricuspid insufficiency (transient myocardial ischemia), coarctation of the aorta, critical aortic stenosis, endocardial cushion defects, Ebstein anomaly, transposition of the great arteries, endocardial fibroelastosis, and cerebral venous malformations.
- D. Perinatal factors.** Asphyxia, perinatal hypoxia, and maternal ingestion of aspirin or indomethacin.
- E. Miscellaneous.** Central nervous system disorders, neuromuscular disease, and upper airway obstruction. Although still contentious, some observational studies have suggested that the use of selective serotonin reuptake inhibitors during the last half of pregnancy may be associated with PPHN in the newborn.

V. Clinical presentation. The primary finding is respiratory distress with cyanosis (confirmed by demonstrating hypoxemia). This may occur despite adequate ventilation. Other clinical findings are highly variable and depend on the severity, stage, and other associated disorders (particularly pulmonary and cardiac diseases).

- A. Respiratory.** Initial respiratory symptoms may be limited to tachypnea, and onset may be at birth or within 4 to 8 hours of age. In addition, in an infant with pulmonary disease, PPHN should be suspected as a complicating factor when there is marked lability in oxygenation. These infants may have significant decreases in pulse oximetry readings with routine nursing care or minor stress (eg, movement or noise). Furthermore, a minor decrease in inspired oxygen concentration may lead to a surprisingly large decrease in arterial oxygenation (eg, the alveolar-to-arterial oxygen gradient $[AaDO_2]$ changes more rapidly and is more labile than that seen in the normal course of progression of uncomplicated RDS or other pulmonary disease).
- B. Cardiac signs.** Physical findings may include a prominent right ventricular impulse, a single second heart sound, and a murmur of tricuspid insufficiency. In extreme cases, there may be hepatomegaly and signs of heart failure.
- C. Imaging.** The chest film may show either cardiomegaly or a normal-sized heart. If there is no associated pulmonary disease, the film may show normal or diminished pulmonary vascularity. If there is also a parenchymal lung disorder, the degree of hypoxemia may be out of proportion to the radiographic measure of severity of the pulmonary disease.

VI. Diagnosis. PPHN is essentially a diagnosis of exclusion.

- A. Differential oximeter readings.** In the presence of right-to-left shunting of blood via the patent ductus arteriosus, the partial pressure of oxygen (PaO_2) in preductal blood (eg, from the right radial artery) is higher than that in the postductal

blood (obtained from left radial, umbilical, or tibial arteries). Hence, simultaneous preductal and postductal monitoring of oxygen saturation is a useful indicator of right-to-left shunting at the ductal level. However, it is important to note that PPHN cannot be excluded if no difference is found because the right-to-left shunting may be predominantly at the atrial level (or the ductus may not be patent at all). A difference $>5\%$ between preductal and postductal oxygen saturations is considered indicative of a right-to-left ductal shunt. A difference >10 to 15 mm Hg between preductal and postductal PaO_2 is also considered suggestive of a right-to-left ductal shunt. Preductal and postductal oxygenation should be assessed simultaneously.

- B. Hyperventilation test.** (See pages 489 and 490.) PPHN should be considered if marked improvement in oxygenation (>30 mm Hg increase in PaO_2) is noted on hyperventilating the infant (lowering arterial partial pressure of carbon dioxide [PaCO_2] and increasing pH). When a "critical" pH value is reached (often ~ 7.55 or greater), PVR decreases, there is less right-to-left shunting, and PaO_2 increases. This test may differentiate PPHN from cyanotic congenital heart disease. Little or no response is expected in infants with the latter diagnoses. It has been suggested that infants subjected to this test should be hyperventilated for 10 minutes. Prolonged hyperventilation is not recommended, however, particularly in premature infants (see later discussion).
- C. Imaging.** Clear lung fields or only minor disease in the face of severe hypoxemia is strongly suggestive of PPHN, if cyanotic congenital heart disease has been ruled out. In an infant with significant pulmonary parenchymal disease, a chest film is of little help in diagnosing PPHN (although it is indicated for other reasons). In an infant with rapidly worsening oxygenation, the major value of a chest film is in the exclusion of alternative diagnosis (eg, pneumothorax or pneumopericardium).
- D. Echocardiography.** Often essential in distinguishing cyanotic congenital heart disease from PPHN because the latter is frequently a diagnosis of exclusion. Furthermore, whereas all the other previously mentioned signs and tests are suggestive, echocardiography (together with Doppler studies) can provide confirmatory evidence that is often diagnostic. The first question that needs to be answered is whether the heart is structurally normal. Then the pulmonary artery pressure can be assessed indirectly by measuring the velocity of the tricuspid regurgitant jet when present. A flattened interventricular septum or one that is bowing into the left ventricle also supports the diagnosis of PPHN. Similarly, information about right-to-left shunting at the atrial and ductal levels supports the diagnosis of PPHN. Echocardiography can also be used to assess ventricular output and contractility (both of which may be depressed in infants with PPHN).

VII. Management

- A. Prevention.** Adequate resuscitation and support from birth may presumably prevent or ameliorate, to some degree, PPHN when it may occur superimposed on a preexisting condition. An example is adequate and timely ventilation of an asphyxiated infant with appropriate attention to temperature control.
- B. General management.** Infants with PPHN clearly require careful and intensive monitoring. Fluid management is important because hypovolemia aggravates the right-to-left shunt. However, once normovolemia can be assumed, there is no known benefit to be gained from repeated administration of either colloids or crystalloids. Normal serum glucose and calcium should be maintained because hypoglycemia and hypocalcemia aggravate PPHN. Temperature control is also crucial. Significant acidosis should be avoided. It is useful to use 2 pulse oximeters: 1 preductal and 1 postductal.
- C. Minimal handling.** Because infants with PPHN are extremely labile with significant deterioration after seemingly "minor" stimuli, this aspect of care deserves special mention. Endotracheal tube suctioning, in particular, should be performed only if indicated and not as a matter of routine. Noise level and physical manipulation should be kept to a minimum.

- D. Mechanical ventilation.** Often needed to ensure adequate oxygenation and should first be attempted using “conventional” ventilation. The goal is to maintain adequate and stable oxygenation using the lowest possible mean airway pressures. The lowest possible positive end-expiratory pressure should also be sought. However, atelectasis should be avoided because it may aggravate pulmonary hypertension (PH) and also impair effective delivery of inhaled NO (iNO) to the lungs. Hyperventilation should be avoided, and as a guide, PaCO₂ values should be kept >30 mm Hg if possible; levels of 40 to 50 mm Hg, or even higher, are also acceptable if there is no associated compromise in oxygenation. Initially, it would be wise to ventilate with 100% inspired oxygen concentration. Weaning should be gradual and in small steps. In infants who cannot be adequately oxygenated with conventional ventilation, high-frequency oscillatory ventilation (HFOV) should be considered early. In the presence of parenchymal lung disease, infants treated with HFOV combined with iNO were less likely to be referred for ECLS than those treated with either therapy alone.
- E. Surfactant.** In infants with RDS, administration of surfactant is associated with a fall in PVR. Surfactant may also be of benefit in various other pulmonary disorders (eg, meconium aspiration), although it is unknown whether its actions in these disorders are related to a reduction in PVR. There is evidence for surfactant deficiency in some patients with PPHN.
- F. Pressor agents.** Some infants with PPHN have reduced cardiac output. In addition, increasing systemic blood pressure reduces the right-to-left shunt. Hence, at least a normal blood pressure should be maintained, and some recommend maintaining blood pressure of >40 mm Hg. **Dopamine is the most commonly used drug for this purpose.** Dobutamine has the disadvantage, in this context, that, although it may improve cardiac output, it has less of a pressor effect than dopamine. **Milrinone**, a type 3 PDE inhibitor, is also sometimes employed to improve cardiac output. Milrinone reduces PH in experimental animal models, and a few small case series have reported on its beneficial effects in neonates with PPHN. However, the use of milrinone has been associated with occasional cases of systemic hypotension in adults and of higher heart rates in neonates. Hence, more data are needed before widespread use of milrinone can be recommended.
- G. Sedation.** The lability of these infants has been mentioned previously, and hence, sedation is commonly used. Pentobarbital (1–5 mg/kg) or midazolam (0.1 mg/kg) is frequently used, and analgesia with morphine (0.05–0.2 mg/kg) is also used.
- H. Inhaled nitric oxide.** See also Chapters 9 and 155.
- 1. Background.** Controlled clinical trials have shown that NO, when given by inhalation, reduces PVR and improves oxygenation and outcomes in a significant proportion of term and near-term neonates with PPHN. The administration of iNO to infants with PPHN reduces the number requiring ECLS without increasing morbidity at 2 years of age. In another large multicenter trial, iNO was demonstrated to reduce both the need for ECLS and the incidence of bronchopulmonary dysplasia (BPD)/chronic lung disease (CLD). Oxygenation can also improve during iNO therapy via mechanisms additional to its effect of reducing extrapulmonary right-to-left shunting. iNO can also improve oxygenation by redirecting blood from poorly aerated or diseased lung regions to better aerated distal air spaces (which are better exposed to the inhaled drug), thereby improving ventilation-perfusion mismatching. Although the benefits of iNO have been demonstrated in full- and near-term neonates with PH, iNO treatment of preterm infants was controversial until recently. In preterm neonates, the hope was that iNO would decrease the incidence of BPD/CLD and, possibly, mitigate other morbidities. However, results of clinical trials have shown that the universal (ie, nonselective) administration of iNO to premature neonates with RDS does not confer such benefits. However, there is substantial evidence that the selective administration of iNO to those premature babies who have both RDS and PH

does improve survival and reduce morbidity. Hence, iNO is commonly used for this indication in premature babies and has been shown to be safe.

2. **Physiology.** NO is a colorless gas with a half-life of seconds. Exogenous iNO diffuses from alveoli to pulmonary vascular smooth muscle and produces vasodilation. Excess NO diffuses into the bloodstream, where it is rapidly inactivated by binding to hemoglobin and subsequent metabolism to nitrates and nitrites. This rapid inactivation thereby limits its action to the pulmonary vasculature. Dosage of iNO is measured as ppm (parts per million) of gas.
3. **Toxicity.** NO reacts with oxygen to form other oxides of nitrogen and, in particular, NO₂ (nitrogen dioxide). The latter may produce toxic effects and hence must be removed from the respiratory circuit (which can be done by using an adsorbent). When NO combines with hemoglobin, it forms methemoglobin, and this is also of potential concern. In the several large trials that have been completed, methemoglobinemia has not been a significant complication at NO doses <20 ppm. The rate of accumulation of methemoglobin depends on both the dose and duration of NO administration. Even when using doses >20 ppm, clinically significant methemoglobinemia does not appear to be a frequent complication. NO inhibits platelet adhesion to endothelium. Hence another potential complication is the prolongation of bleeding time described at NO doses of 30 to 300 ppm. NO may also have an adverse effect on surfactant function, but this appears to require much higher doses than those relevant in clinical applications. On the contrary, low-dose NO also has antioxidant effects, and these may be potentially beneficial. Because of these potential complications, when administering NO, NO₂ levels should be monitored. In addition, blood methemoglobin concentration should be measured. Follow-up studies in infants receiving iNO have not shown any adverse effects.
4. **Dosage and administration.** Available evidence supports the use of doses of iNO beginning at 20 ppm. Among infants with a positive response to iNO, the response time is rapid. There is no agreement, however, about the duration of treatment and criteria for discontinuation; these vary and often reflect institutional preferences. Thus, some recommend weaning once PaO₂ is >50 mm Hg; others suggest an oxygenation index <10 as an indication for weaning. Moreover, no evidence suggests the superiority of one weaning regimen over another. However, some observations are available to assist in weaning considerations. One point is, however, beyond contention: weaning should be done under careful and intensive monitoring of each step. Particular note should be made of the observation that sudden discontinuation of iNO can be associated with “rebound” PH (see Section VII.H.4.b).
 - a. **Initial dose.** Start treatment with iNO at 20 ppm. Little is to be gained by administering higher doses because, at most, only a few patients will respond to these higher doses after not having responded to a dose of 20 ppm. Higher doses may significantly increase the rate of methemoglobinemia. Also, initial treatment with subtherapeutic low-dose iNO may diminish the subsequent response to iNO at 20 ppm. Among infants with a positive response to iNO, the response time is rapid.
 - b. **Weaning.** Wean inspired oxygen concentration until fraction of inspired oxygen (FiO₂) is <0.6. Then start weaning iNO concentrations in steps of 5 ppm until iNO is 5 ppm. Weaning may be initiated as early as 4 to 6 hours after starting treatment, or later, and should be attempted at least once per day, but may be done as frequently as every 30 minutes. Hemodynamic stability and adequate oxygenation should be monitored closely 30 to 60 minutes after each weaning step. Significant deterioration should be an indication for reversing the previous weaning step. Once iNO is at 5 ppm, weaning should be continued at a slower pace, in steps of 1 ppm, until iNO is 1 ppm. Once the patient has demonstrated stability at iNO of 1 ppm for a few hours, iNO may

be discontinued. Some decline in oxygen saturation should be anticipated, and an increase of 10% to 20% in required inspired oxygen concentration may be considered reasonable when discontinuing iNO and need not be an indication for reinstating therapy. However, if an $\text{FiO}_2 > 0.75$ is required to maintain adequate oxygenation, the patient may benefit from being placed back on iNO. **Caution:** Although there are various weaning regimens of iNO, evidence suggests that iNO should be discontinued from a dose of 1 ppm and not from a higher one. The rate of success is higher when discontinuation is done from a dose of 1 ppm than from 5 ppm or higher. Moreover, the phenomenon of rebound PH should be kept in mind after discontinuation of iNO. Sudden discontinuation of iNO can be associated with rebound PH, and this rebound can be severe and may occur even in infants who had initially failed to respond to iNO treatment when it was initiated. Clinical observations have suggested that the risk of rebound PH following discontinuation of iNO may be reduced if treatment with sildenafil is started a few hours prior to the discontinuation of iNO (see Section VII.I). We should emphasize that this protocol is merely a suggestion and is compatible with data derived from trials and experience with the use of iNO. Many other regimens would be just as reasonable.

5. Failure to respond to inhaled nitric oxide or the need for prolonged administration. Patients not responding to iNO or those in whom iNO cannot be weaned after 5 days of treatment merit a reevaluation. Effective therapy requires adequate lung inflation, and an infant who fails to respond should be evaluated by chest radiograph for airway obstruction and atelectasis. Lung volume recruitment strategies may be required, as may surfactant treatment in appropriate circumstances. Pressor support or volume administration may be required because impaired cardiac output may render iNO treatment ineffective. An echocardiogram is warranted to rule out cardiac anomalies that may have been missed and to assess cardiac function. Consideration should be directed toward lung diseases that respond poorly to iNO, such as alveolar-capillary dysplasia or those associated with pulmonary hypoplasia. Fewer than 35% of infants with congenital diaphragmatic hernia respond to iNO or survive without ECLS.

I. Sildenafil. PDE5 is abundantly expressed in lung tissue and degrades cGMP. Sildenafil, a PDE5 inhibitor, prolongs the half-life of cGMP and would be expected to enhance the actions of both endogenous and exogenous NO. A few small randomized trials, in addition to observational studies, in infants have shown its effectiveness in treating PH. It has been successful in treating PH in infants after cardiac surgery, and case series have shown it to be useful in attenuating the rebound PH after withdrawal of iNO. In some patients, sildenafil may confer benefit additional to that obtained by iNO alone. In some units, sildenafil is given prophylactically before the final step in weaning off iNO. Patients treated with sildenafil have not shown an increased propensity for systemic hypotension. Concern has been raised about possible adverse effects of this drug in those infants at risk for retinopathy of prematurity, although the putative association has been questioned. Larger trials will be required to address issues of risk and benefits. Although an intravenous (IV) preparation is available, the drug is mostly given enterally. Reported enteral dosages vary and range from 2 to 3 mg/kg/d divided 3 to 4 times daily, which may be increased up to a total maximum of 8 mg/kg/d. Dosage for the IV preparation is 50% that of the enteral, or it may be given as a (IV) loading dose of 0.4 mg/kg (given over 3 hours) followed by a maintenance infusion of 1.6 mg/kg/d (approximately 0.07 mg/kg/h). **Caution:** In 2012, the US Food and Drug Administration (FDA) issued a recommendation against the use of sildenafil in children aged 1 to 17 years. The basis for this recommendation has been strongly contested (even though it does not apply to those under 1 year of age), and with the same data, the European Medicines Agency approved sildenafil for use in the pediatric age group. In 2014,

the FDA issued a clarification, stating that there may be situations in which the risk-benefit profile of sildenafil may be acceptable in individual children. Sildenafil remains one of the most commonly used medications in neonates and infants with PH, although appropriate monitoring is advised and further studies are needed, in particular with prolonged usage in this age group.

- J. Prostacyclin.** Prostacyclin (PGI₂) is a short-acting, potent vasodilator of both the pulmonary and systemic circulations. The greatest experience of its use is as a continuous IV infusion of epoprostenol. Trials in adults and older children with PH have shown an improvement in symptoms and mortality. However, epoprostenol treatment is associated with various limitations. The drug has a very short half-life and requires continuous infusion, preferably through a central vein (to minimize risk of systemic hypotension). There are special storage requirements, and side effects include, as mentioned, systemic hypotension. The data in neonates are sparse and consist of a few case reports and small series of the drug's successful use in this patient population, including some patients who had failed to respond to iNO. Reported dosages have varied between 4 and 40 ng/kg/min IV, and it is suggested that a low starting dose be initiated, with increasing dosage rate being titrated according to response. Higher doses are associated with increased risk of systemic hypotension, and blood pressure should be monitored. There are also reports of the IV preparation being aerosolized and administered by continuous inhalation at a dose of 50 to 100 ng/kg/min. Treprostinil is a stable prostacyclin analog with longer half-life that can be administered by oral, subcutaneous, or IV routes, but data are limited in infants.
- K. Inhaled/nebulized prostaglandin I₂ (iloprost).** This is a stable PGI₂ analogue with a longer half-life, and it acts by stimulating adenylyl cyclase and increasing cyclic adenosine monophosphate. It is gaining wider acceptance due to its selective pulmonary vasodilation without decreasing systemic blood pressure. Randomized trials in adults have shown its effectiveness and safety, but the pediatric and neonatal literature consists of a few case series and case reports, some including infants who were resistant to treatment with iNO. No systemic vascular effects were noted. Dosage varies between reports but is mostly in the range of 0.25 to 2.5 mcg/kg per inhalation, with inhalations being given over 5 to 10 minutes every 2 to 4 hours.
- L. Bosentan.** ET-1 is a potent vasoconstrictor and is increased in newborns with PPHN. Bosentan is an ET receptor antagonist that improves hemodynamics and quality of life in adults with PH. Up to 10% of patients are affected by liver toxicity. Bosentan improved hemodynamics in a study of its use in pediatric patients with PH. Its use also enabled a reduction of the epoprostenol dose. While case series have reported on the successful use of bosentan, controlled trials have shown conflicting results, and further studies are needed to identify patients who may benefit from this drug, especially in combination with other medications used to treat PH in neonates and infants. Dosage is started at 1 mg/kg twice daily and may be advanced to 2 mg/kg twice daily. Liver enzymes should be monitored.
- M. Paralyzing agents.** The use of these agents is *controversial*. Their use has been advocated in infants who have not responded to sedation and are still labile or who appear to "fight" the ventilator. In a retrospective survey, the use of paralysis was associated with increased mortality, although a causal relation cannot be inferred. Pancuronium is the drug most commonly used, although it may increase PVR to some extent and worsen ventilation-perfusion mismatch. Vecuronium (0.1 mg/kg) has also been used.
- N. Alkalinization.** In the past, it had been noted that hyperventilation, with the resulting hypocapnia, improved oxygenation secondary to pulmonary vasodilation. Subsequently, it was shown, in animal studies, that the beneficial effect of hypocapnia was actually a result of the increased pH rather than of the low PaCO₂ values achieved. Furthermore, follow-up of infants with PPHN had suggested that hypocapnia was related to poor neurodevelopmental outcome (especially sensorineural

hearing loss). Hypocapnia is known to reduce cerebral blood flow. The use of alkalization is *controversial*, and there are no adequately controlled trials on its use to alleviate PPHN. If alkalization is employed, it may be advisable to increase pH using an infusion of sodium bicarbonate (0.5–1 mEq/kg/h) if possible. Serum sodium should be monitored to avoid hyponatremia. Improvement in oxygenation has been anecdotally reported with arterial pH of 7.50 to 7.55 (sometimes levels as high as 7.65 are required).

- O. Magnesium sulfate.** Magnesium causes vasodilation by antagonizing calcium ion entry into smooth muscle cells. A few small observational studies have suggested that magnesium sulfate ($MgSO_4$) may effectively treat PPHN, but the evidence is conflicting, and there is some risk of systemic hypotension. The dose reported is a loading dosage of 200 mg/kg followed by an infusion of 20 to 150 mg/kg/h (the drug is given IV). Two small trials in neonates with PPHN have shown that sildenafil and iNO are each superior to IV $MgSO_4$.
- P. Adenosine.** Adenosine causes vasodilation by stimulation of adenosine receptors on endothelial cells and release of endothelial NO. A small randomized trial reported the effectiveness of adenosine infusion (25–50 mcg/kg/min) in treating PPHN in term babies. Subsequently, a few further cases have been published. Despite initial favorable data, the drug has not attracted attention, and its use awaits further clinical trials.
- Q. Extracorporeal life support.** (See Chapter 20.) ECLS may be indicated for term or near-term infants with PPHN who fail to respond to conventional therapy and who meet ECLS entry criteria. The survival rate with ECLS is reportedly >80%, although only the most severely afflicted infants are referred for this treatment.

VIII. Pulmonary hypertension in bronchopulmonary dysplasia/chronic lung disease. A significant number of cases of BPD/CLD exhibit pulmonary hypertension (PH). The pulmonary circulation in BPD/CLD exhibits elevated PVR and increased vasoreactivity, vascular remodeling, and decreased and disrupted growth. The disruption in angiogenesis also impairs alveolarization, and furthermore, there is formation of bronchial and other systemic-to-pulmonary collateral vessels. The presence of PH complicating the course of BPD/CLD is associated with significantly increased mortality and morbidity. The rationale for aggressively diagnosing and treating PH complicating BPD/CLD is the hope that it would affect the increased mortality. Which patients with BPD/CLD should be screened for the presence of PH? There are no data to indicate an optimal approach, but a few guidelines have been suggested. Patients still requiring ventilatory assistance or significant supplemental oxygen at 36 weeks' postconceptional age might benefit from an echocardiographic evaluation. Some suggest echocardiographic screening at an earlier stage (as early as 1–2 months of age if baby is still on mechanical ventilation). Furthermore, infants with severe respiratory disease that fails to improve, those with respiratory disease out of proportion to the expected course or radiologic findings, those with recurrent and persistent cyanotic spells or respiratory deteriorations, and those with repeated need for diuretic administration might also benefit from screening for PH. Screening for PH in patients with BPD/CLD may require serial interval echocardiograms. The echocardiographic evaluation of PH is far from perfect, and certain patients may require cardiac catheterization for diagnosis of PH and to assess its severity and response to treatment. Serial measurements of brain natriuretic peptide (BNP) or N-terminal pro-BNP may help in the assessment of cardiac performance in the context of BPD and PH. BNP and N-terminal pro-BNP are released by the myocardium in response to stretch, although they are not specific for PH. However, serial assays may augment echocardiographic findings and may be useful in monitoring disease progression or improvement. The therapeutic options most commonly used in patients with BPD and PH are iNO, sildenafil, and bosentan. However, treatment of PH should always occur in a context whereby attempts have been made to optimize ventilatory support and complicating factors (eg, reflux and aspirations) have been considered and treated, if necessary.

- IX. Prognosis.** The overall survival rate is >70% to 75%. However, there is a marked difference in survival and long-term outcome according to the cause of the PPHN. More than 80% of term or near-term neonates with PPHN are expected to have an essentially normal neurodevelopmental outcome. Abnormal long-term outcome in PPHN survivors (and a high incidence of sensorineural hearing loss) has been reported to correlate with duration of hyperventilation. However, the relationship may not be causal because prolonged hyperventilation may simply be a marker for the severity of PPHN and hypoxic insult. Full-term survivors of idiopathic PPHN usually have no residual lung or heart disease. However, low birthweight infants with PPHN accompanying severe RDS have a much higher rate of mortality, and there are few data on the long-term outcome of the survivors. These babies are at higher risk of developing BPD and subsequently requiring more prolonged therapy for PH. In some cases, treatment for PH may be required after discharge from the neonatal intensive care unit, and these patients then require close cardiac supervision as outpatients. PH may be exacerbated during episodes of viral respiratory diseases.

116 Polycythemia and Hyperviscosity

- I. Definitions.** Polycythemia is an increased total red blood cell (RBC) mass. Polycythemic hyperviscosity is an increased viscosity of the blood resulting from, or associated with, increased numbers of RBCs.
- A. Polycythemia of the newborn.** Defined empirically as a central venous hematocrit >65%.
- B. Hyperviscosity.** Defined as a viscosity >14 centipoises (cP) at a shear rate of 11.5/s and is measured by a viscometer. Viscosity is the measure of a fluid's resistance to being deformed. It is defined as the **shear stress** (refers to frictional forces within a fluid) divided by the **shear rate** (a measure of flow velocity). In neonates, the major determinant of total blood viscosity is hematocrit, with plasma viscosity playing a minor role. The relationship between hematocrit and blood viscosity is exponential. Hyperviscosity is the cause of clinical symptoms in infants presumed to be symptomatic from polycythemia.
- II. Incidence**
- A. Polycythemia** occurs in 1% to 4% of the general newborn population. Half of these patients are symptomatic, although it is not at all certain whether their symptoms are caused by polycythemia.
- B. Hyperviscosity without polycythemia** occurs in 1% of normal (nonpolycythemic) newborns. In infants with a hematocrit of 60% to 64%, a fourth will have hyperviscosity.
- III. Pathophysiology.** Polycythemia and hyperviscosity are associated with presumed alteration in organ blood flow. In general, there is a decrease in organ blood flow due to changes in red cell mass, arterial oxygen content, and/or viscosity. The decrease in cerebral blood flow and cardiac output may represent a physiologic response to an increase in arterial oxygen content rather than ischemia. Many infants with polycythemia have a reduced plasma volume, which may lead to hypoglycemia (12%–40% of the infants) as glucose is present in the plasma fraction of the blood. Whole blood glucose concentration might be significantly reduced even when the plasma concentration is normal. Clinical signs attributed to polycythemia may result from coexisting perinatal circumstances in the presence or absence of hyperviscosity.

The frictional forces identified within whole blood and their relative contributions to hyperviscosity in the newborn include the following:

- A. **Hematocrit. An increase in the hematocrit is the most important single factor contributing to hyperviscosity in the neonate.** An increased hematocrit results from either an absolute increase in circulating RBC volume or a decrease in plasma volume.
- B. **Plasma viscosity.** A direct linear relationship exists between plasma viscosity and the concentration of plasma proteins, particularly those of high molecular weight, such as fibrinogen. Term infants and, to a greater degree, preterm infants have low plasma fibrinogen levels compared with adults. Consequently, except for the rare case of primary hyperfibrinogenemia, plasma viscosity does not contribute to an increased whole-blood viscosity in the neonate.
- C. **Red blood cell aggregation.** Occurs only in areas of low blood flow and is usually limited to the venous microcirculation. Because fibrinogen levels are typically low in term and preterm infants, RBC aggregation does not contribute significantly to whole blood viscosity in newborn infants. There is some concern that the use of adult fresh-frozen plasma for partial exchange transfusion in neonates might critically alter the concentration of fibrinogen and paradoxically raise whole blood viscosity within the microcirculation.
- D. **Deformability of red blood cell membrane.** RBC deformability is increased in preterm neonates as compared with term neonates and in term neonates as compared with adults. The increase in deformability is presumed to reduce blood viscosity and to reduce the likelihood that polycythemia will cause hyperviscosity. Because infants of diabetic mothers are thought to have RBCs with reduced deformability, hyperviscosity may be more likely at polycythemic hematocrit levels than in unaffected neonates.

IV. Risk factors

A. Conditions that alter incidence

1. **Altitude.** There is an absolute increase in RBC mass as part of physiologic adaptation to high altitude.
2. **Neonatal age.** The normal pattern of fluid shifts during the first 6 hours of life is away from the intravascular compartment. The period of maximum physiologic increase in the hematocrit occurs at 2 to 4 hours of age.
3. **Obstetric factors.** A delay in cord clamping or milking of the umbilical cord results in a higher incidence of polycythemia. However, the subsequent development of symptomatic polycythemia or severe hyperbilirubinemia is rare.
4. **High-risk delivery.** A high-risk delivery is associated with an increased incidence of polycythemia, particularly if precipitous or uncontrolled.

B. Perinatal processes

1. **Enhanced fetal erythropoiesis.** Elevated erythropoietin levels result from a direct stimulus, usually related to fetal hypoxia, or from an altered regulation of erythropoietin production.
 - a. **Placental insufficiency**
 - i. **Maternal hypertensive disease (preeclampsia/eclampsia) or primary renovascular disease**
 - ii. **Abruptio placentae (chronic recurrent)**
 - iii. **Postmaturity**
 - iv. **Maternal cyanotic congenital heart disease**
 - v. **Intrauterine growth restriction**
 - vi. **Maternal cigarette smoking**
 - b. **Endocrine disorders.** Increased oxygen consumption is the suggested mechanism by which hyperinsulinism or hyperthyroxinemia creates fetal hypoxemia and stimulates erythropoietin production.
 - i. **Infant of a diabetic mother (>40% incidence of polycythemia)**
 - ii. **Infant of a mother with gestational diabetes (>30% incidence of polycythemia)**

iii. **Congenital thyrotoxicosis**

iv. **Congenital adrenal hyperplasia**

v. **Beckwith-Wiedemann syndrome (secondary hyperinsulinism)**

c. **Genetic trisomies.** Trisomies 13, 18, and 21.

2. **Hypertransfusion.** Conditions that enhance placental transfusion at birth may create hypervolemic normocythemia, which evolves into hypervolemic polycythemia as the normal pattern of fluid shift occurs. A larger transfusion may create hypervolemic polycythemia at birth, with signs present in the infant. Conditions associated with hypertransfusion include the following:

a. **Delay in cord clamping.** Placental vessels contain up to a third of the fetal blood volume, half of which is returned to the infant within 1 minute after birth. Definition of delayed cord clamping is variable, and ranges from 30 seconds to up to 5 minutes. The risks associated with delayed cord clamping are probably negligible compared with the benefits, which include, in term infants, reduction in the rate of iron deficiency in the first 2 years of life and, in preterm infants, decreased postnatal need for blood transfusions, inotrope support, and incidence of intra-ventricular hemorrhage and necrotizing enterocolitis. Representative blood volumes for term infants with a variable delay in cord clamping are as follows:

i. **15-second delay: 75 to 78 mL/kg**

ii. **60-second delay: 80 to 87 mL/kg**

iii. **120-second delay: 83 to 93 mL/kg**

b. **Gravity.** Positioning the infant below the placental bed (>10 cm below the placenta) may enhance placental transfusion via the umbilical vein. Elevation of the infant >50 cm above the placenta may decrease the placental transfusion. Soon after the birth, under the influence of maternal uterotonics, placing the baby on the mother's abdomen or chest at term vaginal birth had no impact on the volume of placental transfusion and infants can be safely placed on their mothers' chest.

c. **Twin-twin transfusion.** Interfetal transfusion (**parabiosis syndrome**) is observed in monochorionic twin pregnancy with an incidence of 15%. The recipient twin, on the venous side of the anastomosis, becomes polycythemic, and the donor, on the arterial side, becomes anemic. Simultaneous venous hematocrits obtained after delivery usually differ by >12% to 15%.

V. **Clinical presentation.** Clinical signs observed in polycythemia are often nonspecific. The conditions listed next may occur independently of polycythemia or hyperviscosity and must be considered in the differential diagnosis.

A. **Central nervous system.** There may be an altered state of consciousness, including lethargy and decreased activity, hyperirritability, muscle hypotonia, vasomotor instability, and vomiting. Seizures, thromboses, and cerebral infarction are extraordinarily rare.

B. **Cardiopulmonary system.** Respiratory distress and tachycardia may be present. Congestive heart failure with cardiomegaly may be seen but is rarely clinically prominent. Pulmonary hypertension may occur but is not usually severe unless other predisposing factors are present.

C. **Gastrointestinal tract.** Feeding intolerance occurs occasionally. Necrotizing enterocolitis has been reported but rarely without other factors (eg, intrauterine growth restriction), which casts doubt on the primary cause.

D. **Genitourinary tract.** Oliguria, acute renal failure/acute kidney injury, renal vein thrombosis, or priapism may occur.

E. **Metabolic disorders.** Hypoglycemia, hypocalcemia, or hypomagnesemia may be seen.

F. **Hematologic disorders.** There may be hyperbilirubinemia, thrombocytopenia, or reticulocytosis (with enhanced erythropoiesis only).

VI. **Diagnosis**

A. **Venous (not capillary) hematocrit.** Polycythemia is present when the central venous hematocrit is >65%.

- B. The following screening studies may be used:**
 - 1. **A cord blood hematocrit >56% suggests polycythemia.**
 - 2. **A warmed capillary hematocrit >65% suggests polycythemia.**
- VII. Management.** (See also Chapter 76 for polycythemia management.) Clinical management of the polycythemic infant is more expectant now than 2 decades ago. Studies and reviews have created much doubt about any long-term benefits of partial (isovolumetric) exchange transfusion (PET). Consequently, PET should probably be performed only in infants in whom significant morbidity is in question.
 - A. Asymptomatic infants.** Only expectant observation is required for virtually all asymptomatic infants. The possible exception is an infant with a central venous hematocrit of >75%, but even in this group, the risks of central catheter insertion probably outweigh the benefits of PET.
 - B. Symptomatic infants.** When the central venous hematocrit is >65%, PET with normal saline may ameliorate acute signs of polycythemia or hyperviscosity. However, whether treatment of a self-limited problem justifies the risks of central catheter insertion and an exchange procedure is debatable. PET procedures using peripheral vessels may be preferred to avoid the complications related to the central catheter insertion. For the procedure for partial exchange transfusion, see Chapter 34.
- VIII. Prognosis.** The long-term outcome of infants with polycythemia or hyperviscosity and response to PET is as follows:
 - A. A causal relationship may exist** between PET (through an umbilical vessel) and an increase in gastrointestinal tract disorders such as necrotizing enterocolitis.
 - B. Most randomized controlled prospective studies** of polycythemic and hyperviscous infants indicate that PET does not eliminate the risk of neurologic sequelae.
 - C. Infants with “asymptomatic” polycythemia** have an increased risk for neurologic sequelae, but normocythemic controls with the same perinatal histories have a similarly increased risk.
 - D. The efficacy of partial exchange transfusion among infants with “symptomatic” polycythemia** remains unclear at this time.

117 Respiratory Distress Syndrome

- I. Definition.** **Respiratory distress syndrome (RDS) was previously called hyaline membrane disease (HMD).** The Vermont Oxford Network definition for RDS requires that babies have:
 - A. An arterial oxygen tension (PaO₂) <50 mm Hg and central cyanosis** in room air, a requirement for supplemental oxygen to maintain PaO₂ >50 mm Hg, or a requirement for supplemental oxygen to maintain a pulse oximeter saturation >85%.
 - B. A characteristic chest radiographic appearance** (uniform reticulogranular pattern to lung fields and air bronchogram) within the first 24 hours of life. The clinical course of the disease has been changed because of advances in treatment practices, including the use of early continuous positive airway pressure (CPAP).
- II. Incidence.** Incidence of RDS is about 85% at 28 weeks' gestation and increases to 95% at 24 weeks' gestation. However, by using early CPAP, approximately 50% of babies born at 26 to 29 weeks' gestation can be managed without intubation or surfactant. The survival from RDS is generally >90%.

III. Pathophysiology. Surfactant deficiency is the primary cause of RDS, often complicated by an overly compliant chest wall. Both factors lead to progressive atelectasis and failure to develop an effective functional residual capacity (FRC). Surfactant is produced by airway epithelial cells called type II pneumocytes. Surfactant synthesis begins at 24 to 28 weeks' gestation. Type II cells are sensitive to and decreased by perinatal asphyxial insults. The maturation of these cells is delayed in the presence of fetal hyperinsulinemia. The maturity of type II cells is enhanced by the administration of antenatal corticosteroids and by chronic intrauterine stress such as pregnancy-induced hypertension and intrauterine growth restriction. Surfactant, composed chiefly of phospholipid (75%) and protein (10%), is produced and stored in the lamellar bodies of type II pneumocytes. This lipoprotein is released into the airways, where it functions to decrease surface tension and maintain alveolar expansion at physiologic pressures.

A. Lack of surfactant. In the absence of surfactant, the small airspaces collapse; each expiration results in progressive atelectasis. Exudative proteinaceous material and epithelial debris, resulting from progressive cellular damage, collect in the airway and directly decrease total lung capacity. In pathologic specimens, this material stains typically as eosinophilic hyaline membranes lining the alveolar spaces and extending into small airways.

B. Presence of an overly compliant chest wall. In the presence of a chest wall with weak structural support secondary to prematurity, the large negative pressures generated to open the collapsed airways cause retraction and deformation of the chest wall instead of inflation of the lungs.

C. Decreased intrathoracic pressure. The infant with RDS who is <30 weeks' gestational age often has immediate respiratory failure because of an inability to generate the intrathoracic pressure necessary to inflate the lungs without surfactant.

D. Shunting. The presence or absence of a cardiovascular shunt through a patent ductus arteriosus (PDA) and/or foramen ovale may change the course of the disease. Shortly after birth, the predominant shunting is right to left across the foramen ovale into the left atrium, which may result in worsening hypoxemia. After 18 to 24 hours, left-to-right shunting through the PDA may become predominant as a result of falling pulmonary vascular resistance, leading to pulmonary edema and impaired alveolar gas exchange. Unfortunately, this usually occurs when the infant is starting to recover from RDS and can be aggravated by surfactant replacement therapy.

IV. Risk factors. Table 117-1 lists factors that increase or decrease the risk of RDS.

Table 117-1. RISK FACTORS THAT INCREASE OR DECREASE THE RISK OF RESPIRATORY DISTRESS SYNDROME

Increased Risk	Decreased Risk
Prematurity	Prolonged rupture of membranes
Male sex	Intrauterine infection
Familial predisposition	Female sex
Cesarean delivery without labor	Vaginal delivery
Perinatal asphyxia	Narcotic/cocaine use
Multiple gestation	Corticosteroids
Maternal diabetes	Thyroid hormone
European descent	Tocolytic agents
Mutation in single <i>ABCA3</i> gene	African descent

V. Clinical presentation

A. History. The infant is often preterm or has a history of perinatal asphyxia. Infants have at birth some respiratory difficulty, which becomes progressively more severe. The classic worsening of the atelectasis seen on chest radiograph and increasing oxygen requirement for these infants have been greatly modified by exogenous surfactant therapy and effective ventilatory support.

B. Physical examination. The infant with RDS exhibits tachypnea, grunting, nasal flaring, and retractions of the chest wall, and may have cyanosis in room air. Grunting occurs when the infant partially closes the vocal cords to prolong expiration and develop or maintain some FRC. This actually improves alveolar ventilation. The retractions occur and increase as the infant is forced to develop high transpulmonary pressure to reinflate atelectatic air spaces.

VI. Diagnosis

A. Chest radiograph. An anteroposterior chest radiograph should be obtained for all infants with respiratory distress of any duration. The typical radiographic finding of RDS is a uniform reticulogranular pattern, referred to as a ground-glass appearance, accompanied by peripheral air bronchograms (see Figure 12–17). Sequential radiographs may later reveal air leaks secondary to mechanical ventilatory support as well as the onset of changes compatible with bronchopulmonary dysplasia/chronic lung disease (BPD/CLD) (see Figure 12–21).

B. Point-of-care lung ultrasonography showing lung consolidation, pleural line abnormalities, and A-line disappearance provides a sensitivity and specificity of 100% for the diagnosis of neonatal RDS. However, some acute complications secondary to air leak syndrome (eg, pneumomediastinum, interstitial emphysema, pneumopericardium) cannot easily be discovered by using ultrasound (see also Chapter 44).

C. Laboratory studies

1. Blood gas sampling is essential in the management of RDS. Although there is no consensus, most neonatologists agree that arterial oxygen tensions of 50 to 70 mm Hg and arterial carbon dioxide tensions of 45 to 60 mm Hg are acceptable. Most would maintain the pH at or above 7.22 and the arterial oxygen saturation at 90% to 94%. Continuous transcutaneous oxygen and carbon dioxide monitoring and/or oxygen saturation monitoring are valuable in the treatment of these infants.

2. Sepsis workup. A partial sepsis workup, including complete blood cell count and blood culture, should be considered for each infant with RDS because early-onset sepsis (eg, infection with group B *Streptococcus*) can be indistinguishable from RDS on clinical grounds alone.

3. Serum glucose levels must be monitored closely to assess the adequacy of dextrose infusion. Hypoglycemia alone can lead to tachypnea and respiratory distress.

4. Serum electrolyte levels and calcium should be monitored for management of parenteral fluids. Hypocalcemia can contribute to more respiratory symptoms and is common in sick, nonfed, preterm, or asphyxiated infants. Hyponatremia can occur.

D. Echocardiography is used to confirm the diagnosis of PDA and in the evaluation of an infant with hypoxemia and respiratory distress. A significant congenital heart disease can also be excluded.

E. Respiratory severity score. Some facilities in low-resource settings use the respiratory severity score (RSS) designed by Silverman and Andersen to quantify respiratory distress among neonates. The RSS is objective, easy to learn, quick to perform, and requires no expensive equipment. It is rated by giving scores from 0 to 2 from upper chest movement, lower chest retractions, xiphoid retractions, nares dilatation, and expiratory grunting. Details can be found in *Journal of Perinatology* (2018;38:505-511). The RSS can be used for predicting the need for escalation of respiratory support and can help facilitate transfer decision making to higher resourced facilities. Scores ≥ 5 have been the most useful cutoff point for transfer, although the sensitivity of the score is decreased in patients with a higher score.

VII. Management. Listed below are guidelines for the management of RDS. Note that there are specific European Consensus Guidelines that were updated in 2019 by Sweet et al (*Neonatology*, 2019;115(4):432-451).

A. Prevention

1. Antenatal corticosteroids. Treatment with antenatal corticosteroids is associated with an overall reduction in neonatal death, RDS, intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), respiratory support, intensive care admissions, and systemic infections in the first 48 hours of life. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) and the European consensus, which differ in recommendations, are listed in Table 117–2. The optimal treatment to delivery interval is >24 and <7 days after the steroid treatment.

a. Repeated courses of corticosteroids. Because of short-term benefits for babies with less respiratory distress and fewer serious health problems in the

Table 117–2. AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS (ACOG) AND EUROPEAN CONSENSUS ON RECOMMENDATIONS FOR ANTENATAL CORTICOSTEROID TREATMENT

ACOG	European Consensus
Give a course of antenatal corticosteroids to pregnant women (including rupture of membranes [ROM] and multiple gestation) 24 0/7 to 33 6/7 weeks' gestation who are at risk of preterm delivery within 7 days. Consider a course of antenatal corticosteroids to pregnant women (including ROM and multiple gestation) at 23 0/7 weeks' gestation who are at risk of preterm delivery within 7 days, based on the family's decision on resuscitation.	Offer a single course of prenatal corticosteroids to all women at risk of preterm delivery, before 34 weeks' gestation, for whom the pregnancy is considered potentially viable, ideally 24 hours before birth.
Give a single dose of betamethasone to pregnant women 34 0/7 to 36 6/7 weeks' gestation who are at risk of preterm delivery within 7 days who have not received a prior dose of antenatal corticosteroids.	It is appropriate to give a repeat course of antenatal steroids in threatened preterm delivery before 32 weeks' gestation, if the first course was given at least 1 to 2 weeks earlier.
Consider a course of antenatal corticosteroids for pregnant women in the periviable period (defined as 20 0/7 to 25 6/7 weeks' gestation) who are at risk of preterm delivery within 7 days, depending on the family's decision on resuscitation.	
>2 repeat courses are not recommended.	
Consider a repeat course of antenatal corticosteroids to a pregnant woman <34 0/7 weeks' gestation who are at risk of preterm delivery within 7 days and whose prior course was >14 days before. Rescue course prior to 7 days can be given if necessary due to the clinical picture.	
Controversial as to whether to give a repeat/rescue course for preterm/prelabor ROM.	

Data from Committee on Obstetric Practice. Committee Opinion No. 713: Antenatal Corticosteroid Therapy for Fetal Maturation, *Obstet Gynecol*. 2017 Aug;130(2):e102-e109; Sweet D, Carnielli V, Greisen G, et al: European consensus guidelines on the management of neonatal respiratory distress syndrome in preterm infants: 2016 update. *Neonatology*. 2017;111(2):107-125.

first weeks after birth, a repeated course should be considered if the risk of preterm delivery persists or recurs 7 to 14 days after having received the previous course (ie, when the delivery is expected to occur within the following 7 days). Weekly repeated courses are, however, not recommended.

b. The recommended regimen consists of the administration to the mother of 2 doses of betamethasone 12 mg given intramuscularly 24 hours apart. Dexamethasone is not recommended because of increased risk for cystic periventricular leukomalacia among very premature infants exposed to the drug prenatally. The ACOG recommendations differ from the European guidelines; see Table 117–2.

2. Ambroxol. There is insufficient scientific evidence either to support or discourage the use of ambroxol in pregnant women at risk of preterm birth for preventing neonatal RDS.

3. Preventive measures to improve the survival of infants at risk for RDS include **antenatal ultrasonography** for accurate assessment of gestational age and fetal well-being, **continuous fetal monitoring** to document fetal well-being during labor or to signal the need for intervention when fetal distress is discovered, and **tocolytic agents** that prevent and treat preterm labor. **Assessment of fetal lung maturity** before delivery (lecithin-to-sphingomyelin ratio and phosphatidylglycerol or amniotic fluid lamellar bodies; see Chapter 1) might be of help in determining the timing of some late preterm or early term deliveries. Testing is not commonly used because mature test results do not guarantee good neonatal outcomes.

B. Delivery room management. In spontaneously breathing babies, stabilize with CPAP via mask or nasal prongs. Gentle positive-pressure lung inflations should be used for persistently apneic or bradycardic infants. Intubation should be reserved for babies who have not responded to positive-pressure ventilation via face mask. Babies who require intubation for stabilization should be given surfactant (see later in chapter).

C. Respiratory support

1. Continuous positive airway pressure and nasal synchronized intermittent mandatory ventilation. Nasal CPAP (nCPAP) or nasopharyngeal CPAP (NPCPAP) providing a pressure of 5 to 6 cm H₂O can be used early to delay or prevent the need for endotracheal intubation and mechanical ventilation. CPAP treatment is recommended to be started from birth in all infants at risk of RDS, such as those born at <30 weeks' gestation. In this way many, infants with RDS can be managed without surfactant replacement. By not using surfactant, however, the risk of pneumothorax is increased. Use of nCPAP or NPCPAP on extubation after mechanical ventilation decreases the chance of reintubation. **Nasal synchronized intermittent mandatory ventilation (SIMV)** is a potentially useful way of augmenting nCPAP. The ability to synchronize the ventilator breaths with the infant's own respiratory cycle has made this mode of ventilation feasible. Nasal SIMV has reduced the incidence of symptoms of extubation failure when compared with nCPAP. Short binasal prongs should be used instead of a single prong.

2. Humidified high-flow nasal cannula system. This has been introduced as a way to provide positive distending pressure, even comparable to nCPAP, to a neonate with respiratory distress. It aims to maximize patient tolerance by using heated, humidified gas of usually 4.0 to 8.0 L/min flow. It has shown similar efficacy and safety compared with nCPAP and bilevel positive airway pressure (BiPAP) as a primary treatment of moderate RDS in preterm infants >28 weeks' gestational age. Further studies are underway.

3. Endotracheal intubation and mechanical ventilation are mainstays of therapy for infants with RDS in whom apnea or hypoxemia with respiratory acidosis develops.

a. Mechanical ventilation (MV) modes include conventional modes, such as intermittent positive-pressure ventilation (IPPV), and high-frequency oscillatory ventilation (HFOV). Ventilators with the capacity to synchronize

respiratory effort may generate less inadvertent airway pressure and lessen barotrauma. Ventilator settings should be adjusted frequently to maintain the lowest possible pressures and inspired oxygen concentrations in an attempt to minimize damage to parenchymal tissue. Volume-targeted ventilation allows patient-adjusted variability in tidal volumes and weaning from ventilator in accordance with the improving lung compliance.

- i. **High frequency oscillatory ventilation** may be beneficial as a rescue therapy in infants with respiratory failure on IPPV. A recent meta-analysis of randomized controlled trials showed a decreased risk of BPD in infants treated with HFOV compared to those treated with pressure-limited ventilation. In contrast, an increased risk of pulmonary air leaks was shown in the HFOV-treated cases. One randomized controlled trial has reported a better lung function at 11 to 14 years of age in HFOV-treated patients compared to those treated with conventional ventilation. Instead, no differences in neurodevelopmental outcomes have been detected in follow-up studies.
- ii. **Weaning from mechanical ventilation** should be started as soon as satisfactory gas exchange is achieved. Modest hypercarbia can be allowed, if the pH can be maintained above 7.22, in order to facilitate weaning. **Caffeine** should be routinely used for very preterm neonates with RDS to augment extubation.
- iii. **Inhaled nitric oxide (iNO)** has been used mostly off label in extremely premature neonates with RDS. It should not be used in preterm infants with RDS unless there is pulmonary hypertension or hypoplasia. A recent study shows that it does not improve survival, and infants treated with iNO without evidence of PPHN actually had an increased mortality.

D. Surfactant replacement. (See also Chapter 9.) Now considered a standard of care in the treatment of intubated infants with RDS.

1. **Prophylactic versus selective use.** Systematic reviews of >30 randomized trials demonstrate that surfactant, whether used prophylactically in the delivery room or in the treatment of established disease, leads to a significant decrease in the risk of pneumothorax and death. These benefits were observed in both the trials of natural surfactant extracts and synthetic surfactants. According to the recent evidence, prophylactic surfactant replacement to prevent RDS is not recommended in infants receiving noninvasive respiratory support for stabilization in the delivery room. Instead, early CPAP after birth and early selective surfactant treatment in infants with signs of RDS are recommended. However, surfactant is needed in infants who require delivery room intubation for stabilization. Surfactant should be given as early as possible during the course of RDS. Infants of ≤ 26 weeks' gestation should be treated when they need >30% inspired oxygen to maintain oxygen saturation in the normal range. The treatment threshold for infants of >26 weeks' gestational age is recommended to be an inspired oxygen requirement of >40%.
2. **Surfactant preparations.** Natural (derived from animal lungs) surfactant preparations are better than synthetic (protein-free) preparations at reducing pulmonary air leaks (Table 117-3). Synthetic surfactants containing surfactant protein B and protein C analogs are currently studied in clinical trials. Currently, natural surfactants are the treatment of choice. Trials comparing natural bovine surfactants, whether given prophylactically or as rescue therapy, have shown similar outcomes. Trials comparing bovine- and porcine-derived surfactants have shown a more rapid improvement in oxygenation in the latter. A better survival has been demonstrated using a 200-mg/kg dose of poractant alfa compared with 100 mg/kg of beractant or 100 mg/kg of poractant alfa for treatment of moderate to severe RDS.

Table 117–3. SURFACTANT PREPARATIONS

Generic/Trade Name	Source	Manufacturer	Dose (volume)
Beractant/ Survanta	Bovine	Ross Laboratories (United States)	100 mg/kg/dose (4 mL/kg) Prophylaxis^a: 100 mg within 15 min of birth; up to 4 doses during the first 48 h of life; maximum frequency, every 6 h Treatment^a: 100 mg within 8 h of birth; up to 4 doses during the first 48 h of life; maximum frequency, every 6 h
Bovactant/ Alveofact	Bovine	Lyomark (Germany)	50 mg/kg/dose (1.2 mL/kg) (European approval)
Poractant alfa/ Curosurf	Porcine	Chiesi Farmaceutici (Italy) Chiesi (United States)	100–200 mg/kg/dose (1.5–3.0 mL/kg) Prophylaxis^b: 1.25–2.5 mL/kg once within 15 min of birth; additional doses only if infant requires mechanical ventilation/supplemental oxygen Treatment^b: initial 2.5 mL/kg, then 1.25 mL/kg every 12 h × 2 as needed (5 mL/kg total dose); additional doses only if infant continues to require mechanical ventilation/supplemental oxygen
Calfactant/ Infasurf	Bovine	ONY (United States)	105 mg/kg/dose (3 mL/kg) Prophylaxis: 3 mL/kg body weight within 30 min of birth; then as needed every 12 h for a total of up to 3 doses Treatment: same as prophylaxis

Note: Lucinatant (Surfaxin) has been discontinued.

^aEach dose is given as 4 quarter doses, with body in different positions to assure adequate distribution and with 30 seconds of ventilation between positions.

^bEach dose given as 2 half doses, with body in different positions to assure adequate distribution.

- 3. Administration techniques.** Surfactant is administered when the infant is lying supine. Positional maneuvers are not indicated. MV can be avoided by using the **INSURE (intubate-surfactant-extubate) to CPAP technique** when surfactant is administered. This has reduced the need for MV and development of BPD/CLD in randomized trials. Immediate (or early) extubation to noninvasive respiratory support (CPAP or nasal IPPV) following surfactant administration should be considered in otherwise stable infants. Recently, even less invasive techniques for surfactant treatment have been developed, aiming for total avoidance of endotracheal intubation and MV. The **LISA (less invasive surfactant administration)** method uses a thin flexible catheter (5-F end-hole catheter), which is inserted into the trachea using Magill forceps. Surfactant is administered while the spontaneously breathing infant is on nasal CPAP. The **MIST (minimally invasive surfactant treatment)** method is a similar strategy, where a thin but stiff vascular catheter is inserted into trachea under direct laryngoscopy while the baby is on nCPAP.
- 4. Repeated doses.** A second and sometimes a third dose of surfactant should be administered in cases with ongoing evidence of RDS (ie, persistent need of MV

and oxygen supplementation). Using a larger dose (200 mg/kg) of poractant alfa has reduced the need of subsequent doses. Multiple INSURE treatments have been successful without worsening outcomes. The addition of budesonide to natural surfactant preparations may also decrease lung inflammation in ventilated preterm babies and reduce the risk of BPD, although this will need further verification by randomized multicenter trials.

- E. **Inhaled nitric oxide** therapy is not recommended for the routine treatment of RDS in premature neonates. However, persistent pulmonary hypertension of the newborn often occurs concurrently with RDS in very preterm infants. iNO therapy can improve oxygenation in such cases.
 - F. **Fluid and nutritional support.** In the very ill infant, it is possible to maintain nutritional support with parenteral nutrition for an extended period. Full parenteral nutrition and minimal enteral feeding can be initiated on the first day of life. Careful fluid balance should, however, be maintained. The specific needs of preterm and term infants are becoming better understood, and the nutrient preparations available reflect this understanding (see Chapters 10 and 11). Use of diuretics is not recommended in this patient group.
 - G. **Antibiotic therapy.** Antibiotics that cover the most common neonatal infections are usually begun initially.
 - H. **Caffeine.** Should be initiated for all premature infants at high risk of MV, such as those with birthweight of 1250 g who are on CPAP treatment. It should also be used in order to facilitate weaning from MV.
 - I. **Sedation.** Commonly used to control ventilation in these sick infants. **Morphine and fentanyl** may be used for analgesia as well as sedation, preferably by using validated pain scoring systems. Minimal handling to avoid pain is an important means to decrease need for pain management in ventilated infants. Routine sedation is usually not needed in babies, who are stable on ventilation. Opioids have neither decreased mortality rates and duration of MV nor improved short-term and long-term neurodevelopmental outcomes in neonates receiving MV in meta-analyses. Instead, the number of days to reach full enteral feeding has been increased in opioid-treated infants. Advantages of treatment include improved ventilator synchrony and pulmonary function, especially in infants who “fight” against the ventilator. Adverse effects of medication, especially opioids, including hypotension with morphine and chest wall rigidity with fentanyl, should be kept in mind. Tolerance, dependence, and withdrawal occur. Muscle paralysis with **pancuronium** for infants with RDS remains *controversial*. Sedation of infants with fluctuating cerebral blood flow velocity theoretically decreases the risk of IVH. (See also Chapter 81.)
 - J. **Complications.** Pulmonary air leaks, such as pneumothorax, pneumomediastinum, pneumopericardium, and pulmonary interstitial emphysema, as well as pulmonary hemorrhage, may occur (see Chapter 87). Chronic complications include respiratory problems such as BPD/CLD (see Chapter 90) and tracheal stenosis.
- VIII. Prognosis.** Although the survival of infants with RDS has improved greatly, the survival with or without respiratory and neurologic sequelae is highly dependent on birth-weight and gestational age. Major morbidity (BPD/CLD, NEC, and severe IVH) and poor postnatal growth remain high for the smallest infants.

118 Retinopathy of Prematurity

I. Definitions

- A. Retinopathy of prematurity** is a disorder resulting from the disruption of the normal development of retinal vasculature. Vasoconstriction and obliteration of the advancing capillary bed are followed in succession by neovascularization extending into the vitreous, retinal edema, retinal hemorrhages, fibrosis, and traction on, and eventual detachment of, the retina. In most cases, the process is reversed before fibrosis occurs. Because it is found chiefly in premature infants, it is called *retinopathy of prematurity (ROP)*. **Advanced stages may lead to blindness.**
- B. Retrolental fibroplasia.** ROP was previously termed *retrolental fibroplasia (RLF)*. The condition was first described in its most advanced form, after extensive fibrosis had already occurred behind the lens.
- C. Cicatricial retinopathy of prematurity.** The term *cicatricial ROP* refers to fibrotic disease.

- II. Incidence.** Overall, approximately 65% of infants weighing <1251 g develop some form of ROP. Approximately 2% of infants weighing 1000 to 1250 g develop threshold stage 3+ disease eligible for treatment, and approximately 16% of infants weighing <750 g do so. Three large National Institutes of Health–sponsored studies have supported these numbers: the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study in 1986 to 1987, the Early Treatment for Retinopathy of Prematurity study (ETROP) in 2000 to 2002, and the Telemedicine Approaches for the Evaluation of Acute-Phase Retinopathy of Prematurity (e-ROP) from 2011 to 2013. These numbers have stayed consistent over almost 3 decades of study, although the incidence and survival of low birthweight infants have increased. This suggests that the overall care of these infants has improved. **Threshold disease occurred at a median postconceptional age of 36 to 37 weeks, regardless of gestational age at birth or chronologic age.** Of note, the International NO-ROP Group in 2005 suggested that severe ROP in larger infants is an emerging worldwide issue. Care and survival of these premature infants are improving, whereas specialized treatment for ROP is not yet as prevalent, making ROP a significant long-term morbidity in these patients.

III. Pathophysiology

- A. Historical perspective.** RLF was first described by Terry in the 1940s and was associated with the use of oxygen in newborn infants by Patz in 1984. The **first epidemic**, estimated to be responsible for 30% of cases of blindness in preschool children by the end of the 1940s, occurred during a period of relatively liberal oxygen administration. After this association was recognized, oxygen use in nurseries was curtailed. Although the incidence of RLF fell, mortality rates in newborn infants increased. In the 1960s, improved oxygen monitoring techniques made possible the cautious reintroduction of oxygen into the nursery. Despite improved oxygen monitoring, however, a **second epidemic** of RLF (ROP) appeared in the late 1970s and was associated with the increased survival of very low birthweight infants.
- B. Normal embryology of the eye.** In the normally developing retina, there are no retinal vessels until approximately 16 weeks' gestation. Until then, oxygen diffuses from the underlying choroidal circulation. At 16 weeks, in response to a stimulus (experimental evidence suggests relative hypoxia stimulating the release of angiogenic factors as the retina thickens), cells derived from mesenchyme traveling in the nerve fiber layer emanate from the optic nerve head. These cells are the precursors of the retinal vascular system. A fine capillary network advances through the retina to the ora serrata, or retinal edge. More mature vessels form behind this advancing network. Vascularization on the nasal side of the ora serrata is complete at approximately 8 months' gestation and at term on the temporal side. Regulation

of this process involves various factors including vascular endothelial growth factor (VEGF) and insulin-like growth factor 1 (IGF-1) working in combination. Once the retinal vasculature is completely vascularized, it is no longer susceptible to insults of the type that lead to ROP.

C. Causes. There appear to be 2 phases in the development of ROP.

1. Early vasoconstriction and obliteration of the capillary network occurs in response to high oxygen concentrations or another vascular insult. Concentrations of IGF-1 are low in the very low birthweight infant in the early postnatal period as maternal levels are no longer available. Experimental evidence in the mouse model suggests that low IGF-1 contributes to the lack of retinal blood vessel formation in early ROP.

2. Vasoproliferation follows the period of high oxygen exposure or insult, in response to angiogenic factors such as VEGF released by the hypoxic retina. Recent data suggest that VEGF only leads to angiogenesis in the presence of adequate tissue concentrations of IGF-1. When endogenous IGF-1 levels rise in the maturing at-risk premature infant, vasoproliferation is triggered in the presence of VEGF. Considerable evidence has been developed to support this hypothesis. Further research will surely elucidate other modulators of this process.

IV. Risk factors. The association of ROP with oxygen alone is not so clear. Transient hyperoxemia alone is not sufficient. Many other factors, such as extreme prematurity, apnea, sepsis, hyper- and hypocapnia, intraventricular hemorrhage, anemia, exchange transfusion, hypoxia, lactic acidosis, and possibly erythropoietin, which is angiogenic, have been implicated. Experimental studies have focused chiefly on the role of oxygen. Oxygen monitoring is an important part of the care of the premature infant, although **extreme prematurity is known to be the significant risk factor**. Data from Wu et al have shown that postnatal weight gain also significantly affects the development of ROP.

V. Clinical presentation. Several methods of classification of ROP have been used. Here the **International Classification of ROP** is described.

A. Stage 1. A thin demarcation line develops between the vascularized region of the retina and the avascular zone.

B. Stage 2. This line develops into a ridge protruding into the vitreous.

C. Stage 3. Extraretinal fibrovascular proliferation occurs with the ridge. Neovascular tufts may be found just posterior to the ridge (Figure 118–1).

D. Stage 4. Fibrosis and scarring occur as the neovascularization extends into the vitreous. Traction occurs on the retina, resulting in partial retinal detachment.

E. Stage 5. Complete retinal detachment.

F. Plus disease (eg, stage 3+). This occurs when vessels posterior of the posterior pole become dilated and tortuous. **Plus disease has become a primary factor in treatment decisions.**

G. Pre-plus disease. Dilation and tortuosity of posterior pole vessels in zone I; less severe than plus disease.

H. Aggressive posterior retinopathy of prematurity. Rapidly progressive ROP primarily in zone I. **Requires immediate treatment.**

I. Zones. The retina is divided into circumferential **zones I, II, and III** to designate how far from the posterior pole disease is present. The most severe disease is any stage with plus disease close to the posterior pole, in zone I. The least severe is disease in the temporal peripheral retina, in zone III. No treatment is necessary for peripheral zone III disease, as it regresses spontaneously.

VI. Diagnosis. Ophthalmoscopic examination by an experienced examiner usually confirms the diagnosis. **Binocular indirect ophthalmoscopy (BIO)** is generally used. Increasingly, fundus photography of the posterior retina with remote interpretation of the images is being used for screening in areas where no ophthalmologist is available. Validated through e-ROP, this technique is limited in that it does not permit adequate assessment of ROP in the retinal periphery. BIO must be employed to determine when screening can be discontinued.

FIGURE 118–1. Schematic drawing of moderate stage 3 retinopathy of prematurity. Optic nerve head is shown at the bottom, and periphery of the retina is at the top.

For BIO to be performed, dilation drops must be administered prior to examination. Protocols vary depending on the institution and the location throughout the world, but in general, cyclopentolate (0.2% or 0.5%) and phenylephrine (1% or 2.5%) are used at the lowest concentration deemed reasonable to achieve sufficient examination of the peripheral retina. (See Table 118–1 for a full list of medications used and their side effects.) Just prior to examination, proparacaine drops are also often administered to provide topical anesthesia. The American Academy of Pediatrics (AAP) pain management recommendations from 2006, reaffirmed in 2010, state that retinal examinations are painful, and pain relief measures should be used. They further state that a reasonable approach would be to administer local anesthetic eye drops, pacifiers, and oral sucrose. A 2013 joint statement by the AAP, the American Association for Pediatric Ophthalmology and Strabismus, and the American Academy of Ophthalmology provided updated recommendations for ROP screening examinations in premature infants.

A. Infants weighing ≤ 1500 g or ≤ 30 weeks' gestation and those weighing >1500 g or >30 weeks' gestation with an unstable clinical course should have dilated eye examinations starting at 4 to 6 weeks of age or 31 to 33 weeks' postmenstrual age. Examinations should continue every 2 to 3 weeks until retinal vascular maturity is reached, if no disease is present.

B. Infants with retinopathy of prematurity or very immature vessels should be examined every 1 to 2 weeks until vessels are mature or the risk of disease requiring treatment has passed. Those at greatest risk should be examined every week.

VII. Management. Disease that requires treatment was defined by the ETROP study and includes zone I ROP of any stage with plus disease, zone I ROP stage 3 with no plus disease, and zone II ROP stage 2 or 3 with plus disease. The possible interventions are as follows:

A. Circumferential cryopexy. Proven to be an effective treatment for progressive disease, this approach prevents further ROP progression by destroying cells that

Table 118–1. COMMON OCULAR AGENTS USED FOR RETINOPATHY OF PREMATURITY EVALUATION IN NEONATES (ANESTHETIC AND MYDRIATIC AGENTS; EXCLUDES ANTIBIOTICS)

Medication	Form	Concentration	Frequency	Class	Indication	Side Effects
Proparacaine	Ophthalmic solution	0.50%	1 time ^a	Anesthetic	Topical anesthesia prior to dilation eye drops	Conjunctival hemorrhage, corneal erosion, cycloplegia (rare), passive conjunctival congestion
Cyclopentolate	Ophthalmic solution	0.2%, 0.5%, 1%, 2%	1 time ^a	Anticholinergic	Mydriasis induction, cycloplegia	Blurred vision, burning sensation in eye, photophobia, conjunctivitis, raised intraocular pressure, tachyarrhythmia, vasodilatation, ataxia, confusion, seizure, psychotic disorder
Phenylephrine hydrochloride	Ophthalmic solution	1%, 2.5%	1 time ^a	Adrenergic alkylarylamine	Mydriasis induction	Eye irritation, nasal congestion, sneezing. Note: Topical instillation of phenylephrine 10% ophthalmic solution has resulted in rare occurrences of tachycardia, ventricular arrhythmias, myocardial infarction, subarachnoid hemorrhage, and rupture of aneurysms. Phenylephrine 10% is not used routinely in neonates.
Tropicamide	Ophthalmic solution	0.5%, 1%	1 time ^a	Anticholinergic	Mydriasis induction, cycloplegia	Blurred vision, burning sensation in eye, photophobia, raised intraocular pressure

^aMay repeat 1–2 times after 5–10 minutes, if needed, for additional dilation.

may be releasing angiogenic factors. Results of the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study indicate that cryopexy carried out at stage 3+ can reduce the incidence of severe visual impairment by approximately 50% if performed within 72 hours of detecting threshold disease. Ten-year follow-up shows significant improvement in visual acuity of treated versus control eyes. It is imperative that an ophthalmologist skilled in cryopexy performs the procedure.

- B. Laser photocoagulation.** This technique is equally effective yet safer than cryopexy, and it has become **the treatment of choice**. In 1994, the Laser ROP Study Group conducted a meta-analysis of 4 laser ROP trials. Treatment was based on the same criteria used in the CRYO-ROP trial. Recognizing the limitations of a meta-analysis, the study group concluded that laser therapy is at least as effective as cryotherapy for ROP, despite a small risk of cataract formation. Ten-year follow-up of a small group of patients suggested better outcomes with laser photocoagulation. The ETROP study (2002) demonstrated improved outcomes with treatment at any stage when plus disease is present. AAP pain recommendations from 2006, reaffirmed in 2010, state that retinal surgery should be considered major surgery, and effective opiate-based pain relief should be provided while monitoring the infant with an appropriate pain assessment scale.
- C. Oxygen for treatment of retinopathy of prematurity.** In an attempt to reduce angiogenic factors from the hypoxic retina and to prevent the progression of ROP, oxygen therapy was administered in a large collaborative trial, the Supplemental Therapeutic Oxygen for Prethreshold Retinopathy of Prematurity (STOP-ROP) study. Oxygen saturations were targeted at 96% to 99% in the treatment group and 89% to 94% in the conventional group once prethreshold ROP was diagnosed. No significant difference was seen in the rate of progression to threshold disease between the 2 groups, although there was a significant increase in bronchopulmonary dysplasia/chronic lung disease in the high-saturation group. The appropriate saturation ranges remain **controversial** and under study, although most neonatal intensive care units keep infants <1250 g at saturations <95% when on supplemental oxygen.
- D. Intravitreal injection of anti-vascular endothelial growth factor therapy.** Given the contribution of VEGF to the pathophysiology of ROP, recent studies have explored the use of intravitreal injection of anti-VEGF agents as an alternative to traditional ablative therapies. In 2011, Mintz-Hittner et al published their results for the Bevacizumab Eliminates the Angiogenic Threat of Retinopathy of Prematurity BEAT-ROP collaborative trial in which infants with stage 3+ ROP were randomly assigned to intravitreal bevacizumab monotherapy versus laser therapy. A significant benefit for zone 1 ROP (the most difficult to treat conventionally) was demonstrated. The time to recurrence of ROP after bevacizumab was much later, however, than after laser photocoagulation (~16 weeks vs ~6 weeks), necessitating longer follow-up time to ensure no recurrence of ROP requiring treatment. Further studies are being conducted to determine if lower concentrations of bevacizumab will be equally effective at treating ROP with less risk of systemic suppression of VEGF. In addition, treatment with other anti-VEGF agents is being explored.
- E. Insulin-like growth factor 1 supplementation.** A recent multicenter phase II study investigated the administration of mecasermin rinfabate in 121 infants of 23 to 27 weeks' gestation until 30 weeks' gestation in an effort to prevent ROP. The study found no change in the incidence of ROP, although the rates of intraventricular hemorrhage and bronchopulmonary dysplasia were significantly decreased. Further study is needed to elucidate the possible prevention of ROP through IGF-1 supplementation.
- F. Dietary supplementation of omega-3 polyunsaturated fatty acids.** The balance of omega-3 and omega-6 polyunsaturated fatty acids in the retina affects cell survival. Studies in the mouse model have shown a protective effect of omega-3 supplementation.

- G. Vitamin E.** The administration of pharmacologic doses of vitamin E for ROP has been studied with no proof of clear benefit. Reported side effects include sepsis, necrotizing enterocolitis, and intraventricular hemorrhage. Even so, maintenance of normal serum vitamin E levels is a prudent management objective. (For doses, see Chapter 155.)
- H. Retinal reattachment surgery.** Stage 4 and 5 disease has been treated surgically with vitrectomy and scleral buckle with some anatomic success. Visual prognosis, however, remains guarded to poor in these patients.
- I. Follow-up eye examinations.** Advocated every 1 to 2 years for infants with fully regressed ROP and every 6 to 12 months for those with cicatricial ROP. Premature infants are at risk for myopia even in the absence of ROP and should have an eye examination by 6 months of age.
- VIII. Prognosis.** Ninety percent of cases of stage 1 and stage 2 disease regress spontaneously. Approximately 50% of cases of stage 3+ disease regress spontaneously. Of those that do progress to stage 3+, the incidence of unfavorable structural outcomes can be reduced by approximately 50% and unfavorable visual outcomes by approximately 30% if circumferential cryopexy is carried out by a skilled ophthalmologist. Laser photocoagulation appears equally and possibly more effective than cryopexy and is now the procedure of choice in the United States. Sequelae of regressed disease such as myopia, strabismus, amblyopia, glaucoma, and late detachment require regular follow-up.

119 Rh Incompatibility

- I. Definition.** Rh incompatibility is a condition that occurs during pregnancy when a mother with Rh-negative blood [who is previously sensitized to the Rh(D) antigen] is exposed to her fetus who is Rh-positive leading to the development of Rh antibodies and resulting in fetal isoimmune hemolytic anemia of variable severity. The onset of clinical disease begins in utero as the result of active placental transfer of maternal immunoglobulin (Ig)G-Rh antibody. It is manifested as a partially compensated, moderate to severe hemolytic anemia at birth, with unconjugated hyperbilirubinemia developing in the early neonatal period.
- II. Incidence.** Historically, Rh hemolytic disease of the newborn accounted for up to a third of symptomatic cases seen and was associated with detectable antibody in approximately 15% of Rh-incompatible mothers. **The use of Rh immunoglobulin (RhoGAM) prophylaxis has reduced the incidence of Rh sensitization to <1% of Rh-incompatible pregnancies.** In developing countries without prophylaxis, stillbirth still occurs in 14% of affected pregnancies, and 50% of pregnancies survivors either die in the neonatal period or develop cerebral injury. Other alloimmune antibodies have become relatively more important as a cause of hemolysis. Anti-c, Kell (K and k), Duffy (Fya), Kidd (Jka and Jkb), MNS (M, N, S, and s), and less commonly anti-C and anti-E may cause severe hemolytic disease of the newborn.
- III. Pathophysiology.** Initial exposure of the mother to the Rh antigen occurs most often during parturition, miscarriage, abortion, and ectopic pregnancy. Invasive investigative procedures such as amniocentesis, chorionic villus sampling, and fetal blood sampling also increase the risk of fetal transplacental hemorrhage and alloimmunization. Recognition of the antigen by the immune system ensues after initial exposure, and reexposure to the Rh antigen induces a maternal anamnestic response and elevation

of specific IgG-Rh antibody. Active placental transport of this antibody and immune attachment to the Rh-antigenic sites on the fetal erythrocyte are followed by extravascular hemolysis of erythrocytes within the fetal liver and spleen. The rate of the hemolytic process is proportionate in part to the levels of the maternal antibody titer but is more accurately reflected in the antepartum period by elevation of the amniotic fluid bilirubin concentration and in the postpartum period by the rate of rise of unconjugated bilirubin. In contrast to ABO incompatibility, the greater antigenicity and density of the Rh-antigen loci on the fetal erythrocyte facilitates progressive, rapid clearance of fetal erythrocytes from the circulation. A demonstrable phase of spherocytosis will be absent. Compensatory reticulocytosis and shortening of the erythrocyte generation time, if unable to match the often high rate of hemolysis in utero, result in anemia in the newborn infant and a risk of multiple systemic complications.

IV. Risk factors

- A. Birth order.** The first-born infant is at minimum risk (<1%) unless sensitization has occurred previously. Once sensitization has occurred, subsequent pregnancies are at a progressive increased risk for fetal disease.
- B. Fetomaternal hemorrhage.** The volume of fetal erythrocytes entering the maternal circulation correlates with the risk of sensitization. The risk is approximately 8% with each pregnancy but ranges from 3% to 65%, depending on the volume of fetal blood (3% with 0.1 mL compared with 22% with >0.1 mL) that passes into the maternal circulation.
- C. ABO incompatibility.** Coexistent incompatibility for either the A or B blood group antigen reduces the risk of maternal Rh sensitization to 1.5% to 3.0%. Rapid immune clearance of these fetal erythrocytes after their entry into the maternal circulation exerts a partial protective effect. It confers no protection once sensitization has occurred.
- D. Obstetric factors.** Cesarean delivery or trauma to the placental bed during the third stage of labor increases the risk of significant fetomaternal transfusion and subsequent maternal sensitization.
- E. Gender.** Male infants are reported to have an increased risk of more severe disease than females, although the basis for this observation is unclear.
- F. Ethnicity.** Approximately 15% of whites are Rh negative compared with 7% of blacks and almost 0% of Asiatic Chinese and Japanese. The risk to the fetus varies accordingly.

V. Clinical presentation

A. Symptoms and signs

- 1. Jaundice.** Unconjugated hyperbilirubinemia is the most common presenting neonatal sign of Rh disease, usually appearing within the first 24 hours of life.
- 2. Anemia.** Low cord blood hemoglobin at birth reflects the relative severity of the hemolytic process in utero and is present in approximately 50% of cases.
- 3. Hepatosplenomegaly.** Enlargement of the liver and spleen is seen in severe hemolysis, sometimes occurring in association with ascites, with an increased risk for splenic rupture.
- 4. Hydrops fetalis.** Severe Rh disease has a historical association with hydrops fetalis and at one time was its most common cause. Clinical features in the fetus include progressive hypoalbuminemia with ascites, pleural effusion, or both; severe chronic anemia with secondary hypoxemia; and cardiac failure. There is an increased risk of late fetal death, stillbirth, and intolerance of active labor. The neonate frequently has generalized edema, notably of the scalp, which can be detected by antepartum ultrasonography; cardiopulmonary distress often involving pulmonary edema and severe surfactant deficiency; congestive heart failure; hypotension and peripheral perfusion defects; cardiac rhythm disturbances; and severe anemia with secondary hypoxemia and metabolic acidosis. Currently, nonimmune conditions are more commonly associated with hydrops fetalis. Secondary involvement of other organ systems may result in hypoglycemia or thrombocytopenic purpura.

VI. Diagnosis. Obligatory screening in an infant with unconjugated hyperbilirubinemia includes the following studies:

- A. Blood type and Rh type (mother and infant).** The Rhesus (Rh) factor is an inherited protein found on the surface of red blood cells (RBCs). If the RBCs have the protein, then one is Rh-positive; if the RBCs lack the protein, then one is Rh-negative. Obtaining the blood type and Rh type establish the likelihood of Rh incompatibility and exclude the diagnosis if the infant is Rh negative, with 1 exception (see direct antiglobulin test [direct Coombs test], Section VI.C). This can be done prenatally by detection of cell-free fetal DNA of the *RHD* gene in the maternal blood.
- B. Reticulocyte count.** Elevated reticulocyte levels, adjusted for the degree of anemia and gestational age in preterm infants, reflect the degree of compensation and support a diagnosis of an ongoing hemolytic process. Normal values are 4% to 5% for term infants and 6% to 10% for preterm infants (30–36 weeks' gestational age). In symptomatic Rh disease, expected values are 10% to 40%.
- C. Direct antiglobulin test (direct Coombs test).** A strongly positive direct Coombs test indicates that fetal RBCs are coated with antibodies and is diagnostic of Rh incompatibility in the presence of the appropriate setup and an elevated reticulocyte count. If Rh immunoglobulin was given at 28 weeks' gestation, subsequent passive transfer of antibody will result in a false-positive direct Coombs test without associated reticulocytosis. Very rarely, a strongly positive direct Coombs test is associated with a falsely Rh-negative infant when all fetal RBC Rh-antigenic sites are covered by a high titer of maternal antibodies.
- D. Blood smear.** Polychromasia and normoblastosis proportionate to the reticulocyte count are typically present. Spherocytes are not usually present. The nucleated RBC count is often >10 per 100 white blood cells.
- E. Bilirubin levels.** Progressive elevation of unconjugated bilirubin on serial testing provides an index of the severity of the hemolytic process. An elevated direct fraction is most likely to be secondary to a laboratory artifact in the first 3 days of life and should not be subtracted from the total bilirubin when making management decisions. In the most severely affected infants, particularly those who are hydroptic, the intense extramedullary erythropoiesis may cause hepatocellular dysfunction and biliary canalicular obstruction with significant elevated direct bilirubin by 5 to 6 days of age (inспissated bile syndrome).
- F. Bilirubin-binding capacity tests.** Correlation between measurements of serum albumin, free bilirubin, bilirubin saturation index, and reserve binding capacity and outcome has been variable. The role of these values in directing the management of patients remains unclear.
- G. Glucose and blood gas levels.** These should be monitored closely.
- H. Supplementary laboratory studies.** Supportive diagnostic studies may be required when the basis of the hemolytic process remains unclear.
 - 1. Indirect antiglobulin titer (indirect Coombs test).** This test detects the presence of antibodies in the maternal serum. Rh-positive RBCs are incubated with the serum being tested for the presence of anti-D. If present, the RBCs now coated with anti-D are agglutinated by an antihuman globulin serum reflecting a positive indirect antiglobulin (Coombs) test result. The reciprocal of the highest dilution of maternal serum that produces agglutination is the indirect antiglobulin titer.
 - 2. Carbon monoxide.** The severity of Rh disease may be determined by measurement of endogenous carbon monoxide (CO) production. When heme is catabolized to bilirubin, CO is produced in equimolar amounts. Hemoglobin binds the CO to form carboxyhemoglobin (COHb) and then is finally excreted in the breath. COHb levels are increased in neonates with hemolysis. COHb levels >1.4% have been correlated with an increased need for exchange transfusion.

VII. Management

A. Antepartum treatment. Verification of the Rh-negative status at the first prenatal visit may be obtained by the following measures:

- 1. Maternal antibody titer.** Once an IgG-Rh antibody has been identified, it is important to determine the titer. Serial antibody titer determinations are required every 1 to 4 weeks (depending on the gestational age) during pregnancy. Invasive fetal testing becomes indicated when the titer is above a critical level, usually between 1:8 and 1:16. A negative antibody screen (indirect Coombs test) signifies absence of sensitization. This test should be repeated at 28 to 34 weeks' gestation.
- 2. RhoGAM.** Current obstetric guidelines suggest giving immunoprophylaxis at 28 weeks' gestation in the absence of sensitization.
- 3. Amniocentesis.** If maternal antibody titers indicate a risk of fetal death (usual range, 1:16–1:32), amniocentesis may be performed to assess fetal Rh genotype and assess severity. Fetal Rh genotype determination can also be made from fetal cell-free DNA found in maternal plasma. To reasonably predict the risk of moderate to severe fetal disease, serial determinations of amniotic fluid bilirubin levels present photometrically at 450 nm (ΔOD_{450}) are plotted on standard graphs according to gestational age (known as the **Liley curve**). Readings falling into very high zone II or zone III indicate that hydrops will develop within 7 to 10 days. Zone I indicate no fetal hemolytic disease or no anemia.
- 4. Ultrasonography.** As a screening study in pregnancies at risk, serial fetal ultrasound examinations allow detection of scalp edema, ascites, or other signs of developing hydrops fetalis. Serial peak systolic middle cerebral artery velocity can reliably detect moderate and severe fetal anemia and thus is now replacing the more invasive and less predictive ΔOD_{450} analysis for fetal anemia monitoring.
- 5. Intrauterine transfusion.** Based on the studies just mentioned, intrauterine transfusion may be indicated because of possible fetal demise or the presence of fetal hydrops. This procedure must be performed by an experienced team. The goal is maintenance of effective erythrocyte mass within the fetal circulation and maintenance of the pregnancy until there is a reasonable chance for successful extrauterine survival of the infant.
- 6. Glucocorticoids.** If premature delivery is anticipated, glucocorticoids should be given to accelerate fetal lung maturation and reduce the risk of intraventricular hemorrhage.
- 7. Reduction of maternal antibody level.** Intensive maternal plasma exchange and high-dose intravenous immunoglobulins (IVIGs) have been reported to be of value in the severely alloimmunized pregnant woman to reduce circulating maternal antibodies levels by >50%.

B. Postpartum treatment

- 1. Resuscitation.** Moderately to severely anemic infants with or without hydropic features are at risk for high-output cardiac failure, hypoxemia secondary to decreased oxygen-carrying capacity or surfactant deficiency, and hypoglycemia. These infants may require immediate single-volume exchange blood transfusion at delivery to improve oxygen-carrying capacity, mechanical support of ventilation, and an extended period of monitoring for hypoglycemia.
- 2. Cord blood studies.** A cord blood bilirubin level >4 mg/dL, a cord hemoglobin <12 g/dL, or both usually suggests moderate to severe disease. The cord blood is used for these and initial screening studies, including blood typing, Rh typing, and Coombs test.
- 3. Serial unconjugated bilirubin studies.** Determination of the rate of increase in unconjugated bilirubin levels provides an index of the severity of the hemolytic process and the need for exchange transfusion. Commonly used guidelines include a rise of >0.5 mg/dL/h or >5 mg/dL over 24 hours within the first 2 days

- of life or projection of a serum level that will exceed a predetermined “exchange level” for a given infant (usually 20 mg/dL in term infants).
4. **Phototherapy.** In severe Rh hemolytic disease, phototherapy is used only as an adjunct to exchange transfusion. Phototherapy decreases bilirubin levels and reduces the number of total exchange transfusions required. See Chapters 63 and 99 for phototherapy details.
 5. **Exchange transfusion.** For the procedure, see Chapter 34. Exchange transfusion is indicated if the unconjugated bilirubin level is likely to reach a predetermined “exchange level” for that patient. Optimally, exchange transfusion is done well before this exchange level is reached to minimize the risk of entry of unconjugated bilirubin into the central nervous system. Consideration should be given to irradiation of blood before the transfusion is given, particularly in preterm infants or infants expected to require multiple transfusions, to reduce the risk of graft-versus-host disease. The process removes 70% to 90% of the fetal red cells, but only 25% of the total bilirubin because most of the bilirubin is in the extravascular space. A rapid rebound of serum bilirubin is common after reequilibration, and thus, additional exchange transfusions may be required.
 6. **Heme oxygenase inhibitors (stansoporphin).** See Chapter 85 on ABO incompatibility. Tin (Sn) porphyrin is an inhibitor of heme oxygenase, the enzyme that allows the production of bilirubin from heme.
 7. **Intravenous immunoglobulin.** By blocking neonatal reticuloendothelial Fc receptors, and thus decreasing hemolysis of the antibody-coated RBCs, high-dose IVIG (1 g/kg over 4 hours) reduces serum bilirubin levels and the need for blood exchange transfusion with ABO or Rh hemolytic diseases. (See Chapter 85.) Caution should be used when considering treatment with IVIG because there are emerging reports of increased incidence of necrotizing enterocolitis in term and late preterm infants with hemolytic disease of the newborn and isoimmune neonatal thrombocytopenia who were treated with IVIG.
- C. **RhoGAM prophylaxis.** Most cases of incompatibility involve the D antigen. RhoGAM given at 28 weeks’ gestation, within 72 hours of suspected Rh-antigen exposure, or both reduces the risk of sensitization to <1%; the recommended dosage (300 mcg) should be well in excess of the amount of Rh antigen transfused (300 mcg for every 25 mL of fetal blood in maternal circulation). The amount of fetal blood entering the maternal circulation may be estimated using the Kleihauer-Betke acid elution technique (pages 819 and 820) during the immediate postpartum period.
- D. **Hydrops fetalis.** Skilled resuscitation and anticipation of selective systemic complications may prevent early neonatal death.
1. **Isovolumetric partial exchange transfusion with type O Rh-negative packed erythrocytes.** Raises the hematocrit and improves the oxygen-carrying capacity (see Chapter 34).
 2. **Central arterial and venous catheterization.** May be performed to provide the following measures:
 - a. **Isovolumetric exchange transfusion.**
 - b. **Monitoring of arterial blood gas levels** and central venous and systemic blood pressures.
 - c. **Monitoring of fluid and electrolyte balance,** particularly renal and hepatic function, calcium-to-phosphorus ratio, and serum albumin levels, as well as appropriate hematologic studies and serum bilirubin levels.
 3. **Positive-pressure mechanical ventilation.** This measure may include increased levels of positive end-expiratory pressure, if pulmonary edema is present, as a means of stabilizing alveolar ventilation. Treatment with exogenous surfactant may be considered in particular when the infant is judged to be not fully mature.
 4. **Therapeutic thoracentesis or paracentesis** may be performed to remove fluid that may further compromise respiratory effort. Excessive removal of ascitic fluid may lead to systemic hypotension. (See Chapters 31 and 40.)

5. **Volume expanders** may be necessary, in addition to erythrocytes, to improve peripheral perfusion defects. This should be done with caution because most hypoxic infants are hypotensive or poorly perfused because of hypoxic heart failure rather than hypovolemia, or both.
 6. **Drug treatment.** Includes diuretics for pulmonary edema and pressor agents such as dopamine (for dosing, see Chapter 155). Diuretics that contain a sulfonamide group (such as furosemide) should be avoided.
 7. **Electrocardiography or echocardiography.** May be used to determine whether cardiac abnormalities are present.
- VIII. Prognosis.** Prenatal mortality for infants at risk of anti-D Rh isoimmunization is currently approximately 1.5% and has decreased significantly over the past 2 decades. Antenatal immune prophylaxis and improved management techniques, including amniotic fluid spectrophotometry, intrauterine transfusion, and advances in neonatal intensive care, have been largely responsible for this reduction. Isolated cases of severe isoimmunization still occur because of isoimmunization by other than anti-D antibody or failure to receive immune prophylaxis and may exhibit the full spectrum of disease, including an increased risk of stillbirths and early neonatal morbidity and mortality.

120 Seizures

- I. **Definition.** A seizure is defined clinically as a paroxysmal alteration in neurologic function (ie, behavioral, motor, or autonomic function). (See also Chapter 82 for on-call management of seizures).
- II. **Incidence.** Neonatal seizures are relatively common and occur in 2 to 3 neonates per 1000 births of all neonates; the incidence is more common in premature infants, with an occurrence in up to 130 per 1000.
- III. **Pathophysiology.** The neurons within the central nervous system (CNS) undergo depolarization as a result of inward migration of sodium. Repolarization occurs via efflux of potassium. A seizure occurs when there is excessive depolarization, resulting in excessive synchronous electrical discharge. Volpe (2001) proposed the following 4 possible reasons for excessive depolarization: failure of the sodium-potassium pump because of a disturbance in energy production, a relative excess of excitatory versus inhibitory neurotransmitters, a relative deficiency of inhibitory versus excitatory neurotransmitters, and alteration in the neuronal membrane, causing inhibition of sodium movement. The basic mechanisms of neonatal seizures, however, are unknown.
- IV. **Etiology.** There are numerous causes of neonatal seizures, but relatively few account for most cases. Therefore, only common causes of seizures are discussed here. See Table 120-1 for a more extensive list of causes.
 - A. **Perinatal asphyxia** is the most common cause of neonatal seizures. Hypoxic ischemic encephalopathy (HIE) is seen in approximately 1 to 2 per 1000 live births. In fact, about two-thirds of cases of neonatal seizures are due to HIE. These occur within the first 24 hours of life in most cases. In premature infants, seizures are of the generalized tonic type, whereas in full-term infants they are of the multifocal clonic type. Accompanying subtle seizures are usually present in both types.
 - B. **Intracranial hemorrhage**
 1. **In primary subarachnoid hemorrhage**, convulsions often occur on the second postnatal day, and the infant appears quite well during the interictal period.

Table 120–1. CAUSES OF NEONATAL SEIZURES**Perinatal asphyxia/hypoxic ischemic encephalopathy**

Intracranial hemorrhage: Subarachnoid hemorrhage; intraventricular hemorrhage; subdural hemorrhage; parenchymal hemorrhage

Acute metabolic abnormalities: Hypoglycemia; hypocalcemia; hyponatremia; hypernatremia; hypomagnesemia

Inborn errors of metabolism: Amino acid disorders; urea cycle abnormalities; organic acidemias; mitochondrial disorders; peroxisomal disturbances; pyridoxine dependency; pyridoxal phosphate-dependent seizures; folinic acid responsive seizures; multiple carboxylase deficiency; others

Congenital malformations: Lissencephaly; focal cortical dysplasia; schizencephaly; hydranencephaly; hemimegalencephaly

Infections: Meningitis; encephalitis; cerebral abscess

Congenital infections: Syphilis; cytomegalovirus infections; toxoplasmosis; herpes simplex; rubella; coxsackie B virus; Zika

Drug withdrawal**Toxin exposure (particularly local anesthetics)**

Neonatal epilepsy syndromes: Self-limited (benign) familial neonatal epilepsy; early myoclonic encephalopathy; early infantile epileptic encephalopathy (Ohtahara syndrome)

Miscellaneous: Zellweger syndrome; tuberous sclerosis; polycythemia with hyperviscosity; bilirubin encephalopathy; ECLS-related seizures; congenital heart disease; congenital hypothyroidism

ECLS, extracorporeal life support.

2. **Periventricular or intraventricular hemorrhage** arising from the subependymal germinal matrix in preterm neonates is accompanied by subtle seizures, decerebrate posturing, or generalized tonic seizures, depending on the severity of the hemorrhage.
 3. **Subdural hemorrhage** over the cerebral convexities leads to focal seizures and focal cerebral signs. It is usually secondary to trauma.
- C. Metabolic disturbances**
1. **Hypoglycemia** is frequently seen in infants with intrauterine growth retardation and in infants of diabetic mothers. The duration of hypoglycemia and the time lapse before initiation of treatment determine the occurrence of seizures.
 2. **Hypocalcemia** has been noted in low birthweight infants, infants of diabetic mothers, asphyxiated infants, infants with DiGeorge syndrome, and infants born to mothers with hyperparathyroidism. Hypomagnesemia is a frequent accompanying problem.
 3. **Hyponatremia** occurs because of improper fluid management or as a result of the syndrome of inappropriate antidiuretic hormone.
 4. **Hypernatremia** is seen with dehydration as a result of inadequate intake in breast-fed infants or incorrect dilution of concentrated formula.
 5. **Other metabolic disorders**
 - a. **Pyridoxine dependency.** Leads to seizures resistant to anticonvulsants. Infants with this disorder experience intrauterine convulsions.
 - b. **Amino acid disorders.** Seizures in infants with amino acid disturbances are invariably accompanied by other neurologic manifestations. Hyperammonemia and acidosis are commonly present in amino acid disorders.

- D. Infections.** Intracranial infection secondary to bacterial or nonbacterial agents may be acquired by the neonate in utero, during delivery, or in the immediate perinatal period.
- 1. Bacterial infection.** Meningitis resulting from group B *Streptococcus*, *Escherichia coli*, or *Listeria monocytogenes* infection is accompanied by seizures during the first week of life.
 - 2. Nonbacterial infection.** Nonbacterial causes such as toxoplasmosis and infection with herpes simplex, cytomegalovirus, rubella, and coxsackie B viruses lead to intracranial infection and seizures.
- E. Drug withdrawal.** Three categories of drugs used by the mother lead to passive addiction and drug withdrawal (sometimes accompanied by seizures) in the infant. These are **analgesics**, such as heroin, methadone, and others; **sedative-hypnotics**, such as secobarbital; and **alcohol**.
- F. Toxins.** Inadvertent injection of local anesthetics into the fetus at the time of delivery (paracervical, pudendal, or saddle block anesthesia) may cause seizures. Mothers often notice the absence of pain relief during delivery.
- G. Congenital/developmental abnormalities of the brain.** Often the infant has obvious anomalies of the face or head if developmental abnormalities are present. Most common are lissencephaly and holoprosencephaly.
- H. Neonatal cerebral infarction (perinatal stroke).** A common cause of seizures in full-term infants (1 in 2300–5000). Usually presents with focal seizures with cerebral artery or vein infarction.
- V. Clinical presentation.** It is important to understand that **seizures in the neonate are different from those seen in older children**. The differences are perhaps due to the neuroanatomic and neurophysiologic developmental status of the newborn infant. In the neonatal brain, glial proliferation, neuronal migration, establishment of axonal and dendritic contacts, and myelin deposition are incomplete. Clinical seizures may occur without any electrographic correlation and vice versa (electroclinical dissociation). Approximately 80% of electroencephalogram (EEG)-documented seizures are not accompanied by observable clinical seizures. **Four types of seizures**, based on clinical presentation, are recognized: **subtle, clonic, tonic, and myoclonic**.
- A. Subtle seizures** are more common in premature infants than in full-term infants. They consist of tonic horizontal deviation of the eyes with or without jerking; eyelid blinking or fluttering; sucking, smacking, or drooling; “swimming,” “rowing,” or “pedaling” movements; and apneic spells. In premature infants, apnea is less likely to be a manifestation of seizures.
- B. Clonic seizures** are more common in full-term infants than in premature infants and are commonly associated with an EEG seizure. There are 2 types of clonic seizures:
- 1. Focal seizures.** Well-localized, rhythmic, slow jerking movements involving the face and upper or lower extremities on 1 side of the body or the neck or trunk on 1 side of the body.
 - 2. Multifocal seizures.** Several body parts seize in a sequential, non-jacksonian fashion (eg, left arm jerking followed by right leg jerking).
- C. Tonic seizures** occur primarily in premature infants. Two types of tonic seizures are seen.
- 1. Focal seizures.** Sustained posturing of a limb, asymmetric posturing of the trunk or neck, or both. These are commonly associated with an EEG seizure.
 - 2. Generalized seizures.** Most commonly, these occur with a tonic extension of both upper and lower extremities (as in decerebrate posturing) but may also present with tonic flexion of the upper extremities with extension of the lower extremities (as in decorticate posturing). It is uncommon to see EEG seizure disorders.

D. Myoclonic seizures are seen in both full-term and premature infants and are characterized by single or multiple synchronous jerks. Three types of myoclonic seizures are seen.

1. **Focal seizures.** Typically involve the flexor muscles of an upper extremity and are not commonly associated with EEG seizure activity.
2. **Multifocal seizures.** Exhibit asynchronous twitching of several parts of the body and are not commonly associated with EEG seizure activity.
3. **Generalized seizures.** Present with bilateral jerks of flexion of the upper and sometimes the lower extremities. They are more commonly associated with EEG seizure activity. **Note:** It is important to distinguish **jitteriness** from **seizures**. Jitteriness is accompanied by neither abnormal gaze nor eye movements, nor by autonomic changes. It is highly stimulus sensitive; tremor is the dominant movement, and it can be stopped by gentle flexion.

VI. Diagnosis

A. History. Although it is often difficult to obtain a thorough history in infants transported to tertiary care facilities from other hospitals, the physician must make a concerted effort to elicit pertinent historical data.

1. **Family history.** A positive family history of neonatal seizures is usually obtained in cases of metabolic errors and benign familial neonatal convulsions.
2. **Maternal drug history.** This is critical in cases of narcotic withdrawal syndrome.
3. **Delivery.** Details of the delivery provide information regarding maternal analgesia, the mode and nature of delivery, the fetal intrapartum status, and the resuscitative measures used. Information regarding maternal infections during pregnancy points toward an infectious basis for seizures in an infant.

B. Physical examination

1. **Physical examination.** A thorough general physical examination (including measurement of head circumference and careful attention to any dysmorphic features) should precede a well-planned neurologic examination. Determine the following:

- a. **Gestational age**
- b. **Blood pressure**
- c. **Presence of skin lesions**
- d. **Presence of hepatosplenomegaly**

2. **Neurologic evaluation.** A neurologic evaluation should include assessment of the level of alertness, cranial nerves, motor function, primary neonatal reflexes, and sensory function. Some of the specific features to look for are the size and “feel” of the fontanelle, retinal hemorrhages, chorioretinitis, pupillary size and reaction to light, extraocular movements, changes in muscle tone, and status of primary reflexes.

3. **Notation of the seizure pattern.** When seizures are observed, they should be described in detail, including the site of onset, spread, nature, duration, and level of consciousness. Recognition of subtle seizures requires special attention.

C. Laboratory studies. In selecting and prioritizing laboratory tests, use the information obtained by history taking and physical examination and look for common and treatable causes.

1. **Complete blood count and differential.** To rule out infection and polycythemia.
2. **Biochemistry.** Estimations of serum glucose, calcium, sodium, blood urea nitrogen, and magnesium and blood gas levels must be performed.
3. **Spinal fluid examination.** Evaluation of the cerebrospinal fluid (CSF) is essential because the consequences of delayed treatment or nontreatment of bacterial meningitis are grave. CSF polymerase chain reaction (PCR) should be performed for herpes simplex virus if suspected. A low CSF glucose and normal blood glucose indicate meningitis or glucose transporter defect. An increase in CSF glycine concentration together with an increased CSF-to-plasma glycine ratio suggests glycine encephalopathy, and elevated CSF lactate suggests a mitochondrial disorder.

4. **Inborn errors of metabolism.** (See also Chapter 100.) With a family history of neonatal convulsions, a peculiar odor about the infant, milk intolerance, acidosis, alkalosis, or seizures not responsive to anticonvulsants, other metabolic causes should be investigated.
 - a. **Blood ammonia levels** should be checked.
 - b. **Amino acids** should be measured in urine and plasma. The urine should be tested for reducing substances and organic acids.
 - i. **Urea cycle disorders.** Respiratory alkalosis is seen as a result of direct stimulation of the respiratory center by ammonia.
- D. **Imaging and other studies**
 1. **Ultrasonography of the head.** Performed to rule out intraventricular hemorrhage (IVH) or periventricular hemorrhage.
 2. **Computed tomography scanning of the head.** Computed tomography scanning is helpful in looking for evidence of infarction, hemorrhage, calcification, and cerebral malformations. It is useful in term infants with seizures, especially when seizures are asymmetric. Be mindful of heavy doses of radiation and avoid repeating unless absolutely essential.
 3. **Magnetic resonance imaging.** Magnetic resonance imaging (MRI) is the study of choice and can detect congenital abnormalities of brain such as lissencephaly, pachygyria, and polymicrogyria, along with IVH with infarct and HIE. A cranial MRI is the most sensitive test to determine the etiology of seizures in the neonate. It is difficult to do in an unstable infant.
 4. **Electroencephalography.** EEGs obtained during a seizure are abnormal. Interictal EEGs may be normal. However, an order to obtain an ictal EEG should not delay other diagnostic and therapeutic steps. The diagnostic value of an EEG is greater when it is obtained in the first few days because diagnostic patterns indicative of unfavorable prognosis disappear thereafter. EEG is valuable in confirming the presence of seizures when manifestations are subtle, when neuromuscular paralyzing agents have been given, and in defining the interictal background features. EEGs are of prognostic significance in full-term infants with recognized seizures. Video EEG monitoring can be done when infrequent seizures occur. Continuous EEG monitoring with **amplitude-integrated EEG (aEEG)** has improved seizure detection and is useful in full-term infants with hypoxia-ischemia.
- VII. **Management.** Optimal treatment for neonatal seizures is **controversial** and highly variable between centers, especially concerning the use of anticonvulsants. Airway, breathing, and circulation should be assessed. Intubation and mechanical ventilation may be necessary to maintain oxygenation and ventilation. In all neonates with seizures, hypoglycemia should be ruled out and treated if present, before antiepileptic drug treatment is considered.
 - A. **Hypoglycemia.** Hypoglycemic infants with seizures should receive 10% dextrose in water, 2 to 4 mL/kg intravenously (IV), followed by 6 to 8 mg/kg/min by continuous infusion. (See Chapter 67.)
 - B. **Hypocalcemia.** Treated with slow IV infusion of calcium gluconate (for dosage and other information, see Chapter 91). If serum magnesium levels are low (<1.52 mEq/L), magnesium sulfate should be given. (See Chapter 105.)
 - C. **Anticonvulsant therapy.** (See also Table 82–1.) Conventional anticonvulsant treatment is used when no underlying metabolic cause is found. Loading doses of phenobarbital and phenytoin control 85% of neonatal seizures.
 1. **Phenobarbital** is usually (for dosage and other pharmacologic information, see Chapter 155) the initial drug of choice in most centers. Neither gestational age nor birthweight seems to influence the loading or maintenance dose of phenobarbital. Gilman et al (1989) found that sequentially administered phenobarbital controlled seizures in term and preterm newborns in 77% of cases. If seizures are not controlled at a serum phenobarbital level of 40 mcg/mL, administer a second agent (eg, phenytoin [Dilantin]).

2. **Phenytoin (Dilantin)** is usually used as second-line treatment for refractory seizures by many practitioners. Fosphenytoin may be a preferred form as it is associated with fewer side effects than phenytoin (less hypotension, fewer cardiac abnormalities, and less soft tissue injury). (For dosage and other pharmacologic information, see Chapter 155.)
3. **Levetiracetam in neonatal seizures.** Over the past decade, there is an increasing interest in levetiracetam usage in neonatal seizures. It has been used off-label by pediatric neurologists for treating neonatal seizures for many years. According to the current research, it has a good safety profile, good efficacy, and favorable pharmacokinetics and seems to be a promising agent for seizure control in neonates. Loading dose is 20 mg/kg, and maintenance dose is 10 to 80 mg/kg/d in 2 divided doses.
4. **If seizures still persist, then the next anticonvulsant usually given is a benzodiazepine.** Midazolam is a short-acting benzodiazepine that can be given by a continuous infusion. IV dose is 0.1 mg/kg, then 0.1 to 0.4 mg/kg/h.
5. **Topiramate.** Although the research is limited, topiramate has been used as an add-on agent for refractory neonatal seizures and has been found to be effective. Furthermore, the benefit of topiramate lies in the fact that it is neuroprotective in hypoxic injury. Bumetanide is another novel neuroprotective agent that has been tried in refractory seizures.
6. **If seizures are still present, then 3 disorders need to be ruled out before more medications are given:**
 - a. **Pyridoxine-dependent seizures.** A trial of pyridoxine (vitamin B6), 50 to 100 mg, given IV with EEG monitoring is now recommended. With pyridoxine dependency, the seizures stop quickly after the medication is given. The administration should be continued, as stoppage leads to recurrence of seizures, requiring reinstatement.
 - b. **Folinic acid-responsive seizures.** Obtain CSF neurotransmitter studies. Then folinic acid is given at 2.5 mg twice daily (up to 4 mg/kg/d initially) in 2 doses. After 24 hours of treatment, seizures may stop. Folinic acid can be given for 48 hours as a trial.
 - c. **DeVivo syndrome (glucose transporter deficiency).** Treatment is a ketogenic diet.
7. **If seizures still persist.** The following salvage drugs may be used depending on institutional preference: pentobarbital 10 mg/kg IV, then 1 mg/kg/h; thiopental 10 mg/kg IV (not available in United States), then 2 to 4 mg/kg/h; clonazepam 0.1 mg/kg orally; and valproic acid 10 to 25 mg/kg, then 20 mg/kg/d in 3 doses.
8. **Duration of anticonvulsant therapy.** The optimal duration of anticonvulsant therapy has not been established. Anticonvulsants may have to be continued when seizures are due to abnormality of the brain. Although International League Against Epilepsy guidelines recommend stopping anticonvulsants if seizure free for >3 days in neonates with normal neurologic examination and/or normal EEG, most neonatologists taper after seizures have been absent for 2 weeks.

VIII. Prognosis. The most reliable early predictors of later neurologic outcomes are the underlying etiology of the seizures and specific EEG background patterns. In infants with transient or metabolic disorders that can be corrected, the outcome is usually favorable. In infants with CNS infections, HIE, or brain malformations, the outcome is not as favorable. Background EEG activity is significantly and independently related to the neurodevelopment outcome. The type of seizure can also dictate outcome. An abnormal neurologic examination appears to be related to an adverse outcome. Prognosis is usually better for term infants than preterm infants.

121 Spontaneous Intestinal Perforation

- I. **Definition.** A spontaneous intestinal perforation (SIP) is a single intestinal perforation typically involving the antimesenteric border of distal ileum and usually occurs in extremely premature infants in the first 1 to 2 weeks of life. These infants, typically, have not been fed (or have received minimum feeds). If laparotomy is performed, a focal hemorrhagic necrosis with well-defined margins is observed, in contrast to ischemic and coagulative necrosis seen in necrotizing enterocolitis (NEC). The bowel proximal and distal to the perforation appears normal.
- II. **Incidence.** Two to three percent in very low birthweight (VLBW, birthweight <1500 g) infants and approximately 5% in extremely low birthweight (ELBW, birthweight <1000 g) infants.
- III. **Risk factors.** Prematurity is the only well-established risk factor for SIP. Several antenatal and postnatal risk factors have been identified based on case series and datasets. These include placental chorioamnionitis, maternal antibiotics, male gender, inotropic agents, lack of initiation of feeding, severe intraventricular hemorrhage (IVH) (\geq grade 3), early administration of glucocorticoids (both dexamethasone and hydrocortisone), and early use of indomethacin to treat symptomatic patent ductus arteriosus. The risk is greater when there is combined exposure to indomethacin and either elevated endogenous cortisol levels or administration of exogenous glucocorticoids in the first 3 days of life.
- IV. **Pathogenesis.** SIP histopathology is characterized by preservation of the mucosal villus architecture and thinning of muscularis propria. Although some cases of SIP (especially in larger infants) can be associated with congenital deficits in the muscularis layer of the bowel, theories have been developed for the unique association of SIP with perinatal stress and postnatal early steroids and indomethacin exposure. The following sequence of events has been proposed: Early postnatal steroids promote mucosal growth at the expense of bowel wall integrity with thinning/necrosis of the submucosal layer (skewed trophism). Indomethacin, in combination with steroids, causes a transient ileus due to depletion of nitric oxide synthase. Swallowing of air and return of bowel motility at about 7 days of age leads to increased intraluminal pressure resulting in bowel perforation. Infection may have a role in the pathogenesis; *Candida*, *Staphylococcus epidermidis*, and cytomegalovirus have been isolated from peritoneal fluid and surgical intestinal specimens of infants with SIP.
- V. **Presentation.** These infants present suddenly with abdominal distension, bluish discoloration of the abdomen, hypotension, and metabolic acidosis. The bluish discoloration may extend into the groin and, in males, the scrotum. According to a large case series, 2 distinct groups have been described based on age of presentation: early SIP (0–3 days) and late SIP (7–10 days). Early SIP infants were larger (median birth weight of 1.4 kg) and less likely to have received antenatal glucocorticoids, indomethacin, surfactant, or mechanical ventilation compared with infants in the late SIP group (median birth weight of 775 g).
- VI. **Diagnosis.**
 - A. **Clinical diagnosis.** This is based on sudden presentation with abdominal distension and bluish discoloration of abdominal wall, often associated with hypotension and clinical deterioration. Three features are helpful in distinguishing SIP from NEC with perforation:
 1. **Early presentation**, usually in the first 1 to 2 weeks of life.
 2. **Physical findings** of abdominal distension and bluish discoloration of abdominal wall, and occasionally the scrotum in male infants. Abdominal wall erythema, crepitus, and induration (typical in NEC) are characteristically absent.
 3. **Free air with absence of pneumatosis or portal venous gas** on abdominal radiograph.

B. Laboratory studies

1. **Complete blood count with differential.** May show elevated or depressed white blood cell count (with occasional left shift and increased immature forms). Low platelet count may be seen as well.
2. **Disseminated intravascular coagulation panel.** Prothrombin time, partial thromboplastin time, fibrinogen degradation products, and fibrinogen level need to be corrected when abnormal and infant needs surgical intervention.
3. **Blood culture.** *Candida albicans* and *S epidermidis* have been cultured from blood or peritoneal fluid in infants with SIP. It is unknown whether the infections with these organisms precede or are a result of bowel perforation.
4. **Electrolyte panel.** May show hyponatremia and hyperkalemia.
5. **Blood gas analysis.** May show respiratory and/or metabolic acidosis.

C. Imaging and other studies

1. **Supine and lateral decubitus or cross-table lateral radiographs of the abdomen.** Typically show pneumoperitoneum (free air); however, a gasless abdomen may be seen as well. Specific radiographic findings associated with NEC are not observed in patients with SIP, such as pneumatosis intestinalis, portal venous air, thickening of the intestinal wall, and fixed dilated small bowel loops.
2. **Ultrasound of the abdomen** can be used in infants with gasless abdomen. Presence of echogenic free fluid is predictive of SIP.

VII. Management

A. Medical management

1. **Nothing by mouth** to allow gastrointestinal rest for 7 to 14 days. Total parenteral nutrition to provide basic nutritional needs.
2. **Gastric decompression** with a large-bore oro- or nasogastric tube at low intermittent or continuous suctioning.
3. **Respiratory support.** Provide optimal respiratory support to maintain acceptable blood gas parameters.
4. **Circulatory support.** There may be third spacing of fluid, which requires effective volume replacement. Inotropic support may be needed to maintain normal blood pressure. Monitor intake/output and maintain urine output of 1 to 3 mL/kg/h.
5. **Antibiotic therapy.** Treat with parenteral antibiotics for 7 to 10 days. Antibiotic regimen to cover pathogens including *S epidermidis* and *Candida*, along with effective gram-positive, gram-negative, and anaerobic coverage. See doses in Chapter 155. Recommendations are to **start fluconazole** and 1 of the following antibiotic regimens:
 - a. **Vancomycin, gentamicin, and clindamycin (or metronidazole)**
 - b. **Vancomycin and piperacillin/tazobactam**

1. **Surgical management.** The optimal surgical management of SIP continues to be **controversial**. The traditional approach has been exploratory laparotomy with bowel resection; however, an alternate option is primary peritoneal drainage (PPD). The prospective randomized trials by Moss et al and Rees et al included infants with NEC or SIP, and both studies showed similar clinical outcomes using the 2 surgical techniques. The concern, expressed more in the latter study, was the high number of infants requiring secondary laparotomies for failure of clinical improvement or later development of bowel obstruction. In another retrospective study that looked exclusively at SIP, PPD was the definitive treatment in 75% of the cases. Peritoneal drain is an attractive option for very unstable low birthweight infants since it can be done with relative ease at the bedside using local anesthesia.

1. **Laparotomy with primary repair.** An abdominal incision is made and the bowel is explored. The segment of the bowel with perforation is resected and followed by end-to-end anastomosis of the bowel loops or creation of an ileostomy and distal mucous fistula. Reanastomosis is usually undertaken after 8 to 12 weeks. Surgical outcomes are not affected by infant's weight at time of enterostomy reversal.

2. **Peritoneal drain placement.** After making a small transverse incision at McBurney's point (two-thirds of the distance from the umbilicus to the anterior superior iliac crest in the right lower quadrant), a Penrose drain is placed. The drain is removed when there is no meconium or intestinal drainage. After return of bowel function, feeds are started or a contrast enema is done to ensure patency of intestine.

- VIII. Prognosis.** SIP in the ELBW infants is associated with high morbidity and mortality. Review of a large database (Vermont Oxford Network) has shown a mortality of 19% in VLBW infants with SIP (compared to 5% in controls and 38% for infants with surgical NEC). Review of ELBW infants registered in the National Institute of Child Health and Human Development Neonatal Research Network (NICHD-NRN) showed mortality before discharge of 39% in SIP cases compared with 54% in surgical NEC cases and 22% in cases without either NEC or SIP. Infants with SIP are at risk for developing bronchopulmonary dysplasia, late-onset sepsis, severe IVH, cystic periventricular leukomalacia, and growth failure. Patients with SIP and NEC appear to have similar risks for either death or neurodevelopmental impairment. In the NICHD-NRN study, death or neurologic impairment occurred in 82%, 79%, and 53% of patients with surgical NEC, patients with SIP, and those without NEC or SIP, respectively. It remains **controversial** whether some of the neurodevelopmental outcome is related to surgical technique (drain vs laparotomy), and results from the multicenter Necrotizing Enterocolitis Surgery Trial (ongoing) are awaited.
- IX. Prevention.** Caution regarding early use of indomethacin (within first week of life), especially in infants who may be stressed with endogenously elevated cortisol levels. Avoid combined use of indomethacin and hydrocortisone in preterm infants. Closely monitor ELBW infants for any signs of SIP.

122 Surgical Diseases of the Newborn: Abdominal Masses

- I. Introduction.** Abdominal masses may be found on initial newborn exam but are increasingly identified on prenatal ultrasound. They can arise from peritoneal viscera (solid organs, mesentery, and GI tract) as well as retroperitoneum (kidneys and adrenal glands). Other causes can include obstruction of the urinary system or reproductive organs which can present as an abdominal or pelvic mass. Ovarian cysts are common in the neonatal period.
- II. Gastrointestinal masses**
- A. Intestinal duplications and mesenteric cysts**
1. Majority of congenital gastrointestinal masses.
 2. Present with obstruction or palpable mass, or remain asymptomatic.
 3. Ultrasound shows simple, smooth, cystic lesion.
 4. Treatment is surgical resection.
- B. Meconium cysts**
1. Associated with in utero perforation.
 2. See Chapter 72.
- III. Hepatic masses**
- A. Smaller masses are usually found incidentally.** Larger masses may present with hepatomegaly or palpable right upper quadrant lesion. Evaluation begins with ultrasound, followed by cross-sectional imaging (MRI or CT scan) for better definition, diagnosis, and surgical planning.

B. Cystic lesions

1. Hepatic cysts

- a. **Benign lesions**; occur in 2.5% of newborns.
- b. **Majority are asymptomatic.**
- c. **May be complicated by infection or rapid growth**, resulting in abdominal pain and compressive symptoms.
- d. **Resection** reserved for symptomatic lesions.
- e. **Multiple cysts** may be associated with polycystic liver and kidney disease.

2. Choledochal cysts (biliary cysts)

- a. **Originate from bile ducts**, resulting in abnormal dilation of biliary tree with an incidence of 1 in 100,000 to 150,000. There is a male-to-female ratio of 1:4.
- b. **Present with cholangitis or biliary obstruction**, but may remain insidious. May cause direct (conjugated) hyperbilirubinemia with jaundice. Management is discussed further in Chapter 62.
- c. **Surgical resection recommended** due to 30% lifetime risk of cholangiocarcinoma.

C. Solid lesions

1. Hemangioendotheliomas

- a. **Most common benign hepatic neoplasm in children.**
- b. **When large, may result in consumptive coagulopathy and thrombocytopenia** (Kasabach-Merritt syndrome) and high output heart failure.
- c. **Majority undergo spontaneous regression** with treatment reserved for symptomatic lesions.
- d. **Systemic therapy with interferon, corticosteroids, or vincristine may be attempted.** Angioembolization, segmental resection, and liver transplantation have been described for refractory neoplasms.

2. Hamartoma

- a. **Is the second most common benign liver neoplasm in the pediatric age group.** Larger lesions can cause neonatal respiratory distress and/or circulatory complications relating to intra-abdominal space-occupying lesion.
- b. **Imaging shows multiseptated lesions** with a cystic component and minimal vascularity.
- c. **Liver function studies and α -fetoprotein** are typically normal.
- d. **Excision or marsupialization** may be pursued.

3. Hepatoblastoma

- a. **Most common hepatic malignancy in neonates.**
- b. **Premature very low birthweight infants are at higher risk.** Associated conditions can include Beckwith-Wiedemann syndrome, hemihypertrophy, and thrombocytosis.
- c. **Diagnosis made with imaging and elevated serum α -fetoprotein.**
- d. **Biopsy** may be needed to guide chemotherapeutic protocols for lesions that are not immediately resectable.
- e. **Cisplatin and doxorubicin and surgical resection** remain the mainstay of therapy, resulting in improved cure rates.
- f. **Hepatic transplantation** is indicated for unresectable lesions and associated with improved survival.

IV. Renal masses

A. Majority of neonatal abdominal masses arise from kidney.

B. May be unilateral or bilateral, and solid or cystic.

C. Physical exam and ultrasound are often sufficient to make diagnosis and assess for other intra-abdominal anomalies. Further assessment is made in conjunction with pediatric surgery, urology, and nephrology. Additional evaluation may be needed depending on the lesion, including MRI, CT scan, renal scan, voiding cystourethrogram and pyelography, venography, and arteriography.

D. Ureteropelvic junction obstruction

1. **Most common etiology of newborn obstructive uropathy**, which may present as a palpable unilateral or bilateral flank mass, associated with hydronephrosis. It is much more common in girls.
2. **Associated conditions** can include congenital heart disease, imperforate anus, contralateral multicystic kidney, VATER/VACTERL (vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia, limb abnormalities) association, and esophageal atresia.
3. **Other lesions to consider in the differential diagnosis** include severe vesicoureteral reflux and bladder outlet obstruction due to posterior urethral valves (males). Renal ultrasound is diagnostic.
4. **Prophylactic antibiotic therapy** is used in the setting of moderate-to-severe dilatation.
5. **Obstructive uropathy** may be suitable for in utero intervention in selected centers. In newborn period, urinary diversion may be needed if kidney remains viable. Nonfunctional kidney is best removed.

E. Cystic renal disease

1. **Multicystic dysplastic kidney disease**
 - a. **More common and usually unilateral.**
 - b. **Diagnosis made with ultrasound.** Renal scan often obtained to ascertain function of contralateral kidney.
 - c. **Affected kidney will often involute**, obviating need for further intervention. Nephrectomy may be warranted for resultant hypertension.
2. **Infantile polycystic kidney disease**
 - a. **Also known as autosomal dominant polycystic kidney disease.**
 - b. **Involves both kidneys and carries a grim prognosis**, unless renal replacement can be instituted in anticipation of renal transplant.

F. Renal vein thrombosis

1. **Typically presents within first days of life with hematuria** and 1 or more flank masses.
2. **Maternal diabetes and dehydration** are risk factors.
3. **Conservative management is generally recommended** and is outlined in Chapter 92.

G. Wilms tumor

1. **Represents the most common form of kidney cancer** in childhood and can present in the newborn period. See Chapter 126.

V. Ovarian masses

A. Simple ovarian cyst

1. **Frequent cause of palpable mass** in females.
2. **Relatively mobile, smooth-walled lesion**, which may spontaneously regress as maternal hormonal effects wane after delivery.
3. **Not associated with malignancy.**
4. **Smaller lesions (≤ 5 cm) are followed** to assure regression.
5. **Larger lesions may benefit from percutaneous aspiration.**
6. **Torsion may occur**, necessitating a surgical intervention.
7. **Surgical goals** are simple cystectomy with preservation of ovarian tissue.

123 Surgical Diseases of the Newborn: Abdominal Wall Defects

I. Gastroschisis

A. Definition

1. **Full-thickness abdominal wall defect, occurring to the right of the intact umbilical cord**, leaving exposed viscera to herniate into amniotic fluid. Ruptured omphalocele may mimic gastroschisis but the omphalocele defect in the abdominal wall is at the umbilicus.
2. **Defect measures 2 to 4 cm**. Stomach, bowel, and occasionally gonads are visible. Solid organs (liver and spleen) remain intraperitoneal. (Figure 123–1).

B. Incidence

1. **Rare malformation** but incidence remains on the rise.
2. **Latest estimates** range between 1.5 and 5 per 10,000 births.

C. Pathophysiology

1. **Defect occurs sporadically**, but familial clusters suggest genetic component.
2. **Improper involution of right umbilical vein and other vascular accidents** have been implicated in pathogenesis, as have environmental influences, vasoactive drugs, and nutritional deficiencies.

D. Clinical presentation

1. **The infant is born** with varying amounts of herniated intestine.
2. **Prenatal exposure to amniotic fluid** results in intestinal edema, induration, and foreshortened mesentery.

FIGURE 123–1. Gastroschisis. (Used with permission from Drs. Ana Ruzic and John Draus.)

3. **Inflammatory peel covers the bowel**, leading to intestinal dysmotility and delayed feeding tolerance.
 4. **Up to 10% have an intestinal atresia**, and all are malrotated. Other congenital anomalies are rare.
- E. Diagnosis**
1. **Usually identified on prenatal ultrasound** and readily apparent at birth.
 2. **Ruptured omphalocele may mimic gastroschisis**, and the 2 conditions must be distinguished to optimize care.
- F. Management**
1. **General considerations**
 - a. **Prenatal diagnosis affords prenatal counseling and planned delivery at a center capable of providing definitive care.**
 - b. **Safety has been established for both vaginal and cesarean deliveries.**
 - c. **Some centers advocate elective, late preterm delivery**, with data favoring earlier time to feeds and decreased length of stay, presumably due to decreased inflammatory effects on the bowel. This practice remains controversial.
 2. **Specific measures**
 - a. **Care in the delivery room**
 - i. **The exposed bowel is at risk for injury, hypoperfusion, and fluid and heat loss.** The baby's abdomen and legs should be placed in a plastic bag. Alternatively, the viscera may be covered with saline-soaked gauze and wrapped in cellophane.
 - ii. **While awaiting surgical evaluation, the newborn is laid on either flank** to minimize occlusion of the narrow mesentery.
 - iii. **Orogastric tube should be placed.**
 - b. **Fluid resuscitation**
 - i. **Due to exposed viscera, insensible losses** begin at birth and remain significant until abdominal domain is restored.
 - ii. **Prompt venous access and fluid resuscitation are needed to replace losses** leading to further bowel compromise. Delay in care worsens the shock state.
 - c. **Thermoregulation.** Hypothermia risk due to evaporative losses occurs rapidly. Immediate measures are needed to restore and maintain normal temperature.
 - d. **Prophylactic antibiotics. Broad-spectrum antibiotics** are generally recommended, due to unavoidable seeding of the peritoneum during delivery and handling of the defect. Prolonged use is discouraged.
- G. Surgical management**
1. **Surgical options** include primary closure (when possible) or placement of silastic silo with staged reduction (Figure 123–2).
 2. **Operative decision** is guided by bowel appearance, defect size, and baby's general condition. Primary reduction is contraindicated with respiratory distress syndrome, lung hypoplasia, or concern for compartment syndrome.
- H. Nutrition**
1. **Gastroschisis places the newborn in a catabolic state**, necessitating early focus on nutrition.
 2. **Intestinal dysmotility leads to delayed tolerance of enteral feeds**, necessitating total parenteral nutrition and early central venous access.
 3. **Aggressive feeding strategies** may lead to necrotizing enterocolitis.
- II. Omphalocele**
- A. Definition**
1. **Central abdominal wall defect at the base of the umbilical cord**, covered by a protective sac made of amnion, Wharton's jelly, and peritoneum. Antenatal rupture is possible and should be differentiated from a gastroschisis. A normal cord inserts into the sac (Figure 123–3).

FIGURE 123-2. Gastroschisis with a protective silastic silo in place. (Used with permission from Drs. Ana Ruzic and John Draus.)

FIGURE 123-3. Omphalocele. (Used with permission from Drs. Ana Ruzic and John Draus.)

2. **Other congenital anomalies are present in up to 80% of patients** and are more likely with smaller defects.
 3. **Latest incidence estimate is 1 in 3000 births.**
 4. **Incidence decreases over the course of gestation**, secondary to fetal demise or termination of pregnancy.
- B. Clinical presentation**
1. **Prenatal diagnosis is common based on maternal ultrasound**, prompting multidisciplinary counseling and investigation into associated anomalies. Cardiac, pulmonary, renal, central nervous system, and chromosomal anomalies can occur. Cardiopulmonary defects drive the ultimate prognosis.
 2. **From 10% to 12% occur within a syndrome**, including Beckwith-Wiedemann, pentalogy of Cantrell, and bladder exstrophy.
- C. Diagnosis**
1. **Small omphalocele (<5 cm)** contains intestine only.
 2. **Giant omphalocele** with liver herniation results in significant loss of abdominal domain, presenting a treatment challenge.
 3. **Ruptured omphalocele may be confused with gastroschisis**, but the location of the umbilical cord helps clarify the diagnosis.
 4. **Echocardiography and renal and sacral ultrasound** are performed to assess for other anomalies.
- D. Management**
1. **Unless ruptured, most require no immediate surgical intervention.** A ruptured omphalocele resembles gastroschisis and is managed similarly.
 2. **Initial priorities focus on cardiac and pulmonary stabilization.** Mechanical ventilation may be needed. Fluid management is more judicious, particularly in cases of complex cardiac disease.
 3. **Once the baby is stabilized, most small defects (2–4 cm) can be repaired primarily.**
 4. **When primary repair is not possible**, the sac must be kept intact, allowing for slow, staged reduction, and regain of abdominal domain. Escharotic agents are applied to protect and thicken the sac, ultimately resulting in epithelialization. The defect is slowly reduced with a compressive dressing until final closure. This may take years for large defects.
- III. Umbilical cord hernia**
- A. **Typically an isolated entity; may be mistaken for small omphalocele.**
 - B. **The defect is small (<2 cm)**, and carries no risk of associated anomalies.
 - C. **Umbilical cord is anatomically normal**, but may be associated with a persistent omphalomesenteric remnant.
 - D. **Usually observed.**
- IV. Umbilical hernia**
- A. **Skin-covered defect in the umbilical fascia with associated protrusion of intra-abdominal contents.**
 - B. **Physical examination establishes the diagnosis.**
 - C. **Most remain asymptomatic in early childhood**, allowing for expectant management. Operative closure is rarely warranted, and the majority undergo spontaneous closure. If persistent after 4 years, herniorrhaphy should be considered.
- V. Inguinal hernia and hydrocele**
- A. Definitions**
1. **Processus vaginalis (PV)** connects the peritoneal cavity with the inguinal canal. Following testicular descent, PV slowly obliterates. A patent PV may result in inguinal hernia, hydrocele, or both.
 2. **With inguinal hernia**, the processus vaginalis opening is large enough to allow herniation of abdominal viscera into inguinal canal.
 3. **With hydrocele, the narrow processus vaginalis allows peritoneal fluid to accumulate along its path.** May be communicating (if PV remains patent) or noncommunicating (if PV obliterates and fluid is trapped distally).

B. Diagnosis

1. **Inguinal hernia presents as a bulge along the inguinal canal** and, less commonly, in the scrotum.
2. **Hydroceles are found in the groin or scrotum**, usually transilluminate, and often cannot be reduced.

C. Management

1. **Inguinal hernias carry 5% to 15% risk of incarceration** during first year of life, necessitating repair once infant's general condition permits.
2. **Hydroceles frequently resolve without intervention** as PV slowly obliterates. Repair is advised if still present after 6 to 12 months.

124 Surgical Diseases of the Newborn: Alimentary Tract Obstruction

I. Esophageal atresia**A. Definitions**

1. **Type C esophageal atresia** is the most common type, accounting for up to 85% of cases. It consists of proximal esophageal atresia with distal tracheoesophageal fistula.
2. **Type A esophageal atresia** is the second most common type, accounting for about 10% of cases. This is a pure esophageal atresia without fistula.
3. **Other forms of esophageal atresia are less common.**

B. Pathophysiology

1. **Embryologic failure** of migration and separation of longitudinal tracheoesophageal fold. Normally, folding results in larynx and trachea anteriorly and esophagus posteriorly.

C. Clinical presentation

1. **Polyhydramnios** due to proximal esophageal obstruction; fetus cannot swallow amniotic fluid.
2. **Neonates display feeding intolerance**, excess salivation, and respiratory distress from aspiration of feeds.
3. **In type C, gastric distention may cause respiratory compromise**, and gastric reflux into airway may cause chemical pneumonitis and pneumonia.

D. Diagnosis

1. **Prenatal ultrasound** may show small or absent gastric bubble if pure esophageal atresia.
2. **Inability to pass an orogastric tube.** The chest radiograph shows an orogastric tube in the proximal esophagus. Air below the diaphragm confirms presence of a distal fistula.
3. **VATER/VACTERL association** (vertebral defects, *a*nal atresia, *t*racheoesophageal fistula, and *r*adial or *r*enal dysplasia/vertebral defects, *a*nal atresia, cardiac malformations, *t*racheoesophageal fistula, *r*enal dysplasia, and *l*imb abnormalities) workup necessary.

E. Management

1. **Preoperative optimization is focused on minimizing risk of aspiration and gastric distention.**
 - a. **Place Replogle tube in proximal esophageal pouch** to evacuate oral secretions.
 - b. **Keep baby in upright position** (45 degrees) to lessen risk of reflux and aspiration.

- c. **If possible, avoid positive-pressure ventilation.**
 - d. **If mechanical ventilation is necessary, low tidal volumes and inspiratory pressures are preferable.** In select babies, high-frequency oscillatory ventilation may provide gentler ventilation.
 - e. **Broad-spectrum antibiotics** should be administered.
 - f. **VATER/VACTERL association workup should be performed.** This includes an echocardiogram prior to surgery to assess for cardiac and aortic arch anomalies.
2. **Goals of operative therapy are to ligate fistula and establish esophageal continuity if possible.**
- a. **Repair via open or thoracoscopic techniques.**
 - b. **If long-gap esophageal atresia (>3 vertebral bodies) is present,** one may not be able to perform immediate esophageal anastomosis and a gastrostomy tube should be placed.
 - c. **If defect cannot be bridged** with native esophagus, use of gastric or intestinal conduits may be necessary.

II. Duodenal obstruction

- A. **Definition.** Duodenal luminal obstruction can be classified as complete or partial; as pre- or postampullary; and as caused by intrinsic or extrinsic problems.
- B. **Pathophysiology**
- 1. **Intrinsic obstruction** results from either failure of endodermal proliferation or luminal recanalization.
 - 2. **Atresia** may occur in the setting of external compression, such as annular pancreas.
- C. **Internal duodenal obstruction**
- 1. **Results from classic atresia with resultant stenosis** or complete obstruction.
 - 2. **Frequently associated with trisomy 21 (33%).**
- D. **External duodenal obstruction**
- 1. **Annular pancreas.** Occurs secondary to incomplete rotation of ventral pancreatic bud, resulting in ring of pancreatic tissue that encircles second portion of duodenum. Results in either complete or partial obstruction.
 - 2. **Malrotation.** Abnormal midgut rotation and fixation causing complete or partial duodenal obstruction. Abnormal peritoneal attachments (Ladd bands) extrinsically compress duodenum. The **narrow vascular pedicle** (superior mesenteric artery) can cause ischemia of the entire midgut due to the volvulus.
- E. **Clinical presentation**
- 1. **General**
 - a. **Neonates with duodenal obstruction present with bilious emesis,** unless obstruction is proximal to ampulla.
 - b. **Abdominal distention** is not common.
 - c. **Polyhydramnios** may be evident on prenatal exam.
 - 2. **Duodenal atresia.** Down syndrome, esophageal atresia, and imperforate anus are associated with duodenal atresia. **Classic double-bubble sign** may be seen prenatally and confirmed with abdominal radiograph at delivery.
 - 3. **Midgut volvulus. Presents with bilious vomiting** in an otherwise well baby, and represents a true surgical emergency. Incidence highest in first few weeks of life and remains elevated for first year. If care is delayed or diagnosis unrecognized, infant can develop peritonitis and shock secondary to irreversible intestinal ischemia.
- F. **Diagnosis**
- 1. **In a stable infant, upper gastrointestinal imaging is diagnostic,** but imaging should not delay definitive care of critically ill baby.
 - 2. **If prenatal history suggests duodenal atresia, air may be injected via orogastric tube, looking for the double-bubble sign.**
 - 3. **Exact cause of obstruction may not be apparent until laparotomy,** but prompt exploration is needed if diagnosis is unclear or malrotation is suspected.

G. Management

1. **In cases of atresia or annular pancreas, gastric decompression with an orogastric tube allows for “elective” surgical correction.**
2. **Insensible fluid losses may be high**, particularly with postampullary lesions, and need to be replaced with isotonic fluids.
3. **Malrotation necessitates prompt surgical evaluation, and volvulus mandates emergent laparotomy.** Fluid resuscitation and antibiotics are started while the operating room is mobilized.

III. Proximal intestinal obstruction

A. Definition. Proximal intestinal obstruction occurs at level of jejunum, most often from segmental atresia.

B. Pathophysiology. Jejunum atresia usually results from an in utero vascular accident with possible loss of significant portion of bowel, leading to short gut syndrome.

C. Clinical presentation. Bilious emesis is seen with minimal abdominal distention.

D. Diagnosis

1. **Abdominal radiograph shows dilated small bowel loops with no distal gas, and contrast enema shows microcolon.**
2. **May be difficult to distinguish from midgut volvulus**, necessitating early surgical evaluation.

E. Management

1. **Surgical correction consists of resection and/or tapering of dilated proximal bowel with enteroenterostomy.**
2. **Multiple atresias** may be present.
3. **Outcome** is determined by length and motility of the remaining bowel.

IV. Distal intestinal obstruction

A. Definition. Distal intestinal obstruction occurs in either small bowel (distal jejunum and ileum) or colon. It may be a physical obstruction (meconium disease or atresia) or functional obstruction (small left colon syndrome or Hirschsprung disease).

1. **Jejunal/ileal atresia.** Can be found at a single site or multiple sites, and it occurs as result of fetal vascular accident or complication of meconium ileus.

2. **Meconium ileus** is due to inspissated, thick meconium in distal bowel, often in setting of cystic fibrosis. It can be further classified as simple or complicated.

a. **Complicated meconium ileus** results from compromise of bowel viability, either prenatally or postnatally, due to perforation, volvulus, or atresia.

b. **Cystic fibrosis testing** with newborn screening and sweat chloride measurement is essential.

3. **Meconium peritonitis** is seen in cases of prenatal bowel perforation, most commonly resulting in atresia. Radiographs typically show peritoneal calcifications. If the perforation becomes walled off, it can develop into a large meconium cyst. Babies with meconium peritonitis have a surgically hostile abdomen and complications similar to meconium ileus.

4. **Colonic atresia is a rare cause of intestinal obstruction**, likely due to compression of mesocolon, resulting in vascular compromise. It is often associated with **choledochal (biliary) cysts and Hirschsprung disease.**

5. **Meconium plug syndrome** is a colonic obstruction due inspissated meconium. Usually associated with Hirschsprung disease.

6. **Hypoplastic left colon syndrome** is frequently found in babies of diabetic mothers.

7. **Hirschsprung disease** is a congenital aganglionic megacolon. It results from failure of ganglion cells to migrate distally, rendering the bowel contracted and aperistaltic. The rectosigmoid colon is most commonly affected, but more proximal pathology is possible.

- B. Clinical presentation** is usually abdominal distension, failure to pass meconium, and bilious emesis, which may be delayed by 1 to 2 days.
- C. Diagnosis**
- 1. Plain abdominal radiographs** show multiple dilated loops of bowel and paucity of rectal air.
 - 2. Site of obstruction is better ascertained with a contrast enema**, which may be therapeutic in cases of meconium plug syndrome, simple meconium ileus, and small left colon syndrome.
 - 3. Contrast enema shows microcolon** in babies with distal small bowel atresias or complicated meconium ileus. May define transition zone in Hirschsprung disease.
 - 4. Suction rectal biopsy** shows absence or paucity of ganglion cells and hypertrophic nerves in Hirschsprung disease.
- D. Management** (see also Chapter 72)
- 1. Nonoperative management**
 - a. Meconium plug syndrome**, small left colon syndrome, and simple meconium ileus may be treated with the contrast enema alone. May need to be repeated until meconium is evacuated and peristalsis returns.
 - b. If ongoing stimulation is needed, Hirschsprung disease should be considered** and biopsy performed.
 - c. Water soluble contrast enemas** may be useful to clear residual contents in meconium ileus.
 - E. Surgical therapy**
 - 1. Urgent surgical intervention** required for atresias and complicated meconium ileus.
 - 2. Hirschsprung disease is always treated surgically**, and exploration may be needed if diagnostic dilemma persists.
 - 3. Laparoscopic, open, and transanal pull-through procedures are all used for Hirschsprung disease** and can be undertaken during the neonatal period or several weeks later. If early surgery is contraindicated and colon cannot be decompressed with rectal irrigations, colostomy may be needed.
- V. Imperforate anus**
- A. Definition**
- 1. Absence or improper location of the anal opening.**
 - 2. Anal canal and sphincter complex are present**, but muscles may be attenuated.
 - 3. In absence of normal anal opening**, rectum tapers into fistula that may communicate with genitourinary tract in boys and reproductive tract in girls.
 - 4. Modern classification guided by location of fistula:**
 - a. Imperforate anus with perineal fistula** carries best prognosis, with continence rates >95%.
 - b. Imperforate anus with rectourethral, rectobladder, or rectovaginal fistula (high imperforate anus) has lower continence rates**, but still relatively good outcomes with appropriate bowel management.
 - c. Imperforate anus without fistula may be associated with Down syndrome.**
- B. Diagnosis**
- 1. Perineal inspection** and calibration of any opening that drains meconium.
 - 2. All patients should have radiographic studies of lumbosacral spine** and urinary tract due to high incidence of associated anomalies.
 - 3. Spinal ultrasound and magnetic resonance imaging** to evaluate for tethered cord.
 - 4. VATER/VACTERL association workup.**
- C. Management**
- 1. Neonatal surgical intervention** consists of colostomy for high anomalies and perineal anoplasty or fistula dilation for low lesions.
 - 2. If level is unknown**, divided colostomy is created and anatomy is delineated with a contrast study at later date.

- VI. Necrotizing enterocolitis.** Necrotizing enterocolitis (NEC) is caused by a combination of mucosal injury, relative hypoxia, and infection of intestinal wall. In most centers, NEC is the most common indication for abdominal operation in neonates. Surgery is indicated for pneumoperitoneum or sepsis with poor source control. **Peritoneal drain placement** and/or celiotomy with bowel resection may be necessary. (See details in Chapter 109.)

125 Surgical Diseases of the Newborn: Diseases of the Airway, Tracheobronchial Tree, and Lungs

- I. Overview of airway problems in the newborn.** Any newborn experiencing feeding problems, repeated aspiration, and respiratory distress should have a complete evaluation of the airway. Temporary or permanent feeding difficulty may be caused by congenital infections, maternal drug use, hypoxia, or some type of birth trauma. A variety of surgical diseases (intrinsic airway abnormalities such as vocal cord paralysis or laryngomalacia), choanal atresia, laryngotracheal esophageal cleft, tracheoesophageal fistula, cricopharyngeal spasm, syndromic anomalies, and others should be included in the differential diagnosis of these patients. Respiratory distress in the absence of feeding can also be caused by intrinsic and extrinsic pulmonary issues.

II. Intrinsic abnormalities of the airway

A. There are 4 common intrinsic upper airway diseases in the newborn.

- Laryngomalacia** is due to delayed development of supraglottic pharynx.
- Congenital vocal cord paralysis** can be congenital or acquired (birth trauma, patent ductus arteriosus ligation) and unilateral or bilateral.
- Subglottic web** is a congenital short segment obstruction that may be partial or complete.
- Hemangioma** is a vascular malformation that can occur below the glottis, engorge, and obstruct with agitation.

B. Clinical presentation.

Varies from mild respiratory stridor to complete airway obstruction.

C. Diagnosis.

Airway endoscopy with careful visual inspection.

D. Management

- Individualized based on pathology and endoscopic findings.**
- Some problems (laryngomalacia)** may be outgrown and require supportive care only.
- Other lesions (subglottic webs and hemangiomas)** may require endoscopic resection or laser therapy.

III. Choanal atresia

A. Definition

- Choanal atresia is congenital blockage of posterior nares** caused by persistence of the bony septum (90%) or soft tissue membrane (10%). It can be associated with Treacher Collins, Tessier, and CHARGE (coloboma, central nervous system abnormalities, heart defects, atresia of the choanae, restricted growth and/or development, genital abnormalities, and ear anomalies) syndromes.

- B. **Pathophysiology**
 1. **Neonates are obligate nose breathers.**
 2. **True choanal atresia is complete and bilateral** and causes immediate respiratory distress in the newborn.
 3. **Unilateral defects** may be well tolerated and often go unnoticed.
 - C. **Clinical presentation**
 1. **Respiratory distress** resulting from partial or complete upper airway obstruction.
 2. **Cyanosis in an infant while breast feeding** is another presentation.
 - D. **Diagnosis.** Inability to pass catheter into nasopharynx via either nostril.
 - E. **Management**
 1. **Stimulating baby to cry** will initiate mouth breathing and temporarily improve respiratory status.
 2. **Insertion of oral airway.**
 3. **Definitive management** requires resection of soft tissue or bony septum.
- IV. **Pierre Robin syndrome/sequence**
- A. **Definition**
 1. **Pierre Robin syndrome/sequence** is a set of anomalies including mandibular hypoplasia (micrognathia) and a tongue that is placed further back than normal (glossoptosis) in association with cleft palate.
 2. **Other associated syndromes** include Stickler, velocardiofacial, craniofacial microsomia, and Treacher Collins syndromes.
 - B. **Pathophysiology.** **Airway obstruction** produced by posterior displacement of the tongue associated with small mandible. Feeding difficulty is also usually present.
 - C. **Clinical presentation.** **Severity of symptoms varies**, but most neonates manifest high-grade partial upper airway obstruction.
 - D. **Management**
 1. **Infants with mild involvement** can be placed in prone position and fed using special **Breck nipple**. Over next few weeks to months, the mandible grows, and the degree of airway obstruction subsides.
 2. **If there is continuing evidence of breathing difficulty** and desaturation, a nasopharyngeal tube is indicated. Attention to feeding and weight gain is important. Some babies need nasogastric tube feeding to maintain weight and grow.
 3. **More severe cases** require mandibular distraction or other procedures to hold tongue in anterior position. Tracheostomy is generally a last resort.
- V. **Laryngotracheal esophageal cleft**
- A. **Definition**
 1. **Laryngotracheal esophageal cleft** is a rare congenital anomaly with incomplete separation of larynx (and sometimes trachea) from the esophagus, resulting in a common channel (1 in 10,000–20,000 live births).
 2. **Communication** may be short or may extend almost entire length of trachea.
 3. **Increased incidence of laryngeal cleft** is seen with Pallister-Hall and Opitz-Frias syndromes.
 4. **Gastrointestinal, genitourinary, and cardiovascular anomalies** may be seen in the laryngeal cleft patient.
 - B. **Pathophysiology.** Persistent communication between larynx (and occasionally trachea) and esophagus results in recurring symptoms of aspiration and respiratory distress with feeding.
 - C. **Clinical presentation.** Respiratory distress during feeding. Stridor, choking, cyanosis, and regurgitation are typically seen.
 - D. **Diagnosis.** Contrast swallow may suggest the anomaly. Endoscopy is essential to establish diagnosis and delineate extent of defect.
 - E. **Management.** Surgical correction is difficult and often unsuccessful. There is an overall mortality rate of 46% due to laryngeal cleft and associated anomalies.

VI. Vascular ring

A. Definition. **Vascular ring** describes a variety of anomalies of the aortic arch and its branches that create a “ring” of vessels around the trachea and esophagus.

B. Pathophysiology. Partial obstruction of trachea, esophagus, or both may result from extrinsic compression by encircling vessels.

C. Clinical presentation

1. **Dysphagia and/or stridor are common.**
2. **Airway compromise is rarely severe.**

D. Diagnosis

1. **Contrast esophagram** identifies esophageal narrowing in the region of aortic arch.
2. **Computed tomography angiography or magnetic resonance angiography** better defines anatomy and assists in surgical planning.

E. Management. Surgical division of vascular ring.

VII. H-type tracheoesophageal fistula (type E)

A. Definition

1. **H-type tracheoesophageal fistula** (type E TEF) is an uncommon type of TEF, accounting for about 5% of all TEFs.

2. **There is no esophageal atresia**, but fistula connects proximal esophagus to airway.

B. Pathophysiology. Similar to other types of esophageal atresia (see Chapter 124).

C. Clinical presentation

1. **Symptoms depend on fistula diameter.** Babies are typically asymptomatic until feeds are started.
2. **If tracheoesophageal fistula is small**, “silent” aspiration occurs, leading to recurrent pneumonitis and aspiration pneumonia.
3. **Large fistulas** present with choking and cyanotic spells while feeding.

D. Diagnosis

1. **Contrast esophagram** may show fistula.
2. **Bronchoscopy** identifies tracheal side of fistula, allowing for passage of small catheter from trachea into the esophagus.
3. **Esophagoscopy** is then performed.

E. Management. Surgical ligation of fistula.

VIII. Congenital lobar emphysema

A. Definition

1. **Congenital lobar emphysema** (congenital alveolar overdistension/infantile lobar emphysema) generally affects entire lobe with hyperexpansion of small airways and expiratory air trapping.

2. **More common** in upper lung segments.

3. **Cause of congenital lobar emphysema** is obstruction of the developing airway with air trapping.

B. Pathophysiology. As amount of air entrapped increases, normal lung is increasingly compressed, leading to mass effect and respiratory compromise.

C. Clinical presentation

1. **Small cysts** may cause few or no symptoms.
2. **Giant cysts** may cause significant respiratory distress with mediastinal shift and compromise of contralateral lung.

D. Diagnosis

1. **Cyst is usually seen on chest radiographs and may be confused with tension pneumothorax.**
2. **Chest computed tomography** is often useful for better definition and surgical planning.

E. Management

1. **Small asymptomatic lesions** can be observed.
2. **Symptomatic lesions can be temporarily managed** by selective intubation of contralateral lung. Ultimately, these lesions need to be resected. Lobectomy is the operation of choice.

IX. Cystic pulmonary airway malformations

A. Definition

1. **Cystic pulmonary airway malformations** were formerly known as cystic adenomatoid malformations.
2. **Lobar lesions** that may involve >1 lung segment.
3. **Cystic changes occur within the lobe** with presence of microcysts, macrocysts, or both, and they communicate with normal tracheobronchial tree.

B. Pathophysiology

1. **Severity of symptoms** is related to amount of lung involved and degree to which normal lung is compressed.
2. **Rarely, large cysts may be confused with congenital diaphragmatic hernia.**

C. Clinical presentation

1. **Small lesions** are asymptomatic.
2. **Large lesions** may cause respiratory distress, lung hypoplasia of contralateral lung, and pulmonary hypertension.

D. Diagnosis

1. **Chest radiograph** may show multiple discrete air bubbles, occasionally with air-fluid levels, involving a region of the lung.
2. **Cross-sectional imaging (computed tomography)** is obtained for operative planning around 6 months of age or sooner if more urgent resection is needed.

E. Management

1. **Surgical resection** of involved lobe of lung is advised.
2. **Preferably delayed until 3 to 6 months of age**, when thoroscopic resection can be attempted.
3. **Some advocate observation of asymptomatic lesions**, but many recommend resection, given risk of infection and malignant transformation.

X. Pulmonary sequestration

A. Definition

1. **Pulmonary sequestration** is when nonfunctioning lung tissue is separated from main tracheobronchial tree.
2. **Intralobar and extralobar forms.**
3. **Have a systemic (rather than pulmonary) blood supply.**

B. Pathophysiology

1. **Usually not recognized in the neonate.** Intralobar sequestrations are found after frequent recurrent infections.
2. **Extralobar sequestrations are often an incidental finding** and are often associated with diaphragmatic hernia and other lung malformations (congenital cystic adenomatoid malformation and bronchogenic cysts), pectus excavatum, pericardial problems, and duplication cysts.

C. Clinical presentation. Lung mass is found with or without frequent recurrent infections.

D. Diagnosis. Chest radiograph and computed tomography scan.

E. Management. Intralobar masses are usually surgically resected due to the risk of recurrent infections. Extralobar pulmonary sequestration sites can be resected or, in some cases, embolized.

XI. Congenital diaphragmatic hernia

A. Definition

1. **Congenital diaphragmatic hernia** is most commonly due to a patent pleuro-peritoneal canal through foramen of Bochdalek (95%).
2. **Central, anterior defect (Morgagni hernia)** is less common and usually not associated with lung hypoplasia.

B. Pathophysiology

1. Prenatal

- a. **Abnormal communication** allows herniation of intestine into pleural space.

126 Surgical Diseases of the Newborn: Retroperitoneal Tumors

I. Neuroblastoma

A. Definition

1. **Primitive malignant neoplasm** that arises from neural crest tissue.
2. **Usually located in adrenal gland** but can occur anywhere neural crest cells migrate.
3. **Most common extracranial solid malignancy of childhood.**
4. **Incidence of 1 per 100,000 children** in the United States.

- ### B. Clinical presentation.
- Typically presents as firm, fixed, irregular mass extending obliquely from costal margin, occasionally across midline, and into lower abdomen.

C. Diagnosis

1. Laboratory studies

- a. **Twenty-four-hour urine collection** should be analyzed for vanillylmandelic acid and other catecholamine metabolites.
- b. **Elevated lactate dehydrogenase** is associated with poor prognosis.

2. Radiologic studies

- a. **Plain abdominal radiograph** may reveal calcifications within tumor.
- b. **Computed tomography scan** typically shows extrinsic compression and inferolateral displacement of kidney.
- c. **Metastatic evaluation** involves bone marrow aspiration and biopsy, bone scan, chest radiograph, and chest computed tomography (CT) scan.

D. Management

1. **Treatment based on tumor stage.** Two staging systems are used:
 - a. **International Neuroblastoma Risk Group Staging System** (INRGSS). Uses image-defined risk factors to determine suitability for surgery.
 - b. **International Neuroblastoma Staging System** (INSS). Takes into account the surgical staging.
2. **Complete surgical resection** remains best hope for cure.
3. **Infants with type 4S disease** (“special” neuroblastoma) are typically younger than 1 year old and may undergo spontaneous regression. Planned therapy should consider this well-recognized, but poorly understood, fact.
4. **Advanced tumors require multimodality therapy with surgery, radiation, and chemotherapy**, but this is uncommon in neonates.

II. Congenital mesoblastic nephroma

A. Definition

1. **Embryonic solid renal tissue** that is not usually malignant.
2. **Most common renal tumor** in neonates and young infants.
3. **Pathologically divided into 3 groups:** classic, cellular, and mixed.

B. Clinical presentation

1. **Can be identified on prenatal ultrasound.**
2. **More commonly, palpable mass** found on abdominal exam.
3. **Paraneoplastic syndromes** (hypertension or hypercalcemia) are possible.

C. Diagnosis

1. Physical examination

- a. **Mass found on examination in newborn period** or becomes apparent in first few months of life.

FIGURE 126-1. Congenital mesoblastic nephroma. (Used with permission from Drs. Ana Ruzic and John Draus.)

2. Radiologic studies (Figure 126-1)

- a. **Ultrasonography** obtained when a solid mass is identified.
- b. **Cross-sectional imaging** needed to assess tumor origin, local extension, and impact on surrounding structures (magnetic resonance imaging/CT scan).

D. Management

1. **Nephrectomy and lymph node sampling** to assess for rare malignant degeneration.
2. **Classic form** effectively treated with complete resection.
3. **Cellular form** has propensity to recur locally or metastasize.

III. Wilms tumor (nephroblastoma)

A. Definition

1. **Embryonal renal neoplasm** with blastemic, stromal, and epithelial cell types. Histology can be either favorable or unfavorable (anaplastic).
2. **Usually unilateral renal involvement**, but may be bilateral (5%).

B. Clinical presentation. Palpable abdominal mass extending from below costal margin is usual presentation.

C. Risk factors. Aniridia, hemihypertrophy, certain genitourinary anomalies, and family history of nephroblastoma are well recognized.

D. Diagnosis

1. **Ultrasonography generally followed by computed tomography scan**, which reveals intrinsic distortion of caliceal system of involved kidney.
2. **Possibility of tumor thrombus** in renal vein and inferior vena cava should be evaluated.

E. Management

1. **Children's Oncology Group** staging system is used most often.
2. **Unilateral renal involvement**
 - a. **Radical nephrectomy** with lymph node sampling.
 - b. **Surgical staging** determines the need for radiotherapy and chemotherapy.
3. **Bilateral renal involvement**
 - a. **Treatment highly individualized.**
 - b. **Neoadjuvant therapy followed by nephron-sparing resection** may be attempted.

FIGURE 126–2. Sacrococcygeal teratoma. (Used with permission from Drs. Ana Ruzic and John Draus.)

IV. Teratoma

A. Definition

1. **Neoplasm containing elements derived from all 3 germ cell layers:** endoderm, mesoderm, and ectoderm. Mainly isolated lesions and may occur anywhere in the body.
2. **Primarily sacrococcygeal teratomas** are seen in neonates, followed in frequency by the anterior mediastinum (Figure 126–2).

B. Clinical presentation

1. **Usually evident as large external mass in sacrococcygeal area.**
2. **Occasionally, may be presacral and retroperitoneal** in location or may present as abdominal mass.

C. Diagnosis

1. **Most sacrococcygeal teratomas identified on prenatal ultrasound.**
2. **Digital rectal examination of presacral space is important.**
3. **α -Fetoprotein levels** should be assayed.

D. Management

1. **Prompt surgical excision** is required.
2. **Incidence of malignant tumors** increases with age.

127 Surgical Diseases of the Newborn: Urologic Disorders

Renal masses are discussed in Chapter 126.

UNDESCENDED TESTIS (CRYPTORCHIDISM)

- I. **Definition.** Undescended testis (UDT), or cryptorchidism, refers to the absence of the testis within the scrotum and is the most common congenital anomaly of the male genitalia. The incidence is 1% to 4% in full-term neonates and up to 45% in preterm neonates; 10% to 25% of patients with UDT at birth have bilateral cryptorchidism.
- II. **Clinical presentation.** UDT is diagnosed by physical exam. A UDT may be nonpalpable or palpable. Other exam findings may include ipsilateral hypoplastic scrotum, inguinal hernia, and hydrocele. UDT can be an isolated finding or occur as part of a syndrome (eg, disorder of sexual differentiation, Eagle-Barrett syndrome, bladder exstrophy).
- III. **Diagnosis.** Begin the exam with the patient in a supine position and legs abducted. Sweep a hand lateral to medial from the anterior superior iliac spine toward the ipsilateral scrotum. If the UDT is palpable, note the location, size, mobility, and consistency of the testis. The contralateral testis and penis should be examined as well.
 - A. **Palpable testis.** A palpable testis is a testis that can be felt on exam within the inguinal canal, upper scrotum, perineum, or an ectopic location. Neonates with palpable UDT should be reexamined as they grow to ensure proper descent by age 6 months.
 - B. **Nonpalpable testis.** If the testis cannot be palpated on exam, it may be intra-abdominal, absent, or atrophic (vanishing testis or testicular regression). If both testes are nonpalpable, urgent evaluation for congenital adrenal hyperplasia (CAH) in a genetic female or other disorder of sexual differentiation (DSD) is warranted.
- IV. **Management.** Spontaneous descent of the testis can occur within the first 3 to 6 months of life. After age 6 months corrected for gestational age, surgery is recommended for a UDT. Inguinal or scrotal orchiopexy is done for palpable testes. Diagnostic laparoscopy and potential laparoscopic orchiopexy are standard of care for nonpalpable testes. Imaging studies are not recommended to help locate nonpalpable undescended testes, as they usually do not alter management recommendations. Neonates with hypospadias and UDT should undergo urgent evaluation for underlying genetic or endocrine anomaly such as CAH or other DSD. CAH with salt wasting can be life threatening.

SCROTAL AND TESTICULAR MASSES

- I. **Definition and clinical presentation.** The differential diagnosis of neonatal scrotal masses includes the following:
 - A. **Hydrocele.** Characterized by transilluminating fluid within the scrotum, which often has a bluish tint. Communicating hydroceles are contiguous with the peritoneal cavity via a patent processus vaginalis and present with size fluctuation in the scrotum. Simple hydroceles are confined to the tunica vaginalis and present as painless scrotal enlargement that does not fluctuate in size.
 - B. **Inguinal hernia.** Protrusion of intra-abdominal contents through a patent processus vaginalis (ie, indirect inguinal hernia). These are usually painless and present with intermittent inguinal or scrotal bulge. They may become painful if contents within the hernia become incarcerated.

- C. **Perinatal testicular torsion.** Testicular torsion is defined as twisting of the spermatic cord with severe reduction of testicular blood flow. This can occur prenatally, during delivery, or postnatally. It presents with enlarged, hardened, discolored hemiscrotum with or without scrotal swelling.
 - D. **Testicular tumor.** Rare in neonates. Presents as a painless, firm mass. Tumors reported in infants <1 month old include yolk sac tumors, gonadal stromal tumors, granulosa cell tumors, and others in case reports. Note that a common tumor marker, α -fetoprotein, can remain elevated for 6 to 8 months postpartum.
 - E. **Rare lesions** include teratomas, supernumerary testis (polyorchidism), splenogonadal fusion, and adrenal rests.
- II. **Diagnosis.** Diagnosis is based on history and physical exam. Scrotal ultrasound with Doppler studies can diagnose testicular torsion or suspected tumor.
- III. **Management**
- A. **Most simple hydroceles** resolve spontaneously within the first year of life and should be observed.
 - B. **Communicating hydroceles and inguinal hernias** should be repaired when diagnosed in order to prevent incarceration of intra-abdominal contents.
 - C. **Timing of repair for perinatal torsion** is controversial. If the infant is hemodynamically stable, he should undergo emergent scrotal exploration and contralateral orchiopexy. This is especially the case if there is an acute change in the scrotal exam after a previously normal scrotal exam was documented.
 - D. **If a testicular tumor is suspected**, orchiectomy via an inguinal approach should be done. In selected cases, testis-sparing surgery is appropriate because many tumors are not malignant.

HYPOSPADIAS

- I. **Definition.** Hypospadias is characterized by altered development of the ventral urethra, ventral (downward) penile curvature, and dorsal hooded prepuce with deficient ventral foreskin. It occurs in about 1 in 200 to 300 live births.
- II. **Clinical presentation/diagnosis.** The urethral abnormality is usually noted on physical exam. In most cases, the urethral meatus is on the distal third of the penile shaft. Moderate or severe cases include cases where the meatus is more proximal on the penile shaft, scrotum, or perineum. In general, the more proximal the location of the urethral meatus, the more severe is the degree of curvature. Megameatus with an intact prepuce is an uncommon variant and is usually found at the time of circumcision.
- III. **Management.** Surgical correction of hypospadias is ideally done between 6 and 18 months of age. Because the foreskin is sometimes used for surgical repair, **a neonatal circumcision should not be done.** If the infant with hypospadias also has a UDT and in cases of severe penoscrotal hypospadias, an evaluation for DSD is warranted.

EPISPADIAS-EXSTROPHY COMPLEX

- I. **Definition.** Epispadias-exstrophy complex is a spectrum of genitourinary malformations ranging from isolated epispadias (least severe) to cloacal exstrophy (most severe).
- A. **Isolated epispadias** ranges from a mild defect of the dorsal urethra at the glans penis to a penopubic variant with complete incontinence. Incidence is about 1 in 117,000 males.
- B. **Classic bladder exstrophy** occurs in 1 in 10,000 to 50,000 live births. It is defined by incomplete formation of the anterior abdominal wall, bladder, and dorsal phallus due to altered development of the cloacal membrane. Male-to-female ratio is 3:1 to 6:1 (Figure 127-1).
- C. **Cloacal exstrophy** includes the features of bladder exstrophy in addition to altered hindgut development and presence of an omphalocele.

FIGURE 127–1. Exstrophy, bladder (classic exstrophy). In this newborn, the bladder is exposed on the abdominal wall. The penis is short and broad with a bivalved urethra and bifid scrotum.

II. Clinical presentation

- A. Epispadias is usually diagnosed** at birth on physical exam. Males have an incomplete dorsal urethra, incomplete glans fusion, exposed urethral plate, and dorsal penile curvature. Females present with bifid clitoris and anteriorly positioned vagina.
- B. Bladder exstrophy** may be identified prenatally or at birth. In addition to epispadias findings, there is a large abdominal wall defect and visible bladder plate.
- C. Cloacal exstrophy** can present on prenatal ultrasound as absence of a full bladder, infraumbilical abdominal wall defect, or omphalocele. On exam, an open bladder plate is divided by hindgut structures, and the omphalocele extends superiorly. Genital malformations are similar to bladder exstrophy but more severe.

III. Diagnosis

- A. Most abnormalities are easily visible at birth.** In bladder exstrophy, the pelvic bones are externally rotated with a wide pubic diastasis and anterior displacement of the anus.
- B. Cloacal exstrophy** is associated with renal abnormalities, müllerian fusion anomalies, intestinal anomalies, hip or limb defects, and neural tube defects. Renal and spinal ultrasound and skeletal imaging should be done.

IV. Management

- A. In epispadias, surgical correction of the urethra and penile curvature is done electively between 6 and 18 months of age.** The bladder neck and continence mechanism repair are delayed until 4 to 5 years of age.
- B. In bladder and cloacal exstrophy, the bladder plate must be protected with a thin plastic nonadherent covering.** Do not use saline-soaked gauze. Timing and method of closure in bladder exstrophy are variable across institutions. Most children will require multiple surgeries to correct the defects.

- C. **Cloacal exstrophy repair requires multiple staged procedures.** First, the bladder plate and omphalocele are repaired. Subsequent procedures address the hindgut and genital malformations.
- D. **Latex precautions** should be instituted as there is a high incidence of latex sensitization in these patients.

PRUNE BELLY (EAGLE-BARRETT OR TRIAD) SYNDROME

- I. **Definition.** Prune belly syndrome is characterized by the triad of dilation of the urinary tract resulting in renal dysplasia, deficient abdominal wall musculature, and bilateral intra-abdominal undescended testes.
- II. **Clinical presentation.** The term *prune belly* refers to the classic wrinkled appearance of the abdominal wall with bulging flanks due to abnormal abdominal musculature. Presentation ranges in severity with the degree of renal dysplasia as the single most important factor in determining the severity of the disease. The most severe cases present with oligohydramnios, renal insufficiency, and pulmonary hypoplasia.
- III. **Diagnosis.** While prenatal imaging may reveal urinary tract anomalies, diagnosis is based on physical exam, noting the appearance of the abdominal wall and bilateral nonpalpable undescended testes. Renal ultrasound and voiding cystourethrogram (VCUG) are the first imaging studies done to evaluate the urinary tract abnormalities.
- IV. **Management.** Initial evaluation should consist of renal function assessment, optimizing pulmonary function, and management of the urinary tract. Antibiotic prophylaxis against urinary tract infection should be started. Most patients undergo elective surgical repair of the abdominal wall defect and bilateral orchiopexy. More extensive surgical decompression of the urinary tract is controversial.

POSTERIOR URETHRAL VALVES

- I. **Definition.** Posterior urethral valves (PUVs) are aberrant obstructive folds of tissue in the male urethra just proximal to the external urethral sphincter. PUVs result in bladder outlet obstruction and subsequent urinary tract dysfunction. The incidence is approximately 1 in 5000 live births.
- II. **Clinical presentation.** There is wide variation in the presentation of a male child with a PUV, ranging from mild bladder outlet obstruction to severe obstructive uropathy, renal insufficiency, and pulmonary hypoplasia.
- III. **Diagnosis.** Most cases present prenatally with hydronephrosis and enlarged bladder with or without oligohydramnios. Postnatally, a VCUG is the gold standard for diagnosis; classic findings are a thickened bladder wall, dilated prostatic urethra, and decreased urethral caliber distal to the obstruction.
- IV. **Management.** Placement of an indwelling urethral catheter to decompress the urinary tract allows time to stabilize the neonate postnatally. When the patient is hemodynamically stable, cystoscopic ablation of the PUV is performed. Serial chemistries will allow determination of renal function, and a nadir serum creatinine of <0.8 mg/dL in the first year of life suggests better long-term prognosis. Lifelong urologic follow-up is needed.

HYDRONEPHROSIS (URINARY TRACT DILATION)

- I. **Definition.** Hydronephrosis refers to dilation of the renal pelvis and calyces on imaging studies. The underlying causes of urinary tract dilation (UTD) vary from obstructive lesions to vesicoureteral reflux or other etiology. The Urinary Tract Dilation Classification System is used to determine risk of postnatal uropathy.

- II. Clinical presentation.** Prenatal UTD occurs in 1% to 2% of all pregnancies. Prenatal ultrasound is the most common way to identify UTD. In some patients, hydronephrosis will be detected after a urinary tract infection or as an incidental finding on imaging for another anomaly. Severe dilation, bilateral hydronephrosis, and oligohydramnios are all suggestive of a significant urinary tract obstruction.
- III. Diagnosis.** Based on the UTD classification, the anterior-posterior renal pelvis diameter, calyceal dilation, renal parenchymal thickness and appearance, ureter and bladder appearance, and presence of unexplained oligohydramnios are all key factors to note on fetal ultrasound. Postnatally, a renal and bladder ultrasound should be performed 24 to 48 hours after birth, especially when bladder outlet obstruction is suspected (eg, in males with bilateral hydronephrosis). Based on the postnatal ultrasound findings, other studies such as VCUG or diuretic renogram can be done to diagnose the underlying cause of UTD. The differential diagnosis of UTD can vary based on the timing of the imaging study and the age of the infant. These may include ureteropelvic junction obstruction, vesicoureteral reflux, posterior urethral valves, prune belly syndrome, megaureter, duplicated collecting system, ureterocele, ectopic ureter, and a variety of cystic renal diseases.
- IV. Management.** A normal postnatal ultrasound precludes the need for additional studies unless the patient develops symptoms such as urinary tract infection. Specific management is dictated by the underlying cause of hydronephrosis. Prophylactic antibiotic use for infants with hydronephrosis is highly variable and *controversial*. In our practice, it is usually reserved for patients with severe hydronephrosis, hydroureter, or vesicoureteral reflux.

128 Thrombocytopenia and Platelet Dysfunction

- I. Definition.** Thrombocytopenia is defined as a platelet count $<150,000/\mu\text{L}$ and is further classified as **mild** (100,000–149,000/ μL), **moderate** (50,000–99,000/ μL), or **severe** ($<50,000/\mu\text{L}$).
- II. Incidence.** Thrombocytopenia is more common in preterm (20%–30%) than term ($<1\%$) infants. It is the **most common hematologic abnormality among sick newborn infants in the neonatal intensive care unit (NICU)**. Pseudothrombocytopenia (lab error due to clumping) accounts for 15% of all isolated thrombocytopenia.
- III. Pathophysiology**
- A. Normal platelets.** Similar to older children and adults, the platelet life span in neonates is 7 to 10 days, and the mean platelet count is $>200,000/\mu\text{L}$.
- B. Etiology of thrombocytopenia.** See Figure 128–1.
- 1. Maternal disorders causing thrombocytopenia in infant**
- Chronic intrauterine hypoxia** is the most frequent cause of thrombocytopenia in preterm neonates in the first 72 hours of life. This is seen in cases of placenta insufficiency such as diabetes and pregnancy-induced hypertension.
 - Preeclampsia** (in particular with HELLP syndrome [*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelet count]). Thrombocytopenia is present at birth, is usually associated with neutropenia, and should recover by the second week of life.
 - Maternal medications** (eg, heparin, quinine, hydralazine, tolbutamide, and thiazide diuretics).

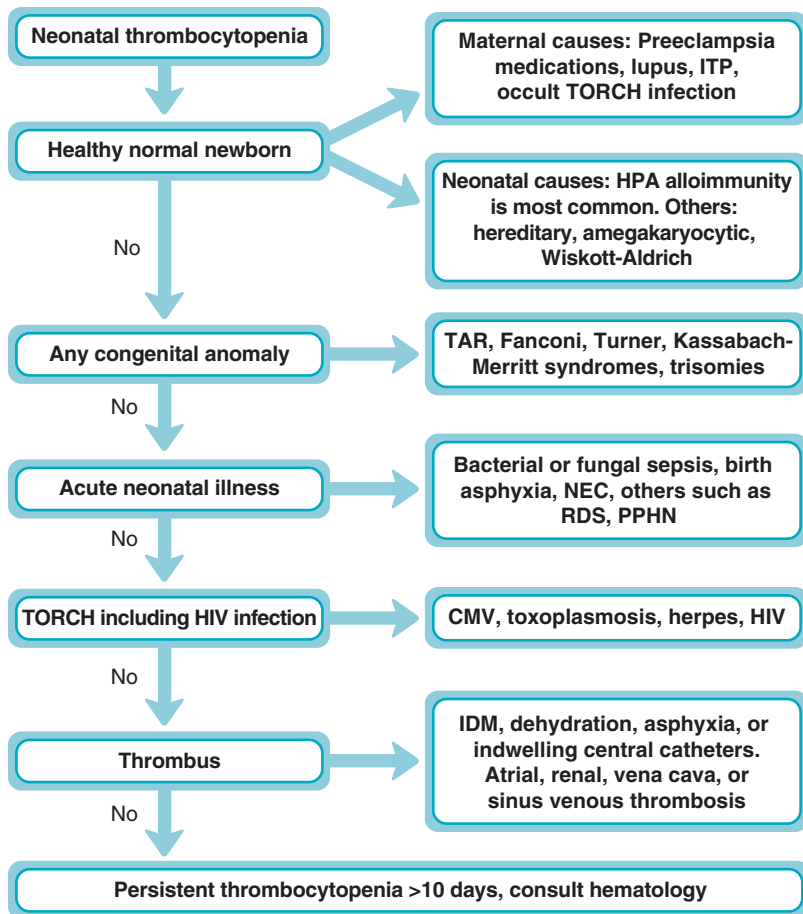

FIGURE 128–1. Algorithm for the evaluation of neonatal thrombocytopenia. CMV, cytomegalovirus; HIV, human immunodeficiency virus; HPA, human platelet antigen; IDM, infant of diabetic mother; ITP, idiopathic thrombocytopenic purpura; NEC, necrotizing enterocolitis; PPHN, persistent pulmonary hypertension of the newborn; RDS, respiratory distress syndrome; TAR, thrombocytopenia and absent radius; TORCH, *toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex virus.*

- d. **Infections** (eg, TORCH [*toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex virus*] infections, bacterial or viral infections). Not a component of perinatal Zika infection.
- e. **Disseminated intravascular coagulation.**
- f. **Antiplatelet antibodies**
 - i. **Antibodies against maternal and fetal platelets** (autoimmune thrombocytopenia)
 - (a) **Idiopathic thrombocytopenic purpura**
 - (b) **Drug-induced thrombocytopenia**
 - (c) **Systemic lupus erythematosus**

- ii. **Antibodies against fetal platelets** (isoimmune thrombocytopenia)
 - (a) **Neonatal alloimmune thrombocytopenia** is the most common cause of severe thrombocytopenia, seen mostly in term infants <72 hours of age. It is due to an incompatibility in human platelet antigen (HPA) between the newborn infant and its HPA-negative mother. HPA-1a is the most common incompatibility in Caucasians, whereas HPA-4b incompatibility is mostly seen in Asians. Only 10% of HPA-1a-negative women become sensitized after being exposed to HPA-1a because this immunologic response occurs only in the presence of specific human leukocyte antigens (HLAs) such as HLA-B8, HLA-DR3, and HLA-DR52a. HLA antibodies, although common, do not by themselves cause significant thrombocytopenia.
 - (b) **Immune thrombocytopenia** can be found in some cases of hemolytic disease of the newborn.
- 2. **Placental disorders causing thrombocytopenia in infant (rare):** Chorioangioma, vascular thrombi, and placental abruption.
- 3. **Neonatal disorders causing thrombocytopenia**
 - a. **Decreased platelet production**
 - i. **Isolated.** No identified cause.
 - ii. **Thrombocytopenia and absent radius syndrome** is characterized by normal neutrophil and red blood cell counts; absent radii, usually bilateral; and the presence of a normal thumb.
 - iii. **Fanconi anemia** is characterized by pancytopenia and the presence of an abnormal (hypoplastic or aplastic) thumb.
 - iv. **Rubella syndrome.**
 - v. **Congenital leukemia.**
 - vi. **Trisomies 13, 18, or 21 or Turner syndrome.**
 - vii. **Inherited metabolic disorders** include methylmalonic, propionic, and isovaleric acidemia; ketotic glycinemia.
 - viii. **Congenital amegakaryocytic thrombocytopenia.**
 - b. **Increased platelet destruction**
 - i. Many “sick” newborns develop thrombocytopenia that is not associated with any specific pathologic state. About 20% of newborns admitted to the NICU have thrombocytopenia, and 20% of those counts are <50,000/ μ L. This form of thrombocytopenia generally improves after the primary sickness (respiratory distress syndrome, persistent pulmonary hypertension of the newborn) resolves.
 - ii. **Pathologic states associated with thrombocytopenia**
 - (a) **Sepsis.** Bacterial and *Candida* species.
 - (b) **Congenital infections.** TORCH infections, especially cytomegalovirus (CMV). Neonates with human immunodeficiency virus (HIV) and *Enterovirus* frequently have thrombocytopenia.
 - (c) **Thrombosis** (major blood vessels, intracardiac).
 - (d) **Disseminated intravascular coagulation.**
 - (e) **Intrauterine growth restriction.**
 - (f) **Birth asphyxia.**
 - (g) **Necrotizing enterocolitis or bowel ischemia.**
 - (h) **Platelet destruction** associated with giant hemangioma (Kasabach-Merritt syndrome).
- C. **Platelet dysfunction**
 - 1. **Drug-induced platelet dysfunction**
 - a. **Maternal use of aspirin**
 - b. **Indomethacin**
 - 2. **Metabolic disorders**
 - a. **Phototherapy-induced metabolic abnormalities**

- b. Acidosis
- c. Fatty acid deficiency
- d. Maternal diabetes

3. **Inherited thrombasthenia** (Glanzmann disease)

IV. **Risk factors.** Low birthweight; low gestational age; small for gestational age; hypoxia at birth (Apgar score <5 at 5 minutes); umbilical line placement; respiratory assistance; phototherapy; respiratory distress syndrome; sepsis, especially by fungal infection; meconium aspiration; necrotizing enterocolitis; mother with idiopathic thrombocytopenic purpura (ITP); preterm infants of hypertensive mothers.

V. **Clinical presentation.** Other coagulation disorders are discussed in Chapter 92.

A. **Symptoms and signs.** Summarized in Figure 128–1.

1. **Generalized superficial petechiae** are often present, particularly in response to minor trauma or pressure or increased venous pressure. Platelet counts are usually <60,000/ μL . **Note:** Petechiae are common in normal infants and tend to be clustered on the head and upper chest, do not recur, and are associated with normal platelet counts. They are a result of a transient increase in venous pressure during birth.
2. **Gastrointestinal bleeding, mucosal bleeding, or spontaneous hemorrhage** in other sites may occur with platelet counts <20,000/ μL .
3. **Intracranial hemorrhage** may occur with severe thrombocytopenia.
4. **Large ecchymosis and muscle hemorrhages** are more likely to be due to coagulation disturbances than to platelet disturbances.

B. **History**

1. **Family history** of thrombocytopenia (hereditary) or a history of intracranial hemorrhage in a sibling (alloimmune or ITP).
2. **Maternal diabetes.**
3. **A history of any infection** should be noted.
4. **Previous episodes of bleeding** may have occurred.
5. **Presence of intravascular catheter**

C. **Placental examination.** The placenta should be carefully examined for evidence of chorioangioma, thrombi, or abruptio placentae.

D. **Physical examination**

1. **Petechiae and bleeding sites** should be noted.
2. **Physical malformations** may be present. Thrombocytopenia and absent radius syndrome, rubella syndrome, giant hemangioma, or trisomy syndromes.
3. **Hepatosplenomegaly** may be caused by viral or bacterial infection or congenital leukemia.

VI. **Diagnosis**

A. **Laboratory studies**

1. **For all newborns**

- a. **Pseudothrombocytopenia.** Isolated thrombocytopenia diagnosed from a capillary sample should be confirmed by a repeated count from a venous sample and processed immediately. In addition, careful examination of peripheral blood smear can identify clumping on the original specimen.
- b. **Complete blood count and differential.**
- c. **Blood typing.**

2. **For healthy newborns without congenital anomalies**

- a. **Coombs test.**
- b. **Maternal sample** for rapid HPA-1a (PLA1) phenotyping plus screen for anti-HPA alloantibodies. **Platelet antibody results are usually available within 24 hours.** These antibodies are detected in 90% of sensitized mothers.
- c. **Maternal, paternal, and infant genotyping** of HPA-1 to HPA-5 and HPA-15 is required for diagnosis and for matching platelet donors.
- d. **TORCH evaluation and rapid human immunodeficiency virus test.** Most are available as prenatal universal screen in the United States, except for toxoplasmosis and CMV.

- e. **Test for maternal thrombocytopenia.** A low maternal count suggests autoimmune thrombocytopenia or inherited thrombocytopenia (X-linked recessive thrombocytopenia or autosomal dominant thrombocytopenia).
- f. **In cases of unexplained and severe thrombocytopenia, a bone marrow study is indicated.** However, because of its technical difficulties in neonates, new blood tests are being developed to evaluate platelet production. Many have shown promising results (serum thrombopoietin concentrations, megakaryocyte progenitors, reticulated platelet percentages [RP%], and glycofibrinogen concentrations). An immature platelet fraction test is similar to RP% and readily available in automated cell counters. Bone marrow studies are still indicated in selected few patients (marrow cellularity or megakaryocyte morphology).
- 3. **For healthy newborns with congenital anomalies**
 - a. **Chromosome analysis for trisomies and Turner syndrome.**
 - b. **Diepoxybutane/mitomycin C stress test** to establish DNA breakage in peripheral blood lymphocytes.
- 4. **For “sick” newborns**
 - a. **Differential of white blood count**, serum C-reactive protein, and bacterial and fungal blood cultures.
 - b. **TORCH panel.** (See Chapter 148.) Culture of CMV from urine samples and other viruses if indicated (coxsackie, echovirus).
 - c. **Coagulation studies.** Prothrombin time, activated partial thromboplastin time, fibrinogen, and D-dimer level.

VII. Management

- A. **Obstetric management of maternal autoimmune thrombocytopenia**
 - 1. **The occurrence of fetal hemorrhage (in utero) is very rare** compared with the risk of such hemorrhage in alloimmune thrombocytopenia (10%).
 - 2. **Treatment is aimed at prevention** of an intracranial hemorrhage during vaginal delivery.
 - 3. **There is an increased risk of severe neonatal thrombocytopenia and intracranial hemorrhage** if antibody is present in the maternal plasma or if fetal scalp platelet counts are $<50,000/\mu\text{L}$.
 - 4. **Cesarean delivery may be indicated.**
- B. **Management of maternal alloimmune thrombocytopenia**
 - 1. **After a pregnancy has been affected by alloimmune thrombocytopenia**, the proportion of subsequent pregnancies affected mostly depends on the father's genotype. If the father is heterozygous (HPA-1a/HPA-1b), the risk is 50%, and the risk is close to 100% if he is homozygous (HPA-1a/HPA-1a). The history of intracranial hemorrhage in a previous sibling is predictive of the presence of severe thrombocytopenia for the next fetus. In subsequent pregnancies, administering corticosteroids and intravenous immunoglobulin (IVIg) during the third trimester coupled with transfusions of platelets to the fetus using ultrasound-guided intraumbilical cord infusion has been advocated.
 - 2. **Instrumental vaginal delivery, fetal scalp electrodes**, and fetal scalp blood sampling should be avoided. Vaginal delivery is allowed when fetal platelet count is known to be $>50,000/\mu\text{L}$ and presentation and labor are normal. Otherwise cesarean delivery is indicated.
- C. **Treatment of infants with thrombocytopenia**
 - 1. **Treat the underlying cause (eg, sepsis).** If drugs are the cause, stop their administration.
 - 2. **Platelet transfusions**
 - a. **Indications**
 - i. **Platelets must be given urgently** if active bleeding is occurring with any degree of thrombocytopenia or if there is no active bleeding but platelet counts are $<20,000/\mu\text{L}$.

2. **Stimulated by the thyroid-stimulating hormone surge, thyroxine, free thyroxine, and triiodothyronine rapidly increase**, reaching peak levels by 24 to 36 hours. TSH level decreases slowly over the first 2 weeks of life to values slightly higher than what are found typically in adults.
- C. **Thyroid function in the premature infant.** Similar changes in TSH, T_4 , and T_3 are seen in premature infants; however, absolute values are lower in proportion to the gestational age and birthweight. TSH levels return to normal by 5 to 10 days of life.
- II. **Physiologic action of thyroid hormones.** Thyroid hormones have profound effects on growth and neurologic development. They also influence oxygen consumption, thermogenesis, and the metabolic rate of many organs. Maternal T_4 is critical for normal central nervous system maturation in the fetus.
- III. **Biochemical steps involved in thyroid hormone synthesis.** Thyroid hormone production involves the steps of iodide transport/trapping, thyroglobulin synthesis, organification of iodide, monoiodotyrosine and diiodotyrosine coupling, thyroglobulin endocytosis, proteolysis, and release. In addition, T_4 is converted to T_3 in peripheral tissue.
- IV. **Maternal thyroid disease and pregnancy outcome.** Maternal thyroid diseases (hypo- and hyperthyroidism) are associated with increased risk for pregnancy complications including miscarriage, preeclampsia, placental abruption, preterm birth, and cesarean section. Maternal symptoms of autoimmune thyroid diseases tend to improve during pregnancy. Maintaining euthyroidism and achieving a serum total T_4 in the upper limit of normal throughout pregnancy is key to reducing the risk of maternal, fetal, and newborn complications.
- V. **Assessment of thyroid function.** Thyroid tests are intended to measure the level of thyroid activity and to identify the cause of thyroid dysfunction.
 - A. **Thyroxine concentration** is important in the evaluation of thyroid function. More than 99% of T_4 is bound to thyroid hormone-binding proteins. Therefore, changes in these proteins may affect T_4 levels. Serum levels for term newborn infants range between 6.4 and 23.2 mcg/dL.
 - B. **Free thyroxine** reflects the availability of thyroid hormone to enter tissues. Serum levels vary widely by gestational age; term newborn infant levels (2.0–5.3 ng/dL) are higher than those of infants who are 25 to 30 weeks' gestation (0.6–3.3 ng/dL).
 - C. **Thyroid-stimulating hormone measurement** is valuable in evaluating thyroid disorders, particularly primary hyperthyroidism. Serum levels over all gestational ages of 25 to 42 weeks range from 2.5 to 18.0 mU/L. Levels should drop to <10 mU/L by 1 month of age.
 - D. **Triiodothyronine concentration** is useful in the diagnosis and treatment of hyperthyroidism. Serum levels of T_3 are very low in the fetus and cord blood (20–75 ng/dL). Shortly after birth, levels exceed 100 to approximately 400 ng/dL. In hyperthyroid states, levels may exceed 400 ng/dL. In sick preterm infants, a very low T_3 (hypothyroid range) may signal the **euthyroid sick syndrome**, also known as the **nonthyroidal illness syndrome**.
 - E. **Thyroid-binding globulin** can be measured directly by radioimmunoassay.
 - F. **The thyrotropin-releasing hormone stimulation test** assesses pituitary and thyroid responsiveness and differentiates between secondary and tertiary hypothyroidism.
 - G. **Thyroid imaging**
 1. **Thyroid scanning** with iodine-123 (preferred isotope) is used to identify functional thyroid tissue.
 2. **Color Doppler ultrasonography** has shown improved sensitivity in detecting ectopic thyroid tissue in recent studies.

CONGENITAL HYPOTHYROIDISM

- I. **Definition.** Congenital hypothyroidism (CH) is defined as a significant decrease in, or the absence of, thyroid function at or shortly after birth. Unrecognized CH leads to intellectual disability.

II. Incidence. The overall incidence is 1 in 2000 to 3000 live newborn infants. Sporadic cases account for 85% of patients, whereas 15% are hereditary. The incidence of CH is higher in Hispanic individuals and lower in blacks. There is a 2:1 female-to-male ratio. In addition, there is an increased risk in infants with Down syndrome.

III. Pathophysiology

A. Primary hypothyroidism

- 1. Developmental defects** such as ectopic thyroid (most common), thyroid hypoplasia, or agenesis. In a minority of cases (2%–5%), a mutation may be present in 1 of several genes involved in thyroid gland formation, including the TSH receptor (TSHR) or the transcription factors PAX8, NKX2-1, or FOXE1.
- 2. Inborn errors of thyroid hormone synthesis** including total and partial iodide organification defects.
- 3. Maternal exposure** to radioiodine, propylthiouracil (PTU), or methimazole (MMI) during pregnancy.
- 4. Iodine deficiency** (endemic cretinism).

B. Secondary hypothyroidism.

C. Tertiary hypothyroidism. Thyrotropin-releasing hormone (TRH) deficiency.

D. Hypopituitary hypothyroidism. Associated with other hormonal deficiencies.

IV. Risk factors. Genetic or family history, birth defects, female sex, and gestational age >40 weeks.

V. Clinical presentation

A. Antenatal diagnosis is suspected when goiter is incidentally discovered during fetal ultrasound, with a family history of dyshormonogenesis, or with known defects of genes involved in thyroid function or development. Cordocentesis or percutaneous umbilical blood sampling, rather than amniocentesis, should be the reference method for assessing fetal thyroid function but should only be performed if prenatal intervention is considered. In a euthyroid pregnant woman, a large goiter in the fetus with progressive hydramnios and a risk of premature labor and delivery and/or concerns about tracheal occlusion are criteria in favor of fetal treatment in utero. Interventions such as intra-amniotic levothyroxine (L-T₄) injection may be considered only by a multidisciplinary specialist team.

B. Postnatal. Symptoms are usually absent at birth; however, subtle signs may be detected during the first few weeks of life. Obtain a serum free T₄ and TSH for any clinical signs, even if the newborn screening is negative. CH can occur even after a normal newborn screening.

- 1. Early manifestations.** Signs at birth include prolonged gestation, large size for gestational age, large fontanelle, and respiratory distress syndrome. Manifestations as early as 2 weeks include hypotonia, umbilical hernia, lethargy, constipation, hypothermia, prolonged jaundice, and feeding difficulty.
- 2. Late manifestation.** Classic features usually appear after 6 weeks and include puffy eyelids, coarse hair, large tongue, myxedema, and hoarse cry. Late manifestations in borderline hypothyroidism detected in screening programs can present as significant hearing impairment with speech delay.

VI. Diagnosis

A. Screening

- 1. Methods.** The screening strategies include primary TSH with backup T₄ (may miss thyroid-binding globulin [TBG] deficiency, hypothalamic-pituitary hypothyroidism, and hypothyroxinemia with delayed TSH elevation), primary T₄ with backup TSH (will miss delayed TSH elevation with initial normal T₄), and **primary T₄ and TSH (considered the ideal screening approach)**. In other countries such as the Netherlands, the measurement of T₄/TBG ratio in newborns with low T₄ and nonelevated TSH levels and TRH stimulation tests are used to identify central CH.

2. **Timing.** The ideal time for screening is 48 hours to 4 days of age. Infants discharged before 48 hours should be screened before discharge; however, this increases the number of false-positive TSH elevations. A repeat test at 2 to 6 weeks identifies approximately 10% of cases.
3. **American Academy of Pediatrics recommended screening.**
 - a. **Term delivery in hospital.** Filter paper blood spot collection at 2 to 4 days of age or at discharge.
 - b. **Neonatal intensive care unit/preterm birth/home birth.** Within 7 days of birth.
 - c. **Mother on thyroid medication/family history of CH.** Screen cord blood.
4. **A strategy of second screening (2–4 weeks of age)** should be considered for the following conditions: preterm neonates; low birthweight and very low birthweight neonates; ill and preterm newborns admitted to neonatal intensive care units; specimen collection within the first 24 hours of life; and multiple births (particularly same-sex twins).
5. **Results.** Accurate screening results depend on good quality of blood spots. A low T_4 level and TSH concentrations >40 mU/L are indicative of CH. Normal TSH at 2 to 12 weeks is 9.1 mU/L. The update of newborn screening and therapy for CH (June 2006, reaffirmed December 2011) by the American Academy of Pediatrics, American Thyroid Association, and Lawson Wilkins Pediatric Endocrine Society provides a useful algorithm (Figure 129–1). The European Society for Pediatric Endocrinology Consensus Guidelines on Screening, Diagnosis and Management of Congenital Hypothyroidism (Léger et al; February 2014) also has an updated guideline.

B. Diagnostic studies

1. **Serum for confirmatory measurements of T_4 and TSH concentrations.** If an abnormality of TBG is suspected, free T_4 (FT_4) and TBG concentrations should also be evaluated.
2. **Ultrasonography** is used to separate a structural defect from a normal or enlarged gland.
3. **Thyroid scan (scintigraphy) with radioactive iodine or technetium** remains the most accurate diagnostic modality to determine the cause of CH.
4. **Knee radiographs** may be used to assess the severity of intrauterine hypothyroidism by the presence or absence of femoral and tibial epiphyses.
5. **Genetic testing and counseling** are indicated with inborn errors of thyroid hormone synthesis and when a mutation in 1 of genes involved in thyroid gland formation is suspected.

VII. Management

- A. **Consultation with a pediatric endocrinologist** is recommended.
- B. **Goal of therapy** is to ensure normal growth and development, normalize TSH, and maintain T_4 or FT_4 in upper half of reference range.
- C. **Treatment.** L- T_4 is the treatment of choice. L- T_4 treatment should be initiated as soon as possible and no later than 2 weeks after birth or immediately after confirmatory serum test results in infants in whom CH is detected by a second screening test. The average L- T_4 starting dose is 10 to 15 mcg/kg/d orally. Customization of the doses based on underlying cause and severity may result in more rapid normalization of values of TSH and T_4 . The pill, universally available, should be crushed and suspended in breast milk, formula, or water. **Care should be taken to avoid concomitant administration of soy, fiber, or iron.** In Europe, liquid preparations with 5 mcg/drop concentrations are approved. The goal of therapy is to maintain T_4 concentration in the upper normal range (total T_4 : 10–16 mcg/dL; FT_4 : 1.4–2.3 ng/dL) with low-normal serum TSH (0.5–2 mU/L).
- D. **Follow-up.** Clinical evaluation, including assessment of growth and development, should be performed every few months during the first 3 years of life. Infants with CH are at risk of other congenital anomalies. Cardiovascular anomalies, including pulmonary stenosis, atrial septal defect, and ventricular septal defect, are the

most common. Infants need to undergo frequent laboratory and clinical evaluations of thyroid function, growth, and development to ensure optimal T_4 dosage and adherence to their therapy regimen. **Serum T_4 and TSH measurements should be performed as follows:**

1. **At 2 and 4 weeks after initiation of L- T_4 therapy.**
2. **Every 1 to 2 months during the first 6 months of life.**
3. **Every 3 to 4 months between 6 months and 3 years.**
4. **Every 6 to 12 months until growth is completed.**
5. **More frequent intervals with dose change,** abnormal values, and compliance concerns.
6. **Monitoring more intensely during puberty** is recommended to prevent unwanted cardiovascular dysfunction.

VIII. Assess permanence of congenital hypothyroidism

- A. **If initial thyroid scan shows an ectopic or absent gland,** CH is a permanent condition.
 - B. **If initial thyroid-stimulating hormone is <50 mU/L** and there is no increase in TSH after newborn period, then a trial off therapy at 3 years of age may be considered.
 - C. **If thyroid-stimulating hormone increases off therapy,** consider CH as a permanent condition.
- IX. **Prognosis.** CH can adversely influence growth, intelligence, cardiovascular function, and quality of life in the long term. The more severe the thyroid dysfunction at diagnosis, the lower is the performance intelligence quotient (IQ) later in life. Early initiation of therapy within the first 2 weeks of life, at doses of 10 to 15 mcg/kg of L- T_4 , and subsequent management through puberty may help to mitigate these deficits and promote optimal somatic growth.

NEONATAL THYROTOXICOSIS

- I. **Definition.** Neonatal thyrotoxicosis is defined as a hypermetabolic state resulting from excessive thyroid hormone activity in the newborn.
- II. **Incidence.** This is a rare disorder, occurring in only approximately 1 of 70 thyrotoxic pregnancies (autoimmune disease). The incidence of maternal thyrotoxicosis in pregnancy is 1 to 2 per 1000 pregnancies.
- III. **Pathophysiology**
 - A. **Usually results from transplacental passage of TSH receptor antibodies** from a mother with current or past history of Graves disease or Hashimoto thyroiditis.
 - B. **Nonimmune hyperthyroidism** has been identified as a result of activating mutations in the TSH receptor gene, stimulatory G protein in McCune-Albright syndrome, thyroid hormone resistance due to mutation in thyroid hormone receptor gene, or excessive iodine use.
- IV. **Risk factors.** Mother with active or inactive Graves' disease or Hashimoto thyroiditis.
- V. **Clinical presentation.** Both stillbirths and preterm births are increased. Fetal hyperthyroidism due to Graves disease may be seen during the third trimester. Signs include fetal tachycardia, heart failure with nonimmune hydrops, intrauterine growth retardation, preterm birth, advanced skeletal maturation, and craniosynostosis. In symptomatic cases, fetal hyperthyroidism may be treated by administering antithyroid drugs to the mother. **Postnatal signs** are usually apparent within hours after birth to the first 10 days of life. Delayed presentation up to 45 days may occur in the presence of coexisting maternal blocking and stimulating antibodies. Thyrotoxic signs include irritability, tachycardia, dysrhythmia, hepatomegaly, small-for-gestational age, poor weight gain, hypertension, flushing, tremor, and thrombocytopenia. A goiter is usually present and may be large enough to cause tracheal compression. Eye signs such as lid retraction and exophthalmos, as well as premature bone ossification and craniosynostosis, may also be present.

When to Screen
 Normal hospital delivery at term—Filter-paper collection ideally at 2–4 d of age or at time of discharge
 NICU/preterm home birth—Within 7 d of birth
 Maternal history of thyroid medication/family history of CH—Cord blood for screening

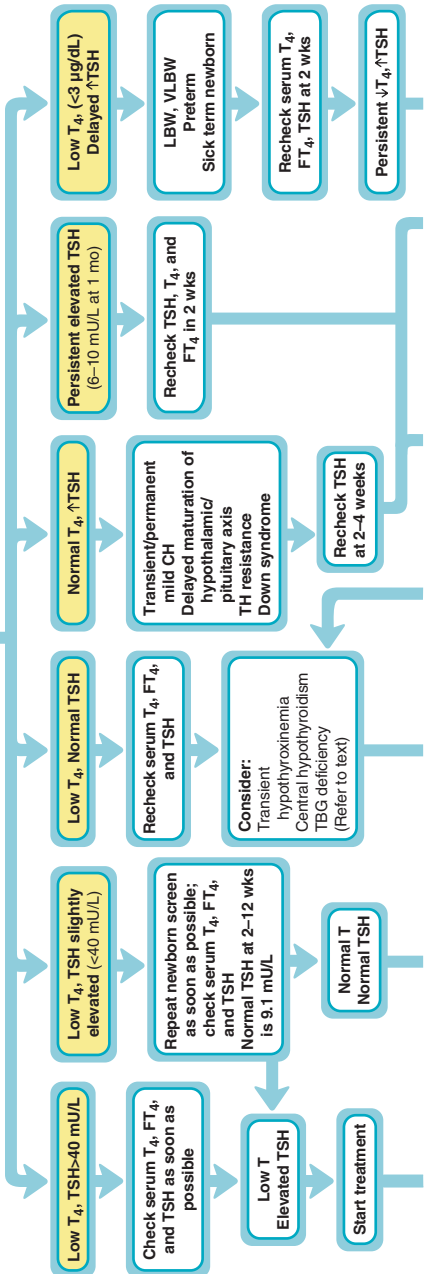

Type of Screening
 Primary T₄, TSH >40 mU/L
 May miss—T₄ deficiency
 Hypothalamic-pituitary hypothyroidism
 Hypothyroxinemia with delayed TSH elevation
 For better sensitivity—Use sensitive TSH assay and Age-adjusted TSH cutoff (20–25 mU/L at 24 h of age)

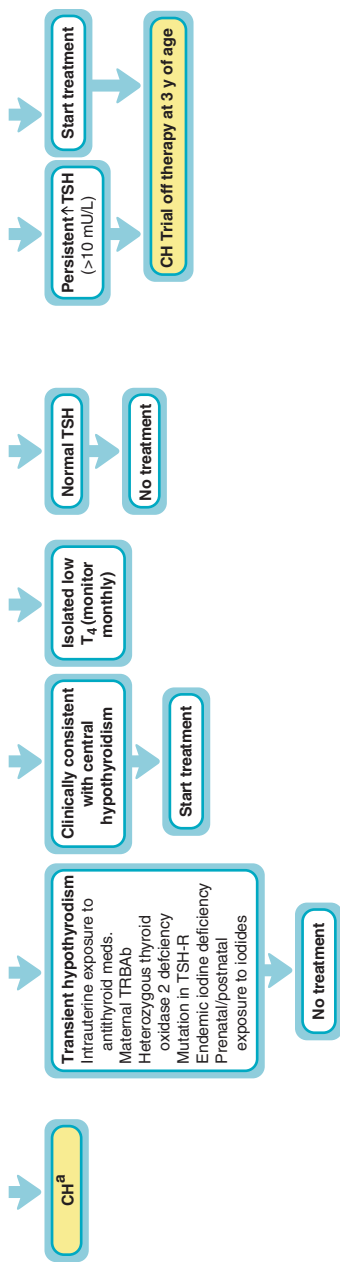

Primary T₄ Backup TSH
 Will miss delayed TSH elevation with initial normal T₄

Primary T₄ and TSH
 Ideal screening approach

TIMELY FOLLOW-UP AND TRANSMISSION OF RESULTS (refer to text)

Interpretation of Results

^aInitial workup

- Detailed history and physical examination
- Referral to pediatric endocrinologist
- Recheck serum TSH and FT₄
- Thyroid ultrasonography and/or thyroid scan (see text for recommendations)

Medications

L-T₄: 10–15 µg/kg by mouth once daily

Monitoring

- Recheck T₄, TSH
- 2–4 wks after initial treatment is begun
- Every 1–2 mo in the first 6 mo
- Every 3–4 mo between 6 mo and 3 y of age
- Every 6–12 mo from 3 y of age to end of growth

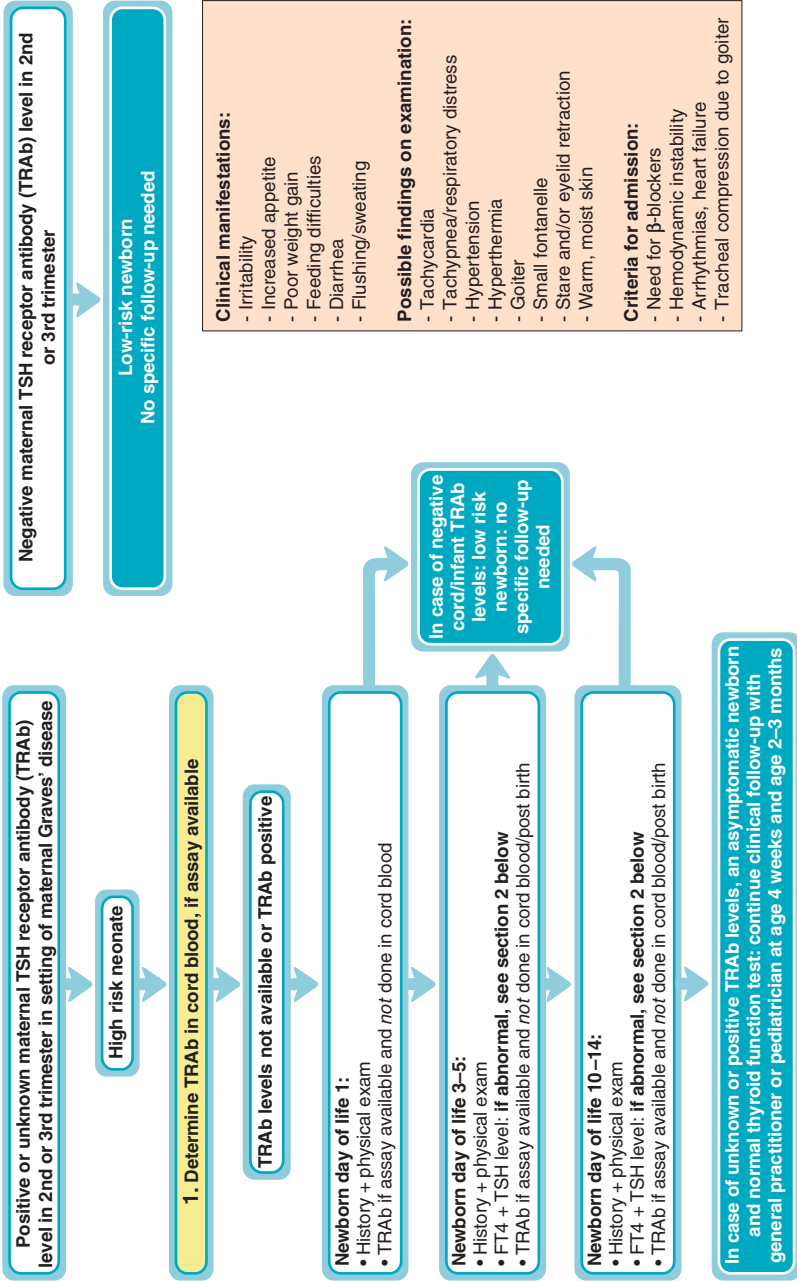

Goal of therapy

Normalize TSH and maintain T₄ and FT₄ in upper half of reference range

Assess permanence of CH

- If initial thyroid scan shows ectopic/absent gland, CH is permanent
- If initial TSH is <50 mU/L and there is no increase in TSH after newborn period, then trial off therapy at 3 y of age
- If TSH increases off therapy, consider permanent CH

FIGURE 129–1. Newborn congenital hypothyroidism screening and therapy. CH, congenital hypothyroidism; FT₄, free thyroxine; LBW, low birthweight; NICU, neonatal intensive care unit; T₄, thyroxine; TBG, thyroid-binding globulin; TRBAb, TSH receptor–blocking antibodies; TSH, thyroid-stimulating hormone; TSH-R, TSH receptor; VLBW, very low birthweight. (Reproduced with permission from *American Academy of Pediatrics, Rose SR; Section on Endocrinology and Committee on Genetics, et al: Update of newborn screening and therapy for congenital hypothyroidism, Pediatrics. 2006 Jun;117(6):2290–2303. Reaffirmed December 2011.*)

2. Abnormal thyroid function test result for any of the above

Biochemical hyperthyroidism and no symptoms:

- Consider Methimazole; 0.2–0.5 mg/kg/d divided in 2 doses

Biochemical hyperthyroidism and symptoms:

- Start Methimazole 0.2–0.5 mg/kg/d divided in 2 doses
- Signs of sympathetic hyperactivity; consider adding Propranolol 2 mg/kg/d divided in 2 doses for 1–2 weeks and strongly consider admission to hospital
- If hemodynamically unstable: consider adding Lugol's solution 1 drop (0.05 mL) 3 times daily or potassium iodine (SSKI) 1 drop (0.05 mL) once daily; give 1st dose at least 1 hour after 1st Methimazole dose
- Maintain normal body temperature, adequate fluid and caloric intake

Central or primary hypothyroidism:

- Repeat FT4+TSH level in 1 week
- In case of central hypothyroidism, no prior neonatal hyperthyroidism and unknown TRAb, consider other pituitary hormone deficiencies.
- Start Levothyroxine 10 µg/kg/d if repeat FT4 level below normal range

- History + physical examination, and FT4+TSH level every 2–3 weeks to titrate Levothyroxine accordingly
- May be able to decrease dose as hypothyroidism is usually transient

Weekly to biweekly history + physical examination, FT4 + TSH level

- Decrease Methimazole dose once FT4 in reference range for age
- Average treatment duration is 1–2 months

FIGURE 129-2. Management algorithm for neonates born to mothers with Graves disease. FT₄, free thyroxine; TSH, thyroid-stimulating hormone. (Reproduced with permission from van der Kaay DC, Wasserman JD2, Palmert MR: *Management of Neonates Born to Mothers With Graves' Disease*, Pediatrics. 2016 Apr;137(4). pii: e20151878.)

VI. Diagnosis

A. History and physical examination. A maternal past history of thyrotoxicosis and presence of maternal thyroid-stimulating antibodies in the last trimester correlate well with the development of neonatal thyrotoxicosis. Determining maternal TSH receptor antibody levels at 20 to 24 weeks' gestation is recommended. At birth, the infant may be euthyroid or even hypothyroid by laboratory values; however, paradoxically, the presence of goiter may be the only abnormal finding in addition to the clinical features of thyrotoxicosis on physical examination, as discussed earlier.

B. Laboratory studies. Diagnosis is confirmed by demonstrating increased levels of T_4 , FT_4 , and T_3 with suppressed levels of TSH.

VII. Management. Although the disorder is usually self-limited, therapy depends on the severity of the symptoms, and thyrotoxicosis is a life-threatening emergency in its most severe form. Care should be exercised not to induce hypothyroidism with excessive medication. Figure 129–2 represents a useful management algorithm proposed by van der Kaay et al.

A. Asymptomatic biochemical hyperthyroidism. Consider MMI 0.2 to 0.5 mg/kg/d in 2 divided doses. Close observation is required. Therapy may not be necessary if FT_4 elevation and/or TSH suppression are mild.

B. Symptomatic biochemical hyperthyroidism. Administer 1 or more of the following medications:

1. Methimazole is the drug of choice. It blocks thyroid hormone synthesis. Start with 0.2 to 0.5 mg/kg/d in 2 divided doses until euthyroid, then the dose can be reduced by 30% to 60%. PTU blocks synthesis and peripheral T_4 to T_3 conversion and may be used instead of MMI. Initial dose is 5 to 10 mg/kg/d in 3 divided doses, then the dose can be reduced by 30% to 60%. Use with caution due to risk of liver toxicity.

2. Propranolol is used to control tachycardia, 2 mg/kg/d in 2 to 3 divided doses. Diuretics and digitalis may be needed to treat congestive heart failure.

3. Oral iodine. Lugol's solution or saturated solution of potassium iodide, 1 drop (0.05 mL) every 8 hours, in conjunction with MMI. Give the first dose 1 hour after the first MMI dose.

4. Corticosteroids inhibit thyroid hormone secretion and inhibit conversion of T_4 to T_3 . Use either **hydrocortisone** 2.5 to 10 mg/kg/d divided every 8 hours or **prednisolone** 1 to 2 mg/kg/d divided every 12 hours; give only in severe cases.

C. Thyroid gland ablation or near-total thyroidectomy is the definitive treatment of permanent thyrotoxicosis resulting from **nonimmune hyperthyroidism** caused by activating mutations.

D. Breastfeeding is regarded as safe with maximal maternal doses of MMI of 20 mg or PTU of 450 mg.

VIII. Prognosis. The disorder is usually self-limited and disappears spontaneously within 2 to 4 months. Mortality in affected infants is 15% to 25% if the disorder is not recognized and treated properly. Potential long-term morbidity includes hyperactivity, impaired intellect, advanced bone age, frontal bossing, and craniosynostosis.

TRANSIENT DISORDERS OF THYROID FUNCTION IN THE NEWBORN

I. EUTHYROID SICK SYNDROME

A. Definition. Also called **nonthyroidal illness syndrome**, euthyroid sick syndrome is a transient alteration in thyroid function associated with a severe nonthyroidal illness.

B. Incidence. The syndrome is frequently seen in premature infants because of their increased susceptibility to neonatal morbidity. Preterm infants with respiratory distress syndrome have been the most frequently reported patients with this disorder.

C. Diagnosis. A low T_3 level is usually present, associated with low or normal T_4 and normal TSH. Infants are euthyroid (normal TSH).

D. Treatment. Treatment has not been shown to be beneficial. Abnormal thyroid functions return to normal as the sick infant improves. However, preterm infants at risk should be monitored by serial determinations of FT_4 and TSH, and treatment should be initiated if there is progressive increase in TSH and decrease in FT_4 . Treatment should be initiated if the illness state is expected to be persistent and TSH remains elevated for a month or longer.

II. TRANSIENT HYPOTHYROXINEMIA OF PREMATURITY

- A. Definition.** Low thyroid levels without elevated TSH, but not as low as CH.
- B. Incidence.** Almost all preterm infants have some degree of hypothyroxinemia (>50% have T_4 levels <6.5 mcg/dL).
- C. Pathophysiology.** The condition is presumed to be related to immaturity of the hypothalamic-pituitary-thyroid axis that cannot compensate for the loss of maternal thyroid hormone.
- D. Diagnosis.** The biochemical profile of transient hypothyroxinemia in premature infants (before 30–32 weeks' gestation) comprises low T_4 and FT_4 levels with normal or low TSH levels. Treatment with L- T_4 causes further drop in TSH levels.
- E. Treatment.** Therapy has not been consistently effective in improving neurologic outcome or reducing morbidity. Therapy is only recommended when low T_4 is accompanied by TSH elevation.

130 Transient Tachypnea of the Newborn

- I. Definition.** Transient tachypnea of the newborn (TTN) is a benign self-limited respiratory distress syndrome of term and late preterm infants related to delayed clearance of lung liquid. The distress appears shortly after birth and usually resolves within 3 to 5 days. **Synonymous terms** include wet lung syndrome, type II respiratory distress syndrome (RDS), transient RDS, neonatal retained fluid syndrome, and benign unexplained respiratory distress in the newborn.
- II. Incidence.** It is the most common perinatal respiratory disorder, responsible for 40% of respiratory distress after birth. Incidence varies in the literature from 4 to 11 cases per 1000 singleton live births.
- III. Pathophysiology.** A delayed resorption of liquid from the lungs is believed to be the central mechanism for TTN. The lung liquid inhibits gas exchange, leading to an increased work of breathing. Tachypnea develops to compensate for that. Hypoxia develops because of poorly ventilated alveoli. The following factors are involved:
- A. Elevated airway liquid volumes**
- 1. Inactivated/immature amiloride-sensitive sodium channels.** During gestation, the pulmonary epithelium actively secretes fluid and chloride into the air spaces. **During labor**, a surge of fetal catecholamines (adrenaline, glucocorticoids) is released, and the lung switches from active chloride and fluid secretion to active sodium absorption. However, when sodium channels are inactivated or ineffective during labor, this will result in a larger volume of lung liquid at birth, leading to reduced postnatal respiratory function. Infants born by elective cesarean section have a higher risk of TTN as they are not exposed to the stress (catecholamines) during labor.

Whatever mechanism is responsible for the liquid remaining in the lung, at birth, the transpulmonary pressure created during inspiration is largely responsible for the direct lung aeration and clearance of lung liquid

(seconds). The pressure moves the column of liquid distally toward the alveolus, where it is transferred passively through the membrane into the interstitium. Then the liquid in the interstitium is slowly absorbed by the lymph and blood vessels (hours), leading temporarily to positive pressure in the interstitium. The role of the activated sodium transport from alveolus to interstitium after birth is to prevent the liquid from going back into the alveolus as a consequence of the positive pressure in the interstitium.

2. **Uterine contractions.** Infants delivered by elective cesarean section miss the lung liquid efflux via the trachea by high transpulmonary pressures caused by uterine contractions. Infants delivered by cesarean and breech deliveries miss the fetal trunk flexion when the head goes through the birth canal first, which increases abdominal pressure, elevates the diaphragm, and increases transpulmonary pressure, thereby forcing liquid out via the nose and mouth.

Both mechanisms will lead to larger airway liquid volumes at birth that must be accommodated within the lung tissue following lung aeration, resulting in higher interstitial pressures and a greater likelihood of liquid flooding back into the airways when the lungs are at functional residual capacity (FRC). The elevated airway liquid volumes will affect respiratory structure and function, resulting in lower FRCs and a reduced ability of the lung to aerate efficiently.

- B. **Pulmonary immaturity.** One study noted that a mild degree of pulmonary immaturity is a central factor in the cause of TTN. The authors found a mature lecithin-sphingomyelin ratio but negative phosphatidylglycerol (the presence of phosphatidylglycerol indicates completed lung maturation) in infants with TTN. Infants who were closer to 36 weeks' gestation than 38 weeks' gestation had an increased risk of TTN. One study demonstrated that a **relative surfactant deficiency** may play a role in prolonged TTN. Surfactant deficiency leads to an increased surface tension and lowers the compliance of the lung. A layer of surfactant also plays a role in preventing lung liquid from going back to the alveoli. A recent study suggested that TTN is associated with surfactant dysfunction by showing that infants with TTN delivered by cesarean section had low stable microbubble counts in oral aspirates at birth.

- C. **Genetic predisposition.** Because of familial clustering of some cases, there is speculation that there may be a genetic predisposition.

1. **Some propose that there may be a genetic predisposition for β -adrenergic hyporesponsiveness** and that this plays a role in TTN.
2. **Polymorphisms** in the β -adrenergic receptor (ADRB)-encoding genes, β_1 Gly-49 homozygosity and TACC haplotype of *ADRB2* gene, may predispose to TTN.
3. **Maternal and fetal mutated alleles** of the *PROGINS* progesterone receptor polymorphism reduce the risk for TTN.

IV. Risk factors

- A. **Cesarean delivery** (with or without labor). Labor prior to a cesarean delivery is not protective for TTN. General anesthesia resulted in higher rates of TTN compared with spinal anesthesia in elective cesarean sections.

B. **Male gender.**

C. **Prematurity/late preterm.**

D. **Macrosomia (birthweight ≥ 4500 g).**

E. **Multiple gestations.**

F. **Prolonged labor with long intervals.**

G. **Negative amniotic fluid phosphatidylglycerol.**

H. **Perinatal/birth asphyxia.**

I. **Fluid overload in the mother, especially with oxytocin infusion.**

J. **Family history of asthma (especially history in the mother).**

K. **Breech delivery.**

- L. **Infant of a diabetic mother (2–3 times more common).** Reasons could be the increased rate of cesarean sections in this group or the decreased fluid clearance in the diabetic fetal lung.
- M. **Infant of drug-dependent mother** (narcotics).
- N. **Exposure to β -mimetic agents.**
- O. **Precipitous delivery** (rapid vaginal delivery)/absence of exposure to labor.
- P. **Urban location.**
- Q. **Nulliparity.**
- R. **History of infertility therapy.**
- S. **Augmentation of labor/vacuum/forceps delivery.**
- T. **Low Apgar score (<7) at 1 and 5 minutes.** A low Apgar at 1 minute was associated the most with TTN.
- U. **Absence of premature rupture of membranes.**
- V. **Hypothyroxinemia in the infant.**
- W. **Maternal epilepsy**
- V. **Increased risk of prolonged transient tachypnea of the newborn/increased severity of transient tachypnea of the newborn**
 - A. **Grunting, maximum respiratory rate >90 breaths/min, and a fraction of inspired oxygen >0.40** within 6 hours of life were associated with an increase in prolonged TTN.
 - B. **Peak respiratory rate in the first 36 hours of life >90 breaths/min** caused a 7-fold increased risk of prolonged tachypnea. The group with prolonged tachypnea had longer hospitalization and antibiotic treatment. The white blood cell count and hematocrit levels were lower in the group with prolonged tachypnea than the group with tachypnea that lasted <72 hours.
 - C. **Absence of labor contractions or reduced labor duration** is associated with a more severe course of TTN at term, requiring longer oxygen supplementation.
 - D. **Long-distance land-based transport in neonates with transient tachypnea of the newborn.** These infants required increased respiratory support in the neonatal intensive care unit (NICU), and incidence of pulmonary air leak syndrome was higher.
- VI. **Clinical presentation.** The infant is usually near term, term, or large and premature. Tachypnea (>60 breaths/min and as high as 100–120 breaths/min) occurs shortly after delivery or within the first 6 hours of delivery. The infant may also have grunting (persistent grunting after birth), nasal flaring, minimal rib retractions, and varying degrees of cyanosis (uncommon, usually mild hypoxemia responsive to oxygen). The infant often appears to have the classic “barrel chest” secondary to the increased anteroposterior diameter (hyperinflation). One can hear crackles on auscultation, and the liver and spleen are palpable because of the hyperinflation. There are usually no signs of sepsis. Some infants may have edema and a mild ileus on physical examination. One can also see tachycardia with usually a normal blood pressure. The infant is neurologically normal and has no signs of sepsis. **Some clinicians differentiate between transitional delay, transient tachypnea, and prolonged tachypnea.**
 - A. **Transitional delay.** Tachypnea right after birth for usually <6 hours (but can be 2–12 hours). Grunting can occur right after birth with transitional delay and usually subsides by 2 hours (93%). Transitional delay usually subsides within 6 hours, and infants are able to feed orally.
 - B. **Transient tachypnea of the newborn.** Tachypnea that lasts from after birth to usually <72 hours. It typically resolves by 12 to 24 hours. One study found that 74% of infants had resolution of their symptoms by 48 hours.
 - C. **Prolonged transient tachypnea of the newborn.** Some infants have prolonged tachypnea, lasting >72 hours. Some have classified this as prolonged tachypnea of the newborn. Infants with prolonged TTN were found to have an increased asymmetric dimethylarginine (ADMA) level. ADMA may decrease nitric oxide synthesis, causing an increase in pulmonary artery pressure and thereby causing the tachypnea to last longer.

VII. Diagnosis. TTN is a clinical diagnosis based on clinical and radiologic findings.

A. Laboratory studies

1. Prenatal testing

- a. **A mature lecithin-sphingomyelin ratio** with the presence of phosphatidylglycerol in the amniotic fluid may help rule out RDS. This test is no longer commonly performed.
 - b. **Quantitative ultrasound texture analysis of the fetal lung (quantusFLM; Transmural Biotech)** is able to predict fetal lung maturity with an accuracy comparable to amniotic fluid tests. It can predict respiratory morbidity (RDS or TTN) with an accuracy of 86.5%.
- 2. Amniotic fluid sampling at delivery.** **Amniotic lamellar body counts** can predict the occurrence of TTN. The count is lower than in controls and higher than in infants with RDS.

3. Postnatal testing

- a. **Arterial blood gas on room air** shows some degree of mild to moderate hypoxemia. Arterial partial pressure of carbon dioxide is usually normal because of the tachypnea. Hypercapnia/hypercarbia, if it exists, is usually mild (partial pressure of carbon dioxide >55 mm Hg), and a mild respiratory acidosis can be seen, but if it worsens, it can be a sign of fatigue and impending respiratory failure or complication such as a pneumothorax. If there is a severe respiratory alkalosis, consider hyperammonemia.
 - b. **Pulse oximetry should be monitored continuously.**
 - c. **Complete blood count with differential** is normal in TTN but should be obtained if an infectious process is being considered. The hematocrit will also rule out polycythemia.
- 4. Other promising tests that may aid in the diagnosis but are usually not needed.** **Plasma endothelin-1 levels** may be higher in RDS compared with those in TTN. This test may prove useful in differentiating RDS from TTN. **Interleukin-6 (IL-6)** may distinguish proven and clinical sepsis from TTN. This may make it possible to avoid antibiotics in this group of infants. **Serum atrial natriuretic peptide levels** were lower in infants with TTN than in normal infants in one study. **Ischemia-modified albumin levels** can be used to predict TTN and severity because they are significantly higher in infants diagnosed with TTN. The **fetal pulmonary artery acceleration to ejection time ratio** seems to be promising to predict or rule out TTN.

B. Imaging and other studies

- 1. Chest radiograph.** (See example in Figures 12–20A and B.) The chest radiograph is the diagnostic standard. The typical findings in TTN are as follows:
- a. **Hyperexpansion (hyperinflation)** of the lungs is a hallmark of TTN. Hyperaeration with wide intercostal spaces is secondary to partial airway obstruction from fluid in the interstitium.
 - b. **Prominent perihilar markings or streaking is generally symmetrical** and is due to engorgement of pulmonary vessels and periarterial lymphatics.
 - c. **Occasionally mild to moderate cardiomegaly.** May be secondary to myocardial insufficiency from hypoxemia, perinatal asphyxia, or abnormal pulmonary vascular transition.
 - d. **Depression (flattening) of the diaphragm** is best seen on a lateral view of the chest.
 - e. **Fluid in the minor fissures** and perhaps fluid in the pleural space (pleural effusions) and laminar effusions.
 - f. **Prominent pulmonary vascular markings.** “Fuzzy vessels,” a sunburst pattern, peripheral air trapping resulting in increased lung volumes.
 - g. **Air leaks** are rarely seen.
 - h. **There should be no areas of consolidation.**

2. Lung ultrasonography. In recent studies, lung ultrasound has been a promising technique in diagnosing lung disease (RDS and TTN) and differentiating between the 2 conditions in infants. Reviews suggest that it is an accurate and reliable tool for diagnosing TTN. The use of ultrasound has many advantages, including the following: It is noninvasive, has no radiation, and can be done at the bedside but does require properly trained staff with available equipment.

Findings vary but may include double lung point (seen more often in severe TTN), interstitial lung syndrome, pleural line abnormalities (disappearance or thickening, partial or total disappearance of A lines, pleural effusion), and white lung (seen more often in severe TTN).

C. Other tests for transient tachypnea of the newborn

1. Hyperoxia test. Infants who are hypoxic on room air should have an evaluation to rule out congenital heart disease. A hyperoxia test can be done, but many institutions are doing away with this test because of the concern of using 100% oxygen in preterm infants. An echocardiogram should be done to rule out congenital heart disease. See pages 489 and 490 for more information on the hyperoxia test.

2. Echocardiography. One study found that infants with TTN had significantly more structural cardiac lesions. Echocardiogram is recommended in infants with persistent tachypnea or persistent or severe hypoxia to rule out congenital cardiac anomalies.

D. Confirm the diagnosis. As noted, TTN is a clinical diagnosis and often a **diagnosis of exclusion**, and other causes of tachypnea (especially pathologic causes) should be excluded first. There are many causes of tachypnea, and usually the history, physical examination, and initial radiograph will help to narrow down the differential. If still uncertain, the clinical course can help guide you. **An infant who does not improve, who worsens, whose radiograph pattern changes, who requires mechanical ventilation, who is on a high concentration of oxygen, and who is not following the typical pattern should alert the provider that the diagnosis may not be TTN.**

1. Causes of tachypnea are extensive in the newborn. Use the mnemonic **TRACHEAS** to help remember some of the causes of tachypnea in a newborn: **T:** TTN; **R:** RDS, respiratory infections (pneumonia); **A:** aspiration syndromes (meconium, blood, or amniotic fluid); **C:** congenital malformations, congenital cyanotic heart disease; **H:** hyperventilation (cerebral), hypoplastic lungs, hypertension (persistent pulmonary); **E:** edema (pulmonary); **A:** air leaks and acidosis; **S:** some other causes (sepsis, metabolic disorders, polycythemia).

2. Respiratory distress syndrome and respiratory infections. (See also Chapter 117.)

a. Respiratory distress syndrome. Approximately 77% of infants with TTN are clinically misdiagnosed with RDS. The infant with RDS is normally premature (<34 weeks), requires higher respiratory support, and has a characteristic radiograph (typical RDS reticulogranular pattern with air bronchograms) and underexpansion (atelectasis) of the lungs.

b. Respiratory infections (pneumonia). If the infant has pneumonia, the prenatal history usually suggests infection. There may be maternal intraamniotic infection, premature rupture of membranes, and fever. The blood cell count may show evidence of infection (neutropenia or leukocytosis with abnormal numbers of immature cells). The urine antigen test may be positive if the infant has group B streptococcal infection. Pneumonia may mimic the x-ray findings of TTN (hyperaeration, pleural effusions). It is best to give broad-spectrum antibiotics if there is any suspicion or evidence of infection as they can be discontinued if the cultures are negative in 36 to 48 hours.

3. **Aspiration syndromes (meconium, blood, or amniotic fluid).** Infants with meconium aspiration syndrome (most common syndrome) are usually fully mature or postmature. Blood and amniotic fluid can also be aspirated. All of these aspiration syndromes can present at birth or several hours after birth. Infants usually have more severe respiratory distress and require more oxygen than in TTN. The x-ray can be similar to that in TTN but usually has perihilar infiltrates/opacities. TTN can have patchy opacities from fluid in the alveoli. The blood gases usually show more hypoxemia, hypercapnia, and acidosis.
4. **Congenital conditions**
 - a. **Congenital diaphragmatic hernia, congenital pulmonary airway malformations).** These can present with respiratory distress, and a chest x-ray will help make the diagnosis.
 - b. **Congenital cyanotic heart disease.** Infants with hypoplastic right and left heart syndromes, tetralogy of Fallot, and transposition of the great arteries can all present after birth with cyanosis, usually with few respiratory symptoms, but they can have tachypnea. Cardiomegaly and vascular engorgement can be seen from congestive heart failure on chest x-ray, which can be similar to perihilar streaking of retained fluid seen in transient tachypnea. The hyperoxia test, pulse oximetry screening, and echocardiogram should be done to rule out heart disease (see pages 489 and 490).
5. **Hyperventilation**
 - a. **Cerebral hyperventilation.** This disorder is seen when central nervous system lesions (eg, subarachnoid hemorrhage, meningitis, hypoxic ischemic encephalopathy) cause overstimulation of the respiratory center, resulting in tachypnea. Arterial blood gas measurements show respiratory alkalosis. Chest x-ray may show cardiomegaly and normal lungs. Infants with severe hyperammonemia can have hyperventilation secondary to cerebral edema, which causes a respiratory alkalosis.
 - b. **Primary pulmonary hypoplasia** can cause persistent tachypnea.
 - c. **Persistent pulmonary hypertension can cause** tachypnea. See Chapter 115.
6. **Edema (pulmonary)** secondary to a patent ductus arteriosus (left-to-right shunt with failure, anomalous venous drainage).
7. **Air leaks and acidosis**
 - a. **Air leaks (pneumothorax, pneumomediastinum).** Chest transillumination and a chest x-ray should be obtained.
 - b. **Metabolic acidosis.** Infants respond to metabolic acidosis with tachypnea to compensate. With a simple metabolic acidosis, there is a decrease in bicarbonate, and the respiratory rate is increased, which results in a decrease in partial pressure of carbon dioxide, which raises the pH toward normal. Rule out causes of metabolic acidosis (see Chapter 51).
8. **Some other causes**
 - a. **Sepsis.** Infants with sepsis can have metabolic acidosis and shock and can thus have tachypnea (clinical response to an infectious insult), but it usually takes time to develop.
 - b. **Metabolic disorders.** Infants with hypothermia, hyperthermia, or hypoglycemia may have tachypnea.
 - c. **Polycythemia and hyperviscosity.** This syndrome may present with tachypnea with or without cyanosis.
 - d. **Very rare causes of full term neonatal respiratory distress** include congenital surfactant dysfunction and primary ciliary dyskinesia, both of which are inherited primary lung diseases. Consider primary ciliary dyskinesia in a term neonate with unexplained respiratory distress with lobar collapse, situs inversus, and/or prolonged oxygen therapy need >2 days. Congenital surfactant deficiency presents like RDS in term infants and the CXR can be consistent with TTN.

VIII. Management

A. Preventive

1. **Limit cesarean sections** and, if necessary, plan the elective cesarean section at a gestational age of 39 weeks or later, which may decrease the frequency of TTN. Labor prior to cesarean section did not prevent TTN. Vaginal birth appears to be protective against TTN (even after 37 weeks of gestation). Spinal anesthesia is better than general anesthesia for elective cesarean section for avoidance of TTN.
2. **Establish fetal maturity** prior to elective cesarean section, although this is not commonly done. See Chapter 1.
3. **Antenatal betamethasone prior to elective cesarean section at term** reduced the incidence of respiratory morbidity in infants (reduced TTN rate from 4% of elective cesarean sections to 2.1%). The steroids encourage the expression of the epithelial channel gene and allow the lung to switch from fluid secretion to fluid absorption. It induces lung Na^+ reabsorption by increasing the number and activity of channels even in hypoxia. In addition, antenatal glucocorticoids induce maturation of the surfactant system.
4. **Prevent low Apgar scores.** A low Apgar score at <1 minute is strongly associated with TTN. Improved obstetric surveillance may decrease low Apgar scores.
5. **Prophylactic continuous positive airway pressure in the delivery room (controversial, not standard of care).** One earlier study did not show any adverse or beneficial effects of prophylactic continuous positive airway pressure (CPAP) in the delivery room to prevent TTN. Two more recent studies showed that it decreased the rate of TTN (not statistically significant) and the rate of NICU admission in newborns delivered by elective cesarean section and that it decreased the duration and severity of respiratory distress in infants with TTN. Some studies have shown an increased risk of pneumothoraces with CPAP use in the delivery room in early term neonates.

B. General. Management is mostly supportive.

1. **Oxygenation and ventilation.** Initial management consists of providing adequate oxygenation. Start with **extra oxygen via hood or nasal cannula** and deliver enough to maintain normal arterial saturation. If there is an increased work of breathing and the oxygen need is >30%, then **nasal CPAP** is an effective alternative treatment. CPAP gives a continuous positive pressure on the airways, helping to oppose the reentry of liquid and maintaining FRC. **Intubation** criteria vary by center, but a common practice is to intubate when the oxygen need is >40% when on a CPAP of 8 cm H_2O .
2. **Surfactant.** If the infant requires intubation, other diseases should be considered, but administration of exogenous surfactant promotes a dramatic clinical response in infants with TTN needing intubation and mechanical ventilation, underlining the role of surfactant deficiency in severe TTN.
3. **Maintain a neutral thermal environment.**
4. **Antibiotics.** Most infants are initially treated with broad-spectrum antibiotics (usually ampicillin and gentamicin) for 36 to 48 hours until the diagnosis of sepsis or pneumonia is excluded (**controversial**). In a randomized controlled trial of restrictive fluid management in TTN, all 73 infants with TTN were not treated with antibiotics and none of the infants manifested neonatal pneumonia or bacteremia. A combined strategy technique (perinatal risk factors, clinical signs, and laboratory tests for infection) to decide whether antibiotics are necessary may be able to decrease the use of antibiotics in this group.
5. **Feeding.** Because of the risk of aspiration, an infant should not be fed by mouth if the respiratory rate is >60 breaths/min. If the respiratory rate is <60 breaths/min, oral feeding is permissible. If the rate is 60 to 80 breaths/min, feeding should be by nasogastric tube. If the rate is >80 breaths/min, intravenous nutrition is indicated.
6. **Fluid and electrolytes** should be monitored and hydration maintained. Fluid management is **controversial**. A small randomized trial of restrictive fluid

management in infants with severe TTN showed a reduced duration of respiratory support and reduced hospitalization cost. However, the control group in this trial received a more liberal fluid intake than currently recommended, and although significant, the differences were small.

7. **Diuretics are not recommended.** Diuretics have been used in practice in some centers with the rationale of accelerating lung liquid absorption with an immediate diuresis-independent lung liquid resorption and a delayed increase in urine output. Furosemide also causes pulmonary vasodilatation, leading to an improved ventilation/perfusion match. However, trials investigating the oral or aerosolized administration of furosemide in infants with TTN have shown no differences in the course of disease. A Cochrane review (2015) noted that neither oral nor intravenous furosemide provided any benefit for the management of TTN and therefore cannot be recommended.
8. **Dopamine treatment.** Low-dose dopamine (3 mcg/kg/min) has been used to increase renal perfusion, and moderate doses (5 mcg/kg/min) may stimulate the clearance of pulmonary edema. One study of low- and moderate-dose dopamine did not improve the outcome of TTN.
9. **Inhaled epinephrine.** Infants with TTN have low levels of epinephrine, and epinephrine helps to mediate fetal lung fluid absorption. However, a recent meta-analysis demonstrated that there is insufficient evidence to determine the safety and efficacy of inhaled racemic epinephrine in the management of TTN.
10. **β_2 -Agonist salbutamol.** Stimulation of β -adrenergic receptors with salbutamol upregulates the activity of the sodium channels. However, a recent meta-analysis demonstrated that there is insufficient evidence to determine the safety and efficacy of salbutamol in the management of TTN. A pilot study showed there was no beneficial effect of early inhaled steroids in TTN.

IX. Prognosis

- A. **Transient tachypnea of the newborn is usually self-limited** and usually lasts only 2 to 5 days.
- B. **Asthma/wheezing syndromes.** Asthma is a multifactorial disease. Recent studies have revealed that TTN is associated with the development of wheezing syndromes (bronchiolitis, acute bronchitis, chronic bronchitis, asthma, or prescription for asthma medication) in early childhood and subsequent diagnosis of childhood asthma. The risk of TTN is increased in babies born to mothers with asthma. In 1 study, the risk was found to be greatest in males of nonwhite race whose mothers lived at an urban address and did not have asthma. Some believe TTN may be a marker for deficient pulmonary function, increasing the (inherited) susceptibility to the development of asthma. Liem et al proposed that environmental and genetic interactions predispose these infants to asthma.
- C. **Increased risk of RSV hospitalization during the first year of life.** The rate of RSV hospitalization is higher in children with TTN compared to children without a TTN diagnosis.
- D. **Complications (rare).** If these occur, it is best to reevaluate the infant.
 1. **Some infants can develop prolonged tachypnea (>72 hours)** and can progress to respiratory failure (hypoxia, respiratory fatigue with acidosis) and require intubation and mechanical ventilation.
 2. **Although rare, a few infants may develop air leaks (usually a pneumothorax or pneumomediastinum).** There is a higher risk of air leak if the infant is on CPAP. Familial neonatal pneumothorax has been associated with TTN in siblings of 2 families.
 3. **Some may develop pulmonary hypertension with right-to-left shunting** across the ductus arteriosus or foramen ovale. This may be present because of possible elevation in the pulmonary vascular resistance associated with retained fetal lung fluid and hyperinflation of the lungs and require extracorporeal membrane oxygenation/extracorporeal life support. (See Chapter 20.)

131 Chlamydial Infection

- I. **Definition.** *Chlamydia trachomatis* is an obligate, intracellular, small, gram-negative bacterium that possesses a cell wall, contains DNA and RNA, and can be inactivated by several antimicrobial agents. It is the most common cause of sexually transmitted genital infections. It may cause urethritis, cervicitis, and salpingitis in the mother. In the infant, it can cause conjunctivitis and pneumonia.
- II. **Incidence.** The prevalence of *C trachomatis* in pregnant women varies from 2% to 20%. The risk of infection to infants born to infected mothers is high; conjunctivitis occurs in 20% to 50% and pneumonia in 5% to 30%. The nasopharynx is the anatomic site most commonly infected. In the Netherlands, where prenatal screening is not routine, 1 study showed *C trachomatis* to be responsible for 64% of all cases of neonatal conjunctivitis.
- III. **Pathophysiology.** *C trachomatis* serovariants B and D through K cause the sexually transmitted form of the disease and the associated neonatal infection. They frequently cause a subclinical infection in the mother. The infant acquires infection during vaginal delivery through an infected cervix. Infection after cesarean delivery is rare and usually occurs with early rupture of amniotic membranes; however, infection associated with intact membranes has been reported. Population-based studies suggest that maternal *C trachomatis* infection is associated with an increased risk of preterm delivery and premature rupture of membranes.
- IV. **Risk factors.** Risk is inversely proportional to gestational age. Risk factors include vaginal delivery of an infant with an infected mother and early or prolonged rupture of the amniotic membranes.
- V. **Clinical presentation**
 - A. **Conjunctivitis.** See Chapter 58.
 - B. **Pneumonia.** This is one of the most common forms of pneumonia in the first 3 months of life. The respiratory tract may be directly infected during delivery. Approximately half of infants presenting with pneumonia have concurrent or previous conjunctivitis. Pneumonia usually presents at 2 to 19 weeks of life. The infants experience a gradual increase in symptoms over several weeks. Initially, there is often a period of 1 to 2 weeks of mucoid rhinorrhea followed by cough and increasing respiratory rate. More than 95% of cases are afebrile. The cough is characteristic, paroxysmal, and staccato, and it interferes with sleeping and eating. Approximately a third of infants have otitis media. Preterm infants may present with apneic spells. *C trachomatis* has been isolated from tracheal secretions of preterm infants with pneumonia in the first week after birth.
 - C. **Asymptomatic** infection of the nasopharynx, conjunctivae, vagina, and rectum can be acquired at birth. Nasopharyngeal cultures have been observed to remain positive for as long as 28 months in infants with infection acquired at birth.
- VI. **Diagnosis**
 - A. **Laboratory studies**
 1. **Tissue culture.** Because chlamydiae are obligate intracellular organisms, culture specimens must contain epithelial cells. **Culture of the organism is the gold standard** for diagnosing neonatal conjunctivitis and pneumonia. The specificity and sensitivity of culture are nearly 100% with adequate sampling and transport. Material should be obtained from the tarsal conjunctiva (for conjunctivitis) or from nasopharyngeal aspiration or deep suctioning of the trachea (for suspected pneumonia).

2. **Nucleic acid amplification tests.** These tests use methods to amplify *C trachomatis* DNA or RNA sequences. Currently available tests are polymerase chain reaction (Amplicor), transcription-mediated amplification (Aptima Combo 2), and strand displacement amplification (ProbeTec). These tests are approved by the US Food and Drug Administration (FDA) to be used in adults and have largely replaced tissue culture as the diagnostic method of choice; limited data in infants suggest that nucleic acid amplification tests are more sensitive than culture.
 3. **Antigen detection tests.** Include direct fluorescent antibody (DFA) and enzyme immunoassay tests. These tests appear to be sensitive and specific when used with conjunctival specimens, but the sensitivity with nasopharyngeal samples is poor. DFA is the only culture-independent method that is FDA approved for the detection of chlamydia from conjunctival swab specimens.
 4. **Serum antichlamydial antibody (immunoglobulin M) concentration.** Difficult to determine and not widely available. In children with pneumonia, a titer >1:32 is diagnostic of infection.
 5. **Other tests.** In cases of pneumonia, the white blood cell count is normal, but there is **eosinophilia** in 70% of cases. Blood gas measurements show mild to moderate hypoxemia.
- B. Imaging and other studies.** In cases of pneumonia, the chest radiograph may reveal hyperexpansion of the lungs, with bilateral diffuse interstitial or alveolar infiltrates.

VII. Management. Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

A. Prevention. Identification and treatment of infected pregnant mothers can reduce the risk of preterm birth and prevent disease in the infant. The US Centers for Disease Control and Prevention recommend that all pregnant women be screened for chlamydia at the first prenatal visit. Women under age 25 and those at increased risk for chlamydial infection should have repeat testing in the third trimester. Pregnant women diagnosed with a chlamydial infection during the first trimester should receive a test to document chlamydial eradication 3 to 4 weeks after treatment and should be tested 3 months after treatment as well as in the third trimester. Infants born to mothers known to have untreated chlamydial infection should be monitored clinically. Prophylactic antimicrobial treatment is not recommended because the efficacy of such therapy is unknown. In addition, erythromycin, the agent most commonly used, is associated with significant risk for **infantile hypertrophic pyloric stenosis (IHPS)**.

B. Chlamydial conjunctivitis or pneumonia. Treated with oral erythromycin base or ethylsuccinate (50 mg/kg/d in 4 divided doses) for 14 days or with azithromycin (20 mg/kg as a single daily dose) for 3 days. Topical therapy for conjunctivitis is ineffective and unnecessary. Treatment not only shortens the clinical course but also decreases the duration of nasopharyngeal shedding. Because the efficacy of erythromycin (and azithromycin) is only about 80% for both of these conditions, a second course may be required, and follow-up of infants is recommended. The mother and her sexual partner(s) should be evaluated and treated. **IHPS** may occur when infants are treated with erythromycin in the first 2 weeks of life. The risk of IHPS after treatment with other macrolides (eg, azithromycin and clarithromycin) is unknown, although IHPS has been reported after use of azithromycin. Because confirmation of erythromycin as a contributor to cases of IHPS will require additional investigation and because alternative therapies are not as well studied, the American Academy of Pediatrics continues to recommend erythromycin to treat neonatal chlamydia infection. Parents should be informed about the signs and potential risks of developing IHPS. Cases of IHPS after the use of oral erythromycin or azithromycin should be reported to MedWatch, the FDA Safety Information and Adverse Event Reporting Program. No isolation measures are necessary.

VIII. Prognosis. Infants who are diagnosed and treated early generally recover. Experimental studies suggest that neonatal chlamydial pneumonia, especially in preterm neonates, may cause airway hyperreactivity and respiratory dysfunction that continues into adulthood.

132 Cytomegalovirus

- I. Definition.** Human cytomegalovirus (CMV), also known as human herpesvirus 5, is a DNA virus and a member of the herpesvirus family (Herpesviridae).
- II. Incidence.** CMV is the most common cause of congenital infection in the United States and occurs in approximately 0.5% to 1.3% of all live births. This results in approximately 40,000 new cases in the United States per year.
- III. Pathophysiology.** CMV is highly species specific, and only human CMV has been shown to infect humans and cause disease. CMV is a ubiquitous virus that is transmitted in secretions, including saliva, tears, semen, urine, cervical secretions, blood (white blood cells), and breast milk. The seroprevalence increases with age and is influenced by many factors, such as hygienic circumstances, socioeconomic factors, breast feeding, and sexual contacts. In addition to **transplacental infection**, CMV may also be transmitted to the infant **intrapartum** (through exposure to CMV in cervical secretions), via **breast milk**, and via **blood transfusion**. CMV infection acquired during delivery or via breast milk is often asymptomatic in full-term infants with no effect on future neurodevelopmental outcome; however, a sepsis-like illness has been described in premature infants.

In developed countries, CMV seroprevalence varies inversely with socioeconomic status, with 40% to 80% of women of childbearing age in the United States having serologic evidence of past CMV infection. Seroconversion and initial infection can occur around the time of puberty, and shedding of the virus may continue for a long time. CMV can also become latent in white blood cells and reactivate periodically. In addition, a seropositive individual can be infected by a different strain of CMV. Reactivation and reinfection are grouped as a “nonprimary” infection.

CMV is capable of penetrating the placental barrier as well as the blood–brain barrier. During early pregnancy, CMV has a **teratogenic potential** in the fetus. CMV infections may result in neuronal migration disturbances in the brain. Both **primary** and **nonprimary** maternal CMV infection can lead to transmission of the virus to the fetus. When primary maternal infection occurs during pregnancy, the virus is transmitted to the fetus in approximately 35% of cases. The rate of fetal transmission appears to increase with advancing gestation; however, infection in early pregnancy causes more severe fetal infection with significant central nervous system (CNS) sequelae compared to infection acquired later. During nonprimary infection, transmission rate is low (only 0.2% to 1.8%), except for human immunodeficiency virus (HIV)-infected women, who show higher transmission despite receiving antiretroviral prophylaxis. Even though the risk for congenital infection is high after primary maternal infection, nonprimary infection is responsible for 75% of the overall burden of congenital CMV disease.

More than 85% of infants born with congenital CMV have a subclinical infection. Symptomatic infants are usually born to women with a primary infection. When the placenta becomes infected with CMV after a primary maternal infection, its ability to provide oxygen and nutrients to the developing fetus becomes

impaired. This leads to placental enlargement due to viral **placentitis and revascularization**. Although not completely elucidated, placental tissue damage occurs due to direct tissue injury by persistent CMV replication, ischemic tissue damage due to vasculitis with viral infection of endothelial cells, and tissue damage by immune complex deposition. Eventual fetal viremia leads to fetal multiorgan involvement. The primary target organs are the CNS, eyes, liver, lungs, and kidneys. Characteristic histopathologic features include focal necrosis, inflammatory response, formation of enlarged cells with intranuclear inclusions (cytomegalic cells), and the production of multinucleated giant cells.

- IV. Risk factors.** CMV infection in neonates is associated with nonwhite race, lower socioeconomic status, drug abuse, and neonatal intensive care unit admittance. Premature infants are more often affected than full-term infants. Transfusion with unscreened blood is an additional risk factor for neonatal disease. Risk factors for primary CMV infection during pregnancy include prolonged exposure to young children (daycare workers, multiparous women) and sexual contact (young maternal age, greater numbers of sexual partners, abnormal cervical cytology, and having a sexually transmitted infection during pregnancy).

V. Clinical presentation

A. Prenatal presentation. Pregnant women who acquire primary CMV may develop a mononucleosis-like illness with mild hepatitis (<25% of the time). Maternal screening is currently not recommended routinely. Fetal anomalies consistent with congenital CMV infection that can be detected on prenatal ultrasound examination include fetal growth restriction, cerebral periventricular echogenicity or calcifications, cerebral ventriculomegaly, microcephaly, polymicrogyria, cerebellar hypoplasia, hyperechogenic fetal bowel, hepatosplenomegaly, hepatic calcifications, amniotic fluid abnormalities, ascites and/or pleural effusion, and placental enlargement. Prenatal magnetic resonance imaging (MRI), especially to evaluate brain anomalies, is increasingly being used. Amniocentesis to perform polymerase chain reaction (PCR) for CMV DNA in amniotic fluid is the preferred diagnostic approach for identifying an infected fetus. Amniocentesis is most sensitive when done after 21 weeks of gestation and after 6 weeks from maternal infection/exposure.

B. Postnatal presentation

- 1. Subclinical infection.** Occurs in 85% to 90% of cases. Despite being asymptomatic at birth, these infants are at risk for **sensorineural hearing loss (SNHL)** during the first 6 years of life. Universal CMV screening at birth is not recommended in the United States at this time; however, some authorities suggest a targeted approach that focuses on newborns who fail their universal hearing screening.
- 2. Low birthweight.** Maternal CMV infection is associated with low birthweight and small for gestational age infants, even when the infant is not infected.
- 3. Classic cytomegalovirus inclusion disease.** Occurs in 10% to 15% of the cases and consists of fetal growth restriction, hepatosplenomegaly with jaundice, transaminitis, thrombocytopenia with or without purpura, and severe CNS involvement. CNS complications include microcephaly, intracerebral calcifications (most characteristically in the subependymal periventricular area), chorioretinitis, and progressive SNHL. Other symptoms include hemolytic anemia and pneumonitis. The most severely affected infants have a mortality rate of approximately 30%. Deaths are usually due to hepatic dysfunction, bleeding, disseminated intravascular coagulation, or secondary bacterial infection.
- 4. Late sequelae.** SNHL occurs in 33% to 50% of symptomatic and in 10% to 15% of asymptomatic infants. CMV-related SNHL may be present at birth or occur later in childhood. Approximately 55% and 75% of symptomatic and

asymptomatic infants, respectively, who ultimately develop congenital CMV-associated SNHL will not have hearing loss detectable within the first month of life. Therefore, repeated auditory evaluation during the first 6 years of life is strongly recommended. Visual impairment and strabismus are common in children with clinically symptomatic CMV infection. Visual complications usually occur secondary to chorioretinitis, pigmentary retinitis, macular scarring, optic atrophy, and central cortical defects.

VI. Diagnosis

A. Laboratory studies

- 1. Culture for demonstration of the virus.** The **gold standard** for the diagnosis of congenital CMV is **urine** or **saliva** culture obtained **before 3 weeks of age**. Most urine specimens from infants with congenital CMV are positive within 48 to 72 hours, especially if shell vial tissue culture techniques are used. Shell vial assay detects CMV-induced antigens by monoclonal antibodies, allowing for identification of the virus within 48 hours compared with the standard tissue culture, which takes 2 to 4 weeks.
- 2. Polymerase chain reaction.** PCR for CMV DNA is as sensitive as a urine or saliva culture for the detection of CMV infection. Studies evaluating saliva for rapid detection of CMV (PCR or shell vial assay) have shown it to be at least as sensitive as urine for detecting congenital CMV infection, although there is risk of contamination of the saliva sample with retained breast milk in the mouth of the newborn. PCR has been used successfully in retrospective diagnosis of congenital CMV beyond 3 weeks of age through CMV DNA analysis of dried blood spots (Guthrie cards). The sensitivity of CMV DNA detection by PCR assay of dried blood spots is low, limiting use of this type of specimen for widespread screening for congenital CMV. A positive PCR assay result from a neonatal dried blood spot confirms congenital infection, but a negative result does not rule it out.
- 3. Serologic tests.** Serologic tests based on the detection of immunoglobulin M (IgM) should not be used to diagnose congenital CMV because they are less sensitive and more subject to false-positive results than culture or PCR. Only 70% of neonates infected with congenital CMV have IgM antibodies at birth.
- 4. Other laboratory tests.** Other lab tests that are indicated in the workup include complete blood count, liver function tests, coagulation panel and cerebrospinal fluid analysis, culture, and PCR.

- B. Imaging and other studies.** Ultrasound or computed tomography scans of the head may demonstrate characteristic periventricular calcifications in addition to other abnormalities (see prenatal presentation earlier). Brain MRI is preferred over other modalities because it is likely to identify most of the brain anomalies associated with congenital CMV.

VII. Management

- A. Prevention and treatment of maternal infection during pregnancy.** These include changes in hygienic behavior for seronegative pregnant women, administration of CMV hyperimmune globulin (CMV-HIG) to pregnant women with a primary infection, administration of antiviral therapy to women with primary infection, and administration of vaccines to girls or women well before or during pregnancy. With regard to **hygienic** measures, epidemiologic studies have shown that instructing mothers who are pregnant on frequent hand washing; wearing gloves for specific childcare tasks; avoiding kissing children under age 6 on the mouth or cheek; not sharing food, drinks, or oral utensils (eg, fork, spoon, toothbrush, pacifier) with young children; and cleaning toys, countertops, and other surfaces that come into contact with children's urine or saliva reduces their chances of acquiring congenital CMV infection. **CMV-HIG** given to women with primary congenital infection before 20 weeks' gestation has shown

promise in reducing congenital CMV infection in the fetus in observational and small randomized trials; however, the benefits need to be confirmed in large randomized controlled studies (a trial is underway by the National Institute of Child Health and Human Development; trial identifier NCT01376778; available at <https://clinicaltrials.gov>; accessed February 11, 2018). Use of **antiviral therapy** for the infected pregnant woman has been studied recently in a multicenter, open-label, phase II trial using high-dose (8 g daily) oral valacyclovir in women carrying CMV-infected fetuses with measurable extracerebral or mild cerebral ultrasound findings starting at a median gestational age of 25 weeks until delivery. The study found that the use of valacyclovir increased the proportion of asymptomatic neonates from 43% without treatment to 82% with treatment. The benefit of valacyclovir needs to be confirmed in large randomized trials before it can be recommended. The most effective preventive strategy is developing a **vaccine** against CMV. A vaccine targeted toward CMV envelope glycoprotein B, an antigen that typically induces a serum antibody response, was tested in phase II clinical trials in adult women as well as adolescent girls. This vaccine has been shown to be immunogenic with an acceptable risk profile with the potential to decrease incident cases of maternal and congenital CMV infection. Phase III trials are underway.

- B. Prevention of cytomegalovirus transmission in the neonatal intensive care unit.** Neonatal intensive care unit infants requiring packed red cell transfusion should be transfused from CMV antibody-negative donors, and the blood should be filtered to remove white blood cells. Pasteurization or freezing of donated human milk can decrease the likelihood of CMV transmission. Short-term pasteurization (72°C for 5 seconds) of milk appears to inactivate CMV; this short-term pasteurization is less harmful to the beneficial constituents of human milk compared to Holder pasteurization. If pasteurization is not available, freezing milk at -20°C for 24 hours will decrease viral titers but does not eliminate CMV reliably. Breast feeding is recommended for CMV antibody-positive mothers as benefits outweigh risks of potential postnatal CMV infection.
- C. Antiviral agents.** Neonates with symptomatic congenital CMV disease with or without CNS involvement have improved audiologic and neurodevelopmental outcomes at 2 years of age when treated with oral **valganciclovir** (a prodrug for ganciclovir) at 16 mg/kg/dose, given orally twice a day for 6 months. The dose should be adjusted each month to account for weight gain. If the infant is unable to absorb the medication due to gastrointestinal illness (eg, necrotizing enterocolitis), intravenous **ganciclovir** at 6 mg/kg/dose is an alternative. Significant neutropenia occurs in 20% of infants treated with oral valganciclovir and in 67% of infants treated with ganciclovir. Absolute neutrophil counts should be performed weekly for 6 weeks, then at 8 weeks, and then monthly for the duration of antiviral treatment; serum aminotransferase concentration should be measured monthly during treatment. Some authorities also recommend monitoring viral load (CMV DNA PCR in the blood) to document response to therapy and check for ganciclovir resistance. Antiviral therapy should be limited to patients with symptomatic congenital CMV disease who are able to start treatment within the first month of life. Preterm infants with perinatally or nosocomially acquired CMV infection can have significant symptomatic disease with end-organ dysfunction (eg, pneumonitis, hepatitis, thrombocytopenia). Antiviral treatment has not been studied in this population; however, these patients are reasonable candidates for oral valganciclovir or intravenous ganciclovir treatment for 2 to 4 weeks, depending on responsiveness of symptoms. The antivirals **foscarnet** and **cidofovir** are reserved for cases of refractory CMV disease, ganciclovir resistance, ganciclovir toxicity, and co-infection with adenovirus. Infants with asymptomatic congenital CMV infection should not receive antiviral treatment.

VIII. Prognosis. Congenital CMV is the leading cause of nonhereditary SNHL. Overall mortality rate among infants with congenital CMV infection is approximately 4% to 8% within the first year of life. For symptomatic infants with fulminant disease at birth, mortality is up to 30%, and late complications including intellectual or developmental impairment, progressive hearing loss, and spasticity develop in 70% to 80% of cases. Visual impairment develops in 10% to 20% of symptomatic newborns. With asymptomatic, congenitally infected infants, the prognosis is uncertain, but they are at risk for SNHL (up to 20% by 6 years of age).

133 Dengue Infection, Neonatal

- I. Definition.** Dengue fever (DF) is a worldwide infection caused by 4 related RNA viruses of the genus *Flavivirus*, dengue viruses (DENV) DENV-1, DENV-2, DENV-3, and DENV-4. DENV is primarily transmitted to humans through the bite of infected *Aedes aegypti* (and less commonly *Aedes albopictus* or *Aedes polynesiensis*) mosquitoes. DENV causes asymptomatic infection, DF, or a severe syndrome (dengue hemorrhagic fever [DHF]/dengue shock syndrome [DSS]). The latter is characterized by systemic capillary leakage, thrombocytopenia, and hypovolemic shock.
- II. Incidence.** Dengue is a major public health problem in the tropics and subtropics; an estimated 50 to 100 million dengue cases occur annually in more than 100 countries, and 40% of the world's population lives in areas with DENV transmission. In the United States, dengue is endemic in Puerto Rico, the Virgin Islands, and American Samoa. Additionally, limited outbreaks with local DENV transmission have occurred in Texas, Hawaii, and Florida in the past decade, but no neonatal cases have been reported from the United States. Millions of US travelers, including children, are at risk. Neonatal dengue has been described in case reports and case series from outside the United States; therefore, its true incidence worldwide is unknown.
- III. Pathophysiology.** Viremia is usually detected about 6 to 18 hours before the onset of symptoms and ends as the fever resolves. Both innate and adaptive immune responses seem to play a role in the clearance of infection. Infection with 1 of the 4 DENVs (primary infection) provides long-lasting immunity to infection with a virus of the same serotype; however, immunity to the other dengue serotypes is transient. Individuals can subsequently be infected with another dengue serotype (secondary infection), often with more severe manifestations. DHF can develop with any of the 4 DENVs, but the risk is highest with DENV-2. DHF can usually be distinguished from DF as it progresses through 3 predictable pathophysiologic phases:
 - A. Febrile phase:** Viremia-driven high fevers.
 - B. Critical/plasma leak phase:** Sudden onset of varying degrees of plasma leak into the pleural and abdominal cavities. This phase probably occurs due to endothelial cell dysfunction rather than injury.
 - C. Convalescence or reabsorption phase:** Sudden arrest of plasma leak with concomitant reabsorption of extravasated plasma and fluids.

Neonates can be infected through mosquito bites but also as a vertical infection from the mother. The highest risk period is when the mother becomes acutely ill with dengue at or near the time of delivery. It has been hypothesized that there is an insufficient level of protective maternal antibodies (immunoglobulin [Ig] G) transferred to the fetus, and therefore, the newborn can manifest serious disease. Endothelial damage and plasma leakage may enable the virus an easy access across the placental barrier.

Dengue virus has been identified in the breast milk of viremic mothers, and postnatal transmission through breast feeding has been documented, albeit this is rare. Blood-borne transmission is possible through exposure to infected blood during the viremic phase; however, it is not known how common this mode of transmission is because blood donations are not systematically screened for DENV.

IV. Risk factors. Maternal DF, especially during late pregnancy, places the fetus/baby at risk. To date, there are no reports of congenital malformations from DF when mothers are infected in the first trimester.

V. Clinical presentation

A. Neonatal consequences of maternal dengue fever. Neonatal dengue has been described in case reports and case series. It typically results from hematogenous spread during the maternal viremic stage, especially if the mother is symptomatic during the last 5 to 8 days of pregnancy. Transmission rate can be as high as 90%. The incubation period is 3 to 8 days. The neonate may stay asymptomatic with only laboratory evidence of infection (positive serology, leukopenia, or thrombocytopenia). Symptomatic neonates may have a high fever that can be biphasic, lethargy, anorexia, abdominal pain, diarrhea, vomiting, hepatomegaly, and purpuric rash. **Severe dengue symptoms can occur by day 5 when fever ceases**, with easy bruising, severe thrombocytopenia ($<30,000$ platelets/ mm^3), and evidence of plasma leakage–induced hypovolemia, hepatomegaly, and circulatory disturbances. **Shock can happen in severe dengue after defervescence** and includes rapid/weak pulse and narrow pulse pressure. Fortunately, this situation is rarely seen during the neonatal period.

B. Consequences of dengue to the pregnant women and adverse pregnancy outcomes. Severe bleeding may complicate delivery and/or surgical procedures performed on pregnant patients with dengue **during the critical phase** (ie, the period coinciding with marked thrombocytopenia with or without plasma leak). DF does not warrant termination of pregnancy. Even though earlier reports and a meta-analysis suggested an increased risk of adverse pregnancy outcome with DF, a recently updated meta-analysis did not suggest an increased risk of premature birth, low birthweight, miscarriage, or stillbirth with maternal DF. DENV is not teratogenic.

VI. Diagnosis

A. Laboratory studies

1. Nonspecific findings: Include increased hematocrit of 20% from baseline (hemoconcentration during capillary leak phase), leukopenia/neutropenia, thrombocytopenia, hyponatremia, hypoalbuminemia, transaminitis, cholestasis, and abnormal coagulation studies (elevated prothrombin and activated partial thromboplastin time).

2. Diagnostic tests: DENV infection can be confirmed by detection of DENV RNA via reverse transcriptase–polymerase chain reaction (RT-PCR) assay or detection of DENV nonstructural protein 1 antigen (NS-1) by immunoassay and testing for anti-DENV IgM or IgG antibodies by enzyme immunoassay (EIA). RT-PCR or NS-1 can be done from the beginning of the febrile phase until day 7 to 10 after illness onset, but anti-DENV IgM antibodies are not detectable until at least 5 days after illness onset. A 4-fold or greater increase in anti-DENV IgG antibody titers between the acute (≤ 5 days after onset of symptoms) and convalescent (>15 days after onset of symptoms) samples confirms recent infection as well.

B. Imaging and other studies. Chest radiographs and ultrasound can show pleural effusion, ascites, hepatomegaly and gallbladder edema.

VII. Management. Treatment is symptomatic with an antipyretic such as acetaminophen. Ibuprofen, aspirin, and other nonsteroidal anti-inflammatory drugs are contraindicated due to hemorrhagic predisposition. **Hemodynamics must be monitored closely when fever resolves (by day 5–7 of illness), because shock can abruptly develop.**

Heart rate, capillary refill time, blood pressure, weight, and serum electrolytes should be checked once or twice a day. Intravenous fluids (colloids and crystalloid) must be prescribed as soon as possible, starting typically with normal saline (0.9% sodium chloride) boluses of 10 to 20 mL/kg to restore perfusion. Total daily fluid intake may vary between 150 and 200 mL/kg/d. Furthermore, extra intravenous sodium chloride may be indicated if shock or hyponatremia (<130 mEq/L) develops. In cases of **severe thrombocytopenia (<30,000/mm³) or serious bleeding**, platelet transfusion is prescribed. **Albumin transfusion** (1 g/kg every 6–12 hours for 2–4 doses) may be indicated with severe hypoalbuminemia (<2 g/dL) or when pleural or peritoneal fluid effusion is present. Prior to establishing the diagnosis in neonates, antibiotics (amoxicillin, cefotaxime, or gentamicin) are empirically prescribed given the high risk of bacterial sepsis at this age. Breast feeding is encouraged despite the minimal risk of transmission via breast milk.

- VIII. Prognosis.** Neonatal dengue can be potentially lethal. Affected newborns should be carefully observed for a minimum of a 2-week period before discharge. Vigilant monitoring and proper hydration often lead to an uneventful recovery. However, poor outcome may occur; a recent study from India that involved 16 women diagnosed with DF (3 had DSS and 8 had DHF) showed that bleeding manifestations occurred in 7 women, and there were 3 maternal deaths. Perinatal complications from the study included 3 intrauterine deaths, 6 nursery admissions, and 1 neonatal death.
- IX. Prevention.** Methods for prevention of dengue infection in endemic areas include mosquito control and vaccine development. Mosquito control is effective but difficult to sustain. Several DENV vaccines are in development, and 1 became commercially available recently; it is licensed in several countries in Latin America and Southeast Asia. It gained the US Food and Drug Administration approval in May 2019. CYD-TDV (Dengvaxia) is a prophylactic, tetravalent, live attenuated viral vaccine administered to individuals age 9 to 45 years (age 9–16 years in the US) who have laboratory-confirmed previous dengue infection and living in dengue-endemic areas. Unfortunately, it is contraindicated in pregnant women because it is a live virus; however, the limited data collected during the clinical trials on inadvertent immunization of pregnant women have yielded no evidence of harm to the fetus or pregnant woman.

134 Enteroviruses and Parechoviruses

- I. Definition.** Enteroviruses (EVs) and parechoviruses (HPeVs) are a large group of viral pathogens represented by 2 different genera of the family Picornaviridae. They are all made of a single strand of RNA in a capsid of individually distinct polypeptides. The capsid proteins impart antigenicity and facilitate transfer of RNA into the cells of newly infected hosts.
- A. Enteroviruses.** The genus of EVs traditionally consisted of 5 groups, each with a well-known human pathogenicity: coxsackie A viruses, coxsackie B virus, echoviruses, EVs 68 to 71, and poliovirus. The new classification (based on viral genomic structure) groups nonpolio EVs into 4 species: human EV types A, B, C, and D. Although they were reclassified, many authorities continue to use their original names.
- B. Parechoviruses.** The genus of HPeVs is made up of at least 16 types. HPeV1 and HPeV2 previously were classified as echoviruses 22 and 23, respectively. HPeVs (especially HPeV3) have been implicated in severe neonatal diseases including

sepsis, hepatitis and coagulopathy, and/or meningoencephalitis with long-term sequelae. Interestingly, severe central nervous system (CNS) disease is associated with normal inflammatory markers and **little or no cerebrospinal fluid (CSF) pleocytosis** in the majority of cases.

II. Incidence

A. Enteroviruses. EVs have worldwide distribution and produce human illness of varying severity, from mild coryza to life-threatening multisystem disease. The diseases have some seasonal variation with increased incidence during summer and fall in temperate zones, but there is little seasonal variation in tropical areas.

Enteroviral infections are spread by fecal–oral and respiratory routes and in neonates transplacentally, perinatally, and possibly via breast feeding. Incubation periods are typically 3 to 6 days. All subgroups of EVs are linked to nursery and neonatal intensive care unit (NICU) outbreaks. Enteroviral infections are not reportable nationally, and the current incidence of EV illness among neonates is unknown. However, there is a National Enterovirus Surveillance System (NESS), which is a passive surveillance system that has been collecting laboratory data on types of EV and HPeV in the United States since the 1960s. During 2009 to 2013, 2724 specimens representing 2532 patients tested positive for EV and HPeV were reported to NESS; 39% were from children <1 year of age, and coxsackie A6 virus (CVA6) was the most reported type overall. The most common serotypes associated with neonatal infections are EV6, EV9, and EV11 and CVB2, CVB4, and CVB5. In 2014, EVD68 caused a nationwide outbreak, with many patients admitted to intensive care units for respiratory symptoms.

B. Parechoviruses. During NESS 2009 to 2013 surveillance, HPeV3 was the most common isolate of that genus (12.3%) and was identified as an important cause of neonatal sepsis. A report from Edinburgh, Scotland, for EV surveillance from 2006 to 2010 revealed an incidence of 2.8% for HPeV, but for infants <3 months of age, HPeV3 was also the predominant isolate (22%–25%). A recent study from Ireland found an HPeV infection rate of 13% in infants being tested for late-onset neonatal sepsis.

III. Pathophysiology

A. Enteroviruses. EVs manifest disease in nearly all body systems. Paradoxically, signs of disease can range from mild to life threatening within the same serotype. Host susceptibility (including absence of serotype-specific maternal neutralizing antibody) seems to be the most important predisposing factor. For the great majority of children and adults, enteroviral illnesses are mild, but for the neonate, EVs can cause serious multiorgan dysfunction and death (sepsis-like illness, meningoencephalitis myocarditis, hepatitis, coagulopathy, and pneumonitis). Some human EVs are more pathogenic than others. Examples of the more serious serotypes include echovirus 11, CVB3, CVA9, CVB1, and EV71.

- 1. Echovirus 11.** This has been particularly associated with neonatal death. Pathologic findings include extensive hepatic necrosis with adrenal hemorrhage and acute tubular necrosis.
- 2. Coxsackievirus B3.** Neonatal infections have been marked by hepatitis, disseminated intravascular infection, fever, thrombocytopenia, and intracranial hemorrhage. CVB3 has also been closely associated with antenatal maternal infection and positive virus cultures from placenta, cord, and infant tissues at death, suggesting probable transplacental infection.
- 3. Coxsackievirus B1.** Until recently, this has been a fairly uncommon strain. In 2006, for the first time, CVB1 became the most commonly reported EV and remained so through 2008. In 2007, there was a significant increase in neonatal disease, including fever, hepatitis, coagulopathy, meningitis, respiratory distress,

and myocarditis; in 4 of 5 cases of neonatal death, mothers had chorioamnionitis or febrile illness near the time of delivery.

4. **Enterovirus 71.** This serotype has evolved as a unique cause of epidemic paralysis, with localized and regional outbreaks. Infants and young children are at risk of brainstem encephalitis associated with high mortality related to rapid cardiovascular collapse and pulmonary edema.
5. **Enterovirus D68.** This strain caused a severe outbreak in 2014 associated with severe respiratory illnesses in infants and children. Nine children died. In addition, a polio-like acute neurologic syndrome was reported in a few cases.

B. Parechovirus. HPeVs are now recognized as agents for nursery outbreaks of diarrhea coupled with respiratory illnesses. Several cases of more severe illness have been reported, including meningoencephalitis, neonatal sepsis-like disease, hepatitis, and coagulopathy. Other conditions have included myocarditis and conjunctivitis. HPeVs are implicated in other conditions such as hemorrhage hepatitis syndrome, necrotizing enterocolitis, myocarditis, herpangina, and other febrile illness.

1. **Human Parechovirus type 1 (previously echovirus 21).** Most common HPeV identified. HPeV1 may cause asymptomatic infection or mild gastrointestinal (GI) or respiratory symptoms. Very rarely, it can cause myocarditis and CNS involvement (encephalitis and paralysis).
2. **Human Parechovirus type 3** is probably the most serious type and is associated with seizures and destructive periventricular white matter lesions in preterm and term infants. Usually, the CSF is unremarkable, but HPeV3 RNA can be amplified from CSF and nasopharyngeal and rectal swabs. It can also be associated with sepsis-like illness and hepatitis.

IV. Risk factors

- A. **Infants born to mothers** who have symptoms of EV/HPeV around the time of the delivery have a higher chance of being infected. The outcome of neonatal infection is strongly influenced by the presence or absence of passively acquired maternal neutralizing antibodies.
- B. **Risk of severe infection** is higher if the infant is infected during the first 2 weeks of life.

V. Clinical presentations. HPeV infections may mimic EV infections. When evaluating an infant clinically, it is not possible to distinguish neonatal HPeV from an EV infection.

- A. **Enteroviruses.** The clinical presentations of EV diseases are varied and overlap with the many subspecies and serotypes. In neonates, the signs that suggest an enteroviral outbreak in a nursery might include a cluster of infants with similar findings of coryza, morbilliform rash, low-grade fever, or diarrhea. A sepsis-like illness is frequently ascribed to enteroviral infection. Sepsis evaluation is often negative, but findings of lethargy, poor feeding, and fever are hallmarks suggesting sepsis. It can also cause hepatitis, coagulopathy, pneumonia, meningoencephalitis, and myocarditis. Hemophagocytic lymphohistiocytosis and severe enteroviral infection can be difficult to distinguish based on clinical presentation and CSF findings.
- B. **Parechoviruses.** May mimic the presentation of EVs. The majority of infants with HPeV1 and HPeV2 have mild GI and respiratory syndromes. HPeV3 has been associated with severe neonatal infections, including CNS involvement. Symptoms include irritability, fever, seizures, and a nonspecific rash. **CSF pleocytosis is characteristically lacking in most cases.** Infants with HPeV may present with an acute distended abdomen accompanied by an erythematous rash, low C-reactive protein, and low lymphocyte count, and HPeV has been associated with small clusters of patients with necrotizing enterocolitis.

VI. Diagnosis

A. Enteroviruses. Reverse transcriptase–polymerase chain reaction (RT-PCR) is the main diagnostic modality; it is readily available in commercial laboratories but lacks specificity for serotyping. Advanced RT-PCR techniques are required to further identify most EV subspecies. **RT-PCR is both more rapid and more sensitive than cell culture.** Some serotypes (EV71 neurologic disease) are difficult to isolate from CSF (even with CSF pleocytosis) but can be readily isolated from either throat or rectal swab. Cell culture was the standard method for isolation and diagnosis, but specific serotype identification requires time-consuming and expensive neutralization assays or genomic sequencing. Several serotypes cannot be grown effectively in culture. Specimens for cell culture or RT-PCR assays should include CSF, blood, urine, nasal swabs, throat swabs, and stool specimens. Positive RT-PCR tests from stool are supportive but less definitive, because detection may represent prolonged carriage from a previous infection. In countries where oral poliovirus vaccine (OPV) is used, OPV viruses are widely transmitted and may produce false-positive results in cell culture and some RT-PCR assays.

B. Parechoviruses. Current EV RT-PCR does not detect HPeV infection because of the genetic differences between the 2 viruses. The best diagnostic tests are PCR primers that have been developed by the Centers for Disease Control and Prevention that detect all known parechoviruses, some of which are commercially available now. White matter injury has been visualized with a cranial ultrasound and magnetic resonance imaging with diffusion-weighted imaging in infants with HPeV3 encephalitis. Many of the HPeVs do not grow well in cell culture. A direct PCR of stool samples can be obtained. **Most neonates with HPeV3 encephalitis have no CSF pleocytosis and can be diagnosed only with CSF PCR.**

VII. Management. Specific therapy for human EVs or HPeVs is limited. Intravenous immunoglobulin (IVIG) may be beneficial for life-threatening neonatal EV infections, severe organ-specific disease (myocarditis, chronic meningoencephalitis), CNS infection with EV71, or in immunocompromised patients to prevent chronic CNS infections. Prophylactic IVIG has been shown to help control hospital outbreaks. High-titer EV71 immunoglobulin is evaluated in epidemic disease areas. Pleconaril, an orally administered capsid inhibitor, has been studied in EV infections recently. In a trial of 61 neonates with suspected EV disease who were randomly assigned to 7 days of pleconaril or placebo, there was a trend toward more rapid viral clearance and lower overall mortality among pleconaril-treated infants (23% vs 44% with placebo); more studies are needed before pleconaril can be recommended. Overall care involves supportive measures, contact isolation in addition to standard precautions, cohorting infected infants in the nurseries to control outbreaks, and close observation for organ-specific disease (eg, meningitis, myocarditis). If fulminant hepatic disease is present, oral neomycin therapy to minimize gut flora may be beneficial. Extracorporeal life support may be indicated for neonatal collapse caused by EV myocarditis.

VIII. Prevention. Simple hygienic measures, such as hand washing, are important to prevent the spread of EVs and HPeVs. IVIG is used to stop outbreaks in NICUs. Three inactivated EVA71 vaccines are licensed in China; these have demonstrated high efficacy in randomized clinical trials against the predominant C4 genotype circulating in that country.

IX. Prognosis. The illness is mild and recoverable in most cases. Mortality is increased with the more severe forms of the infection (hepatitis, coagulopathy, and encephalitis). Infants with encephalitis and white matter abnormalities on magnetic resonance imaging (especially CVB3 and HPeV3) are at risk for cerebral palsy and neurodevelopmental impairment.

135 Gonorrhea

- I. **Definition.** Gonorrhea is a sexually transmitted disease caused by a bacterial infection with *Neisseria gonorrhoeae* (a gram-negative oxidase-positive diplococcus) with possible serious consequences if spread to the newborn.
- II. **Incidence.** In 2017, the Centers for Disease Control and Prevention reported the rate of gonorrhea in the United States at approximately 171.9 gonorrhea cases per 100,000 population. The incidence is highest in females 15 to 24 years of age. If routine ophthalmic prophylaxis was not used, it is estimated that 30% to 40% of newborn infants born to infected mothers would become infected.
- III. **Pathophysiology.** *N. gonorrhoeae* primarily affects the endocervical canal of the mother. The infant may become infected during passage through an infected cervical canal or by contact with contaminated amniotic fluid if rupture of membranes has occurred. Co-infection with *Chlamydia trachomatis* is frequent, and human immunodeficiency virus (HIV) transmission is enhanced in the presence of gonorrhea. Untreated maternal gonococcal disease is associated with increased risk of preterm delivery and small for gestational age infants.
- IV. **Clinical presentations**
 - A. **Ophthalmia neonatorum (neonatal conjunctivitis).** The most common clinical manifestation of neonatal disease (~80% of the cases). This occurs in 1% to 2% of infants born to mothers with gonococcal infection despite appropriate eye prophylaxis. For a description of this disease, see Chapter 58.
 - B. **Gonococcal arthritis.** The onset of gonococcal arthritis can occur at any time from 2 to 21 days after delivery. It is secondary to gonococcemia. The source of bacteremia has been attributed to infection of the mouth, nares, and umbilicus. Multiple joints usually are affected, with the most common sites being the knees and ankles. The infant may present with mild or moderate symptoms.
 - C. **Sepsis and meningitis.** See Chapters 146 and 140, respectively.
 - D. **Scalp abscess.** Usually secondary to intrauterine fetal monitoring.
 - E. **Other localized infections.** Gonococcal infections involving mucous membranes such as the pharynx, vagina, urethra, and anus have been described.
- V. **Diagnosis**
 - A. **Gram stain and culture.** Gram stain of any exudate should be performed. Material may be obtained by swabbing the eye, pharynx, or anorectal areas. Blood should be obtained for culture. Fluid should be aspirated from an affected joint and Gram stain and culture obtained (in case of arthritis). Gonococcal cultures from nonsterile sites (eg, the pharynx, rectum, and vagina) should be done using selective media.
 - B. **Lumbar puncture with spinal fluid studies.** Cell count, protein, glucose, culture, and Gram stain should be ordered to rule out bacterial meningitis.
- VI. **Management.** Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.
 - A. **Hospitalization.** Infants with clinical evidence of ophthalmia neonatorum, scalp abscess, or disseminated infection should be hospitalized. Complete sepsis evaluation including lumbar puncture should be performed. Tests for concomitant *C. trachomatis*, congenital syphilis, and HIV infection should be done. Results of the maternal tests for hepatitis B surface antigen should be confirmed.
 - B. **Antibiotic therapy**
 1. **Known exposure at birth (maternal infection) but asymptomatic.** Because of the serious nature of neonatal disease, it is recommended that exposed infants receive a single injection of ceftriaxone (25–50 mg/kg; maximum 125 mg). The mother and her sexual partner(s) should be evaluated (and treated) for other sexually transmitted infections, including HIV.

2. **Ophthalmia neonatorum (and other localized infections).** Treatment is ceftriaxone (25–50 mg/kg; maximum 125 mg) intravenously or intramuscularly in a single dose. Do not use ceftriaxone in neonates who have hyperbilirubinemia, especially those born preterm or in neonates (28 days of age or younger) receiving or expected to receive calcium containing IV products. Alternative treatment is cefotaxime as a single dose (100 mg/kg). Infants should have their eyes irrigated with saline immediately and at frequent intervals until the discharge is eliminated. Topical antibiotics are inadequate and unnecessary with systemic therapy. Infants with conjunctivitis should be hospitalized and evaluated as described earlier. Treatment of ophthalmia neonatorum may need to be continued beyond the single treatment dose until systemic infection has been ruled out.
3. **Disseminated infections and scalp abscesses.** For **arthritis, septicemia or abscesses:** Ceftriaxone (25–50 mg/kg/d as single daily dose) or cefotaxime (25 mg/kg every 12 hours) for 7 days. For **meningitis:** Ceftriaxone or cefotaxime for 10 to 14 days. Use cefotaxime if the infant has hyperbilirubinemia or if he or she is receiving calcium-containing intravenous fluids.
- C. **Isolation.** All infants with gonococcal infection should be placed in contact isolation until effective parenteral antimicrobial therapy has been given for 24 hours. See Appendix F.

VII. **Prognosis.** Excellent if treatment is started early.

136 Hepatitis

Neonatal hepatitis is an inflammation of the liver tissue in a newborn infant and may be caused by many infectious and noninfectious agents. Typically, viral hepatitis refers to several clinically similar diseases that differ in cause and epidemiology. These include hepatitis A, B, C, D (delta), and E. Chronic lifelong infection has only been documented with hepatitis B and hepatitis C viruses.

The differential diagnosis of newborn liver disease includes idiopathic neonatal hepatitis (giant cell), biliary atresia, metabolic disorders, antitrypsin deficiency, cystic fibrosis, iron storage disease, and other infectious agents that cause hepatocellular injury (eg, cytomegalovirus [CMV], herpes simplex, rubella, varicella, toxoplasmosis, *Listeria monocytogenes*, syphilis, and tuberculosis, as well as bacterial sepsis, which can cause nonspecific hepatic dysfunction). Table 136–1 outlines various hepatitis panel tests useful in the management of this disease. Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F. This chapter will go over neonatal hepatitis caused by Hepatitis A, B, C, D, and E.

HEPATITIS A

- I. **Definition.** Hepatitis A is also known as **infectious hepatitis** and is caused by a non-enveloped 27-nM RNA virus that is a member of the Picornaviridae family (hepatitis A virus [HAV]). It is transmitted by the fecal–oral route. A high concentration of the virus is found in stools of infected persons, especially during the late incubation and early symptomatic phases. Children, especially neonates, may excrete HAV for a more prolonged period than has been noted in adults. HAV RNA is detected in neonatal stool samples for 4 to 5 months in 23% of infants diagnosed with HAV infection. Incubation period is 15 to 50 days. There is no chronic carrier state.

Table 136–1. HEPATITIS TESTING

Specific Test	Description
HAV	Etiologic agent of “infectious” hepatitis
Anti-HAV	Detectable at onset of symptoms; lifetime persistence
Anti-HAV-IgM	Indicates recent infection with HAV; positive up to 4–6 months after infection
Anti-HAV-IgG	Signifies previous HAV infection; confers immunity
HBV	Etiologic agent of “serum” hepatitis
HBsAg	Detectable in serum; earliest indicator of acute infection or indicative of chronic infection if present >6 months
Anti-HBs	Indicates past infection with and immunity to HBV, passive antibody from HBIG, or immune response from HBV vaccine
HBeAg	Correlates with HBV replication; high-titer HBV in serum signifies high infectivity; persistence for 6–8 weeks suggests a chronic carrier state
Anti-HBe	Presence in carrier of HBsAg suggests a lower titer of HBV and lower risk of transmitting HBV
HBcAg	No commercial test available; found only in liver tissue
Anti-HBc	Identifies people with acute, resolved, or chronic HBV infection (not present after immunization); high titer indicates active HBV infection; low titer presents in chronic infection
Anti-HBc-IgM	Recent infection with HBV positive for 4–6 months after infection; detectable in “window” period after surface antigen disappears
Anti-HBc-IgG	Appears later and may persist for years if viral replication continues
HCV	Etiologic agent of hepatitis C
Anti-HCV	Serologic determinant of hepatitis C infection
HDV	Etiologic agent for delta hepatitis
anti-HDV IgG	Serologic determinant of delta hepatitis infection
HEV	Hepatitis E virus, a common cause of infectious hepatitis worldwide
anti-HEV IgG	Serologic determinant of HEV infection

anti-HAV, antibody to HAV (IgM and IgG subclasses); anti-HAV-IgG, IgG class antibody to HAV; anti-HAV-IgM, IgM class antibody to HAV; anti-HBc, antibody to HBcAg; anti-HBc-IgG, IgG class antibody to HBcAg; anti-HBc-IgM, IgM class antibody to HBcAg; anti-HBe, antibody to HBeAg; anti-HBs, antibody to HBsAg; anti-HCV, antibody to hepatitis C; anti-HDV-IgG, IgG class antibody to HDV; anti-HEV-IgG, IgG class antibody to HEV; HBeAg, hepatitis B e antigen; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; IgM and IgG, immunoglobulins M and G.

- II. **Incidence.** The true incidence of HAV infection in neonates is unknown. The overall incidence of HAV infection in the US population decreased significantly after the introduction of HAV vaccine (26,150 cases per year from 1980–1999 to 1390 cases per year in 2015; $\sim 0.4/100,000$).
- III. **Pathophysiology.** In addition to fecal–oral transmission, parenteral transmission is possible via blood transfusion. HAV infection in pregnancy, especially in the second or third trimester, is associated with increased risk of preterm labor. Maternal–infant

transmission appears to be very rare; however, both intrauterine and perinatal transmissions have been documented in case reports. The risk of transmission is limited because the period of viremia is short, and fecal contamination does not occur at the time of delivery. Occasional outbreaks of HAV infection in neonatal intensive care units (NICUs) have been reported, presumably from neonates infected through transfused blood who subsequently transmitted HAV to other neonates and staff. Severe disease in an otherwise healthy infant is rare.

IV. Risk factors. The newborn infant born to an infected mother whose symptoms began between 2 weeks before and 1 week after delivery is at risk. Risk factors for postnatal acquisition of HAV include poor hygiene, poor sanitation, contact with an infected individual (which can be nosocomial), and recent travel to a developing country where the disease is endemic.

V. Clinical presentation. Most infected infants (>80%) are asymptomatic, with mild abnormalities of liver function.

VI. Diagnosis

A. Immunoglobulin M antibody to hepatitis A virus. Present during the acute or early convalescent phase of disease. In most cases, it becomes detectable 5 to 10 days after exposure and can persist for up to 6 months after infection. Occasionally, false-positive results may occur; in addition, anti-HAV immunoglobulin (Ig) M is detectable in up to 20% of vaccine recipients when measured 2 weeks after hepatitis A immunization. **Anti-HAV IgG** appears in the convalescent phase, remains detectable, and confers immunity. Research laboratories also can detect virus in blood or stool by means of reverse transcriptase–polymerase chain reaction (RT-PCR).

B. Liver function tests. Characteristically, the transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) and serum bilirubin levels (total and direct) are elevated, whereas the alkaline phosphatase level is normal.

VII. Management

A. Intramuscular immunoglobulin. A dose of 0.02 mL/kg should be given to the newborn whose mother's symptoms began between 2 weeks before and 1 week after delivery. If an outbreak of hepatitis A is documented in the nursery, postexposure prophylaxis with intramuscular immunoglobulin should be given to susceptible healthcare workers as well as exposed neonates who may have close contact with infectious secretions. Intramuscular immunoglobulin offers >85% protection against symptomatic infection.

B. Hepatitis A virus vaccine. Two inactivated HAV vaccines, Havrix and Vaqta, are available in the United States. They are recommended for all children (1–18 years old). Their protective efficacy in preventing clinical HAV infection is 94% to 100%.

C. Isolation. The infant should be isolated with enteric precautions.

D. Breast feeding. Not contraindicated.

VIII. Prognosis for HAV-infected infants is favorable. Less than 20% are clinically symptomatic after infection. Chronic carrier state does not exist.

HEPATITIS B

I. Definition. Hepatitis B (**serum hepatitis**) is caused by a DNA-containing, 42-nm-diameter hepadnavirus (hepatitis B virus [HBV]). Important components of the viral particle include an outer lipoprotein envelope containing HBsAg and an inner nucleocapsid consisting of hepatitis B core antigen (HBc). HBV has a long incubation period (45–160 days) after exposure.

II. Incidence. Each year in the United States, approximately 20,000 infants are born to HBV-infected pregnant women, and without immunoprophylaxis, approximately 5500 would become chronically infected. As a result of universal immunization against HBV, the incidence of acute HBV infection among US children decreased by 98% between 1990 and 2014.

- III. Pathophysiology.** Transmission in the fetus and newborn has been suggested by the following mechanisms:
- A. Transplacental transmission** is either during pregnancy or at the time of delivery secondary to placental leaks. This is rare and accounts for <2% of neonatal infections.
 - B. Intrapartum transmission** occurs by exposure to HBV in amniotic fluid, vaginal secretions, or maternal blood; accounts for 90% of neonatal infections. Vaginal delivery appears to increase the risk compared with cesarean section.
 - C. Postnatal transmission.** By blood transfusion and other unknown mechanisms. Breast feeding is not a risk factor for postnatal transmission.
 - D. Father-to-child transmission** of HBV can rarely occur through the germ cells to the offspring or postnatal intimate contact. The germline route is considered an intrauterine infection.
- IV. Risk factors**
- A. Factors associated with higher rates of hepatitis B virus transmission to neonates** include the following:
 - 1. The presence of hepatitis B e antigen and absence of anti-hepatitis B e antigen in maternal serum:** Attack rates of 70% to 90%, with up to 90% of these infants becoming chronic carriers. In hepatitis B e antigen (HBeAg)-negative and hepatitis B surface antigen (HBsAg)-positive mothers, the transmission rate is 5% to 20%; however, those infants are at risk for acute hepatitis and acute fulminant hepatitis.
 - 2. Asian racial origin,** particularly Chinese, with attack rates of 40% to 70%.
 - 3. Maternal acute hepatitis in the third trimester or immediately postpartum** (70% attack rate).
 - 4. High maternal Hepatitis B DNA level.**
 - 5. Vaginal delivery**
 - 6. Antigenemia present in older siblings.**
 - V. Clinical presentation.** Maternal HBV infection has not been associated with abortion, stillbirth, or congenital malformations. Prematurity has occurred, especially with acute hepatitis during pregnancy. Fetuses or newborns exposed to HBV present a wide spectrum of disease, but most (>90%) will become chronic carriers. Because of the long incubation period, symptoms do not occur in the neonatal period. Even after the neonatal period, infants are rarely ill; jaundice appears <3% of the time. They typically have normal ALT concentrations and minimal or mild liver histologic abnormalities, with detectable HBeAg and high HBV DNA concentrations ($\geq 20,000$ IU/mL) for years to decades after initial infection (“immune-tolerant phase”). Various clinical presentations include the following:
 - A. Mild transient acute infection**
 - B. Chronic active hepatitis with or without cirrhosis**
 - C. Chronic persistent hepatitis**
 - D. Chronic asymptomatic hepatitis B surface antigen carriage**
 - E. Fulminant fatal hepatitis B (rare)**
 - F. Hepatocellular carcinoma in older children and young adults (rare)**
- VI. Diagnosis**
- A. Differential diagnosis.** Major diseases to consider include biliary atresia and acute hepatitis secondary to other viruses (eg, HAV, CMV, rubella, and herpes simplex virus).
 - B. Liver function tests.** ALT and AST levels may be increased before the rise in bilirubin levels.
 - C. Hepatitis panel testing.** See Table 136–1.
 - 1. Mother.** Test for HBsAg, HBeAg, anti-HBe, and anti-HBc.
 - 2. Infant.** Test for HBsAg and anti-HBc IgM. Anti-HBc IgM is highly specific for establishing the diagnosis of acute infection and is the only marker of acute infection during the “window” period. Most infants demonstrate HBsAg

antigenemia by 6 months of age, with peak acquisition at 3 to 4 months. Nucleic acid amplification testing (NAAT), gene amplification techniques (eg, polymerase chain reaction assay, branched DNA methods), and hybridization assays are available to detect and quantify HBV DNA. Cord blood is not a reliable indicator of neonatal infection because contamination could have occurred with antigen-positive maternal blood or vaginal secretions and possible noninfectious antigenemia from the mother. Transient HBsAg antigenemia can occur following receipt of hepatitis B (HB) vaccine, with HBsAg being detected as early as 24 hours after and up to 2 to 3 weeks following administration of the vaccine.

VII. Management

- A. Hepatitis B surface antigen-positive mother.** If the mother is HBsAg positive, regardless of the status of her HBe antigen or antibody, the infant should be given hepatitis B immune globulin (HBIG), 0.5 mL intramuscularly, within 12 hours after delivery. In addition, HB vaccine is given at birth (within 12 hours), at 1 month, and at 6 months of age. If the first dose is given simultaneously with HBIG, it should be administered at a separate site, preferably in the opposite leg. **For preterm infants weighing <2 kg, this initial dose of vaccine should not be counted in the required 3-dose schedule,** and the subsequent 3 doses should be initiated when the infant is 30 days old. HBIG and HB vaccine do not interfere with routine childhood immunizations. No specific antiviral therapy exists for acute HBV infection in infants <3 months age; however, the US Food and Drug Administration (FDA) licensed lamivudine (≥ 3 months of age) and interferon (≥ 1 year of age) as treatment of chronic HBV in children. The goal of treatment is to prevent progression to cirrhosis, hepatic failure, and hepatocellular carcinoma (HCC). Current indications for treatment of chronic HBV infection include evidence of ongoing HBV viral replication, as indicated by the presence for longer than 6 months of serum HBV DNA >20,000 IU/mL without HBeAg positivity, >2000 IU/mL with HBeAg positivity, and elevated serum ALT concentrations for longer than 6 months or evidence of chronic hepatitis on liver biopsy. Consultation with an infectious disease specialist is recommended for clinical monitoring and treatment.
- B. Infant born to mother whose hepatitis B surface antigen status is unknown.** Test the mother as soon as possible. While awaiting the results, give the infant HBV vaccine within 12 hours of birth. If the mother is found to be HBsAg positive, the infant should receive HBIG (0.5 mL) as soon as feasible (within 7 days) of birth. If the infant's **birthweight is <2000 g** and the maternal HBsAg status cannot be determined within the initial 12 hours after birth, HBIG should be given as well as HB vaccine.
- C. Infant born to hepatitis B surface antigen-negative mother.** For all infants with birth weight ≥ 2000 g, administer HB vaccine as a universal routine prophylaxis within 24 hours of birth. Deferral to a time after birth or discharge from the hospital no longer is considered to be an acceptable option, because it might deprive an HBV-exposed infant of timely administration of HBV prophylaxis. For all infants with birthweight <2000 g, administer HB vaccine as a universal routine prophylaxis at 1 month of age or at hospital discharge (whichever is first).
- D. Isolation.** Precautions are needed in handling blood and secretions.
- E. Breast feeding.** HBsAg has been detected in breast milk of HBsAg-positive mothers but only with special concentrating techniques. With appropriate immunoprophylaxis (HBIG and HB vaccine), breast feeding of infants of chronic HBV carrier mothers poses no additional risk for the transmission of the HBV. Therefore, breast feeding should be encouraged.
- F. Vaccine efficacy.** The overall protective efficiency rate in neonates given HB vaccine and HBIG is approximately 95%. The World Health Organization recommends that all countries add HB vaccine to their routine childhood immunization

programs. Such programs (in Taiwan) have been shown to lower the incidence of chronic HBsAg carrier state, fulminant hepatic failure, and HCC. Infants born to HBsAg-positive women should be tested for anti-HBs and HBsAg after completion of the immunization (1–2 months after the last vaccine dose) at 9 to 12 months of age, generally at the next well-child visit after completion of the vaccine series. Testing should not be performed before 9 months of age to maximize the likelihood of detecting late-onset HBV infections. HBsAg-negative infants with anti-HBs titers <10 mIU/mL after completing the 3-dose vaccine series should be revaccinated with a single dose of HB vaccine and retested for anti-HBs antibody titers 1 to 2 months later. Infants who have anti-HBs titers ≥ 10 mIU/mL after this fourth dose of HB vaccine do not need any additional doses of the HB vaccine. Infants who fail to reach anti-HBs titers ≥ 10 mIU/mL after the fourth dose of HB vaccine should receive 2 additional doses of the HB vaccine followed by retesting for anti-HBs antibody titers 1 to 2 months later.

- G. Prevention of hepatitis B vaccine failure.** Failure of combined immunoprophylaxis (HBIG and HB vaccine) occurs in approximately 5% infants born to HBsAg-positive mothers. Often these infants are HBsAg positive at birth, suggesting the infection is already established in utero. Their mothers may have acquired the infection in the third trimester and/or have had a high viral load at time of delivery. Specifically, women with HBV DNA $>10^6$ to 10^8 IU/mL or who are HBeAg positive have an increased risk of perinatal transmission even if appropriate combined immunoprophylaxis is given to the newborn infant (~15%–30% risk of transmission vs <5% risk of transmission for women with lower HBV DNA or who are HBeAg negative). For these women, antiviral therapy with tenofovir, telbivudine, or lamivudine in the third trimester (in addition to HBIG and HB vaccine to the newborn) may further reduce the transmission rate to 0% to 2%. Telbivudine presents a favorable safety profile during pregnancy.
- VIII. Prognosis.** The majority of perinatally infected infants remain clinically healthy. Approximately 30% to 50% develop persistently elevated transaminase values on liver function tests. About 5% have moderately severe histopathologic changes on liver biopsy. Late complications such as cirrhosis and HCC are rare.

HEPATITIS C

- I. Definition.** Hepatitis C virus (HCV) is a small, single-stranded, enveloped RNA virus that is a member of the Flaviviridae family. At least 6 HCV genotypes exist with multiple subtypes.
- II. Incidence.** The pediatric prevalence of HCV is approximately 0.1%. The true incidence of neonatal HCV is unknown. A 3-fold increase in reported cases of acute HCV was seen recently in the United States, mostly attributed to rising rates of injection-drug use such as heroin and oxycodone.
- III. Pathophysiology.** HCV is transmitted primarily by parenteral means. Historically, exposure to blood and blood products was the most common source of infection; however, because of screening tests to exclude infectious donors, the risk of HCV is currently estimated to be 1 per 2 million units transfused. The most common route of infection for children is maternal–fetal transmission. Seroprevalence among pregnant women is estimated to be at 1% to 2%. The risk of perinatal transmission averages 5% to 6%, and transmission occurs only from women who are HCV RNA positive at the time of delivery. Infants of HCV-positive mothers are more likely to be low birthweight, to be growth restricted, and to require NICU admission.
- IV. Risk factors**
- A. Maternal hepatitis C virus viremia** correlates with transmission. However, viremia levels fluctuate over time, and no “safe level” can be defined below which transmission never occurs.

B. Maternal human immunodeficiency virus–hepatitis C virus coinfection is associated with a 2- to 3-fold increase in risk of transmission. This may be explained, in part, by higher HCV RNA levels resulting from human immunodeficiency virus (HIV)-mediated immunosuppression

C. Maternal intravenous drug use. Several studies have shown that the maternal history of intravenous drug use increases the risk for perinatal transmission of HCV.

D. Prolonged rupture of membranes and obstetric procedures. Rupture of membranes >6 hours before delivery and obstetric procedures, such as amniocentesis and scalp electrode monitoring of the fetus during delivery, may increase the risk of HCV transmission. However, **mode of delivery** (eg, cesarean delivery) does not seem to offer any protection except if the mother is co-infected with HIV.

V. Clinical presentation. The average incubation period is about 6 to 7 weeks. Infants with acute hepatitis C typically are asymptomatic, have mildly elevated transaminases, or occasionally have a mild clinical illness. Spontaneous clearance, typically by 3 years of age, occurs in 10% to 20% of the cases. Of the remainder, approximately 70% experience chronic hepatitis (majority asymptomatic), 20% develop cirrhosis, and 1% develop HCC.

VI. Diagnosis of HCV infection in infants can be made by detecting **anti-HCV IgG** in serum after 15 months of age. Testing for anti-HCV IgG earlier may detect maternal transplacentally acquired antibodies (may persist until 18 months of age). For earlier diagnosis, NAAT to detect **HCV RNA** (commercially available and approved by FDA) can be performed as early as 2 months of age. NAATs carry a low sensitivity if used at birth. All children born to HCV-infected women need to be tested with NAAT at 2 to 3 months of age and again at 6 months of age. Two positive tests are highly suggestive of infection. Regardless of NAAT testing, anti-HCV IgG needs to be done after 15 months of age. Assays for anti-HCV IgM are not available. Liver function tests may be elevated and fluctuate widely over time. Neonates diagnosed with HCV infection should also be screened for co-infection with HBV and HIV due to common modes of transmission.

VII. Management

A. If the mother was infected during the last trimester. The risk of transmission to the infant is highest. Successful treatment of HCV infection (elimination of viremia) significantly reduces the risk of mother-to-infant transmission; however, there are no FDA approved therapies for HCV that can be used during pregnancy. Women with HCV infection should be treated prior to conception if possible, and they should avoid pregnancy for at least 6 months after completing a ribavirin-containing regimen (due to teratogenic effects). Immune globulin prophylaxis is not recommended.

B. Breast feeding. HCV RNA has been detected in breast milk and colostrum of viremic mothers; however, transmission of HCV by breast feeding has not been documented. According to guidelines of the Centers for Disease Control and Prevention and the American Academy of Pediatrics, asymptomatic maternal HCV infection is not a contraindication to breast feeding. Mothers who are HCV positive and choose to breast feed should consider abstaining if their nipples are cracked or bleeding.

C. Treatment. Currently, the only FDA-approved treatment for HCV in children 3 to 17 years of age consists of a combination of peginterferon and ribavirin. The treatment of chronic HCV infection is rapidly evolving, and several trials of **direct-acting antiviral agents** such as ledipasvir and sofosbuvir as well as combination drug regimens are being evaluated in several trials. HCV genotyping is useful for guiding the selection and duration of therapy. In 2017, the FDA approved sofosbuvir plus ribavirin and ledipasvir plus sofosbuvir for treatment of HCV infection in children age 12 years and older. There are different protocols that depend on

the HCV genotype. These agents permit effective, well-tolerated, all-oral, interferon-free regimens for most patients. No specific therapy is currently recommended for HCV-positive infants; consultation with a pediatric infectious disease specialist should be sought as the field and use of direct-acting antiviral agents is rapidly evolving. All infants with chronic HCV infection should be **immunized against HAV and HBV** because of the very high rate of severe hepatitis if co-infection with HAV or HBV develops. Evidence-based consensus recommendations for management of HCV can be found online (www.HCVguidelines.org).

VIII. Prognosis. Approximately 10% to 20% of children with perinatally acquired HCV infection clear the virus during the first 2 years of life; the rest will develop chronic hepatitis. Genotype 3 is associated with better chance of spontaneous clearance. Progression to cirrhosis occurs in 20% of patients with chronic hepatitis, typically over an average of 20 years. Decompensated cirrhosis develops in approximately 2%. Risk factors for end-stage liver disease include perinatal exposure, maternal drug use, and infection with HCV genotype 1a. Children with such features should be considered for early treatment. HCC is rare and occurs almost exclusively in children with additional risk factors such as cirrhosis, co-infection with HBV, and history of childhood leukemia or other malignancy

HEPATITIS D

Hepatitis D virus (HDV), also known as **delta hepatitis**, is a defective RNA virus that cannot survive independently and requires the helper function of HBV DNA. Therefore, it occurs either as coinfection (simultaneous with the initial HBV) or as superinfection (infection in a person already chronically infected with HBV). Acquisition of HDV is by parenteral, percutaneous, or mucous membrane inoculation. The incubation period for HDV superinfection is approximately 2 to 8 weeks. Transmission from mother to newborn infant has been documented but is uncommon. Prevention of HBV infection prevents hepatitis D. There are, however, no available treatments to prevent HDV in HBsAg carriers before or after exposure. Management should be similar to that for HBV infection (see prior discussion). Diagnosis of HDV is based on the detection of antibody to HDV (anti-HDV IgG) by radioimmunoassay or enzyme immunoassay as well as HDV RNA testing (by RT-PCR). HDV status should be assessed in known carriers of HBV because co-infection may lead to acute or fulminant hepatitis or a more rapid progression of chronic hepatitis and development of HCC. HDV is difficult to treat; however, data suggest pegylated interferon- α for 1 year may result in up to 40% of patients having a sustained response to therapy.

HEPATITIS E

Hepatitis E virus (HEV) is a nonenveloped, positive-sense, single-stranded RNA virus; it usually causes a self-limiting acute hepatitis similar to HAV. Transmission is by fecal-oral route. Unlike other viral hepatitis, certain HEV genotypes (genotypes 3 and 4) also have zoonotic hosts, such as swine, and can be transmitted by eating undercooked pork. HEV genotypes 1 and 2 exclusively infect humans. Person-to-person transmission appears to be much less efficient than with HAV virus but occurs in sporadic and outbreak settings. HEV also is transmitted through blood product transfusion. HEV is the most common cause of viral hepatitis in the world. Globally, an estimated 20 million HEV infections occur annually, resulting in 3.4 million cases of acute hepatitis and 70,000 deaths. HEV is particularly common in Africa and the Indian subcontinent. In the United States, HEV infection is uncommon and generally occurs in travelers returning from endemic areas or swine workers. However, seroprevalence is higher than expected based on clinical disease (20% of the population have anti-HEV IgG). HEV commonly causes an acute illness with jaundice, malaise, fever, and arthralgia. Hepatitis E is clinically indistinguishable from hepatitis A. It is rarely symptomatic in children <15 years old. There is a very high maternal mortality (10%–25%) when HEV is acquired during pregnancy, especially during the third trimester. Mother-to-infant transmission is high

(50%–100%). Fetal loss or early neonatal mortality is also significant. Commercial kits are available to detect anti-HEV IgG and IgM. Definitive diagnosis may be made by demonstrating viral RNA in serum or stool by RT-PCR. The only treatment is supportive. It is unclear if breast feeding is a potential route of HEV transmission. A recombinant HEV vaccine evaluated in a phase III clinical trial was demonstrated to be effective in preventing disease and is approved for use by the Chinese Food and Drug Administration.

137 Herpes Simplex Viruses

- I. Definition.** Herpes simplex viruses (HSV-1 and HSV-2) are enveloped, double-stranded DNA viruses. They are part of the herpes group, which also includes cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, and human herpes viruses (HHV-6 and HHV-7). HSV infection is among the most prevalent of all viral infections encountered by humans.
- II. Incidence.** The incidence of neonatal HSV infection is estimated to range from 1 in 2000 to 1 in 3000 live births. As of 2014, seroprevalence of HSV-1 and HSV-2 in pregnant women in the United States was approximately 59.3% and 21.1%, respectively.
- III. Pathophysiology.** HSV enters the human host through inoculation of oral, genital, or conjunctival mucosa or breaks in skin, infects the sensory nerve endings, and then passes via retrograde axonal flow to the dorsal root ganglia, where it remains for the life of the host. Two serologic subtypes can be distinguished by antigenic and serologic tests: HSV-1 (usually affects face and skin above the waist) and HSV-2 (genitalia and skin below the waist). Three quarters of neonatal herpes infections are secondary to HSV-2. HSV-1, however, can be the cause of maternal genital herpes infections in 9% of the cases, and its rate appears to be increasing (eg, HSV-1 is the major serotype causing neonatal disease in Australia). HSV infection of the neonate can be acquired at 1 of 3 times: intrauterine, intrapartum, or postnatal. Most infections (85%) are acquired in the **intrapartum** period as ascending infections with ruptured membranes (the period of 4–6 hours is considered a critical period for this to occur) or by delivery through an infected cervix or vagina. An additional 10% of infected neonates acquire the virus **postnatally** (eg, from someone shedding HSV from the mouth who then kisses the infant). The final 5% of neonatal HSV infections occur **in utero**. In utero infection is acquired transplacentally and occurs only in women with primary HSV infection. It is usually associated with placental infarcts and necrotizing funisitis and may result in miscarriage, congenital anomalies, preterm birth, and/or fetal growth restriction. The incubation period is from 2 to 20 days. Three general patterns of neonatal HSV infection are recognized: **disease localized to the skin, eyes, and mouth (SEM)**; **central nervous system (CNS) disease** (with or without SEM involvement); and **disseminated disease** (which also may include signs of the first 2 groups). Maternal infection can be **classified** as either *first-episode* or *recurrent* infections. First-episode infections are further classified as either *primary* or *first-episode nonprimary* based on type-specific serologic testing. *Primary infections* are those in which the mother is experiencing a new infection with either HSV-1 or HSV-2 and has not already been infected with the other virus type. *First-episode nonprimary* infections are those in which the mother has a new infection with 1 virus type, usually HSV-2, but has antibodies to the other virus type, usually HSV-1. Infants born vaginally to mothers with a true primary infection are at highest risk, with a transmission rate of approximately 60%. Those born to a mother with a first-episode

nonprimary infection are at a somewhat lower risk of 25%. The lowest risk infants (2%) are those born to mothers with recurrent infections. Maternal antibody is not always protective in the fetus.

- IV. Risk factors.** The risk of genital herpes infection varies with maternal age, socioeconomic status, and number of sexual partners. Only approximately 12% of pregnant women who test seropositive for HSV-2 give a clinical history suggestive of the disease. The first-episode infection may stay “active” with asymptomatic cervical shedding for as long as 2 months. Besides a first-episode infection (primary or nonprimary), additional risk factors for neonatal HSV infection include acquisition of HSV shortly before labor, viral genital shedding in labor, genital shedding of HSV-1 rather than HSV-2, the use of a fetal-scalp electrode, preterm birth, and maternal age <21 years.
- V. Clinical presentation.** Congenital in utero HSV infection is rare and is associated with high rate of fetal demise; it shares clinical features such as microcephaly, hydrocephalus, and chorioretinitis with other congenital infections. In addition, skin ulcerations or scarring and eye damage are commonly noted. The neonatal disease is commonly acquired intrapartum. It may be localized or disseminated. Humoral and cellular immune mechanisms appear important in preventing initial HSV infections or limiting their spread. Infants with disseminated and SEM disease generally present at 10 to 12 days of life, whereas patients with CNS disease usually present at 16 to 19 days of life. More than 20% of infants with disseminated disease and 30% to 40% of infants with encephalitis never have skin vesicles (see Figure 80–10).
- A. Skin, eyes, and mouth disease.** HSV disease localized to the skin, eyes, or oral cavity accounts for approximately 45% of the cases. **Skin lesions** vary from discrete vesicles to large bullous lesions and denuded skin. It typically involves the presenting part (eg, vertex) and sites of skin trauma (eg, scalp electrodes). There is skin involvement in 80% to 85% of SEM cases. **Ulcerative mouth lesions** (~10% of SEM cases) with or without cutaneous involvement can be seen. **Ocular findings** include keratoconjunctivitis and chorioretinitis (see Chapter 58). Without treatment, there is a high risk of progression to encephalitis or disseminated disease.
- B. Disseminated disease** accounts for 25% of neonatal HSV disease and carries the worst prognosis with respect to mortality. Patients commonly present with fever, lethargy, apnea, and a septic shock–like picture, including respiratory collapse (hemorrhagic pneumonitis), liver failure, neutropenia, thrombocytopenia, and disseminated intravascular coagulation (DIC). Approximately half of these cases also have SEM manifestations, and 60% to 75% have CNS involvement. Skin involvement may appear late, but approximately 20% of infants with disseminated disease will not develop any cutaneous vesicles during the course of their illness. Recognition of the disseminated HSV disease is often delayed. It should be suspected in any infant presenting with a sepsis-like picture associated with thrombocytopenia, elevated liver enzymes, consumptive coagulopathy, and cerebrospinal fluid (CSF) pleocytosis.
- C. Central nervous system disease** accounts for approximately 30% of neonatal HSV infection. It may develop as a result of localized retrograde spread from the nasopharynx and olfactory nerves to the brain or through hematogenous spread in neonates with disseminated disease. Clinical manifestations include seizures (focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, and a bulging fontanelle. These infants usually present at 16 to 19 days of age, and 30% to 40% have no herpetic skin lesions. CSF findings are variable and typically show a mild pleocytosis, increased protein, and a slightly low glucose. Abnormalities of the CSF may be more pronounced as CNS disease progresses.
- VI. Diagnosis.** Diagnosis of neonatal HSV infection can be challenging, and the diagnosis is often delayed. Early manifestations are subtle and nonspecific (especially for the disseminated form). The maternal history is often not helpful (negative in 80% of the cases).

A. Laboratory studies

- 1. Surface viral cultures.** Isolation of HSV by culture remains the definitive diagnostic method of documenting infection. Skin or mucous membrane lesions or surfaces (mouth, nasopharynx, conjunctivae, and anus) are scraped and transferred in appropriate viral transport media on ice. Swab specimens from mouth, nasopharynx, conjunctivae, and anus can be obtained with a single swab starting with the eyes and ending with the anus and placed in 1 viral transport media tube. With the exception of CNS involvement, the important information gathered from such cultures is the presence or absence of the replicating virus, rather than its precise location. Preliminary results may become available in 24 to 72 hours. Positive cultures obtained from any of these sites more than 12 to 24 hours after birth indicate viral replication and, therefore, are suggestive of infant infection rather than mere contamination after intrapartum exposure.
- 2. Polymerase chain reaction.** Polymerase chain reaction (PCR) is an important tool in the diagnosis of HSV infection. PCR has been used to detect HSV DNA in CSF and blood specimens. PCR is especially useful for the diagnosis of HSV encephalitis. Overall sensitivities of CSF PCR in neonatal HSV disease have ranged from 75% to 100%, with overall specificities ranging from 71% to 100%. Negative CSF PCR does not exclude the diagnosis of HSV CNS disease; it may be negative early in the course of the disease or if the test is done after antiviral therapy has been given for a few days. PCR is especially important in monitoring therapy of CNS disease, with discontinuation of therapy only when PCR is negative. Blood PCR assay should not supplant surface cultures or be used to classify disease because viremia can be present in any of the 3 forms of disease. The performance of PCR assay on skin and mucosal specimens from neonates has not been studied; if used, surface or skin PCR assays should be performed in addition to (and not instead of) the gold standard surface culture.
- 3. Immunologic assays.** Immunologic assays to detect HSV antigen in lesion scrapings, usually using monoclonal anti-HSV antibodies in either an enzyme-linked immunosorbent assay or direct fluorescent antibody staining, are very specific and 80% to 90% sensitive.
- 4. Liver function tests.** Measuring serum liver function tests, especially alanine aminotransferase (ALT), is recommended. HSV characteristically invades the liver and causes hepatocellular damage.
- 5. Serologic tests.** These are not helpful in the diagnosis of neonatal infection but are helpful in diagnosing and classifying maternal disease (primary vs secondary).
- 6. Lumbar puncture** should be performed in all suspected cases including SEM disease. CSF may be normal early in the course of the disease but typically will show a mononuclear cell pleocytosis, normal or moderately low glucose, and mildly elevated protein. Contrary to the historical suggestion, erythrocytes are not notably increased in HSV CNS disease. HSV PCR should always be performed on CSF.

B. Imaging and other studies

- 1. Brain imaging with computed tomography or preferably magnetic resonance imaging** is recommended in all infants with HSV CNS disease. Findings include parenchymal brain edema or attenuation, hemorrhage, and destructive lesions, especially in the temporal lobe.
- 2. Electroencephalogram.** Should be performed in all neonates suspected to have CNS involvement (seizures, abnormal CSF, abnormal neurologic examination). Electroencephalogram is often abnormal very early in the course of the CNS disease; it may show focal or multifocal epileptiform discharges before abnormal changes are detected by computed tomography or magnetic resonance imaging.

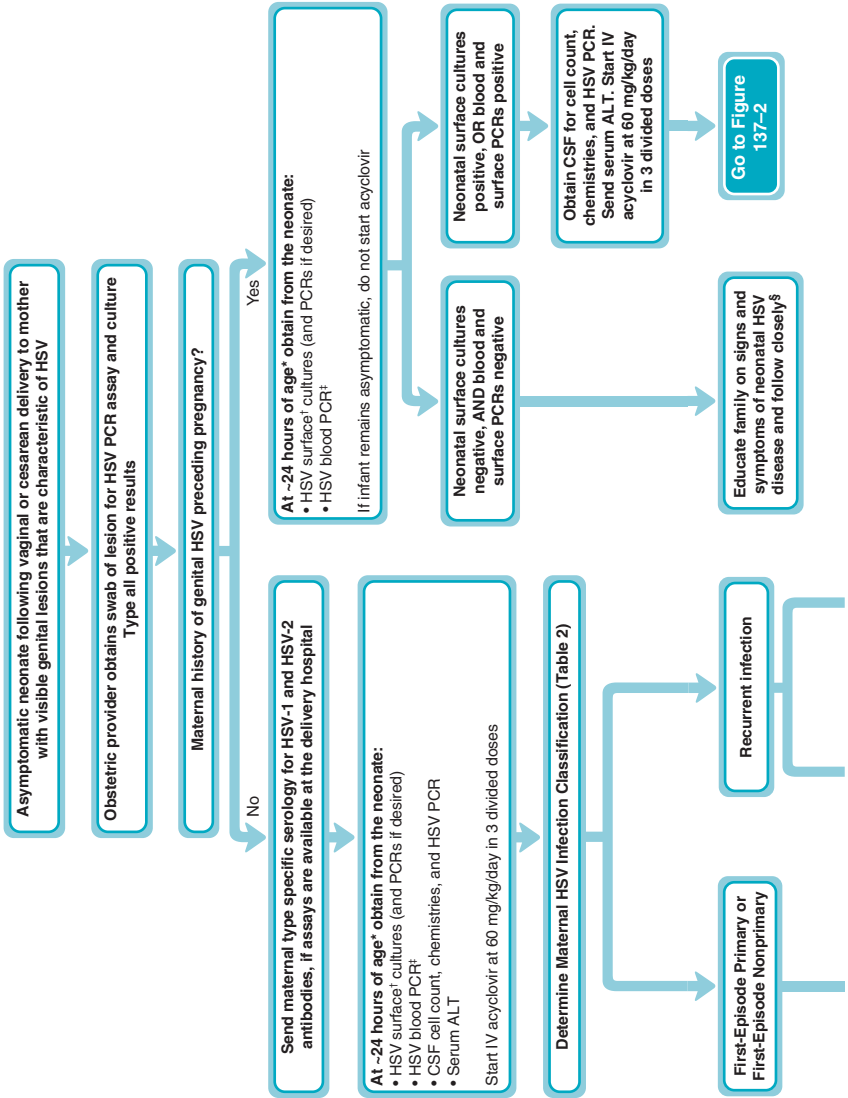

VII. Management

A. Antepartum. The history of genital herpes in a pregnant woman or in her partner(s) should be solicited and recorded in the prenatal record. If a positive history is obtained, the following steps may be taken:

- 1. Antiviral therapy.** **Acyclovir** or **valacyclovir** may be given to pregnant women who have a primary episode of genital HSV as well as to women with an active infection (primary or secondary) near or at the time of delivery. Multiple trials showed that prophylactic acyclovir beginning at 36 weeks' gestation, given to women who present with a genital HSV lesion anytime during pregnancy, reduces the risk of clinical HSV recurrence at delivery, cesarean delivery, and HSV viral shedding at delivery. Valacyclovir also demonstrated similar results in randomized studies. These studies did not identify any neonatal side effects from maternal suppressive therapy. These infants will need to be monitored closely because the risk of neonatal HSV infection is not totally eliminated. See dosing in Chapter 155.
- 2. If there are no visible lesions** at the onset of labor or prodromal symptoms, vaginal delivery is acceptable.
- 3. Cesarean delivery is recommended** in women with a history of HSV who have genital HSV lesions or prodromal HSV symptoms at the time of labor. Some experts also recommend cesarean delivery for women who had a primary or nonprimary first episode genital infection during the latter weeks of pregnancy (eg, within 6 weeks of delivery) even with no active genital lesions at the time of labor, due to significant and prolonged viral shedding. Debate exists if membranes have already been ruptured for >4 hours in the presence of active lesion; most experts still recommend cesarean delivery in this situation. All neonates delivered by cesarean section should be monitored closely because neonatal HSV infections have occasionally occurred despite delivery before the membranes rupture.

B. Neonatal treatment

- 1. Infants born to mothers with a genital lesion.** The American Academy of Pediatrics has published an algorithm (Figures 137-1 and 137-2) addressing management of asymptomatic neonates following vaginal or cesarean delivery to women with active genital HSV lesions. The algorithm calls for obtaining HSV surface cultures and HSV blood PCR (in addition to CSF cell count, chemistries, and HSV PCR, as well as serum ALT when maternal history for HSV is negative) in all exposed infants at approximately 24 hours of age. Because of the high transmission rate after primary or first episode nonprimary maternal infection (25%–60%), the algorithm recommends preemptive therapy for those exposed infants with acyclovir at 60 mg/kg/d for 10 days. Infants exposed to active lesions with maternal recurrent infection have 2% risk of acquiring the neonatal HSV disease; those infants can be monitored clinically with education of the family about signs and symptoms of the disease and treatment only if the infant becomes symptomatic.
- 2. Infants born to mothers with a history of genital herpes but no active genital lesions at delivery.** Should be observed for signs of infection but no surface cultures or parenteral acyclovir is needed. Education of parents and caregivers about the signs and symptoms of neonatal HSV infection during the first 6 weeks of life is prudent.
- 3. Pharmacologic therapy for established herpes simplex virus disease.**
 - a. Intravenous acyclovir.** Neonates with HSV disease should be treated with **intravenous acyclovir at 60 mg/kg/d**, divided every 8 hours (20 mg/kg/dose). The dosing interval of intravenous acyclovir may need to be increased in premature infants, based on their creatinine clearance. Duration of therapy is a minimum of 21 days for patients with disseminated or CNS disease and 14 days for those with SEM disease. All patients with CNS involvement should

TABLE 2. Maternal Infection Classification by Genital HSV Viral Type and Maternal Serology^a

Classification of Maternal Infection	PCR/Culture from Genital Lesion	Maternal HSV-1 and HSV-2 IgG Antibody Status
Documented first-episode primary infection	Positive, either virus	Both negative
	Positive for HSV-1	Positive for HSV-2 AND negative for HSV-1
Documented first-episode nonprimary infection	Positive for HSV-2	Positive for HSV-1 AND negative for HSV-2
	Positive for HSV-1 OR HSV-2	Not available
Assume first-episode (primary or nonprimary) infection	Negative OR not available ^b	Negative for HSV-1 and/or HSV-2 OR not available
Recurrent infection	Positive for HSV-1	Positive for HSV-1
	Positive for HSV-2	Positive for HSV-2

^a To be used for women without a clinical history of genital herpes.
^b When a genital lesion is strongly suspicious for HSV, clinical judgment should supersede the virological test results for the conservative purposes of this neonatal management algorithm. Conversely, if in retrospect, the genital lesion was not likely to be caused by HSV and the PCR assay result or culture is negative, departure from the evaluation and management in this conservative algorithm may be warranted.

FIGURE 137-1. Algorithm for the evaluation of asymptomatic neonates following vaginal or cesarean delivery to women with active genital herpes lesions. ALT, alanine aminotransferase; D/C, discontinue; HSV, herpes simplex virus; IV, intravenous; PCR, polymerase chain reaction. (Reproduced with permission from Kimberlin DW, Baley J: *Committee on infectious diseases, et al: Guidance on management of asymptomatic neonates born to women with active genital herpes lesions*, Pediatrics. 2013 Feb;131(2):e635-e646.)

*Evaluation and treatment is indicated prior to 24 hours of age if the infant develops signs and symptoms of neonatal HSV disease. In addition, immediate evaluation and treatment may be considered if:

- There is prolonged rupture of membranes (>4–6 hours)
- The infant is premature (≤ 37 weeks' gestation)

^f Conjunctivae, mouth, nasopharynx, and rectum, and scalp electrode site, if present.

[†] HSV blood PCR is not utilized for assignment of disease classification.

[§] Discharge after 48 hours of negative HSV cultures (and negative PCRs) is acceptable if other discharge criteria have been met, there is ready access to medical care, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital until HSV cultures are finalized as negative or are negative for 96 hours after being set up in cell culture, whichever is shorter.

This algorithm should be applied only in facilities where access to PCR and type type-specific serologic testing is readily available and turnaround time for test results is appropriately short. In situations where this is not possible, the approach detailed in the algorithm will have limited and perhaps no applicability.

- c. **Oral acyclovir suppressive therapy** is recommended for 6 months after treatment of acute neonatal HSV disease. In particular, improved neurodevelopmental outcome has been observed with suppressive therapy after HSV CNS disease. Moreover, suppressive therapy has been associated with reduced recurrences of skin lesions after other forms of HSV. The oral acyclovir dose is 300 mg/m²/dose, 3 times per day for 6 months; the dose should be adjusted each month to account for growth. Absolute neutrophil counts should be assessed at 2 and 4 weeks after initiating suppressive therapy and then monthly during the treatment period.
- C. **Breast feeding.** The infant may breast feed as long as no breast lesions are present on the mother, and the mother should be instructed in good hand washing technique.
- D. **Parents with orolabial herpes.** Parents should wear a mask when handling the newborn and should not kiss or nuzzle the infant.
- VIII. **Prognosis.** High-dose acyclovir (60 mg/kg/d) therapy has greatly reduced **mortality** for neonatal HSV infection. Twelve-month mortality has been reduced to 29% for disseminated disease and 4% for CNS disease. Predictors of mortality include disease severity (pneumonia, DIC, seizures, and hepatitis), virus type (HSV-1 in systemic disease, HSV-2 in CNS disease), and prematurity. Systemic infection in premature infants is associated with near 100% mortality. Improvements in **morbidity** rates have not been as dramatic as with mortality. The proportion of survivors of disseminated neonatal HSV disease who have normal neurologic development has increased to 83%. In the case of CNS disease, morbidity in survivors has not changed, with only approximately 30% developing normally by 12 months of age. Seizures at or before the initiation of antiviral therapy and persistently positive CSF PCR after 4 weeks of acyclovir therapy are associated with poor neurodevelopmental outcome. The outcome for infants with SEM disease is excellent, with <2% of acyclovir recipients experiencing developmental delays. Survivors of neonatal HSV infections should undergo **developmental assessments** regularly. Cutaneous recurrences are relatively common (~50%), especially for SEM disease, and those can be reduced by suppressive oral acyclovir therapy.

138 Human Immunodeficiency Virus

- I. **Definition.** Two types of human immunodeficiency virus (HIV) cause disease in humans: HIV-1 and HIV-2. These are enveloped RNA cytopathic lentiviruses belonging to the family Retroviridae. Infection is most commonly secondary to HIV-1. HIV-2 is rare in the United States but more common in West Africa. Unless otherwise specified, this chapter addresses HIV-1 infection. HIV results in a broad spectrum of disease, with **acquired immunodeficiency syndrome (AIDS)** representing the most severe end of the clinical spectrum.
- II. **Incidence.** The Joint United Nations Program on HIV/AIDS estimated that 36.7 million people worldwide were infected with HIV at the end of 2015. More than 95% of the total cases reside in developing countries. In the same year, an estimated 150,000 children contracted HIV, down from 290,000 in 2010 (down 50%). This drop reflects the fact that access to services for preventing the mother-to-child transmission (MTCT) of HIV has significantly increased. The estimated number of children living with HIV declined to 1.8 million worldwide in 2015. Among infants born in the United States, the overall annual rate of perinatally acquired HIV infections decreased from 3.6 per 100,000 live births in 2008 to 1.8 per 100,000 live births in 2013.

III. Pathophysiology. HIV is particularly tropic for CD4⁺ T cells and cells of monocyte or macrophage lineage. After infection of the cell, viral RNA is uncoated and a double-stranded DNA transcript is made (through the activity of a viral enzyme, reverse transcriptase). This DNA then moves to the nucleus and integrates into the host genome DNA where it persists as a provirus. There is eventual destruction of both the cellular and humoral arms of the immune system. In addition, HIV gene products or cytokines elaborated by infected cells may affect macrophage, B-lymphocyte, and T-lymphocyte function. Hypergammaglobulinemia, caused by HIV-induced polyclonal B-cell activation, is often detected in early infancy. Disruption of B-cell function results in poor secondary antibody synthesis and response to vaccination. A small proportion (<10%) of patients will develop panhypogammaglobulinemia. Additionally, profound defects in cell-mediated immunity occur, allowing a predisposition to opportunistic infections such as fungus, *Pneumocystis jirovecii* pneumonia (PCP), and chronic diarrhea. The virus can also invade the central nervous system and produce psychosis and brain atrophy.

IV. Risk factors

A. High-risk mother. Any infant born to a high-risk mother is at risk. High-risk mothers include intravenous (IV) drug users, hemophiliacs, spouses of hemophiliacs, spouses of bisexual males, those with a history of exchanging sex for money or drugs, sex partners of HIV-infected persons, and those who were diagnosed with sexually transmitted infection during pregnancy. Several mechanisms account for viral transmission, but **maternal plasma HIV RNA level (viral load) is the best single predictor of MTCT risk**. Other risk factors include mode of delivery, duration of rupture of membranes, prematurity and low birthweight, cervical-vaginal viral load, low maternal CD4⁺ cell count, maternal symptomatic HIV disease/AIDS, viral subtype, and host genetic factors. Most MTCT occurs intrapartum, with smaller proportions of transmission occurring in utero and postnatally through breast feeding. Transplacental infection has been proven by evidence of infection in aborted first-trimester fetal tissues as well as isolation of HIV in blood samples obtained within 48 hours of birth. Potential routes of infection include mixture of maternal and fetal blood and infection across the placenta when its integrity is compromised (eg, placentitis [syphilitic] and chorioamnionitis).

B. Blood transfusion. Screening of blood donors has reduced but has not totally eliminated the risk. This happens because some newly infected persons are viremic but seronegative for 2 to 4 months and because some rare infected persons remain seronegative. The current risk of transmission of HIV per unit transfused is 1 in 2 million. (See also Chapter 19.)

C. Breast milk. Breast feeding is the predominant means of **postnatal HIV transmission to infants** and accounts for an estimated 25% to 45% of all MTCT events in breast-feeding populations. HIV RNA and proviral DNA have been detected in both the cell-free and cellular portions of breast milk. Colostrum viral load appears to be particularly high. Risk from breast milk is highest when maternal primary infection occurs within a few months after delivery, and it correlates with degree of viremia and breast milk HIV DNA/RNA levels. In addition, several studies have noted increased transmission among immunosuppressed women with low CD4 cell counts and in women with mastitis and breast abscesses. In areas where infant formula is accessible, affordable, safe, and sustainable, avoidance of breast feeding has represented 1 of the main components of preventing MTCT. Complete avoidance of breast feeding by HIV-infected women has been recommended by the American Academy of Pediatrics (AAP) and Centers for Disease Control and Prevention (CDC) and remains the only means by which prevention of breast-feeding transmission of HIV can be absolutely ensured. In resource-limited countries where local sanitary conditions are poor and access to infant formulas is limited, the World Health Organization (WHO) guidelines recommend **exclusive** breast feeding in combination with **maternal and infant** antiretroviral prophylaxis/therapy

(discussed later). Exclusive breast feeding is associated with a lower risk of postnatal transmission compared to mixed breast feeding and formula feeding.

- D. Premastication.** Possible transmission of HIV by caregivers who premasticate food for infants has been described in 3 cases in the United States. HIV-infected caregivers should be asked and counseled not to premasticate food for infants.
- V. Clinical presentation.** Disease progression after vertical HIV infection is highly variable.
- A. Incubation period.** The onset of symptoms is approximately 12 to 18 months of age for untreated, perinatally infected infants in the United States; however, some may become ill in the first few months of life (15%–20%).
- B. Signs and symptoms.** The newborn is usually asymptomatic or may have low birthweight, weight loss, or failure to thrive (if infected in utero). The frequency of different opportunistic pathogens among HIV-infected children decreased significantly with the application and widespread use of **combination antiretroviral therapy (cART)**. In the pre-cART era, serious bacterial infection, herpes zoster, disseminated *Mycobacterium avium* complex (MAC), PCP, and esophageal candidiasis were common. History of a previous AIDS-defining opportunistic infection was a predictor of developing a new infection. In the cART era, descriptions of opportunistic infections among HIV-infected children have been limited because of the substantial decreases in morbidity and mortality among children receiving cART. Nonspecific features of HIV infection include hepatosplenomegaly, lymphadenopathy, and fever. Neurologic disease may be either static (delayed attainment of milestones) or progressive, with impaired brain growth, failure to reach milestones, and progressive motor deficits. Common computed tomography (CT) scan findings include basal ganglia calcification and cortical atrophy. Cardiac abnormalities include pericardial disease, myocardial dysfunction, and dysrhythmias.
- VI. Diagnosis.** Diagnosis is based on suspicion of infection based on epidemiologic risk or clinical presentation and confirmation by different virologic assays in infants <24 months old or serologic tests (enzyme-linked immunosorbent assay [ELISA] or Western blot) if the infant is >24 months old. Historically, 18 months was considered the age at which a positive antibody assay could accurately distinguish between presence of maternal and infant antibodies. However, using medical record data for a cohort of HIV-uninfected infants born from 2000 to 2007, it was demonstrated that clearance of maternal HIV antibodies occurred later than previously reported (14% of infants remained seropositive after 18 months, 4.3% after 21 months, and 1.2% after 24 months).
- A. All other causes of immunodeficiency must be excluded.** These include both primary and secondary immunodeficiency states. Primary immunodeficiency diseases include DiGeorge and Wiskott-Aldrich syndromes, ataxia-telangiectasia, agammaglobulinemia, severe combined immunodeficiency, and neutrophil function abnormalities. Secondary immunodeficiency states include those caused by immunosuppressive therapy, starvation, and lymphoreticular cancer.
- B. Laboratory studies**
- 1. Virologic assays.** HIV DNA and RNA polymerase chain reaction (PCR) are considered the gold standard for diagnosis of HIV in infants and children <24 months. With the use of these tests, HIV infection may be diagnosed as early as the first day after birth in some infants and by 1 month of age in most infected infants. The **HIV DNA PCR** assay is the preferred diagnostic tool. Amplification of proviral DNA allows detection of cells that harbor quiescent provirus as well as cells with actively replicating virus. Approximately 30% of infants with perinatal HIV infection have a positive DNA PCR in samples obtained by 48 hours of age. A positive result identifies infants who were infected in utero. The test can routinely detect 1 to 10 DNA copies. The test will be positive in 93% and 95% of all infected infants by 2 weeks and 1 month of age, respectively.

A single HIV DNA PCR assay has a sensitivity of 95% and a specificity of 97% for samples collected from infected children 1 to 36 months of age. **HIV RNA PCR** assays detect plasma (cell-free) viral RNA by PCR amplification. These assays are available as either “standard” or “ultrasensitive,” and the lower limit of detection when using the ultrasensitive assays is in the range of 50 to 75 HIV copies per milliliter of plasma. The reported sensitivity for RNA assays ranges from 25% to 40% within the first few days of life to 100% by 6 to 12 weeks of age. HIV RNA assays are commonly used for quantifying “viral load” as 1 predictor of disease progression. They are used in follow-up testing of patients during treatment for HIV infection. The first test result should be confirmed as soon as possible by a repeat virologic test on a second specimen because false-positive results can occur with both RNA and DNA assays. Zidovudine (ZDV) and nevirapine prophylaxis does not appear to alter the diagnostic sensitivity of either HIV DNA or RNA PCR assays. It is also established that HIV DNA PCR but not HIV RNA PCR remains positive even in infected individuals receiving effective therapeutic cART.

Virologic assays should be performed within the first 48 hours after birth, at 14 to 21 days, between 1 and 2 months, and at 4 to 6 months of age. Cord blood should not be used because of the possibility of contamination with maternal blood. A positive virologic test confirmed at 2 weeks of age warrants a change in the recommended ZDV prophylactic monotherapy. HIV infection can be *presumptively* excluded in non-breast-fed infants with 2 or more negative virologic tests, with 1 test obtained at ≥ 14 days of age and 1 obtained at ≥ 4 weeks of age; or 1 negative virologic test obtained at ≥ 8 weeks of age; or 1 negative HIV antibody test obtained at ≥ 6 months of age. PCP prophylaxis is recommended for infants with indeterminate HIV infection status starting at 4 to 6 weeks of age until they are determined to be HIV uninfected or presumptively uninfected. *Definitive* exclusion of HIV infection in a non-breast-fed infant is based on 2 or more negative virologic tests, with 1 obtained at ≥ 1 month of age and one at ≥ 4 months of age; or 2 negative HIV antibody tests from separate specimens obtained at ≥ 6 months of age (in the absence of hypogammaglobulinemia). For both *presumptive* and *definitive* exclusion of HIV infection, the child must have no other laboratory (eg, no positive virologic test results or low CD4 count/percentage) or clinical evidence of HIV infection and not be breast feeding. Many experts confirm the absence of HIV infection in infants with negative virologic tests by performing an antibody test at 12 to 24 months of age to document seroreversion to HIV antibody-negative status. The p24 antigen assay is less sensitive than DNA or RNA PCR and is generally not recommended. Viral HIV culture is labor intensive and poses a significant biohazard risk; in addition, it is less sensitive, less available, and more expensive than the DNA PCR assay. Definitive HIV culture results may take up to 28 days.

- 2. Rapid tests.** A number of rapid tests for detection of HIV antibodies in blood, urine, or oral fluid have been licensed in the United States (www.fda.gov/cber/products/testkits.htm; accessed September 4, 2018). These tests are comparable to enzyme immunoassays (EIAs) in both sensitivity (99.3%–100%) and specificity (98.6%–100%). As with routine EIAs, confirmation of positive results is necessary, but confirmation of a negative result is not. The rapid tests are valuable as a screening tool for pregnant women with no or limited prenatal care or for infants with unknown maternal HIV status. They have the potential to reduce MTCT, with immediate provision of antiretroviral prophylaxis and formula feeding to prevent postnatal transmission. They should be available in all hospitals providing delivery services in the United States. In 2012, a home HIV test (OraQuick In-Home HIV Test, OraSure Technologies, Bethlehem, PA) received US Food and Drug Administration (FDA) approval.

3. **Surrogate markers for disease.** Immunologic abnormalities found in HIV-infected infants include hypergammaglobulinemia, a low CD4⁺ T-lymphocyte count, or a decreased CD4⁺ percentage.

C. **Presence of an acquired immunodeficiency virus–defining condition that indicates cellular immunodeficiency.** The most common AIDS-defining conditions observed among American children with vertically acquired HIV infection are PCP, recurrent bacterial infections, wasting syndrome, esophageal candidiasis, HIV encephalopathy, and cytomegalovirus pneumonia, colitis, encephalitis, or retinitis.

VII. **Management.** Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

A. **Prevention of mother-to-child transmission in resource-rich settings.** In 2012, the CDC presented a framework for the elimination of MTCT HIV transmission. The framework included prevention of HIV infection in women and girls of childbearing potential, identification of HIV infection among them, assurance of adequate preconception care and family planning services, early identification of HIV infection of pregnant women through universal prenatal screening, provision of adequate prenatal care for women with HIV infection, maximal reduction of maternal viral load through appropriate use of antiretroviral (ARV) drugs, cesarean section (CS) delivery when maternal viral load is not maximally suppressed, provision of neonatal ARV prophylaxis and neonatal replacement feeding, and maternal support for lactation suppression. MTCT can take place in utero, during labor, at delivery, and postnatally through breast feeding; however, most transmissions (50%–80%) are believed to occur around labor and delivery. Before the widespread use of MTCT interventions (described later), transmission rates in the United States ranged from 16% to 30%. More recently, MTCT has dropped to approximately 1% (<0.5% in England).

1. **Identification of human immunodeficiency virus infection in pregnant women and newborns.** The CDC guidelines recommend that HIV screening be included in the routine panel of prenatal screening tests for **all pregnant women**. HIV screening is recommended after the patient is notified that testing will be performed unless the patient declines (opt-out screening). **Separate written consent for HIV testing should not be required.** Repeat screening in the third trimester is recommended in certain jurisdictions with elevated rates of HIV infection. The AAP and American College of Obstetricians and Gynecologists (ACOG) issued similar recommendations supporting routine testing and the opt-out strategy. Most guidelines now state that healthcare providers have a **responsibility** not only to offer, but also **to recommend** antenatal HIV testing. The benefits of antenatal HIV testing extend beyond reducing MTCT and include the opportunity to evaluate the infected woman's health status, to initiate cART if required, and to allow the woman to reduce the risk of transmitting HIV to her sexual partner. For a **newborn infant whose mother's HIV infection status is unknown**, the newborn infant's physician should perform rapid HIV antibody testing on the mother or the infant (with appropriate consent). Test results should be reported to the physician as soon as possible to allow effective ARV prophylaxis, ideally within 12 hours. In some states, rapid testing of the neonate is required by law if the mother refuses HIV testing.

2. **Maternal antiretroviral therapy and perinatal human immunodeficiency virus prophylaxis.** HIV-infected pregnant women should receive cART, both for treatment of the mother's HIV infection and for prevention of MTCT of HIV. Virologic suppression to **undetectable viral load** is the goal. Therapy should be initiated as soon as possible, regardless of plasma HIV RNA copy number or CD4⁺ cell count, even in the first trimester. One study from France showed that the transmission rate increased from 0.2% for women receiving cART before conception to 0.4%, 0.9%, and 2.2% for women initiating cART in the first, second, and third trimesters, respectively. Ideally, women initiating such a

regimen during pregnancy should be tested for the presence of ARV resistance. For optimal prevention of perinatal HIV transmission, cART should continue intrapartum, and the infant should receive ARV prophylaxis as recommended. Maternal cART is usually composed of 3 drugs from 2 different classes of ARV. **The use of ZDV alone is not recommended.** Oral ZDV may be included in the antenatal ARV regimen unless there is severe toxicity or documented resistance. ZDV rapidly crosses the placenta, providing protective drug levels for the fetus. Clinical trial data (including the original ACTG 076 trial published in 1994) clearly demonstrate the efficacy and safety of ZDV in reducing MTCT. HIV-infected women with HIV RNA ≥ 400 copies/mL (or unknown HIV RNA) near delivery should receive IV ZDV during labor, regardless of antepartum regimen or mode of delivery. A pregnant woman already on cART that does not include ZDV need not have her regimen changed if her viral load is suppressed. The details of what combination drugs to use in pregnancy are outlined by guidelines released by the US Department of Health and Human Services. These guidelines are updated regularly and are available online (<http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf>; accessed September 4, 2018). Additionally, there is a National Perinatal HIV hotline that can also be accessed at 1-888-448-8765 for questions and guidance. ARV medications are largely safe during pregnancy, even when used in the first trimester. In particular, efavirenz, which was thought to be teratogenic in the past, is not associated with increased risk of neural tube defects according to a registry's data (www.apregistry.com; accessed September 4, 2018) and is considered safe.

- 3. Mode of delivery.** Historical data from individual patient meta-analysis and a randomized controlled trial showed that CS performed before labor and rupture of membranes can reduce MTCT by 50% to 80%. However, in women with plasma HIV RNA ≤ 1000 copies/mL on cART, the overall incidence of transmission of HIV is low regardless of the mode of delivery or duration of membrane rupture, and a further decrease in transmission risk with CS in such women is unclear. In contrast, in women whose viral loads are unknown or remain >1000 copies/mL prior to 38 weeks' gestation (eg, women not taking cART, women presenting late in pregnancy, or women not responding to their current cART regimen), performing CS at 38 weeks is recommended. Elective CS is associated with a higher rate of postpartum complications among HIV-infected women than vaginal delivery; therefore, women with an undetectable viral load should be allowed to have vaginal delivery regardless of the duration of membrane rupture. The use of invasive procedures in labor (eg, amniocentesis, fetal scalp electrodes, operative vaginal delivery, and episiotomy) should be avoided because of the potential risk for enhanced transmission.
- 4. Postdelivery.** Amniotic fluid and blood should be cleaned thoroughly. The infant should be isolated with the same precautions as for hepatitis B (blood and secretion precautions). When the mother has received cART regimen during pregnancy with sustained viral suppression, a 4-week ZDV postexposure prophylaxis regimen is recommended in infants ≥ 35 weeks' gestation. See dose in Chapter 155. However, if the mother did not receive any ARV before onset of labor, ARV was received intrapartum only, cART regimen was received but without sustained viral suppression achieved, or infant is <35 weeks, then a combination ARV prophylaxis regimen is needed for the infant. Currently, this combination regimen consists of 2 drugs: ZDV for 6 weeks and nevirapine for 3 doses during the first week of life (as soon as possible after delivery up to 48 hours of life, 48 hours after first dose, and 96 hours after second dose). Serial virologic studies should be obtained as discussed previously. The HIV-infected mother may be co-infected with other pathogens that can be transmitted from mother to child, such as cytomegalovirus, herpes simplex virus, hepatitis B, hepatitis C, syphilis, toxoplasmosis, or tuberculosis. Infants born to mothers

with such co-infections should undergo appropriate evaluations as indicated to rule out transmission of additional infectious agents. Breast feeding must be discouraged. Both mother and infant should have prescriptions for the HIV drugs when they leave the hospital, and the infant should have an appointment for a postnatal visit at 2 to 4 weeks of age to monitor medication adherence, obtain virologic testing (HIV DNA PCR), and screen the infant for anemia from ZDV.

- B. Prevention of mother-to-child transmission in resource-limited settings.** Similar to CDC, WHO guidelines recommend initiation of cART, if available, for all HIV-infected pregnant or breast-feeding women, regardless of their CD4 cell count, to reduce the risk of MTCT and to treat their own disease. The preferred regimen is a once-daily, fixed-dose combination of tenofovir, lamivudine (or emtricitabine), and efavirenz. Lifelong continuation of cART is recommended for the mother including the whole duration of breast feeding. As for infants, **exclusive breast feeding is recommended**, in addition to oral **ARV prophylaxis**. When infants are born to mothers who had achieved viral suppression on cART or had been regularly taking cART for >4 weeks, ARV prophylaxis for the infant is daily nevirapine for 6 weeks. However, if the infant is born to an HIV-infected mother with a viral load >1000 copies/mL within the 4 weeks prior to delivery, if the mother received no cART or <4 weeks of cART by the time of delivery, or if the mother acquired HIV infection during late pregnancy or breast feeding, then ARV prophylaxis regimen for the infant is daily nevirapine *plus* twice-daily ZDV for 6 weeks, followed by an additional 6 weeks of the same combination regimen or nevirapine alone. If the mother cannot tolerate or declines cART, then the infant should continue nevirapine prophylaxis throughout the duration of breast feeding, until 1 week following breast-feeding cessation.
- C. Treatment of infants with established human immunodeficiency virus infection.** Management of HIV infection is an area of medicine that is changing rapidly. Current treatment recommendations for HIV-infected children are available online (<http://aidsinfo.nih.gov>; accessed February 20, 2018) and are **continuously updated**. Initiation of cART is recommended for all HIV-infected infants <12 months of age as soon as infection is confirmed, irrespective of clinical symptoms, immune status, or viral load. The principal objectives of therapy are to suppress viral replication maximally, to restore and preserve immune function, to reduce HIV-associated morbidity and mortality, to minimize drug toxicity, to maintain normal growth and development, and to improve quality of life. Aggressive therapy is warranted in the youngest children who are at greatest risk of rapid disease progression. In general, cART with at least 3 drugs from at least 2 classes of ARV is recommended. Drug regimens most often used include 2 nucleoside reverse transcriptase inhibitors plus either a boosted protease inhibitor, a nonnucleoside reverse transcriptase inhibitor, or an integrase strand transfer inhibitor. ARV resistance testing (viral genotyping) is recommended before starting treatment, because infected infants may acquire resistant virus from their mothers.
- D. General supportive care**
- 1. Intravenous immunoglobulin.** HIV-infected infants who have recurrent, serious bacterial infections (eg, bacteremia, meningitis, pneumonia) are appropriate candidates for routine intravenous immunoglobulin (IVIG) prophylaxis (400 mg/kg/dose every 28 days). Trimethoprim-sulfamethoxazole prophylaxis may provide comparable protection.
 - 2. Immunization**
 - a. Active immunization.** All routine infant immunizations should be given to HIV-exposed infants. If HIV infection is confirmed, then guidelines for the HIV-infected child should be followed. Children with HIV infection should be immunized as soon as they are age appropriate with inactivated vaccines. Trivalent inactivated influenza vaccine (TIV) should be given annually. In addition, live virus-containing measles-mumps-rubella (MMR) and varicella

vaccines should be given to asymptomatic HIV-infected children without severe immunosuppression (ie, CD4⁺ T-lymphocyte count >15% for at least 6 months in children 1 through 5 years of age). Severely immunocompromised HIV-infected children should not receive measles virus-containing vaccine because vaccine-related pneumonia has been reported. **The quadrivalent measles-mumps-rubella-varicella vaccine should not be administered to any HIV-infected infants, regardless of degree of immunosuppression because of lack of safety data in this population.** Rotavirus vaccine may be given to HIV-exposed and HIV-infected infants. All HIV-infected children should receive a dose of 23-valent polysaccharide pneumococcal vaccine after 24 months of age, with a minimal interval of 8 weeks since the last conjugate pneumococcal vaccine. Infants and children with HIV infection who are 2 months of age or older should receive an age-appropriate series of the meningococcal ACWY conjugate vaccine. The immunologic response to these vaccines in HIV-infected children may be less robust and less persistent than in immunologically normal children. Members of households in which a child has HIV infection can receive MMR vaccine. Yearly influenza immunization is recommended to all household members 6 months of age or older. Immunization with varicella vaccine of siblings and susceptible adult caregivers of HIV-infected patients is encouraged.

b. Passive immunization. HIV-infected children exposed to measles should receive intramuscular immunoglobulin, with the dose depending on the level of immune suppression. Asymptomatic, mildly or moderately immunocompromised patients should receive intramuscular immunoglobulin at a dose of 0.5 mL/kg (maximum 15 mL), regardless of immunization status. Severely immunocompromised HIV-infected patients should receive IVIG at a dose of 400 mg/kg. In addition, children with HIV infection who sustain wounds classified as **tetanus** prone should receive tetanus immune globulin regardless of immunization status. Finally, for **chickenpox** or shingles exposure, HIV-infected children without a history of previous chickenpox or varicella vaccination should receive varicella-zoster immune globulin (VariZIG), especially when they are moderately or severely immunocompromised, within 10 days after exposure. If VariZIG is not available, IVIG should be given.

3. Nutrition. Close nutritional monitoring should be part of the routine care of these children.

4. *Pneumocystis jirovecii* prophylaxis. CDC guidelines state that all infants born to HIV-infected women receive prophylaxis for 1 year beginning at 4 to 6 weeks regardless of CD4⁺ lymphocyte count. If HIV infection is excluded, then prophylaxis can be stopped. The drug of choice for this is trimethoprim-sulfamethoxazole. The need for prophylaxis after 1 year can be determined by the degree of immunosuppression as determined by CD4⁺ T-lymphocyte count.

5. Other aspects of supportive care. Neurodevelopmental supportive services including preschool early intervention programs and school-based developmental disability programs should be offered to all HIV-infected children.

VIII. Prognosis. In developed countries, a bimodal pattern of symptomatic HIV infection has been recognized in children who are not treated. Some children become symptomatic quickly and die before 4 years of age, with a median age of death of 11 months (15%–20%, termed *rapid progressors*). The majority (80%–85%) of untreated children, on the other hand, have delayed onset of milder symptoms and survive beyond 5 years of age (termed *slow progressors*). Only a minority of patients remain asymptomatic by 8 years. Clinical and laboratory factors associated with poor prognosis include being born to mothers with low CD4⁺ counts or high viral load (ie, >100,000 copies/mL), high virus copy number in the cord blood, and early manifestation of symptoms (opportunistic infections, encephalopathy, severe wasting, and hepatosplenomegaly). Use of

cART has substantially reduced both mortality and morbidity and improved quality of life in HIV-infected children. Children with HIV infection acquired through blood transfusion tend to have a prolonged asymptomatic period. In the United States, mortality in HIV-infected children has declined from 7.2 per 100 person-years in 1993 to 0.66 per 100 person-years in 2010 to 2014. In resource-limited developing countries, before the use of cART, the prognosis was much worse, with 1 study showing 89% of the infected children dying by 3 years of age, 10% being in HIV disease category B or C, and only approximately 1% remaining without HIV symptoms. With availability of ARVs to some developing countries, the prognosis is significantly improving. Recent studies from South Africa showed that implementation of a national ARV treatment program resulted in 1- and 3-year mortality rates of 4.6% and 7.7%, respectively.

139 Lyme Disease

- I. **Definition.** Lyme disease is a zoonotic infection and was first reported in 1977, following an unusual cluster of adults and children with oligoarticular arthritis in a certain neighborhood of Lyme, Connecticut. Subsequently, a multisystem disease was described and attributed to the spirochete *Borrelia burgdorferi*. Lyme disease manifests as a spectrum of skin, musculoskeletal, cardiac, and neurologic findings. It is a vector-borne disease that follows the bite of an *Ixodes* tick, usually the black-legged *Ixodes scapularis*, commonly known as the deer tick. Lyme disease has a worldwide distribution and is known to be endemic in the Americas, Europe, Asia, Africa, and Australia. **Prenatal exposure to *B burgdorferi* and the development of gestational borreliosis can result in maternal Lyme disease with placentitis and possible transplacental infection of the fetus and newborn.**
- II. **Incidence.** In 2017, a total of 42,743 cases of Lyme disease were reported and confirmed by the Centers for Disease Control and Prevention with an incidence of 106.6 cases per 100,000 nationwide. No specific data on pregnancy-related Lyme disease is available; however, the number of infected pregnant women in the United States is presumably small. Estimates for active infection after exposure to a deer-tick bite are only 1% to 3%.
- III. **Pathophysiology**
 - A. **Transmission.** The *Ixodes* tick lives a 2-year life cycle consisting of 3 stages: larval, nymph, and adult. The preferred reservoirs are the white-footed field mouse for the larval and nymph tick and the white-tailed deer for the adult tick. The larval stage emerges from eggs in early summer and feeds on previously infected mice, from which they acquire the *B burgdorferi* spirochete. The infected nymph stage emerges in the next spring and is the most likely source of human infection as its activity corresponds to outdoor human activities in spring and summer. The adult tick may infect before laying eggs in summer and dying soon after.
 - B. **Human spirochetemia.** After the tick bite, the incubation period of the spirochetes is 1 to 32 days, with a median of 11 days. The disease is characterized by “early” and “late” manifestations. Early disease occurs in 2 stages (early localized and early disseminated). Spirochete dissemination is presumed to be facilitated by the surface of the organism binding to human plasminogen and subsequently binding to integrins, matrix glycosaminoglycans, and extracellular matrix proteins. These complexes may explain the propensity of the spirochetes to localize to collagen fibrils in the extracellular matrices of the heart, nervous system, and joints. Late Lyme disease occurs months to a year or more after dissemination.

C. **Placentitis and transplacental disease.** Before 1990, a number of case reports had confirmed the transplacental passage of *B burgdorferi* by identifying spirochetes in placental tissues, umbilical vessels, fetal brain, heart, spleen, kidneys, bone marrow, liver, and adrenal glands. However, several recent clinical, serologic, and epidemiologic studies have failed to confirm a causal association between Lyme disease in pregnancy and adverse fetal outcomes, congenital malformations, or cardiac defects.

IV. **Risk factors.** Maternal Lyme disease is a result of exposure to deer ticks in known endemic areas. If an expectant mother presents with a history of outdoor exposure or has dogs or cats in the home, a known tick embedment, or cutaneous lesions consistent with early disease, **prompt antibiotic therapy lessens the risk for transplacental transmission of spirochetes.** There are no other known predilections to Lyme disease related to pregnancy.

V. Clinical presentation

A. Maternal

1. **Early localized.** The cutaneous stage begins with a papule at the site of the tick bite, becoming an annular erythematous migrating rash (also known as erythema migrans) with central clearing. Rash may last 3 to 4 weeks and is nonpruritic and painless. The early stage is often accompanied by low-grade fever, evanescent arthralgia, myalgia, fatigue, headache, and neck muscle stiffness.
2. **Early disseminated.** This is most often characterized by multiple erythema migrans several weeks after the tick bite. This stage is accompanied by worsening fatigue, severe malaise, and migratory musculoskeletal pain. Systemic disease affecting target organs becomes more apparent, namely as mono- or pauciarticular arthritis and cardiac manifestations, such as heart block. Nervous system involvement can include lymphocytic meningitis or cranial nerve palsies.
3. **Late Lyme disease.** Months after exposure to disease, arthralgia and pauciarticular arthritis persist and recur. The knees are the most often affected joint with marked swelling, but with pain that is less than that of rheumatoid-type arthritis. On rare occasions, chronic neurologic conditions of encephalopathy, peripheral neuropathy, demyelination, or dementia have been reported.

B. Neonatal

1. **No specific clinical presentation of Lyme disease in the newborn has been described as a result of transplacental transmission.** Of importance is the maternal history of disease and whether or not the mother has been adequately treated. Placental pathology in suspected cases may offer information that would prompt testing and perhaps treatment for at-risk neonates. A case of postnatal transmission has been reported recently in a 2-week-old female infant presenting to the emergency department with 5-cm annular area of abdominal wall erythema with central clearing that was confirmed to be neonatal Lyme disease; it developed after a tick bite at 1 week of age. The rash resolved with treatment, and the patient was well at her 3-month well-child visit.
2. **Congenital Lyme disease as a clinical entity has been reviewed and found not to be substantive.** In particular, congenital heart defects have been reviewed in large follow-up studies of mothers with positive *B burgdorferi* serology, and no association was found by multiple researchers. Walsh et al searched the worldwide literature for obstetric associations to Lyme disease and came up with the following conclusions:
 - a. **Women who are seropositive at conception** have no increased incidence of adverse pregnancy.
 - b. **Women who develop a confirmed diagnosis** of Lyme disease in pregnancy should receive appropriate antimicrobial treatment.
 - c. **Women with Lyme disease in pregnancy** and who have been appropriately treated have shown no association with specific adverse fetal outcomes.

- VI. Diagnosis.** Laboratory testing for Lyme disease should be done if careful history taking and physical examination strongly suggest active disease.
- A. Early localized disease.** Diagnosis is made largely on clinical grounds (history of exposure, rash, and symptoms). Serologic tests are not recommended secondary to late development of antibodies to *B burgdorferi*.
- B. Early disseminated disease.** Dissemination of the disease is diagnosed clinically as described earlier. If rash is not present, serologic studies should be obtained.
- 1. Enzyme immunoassay.**
 - 2. Immunofluorescent antibody assay.**
 - 3. If both tests are negative, no further testing is needed, and clinical reevaluation for other conditions is indicated.** Screening tests are known to have high false-positive rates.
 - 4. If either is positive, it should be followed by:**
 - a. Western immunoblot standardized for antibodies to *B burgdorferi*.** Subsequently, positive Western blot assays should include specific immunoglobulin (Ig) G and IgM. If the Western blot assays are negative, the false-positive enzyme immunoassay (EIA) or immunofluorescent antibody assay (IFA) testing suggests other spirochetal diseases, such as syphilis, leptospirosis, an intercurrent viral disease (eg, Epstein-Barr), or an autoimmune condition such as lupus erythematosus.
 - b. Late disease.** If late disease is suspected, only a positive IgG immunoblot is needed.

VII. Management

A. Maternal

- 1. Early localized disease. Note:** Doxycycline is the drug of choice for Lyme disease. It can be used in children of any age. Doxycycline has not been adequately studied during pregnancy to make a recommendation regarding its use in the pregnant woman.
 - a. Amoxicillin**
 - b. Cefuroxime axetil (alternative)**
- 2. Early disseminated or late disease**
 - a. Oral antibiotic therapy is considered adequate.**
 - b. Parenteral antibiotics for a maximum of 4 weeks** are only indicated in patients with symptoms of increased intracranial pressure and pleocytosis in cerebrospinal fluid. Routine lumbar puncture is not recommended.

B. Newborn

- 1. Treat if infant is thought to be symptomatic at birth** especially if mother is confirmed with Lyme disease but has not been adequately or appropriately treated. **Doxycycline is the drug of choice.** Amoxicillin, cefuroxime, and azithromycin (for a patient unable to take a β -lactam or doxycycline) are alternatives. Obtain infectious disease consultation before starting treatment.
- 2. If the infant is asymptomatic at birth,** given low risk for active disease, current recommendations do not call for empirical treatment, especially if the mother was appropriately treated during pregnancy. Placental pathology may offer information helpful in the decision of whether or not to treat; consultation with an infectious disease specialist is recommended.
- 3. Lyme disease is not a contraindication for breast feeding.** No evidence is known for the passage of *B burgdorferi* to the infant through breast feeding.

- VIII. Prognosis.** Prompt diagnosis and antibiotic therapy are essential for the pregnant woman; however, there is no evidence that Lyme disease during pregnancy causes harm to the developing fetus.

140 Meningitis

- I. **Definition.** Neonatal meningitis is an infection of the meninges and central nervous system (CNS) in the first month of life. This is the most common time of life for meningitis to occur.
- II. **Incidence.** The incidence is approximately 0.16 to 0.45 per 1000 live births in developed countries. The incidence may be higher in underdeveloped countries.
- III. **Pathophysiology.** In most cases, infection occurs because of hematogenous seeding of the meninges and CNS. After attaching to the endothelium of the cerebral microvasculature and choroid plexus, bacteria can enter the cerebrospinal fluid (CSF) by several mechanisms including transcellular movement across the endothelial cell (eg, *Escherichia coli*), paracellular movement by disruption of intercellular tight junctions, and through transport across the blood–brain barrier within infected phagocytes (so-called “Trojan horse mechanism,” eg, *Listeria monocytogenes*). Inflammatory mediators are then released into the CSF in reaction to bacterial products, resulting in meningitis and increased permeability of the blood–brain barrier. In cases of CNS or spinal anomalies (eg, myelomeningocele), there may be direct inoculation by flora on the skin or in the environment. Neonatal meningitis is often accompanied by **ventriculitis**, which makes resolution of infection more difficult. There is also a predilection for **vasculitis**, which may lead to hemorrhage, thrombosis, and infarction. Subdural effusions and brain abscess may also complicate the course.

Most organisms implicated in neonatal sepsis also cause neonatal meningitis. Some have a definite predilection for CNS infection. **Group B *Streptococcus* (GBS)** (especially type III) and the **gram-negative rods** (especially *E coli* with K1 antigen) are the **most common causative agents**. GBS and *E coli* account for approximately two-thirds of all cases of neonatal meningitis. **Galactosemia** should be considered if *E coli* is the causative agent in late-onset meningitis. Multidrug-resistant *E coli* (eg, extended-spectrum β -lactamase producing) is an emerging problem in some neonatal units. Other causative organisms include *L monocytogenes* (serotype IVb), other streptococci (enterococci, *Streptococcus pneumoniae*), other gram-negative enteric bacilli (*Klebsiella*, *Enterobacter*, and *Serratia* spp), and rarely, *Neisseria meningitidis*. In the very low birthweight (VLBW) infant, coagulase-negative staphylococci (CONS) need to be considered as causative organisms in bacterial meningitis.

With CNS anomalies involving open defects or indwelling devices (eg, ventriculoperitoneal shunts), staphylococcal disease (*Staphylococcus aureus* and *Staphylococcus epidermidis*) is more common, as is disease caused by other skin flora, including streptococci and diphtheroids. Many unusual organisms, including *Ureaplasma*, fungi, and anaerobes, have been described in case reports of neonatal meningitis.

- IV. **Risk factors.** Risk factors for neonatal meningitis are similar for neonatal sepsis and include low birthweight, prematurity, premature or prolonged rupture of membranes, septic or traumatic delivery, fetal hypoxia, maternal peripartum infection, and galactosemia. The characteristics of some bacteria make them more virulent, especially for neonates (eg, capsular polysaccharide of GBS type III, *E coli* K1, and *L monocytogenes* serotype IVb all contain sialic acid in high concentrations). Infants with CNS defects necessitating ventriculoperitoneal shunt procedures also are at increased risk.
- V. **Clinical presentation.** The clinical presentation is usually nonspecific and indistinguishable from that caused by sepsis. Meningitis must be excluded in any infant being evaluated for sepsis or infection. **Signs and symptoms of meningitis include** temperature instability (the most common, found in 60% of the cases), lethargy, irritability, poor tone, seizures, feeding intolerance, vomiting, respiratory distress, apnea, or cyanotic episodes. Term infants are more likely to have fever, whereas preterm infants are more likely to have hypothermia. Seizures, often focal, can be the presenting

manifestation in up to 50% of the cases. Late manifestations of meningitis include a full or bulging anterior fontanelle and coma. Syndrome of inappropriate antidiuretic hormone may accompany meningitis.

VI. Diagnosis

A. Laboratory studies. The clinical presentation of bacterial meningitis in the neonate is nonspecific; therefore, neonates with suspected bacterial meningitis should undergo a full sepsis evaluation including a complete blood count with differential, blood culture, urine culture (if >3–5 days), and lumbar puncture (LP) to obtain CSF for Gram stain, culture, protein, glucose, and cell count. CSF examination is critical in the investigation of possible meningitis and the only way to confirm the diagnosis. Approximately 15% to 50% of all infants with positive CSF cultures for bacteria have negative blood cultures. Conversely, initial CSF findings may be questionable, and a repeat LP 24 to 48 hours later will provide definitive diagnosis (when the meninges are inflamed, the second LP always shows a pleocytosis and other parameters consistent with the diagnosis of meningitis). The technique for obtaining CSF fluid and CSF normal values are discussed in Chapter 38.

- 1. Culture and Gram stain.** A CSF culture is the gold standard for the diagnosis of bacterial meningitis. It may be positive in association with a normal or minimally abnormal CSF analysis. However, CSF culture may be negative in some neonates with bacterial meningitis whose LP was delayed until after antibiotic administration (eg, critically ill infants). **Gram-stained smear** can be helpful in making a more rapid definitive diagnosis; however, the absence of organisms on Gram stain does not exclude the diagnosis.
- 2. Cerebrospinal fluid pleocytosis is variable.** There are usually more cells with gram-negative rods than with GBS disease. Normal values range from 0 to 30 white blood cells (WBCs), some of which may be polymorphonuclear cells. Traumatic LP (>500 red cells/mm³) occurs in up to 40% of the attempts, and adjustment of CSF WBCs down to account for increased red cells does not improve diagnostic utility of the CSF examination. Reactive pleocytosis may be seen secondary to CNS hemorrhage.
- 3. Decreased cerebrospinal fluid glucose.** CSF glucose level must be compared with serum glucose level. Normal CSF values are one-half to two-thirds of serum values. Typically, neonates with meningitis have a CSF glucose level of <20 (preterm) or <30 (term) mg/dL.
- 4. Cerebrospinal fluid protein** is usually elevated (>100 [term] or >150 [preterm] mg/dL), although normal values for infants, especially premature infants, may be much higher than in later life, and the test may be confounded by the presence of blood in the specimen.
- 5. Cerebrospinal fluid biomarkers.** A number of CSF biomarkers have been examined for differentiating bacterial meningitis from viral meningitis and noninfectious origins, with some encouraging results. These CSF biomarkers include tumor necrosis factor- α , interleukin (IL)-1 β , IL-6, IL-8, IL-12, IL-17, procalcitonin, and lipocalin, among others. However, the clinical utility of using these markers is currently limited.

B. Imaging studies are recommended to detect the complications of meningitis, especially when the clinical course is complicated. Infection with certain microorganisms such as *Citrobacter koseri*, *Serratia marcescens*, *Proteus mirabilis*, and *Enterobacter sakazakii* predispose for the development of brain abscesses. The most useful and noninvasive method of imaging is **ultrasonography** (especially early in the course when the infant is critically ill), which provides information regarding ventricular size, inflammation (echogenic strands), and the presence of hemorrhage. Contrast-enhanced **computed tomography (CT)** or **magnetic resonance imaging (MRI)** is needed later in the course of the illness; they are useful in detecting cerebral abscesses, areas of infarct or encephalomalacia, and degree of cerebral cortical and white matter atrophy. **MRI is preferred over CT** because it

provides better detail, optimizes assessment of injury to white matter, and avoids radiation exposure.

VII. Management. General supportive measures such as ventilation/oxygenation, cardiovascular support, intravenous dextrose, and anticonvulsant therapy are considered essential components of managing the neonate with bacterial meningitis. Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

A. Drug therapy. For drug dosages and other pharmacologic information, see Chapter 155. (*Note:* Dosages for ampicillin, nafcillin, and penicillin G are **doubled** when treating meningitis.)

- 1. Empirical therapy.** Optimal antibiotic selection depends on culture and sensitivity testing of the causative organisms. **Ampicillin** and **gentamicin** are usually started as empirical therapy for suspected early sepsis. If meningitis is suspected, **cefotaxime** should be added. High rates of ampicillin resistance among *E coli* isolates and a link between maternal intrapartum ampicillin and *E coli* resistance have been well documented in VLBW infants. For hospitalized infants with late-onset presentation, empiric therapy consists of **vancomycin** (to cover gram-positive organisms, especially CONS and *S aureus* [methicillin sensitive and methicillin resistant]) and **gentamicin** with the addition of **cefotaxime** when CSF findings suggest meningitis (extended coverage of gram-negative rods). Lastly, for the infant <60 days who is coming from home to the emergency department, the empiric therapy consists of **ampicillin** and **cefotaxime**. If cefotaxime is unavailable, alternative agents include cefepime or ceftazidime.
 - 2. Gram-positive meningitis (group B *Streptococcus* and *Listeria*).** **Penicillin** or **ampicillin** is the drug of choice. Gentamicin (for **synergism**) can be added until sterility of the bloodstream and CSF has been documented. Monotherapy is continued for 14 days.
 - 3. Staphylococcal disease.** Because of the increased prevalence of MRSA in the nosocomial setting, **vancomycin** should be substituted for ampicillin as initial coverage. For MSSA, therapy can be switched to nafcillin. If the CSF is persistently positive, consideration should be given to adding rifampin for synergy.
 - 4. Gram-negative meningitis.** Most clinicians would use **ampicillin plus cefotaxime plus an aminoglycoside** as initial therapy. Further therapy is dictated by sensitivity results. "Double" gram-negative coverage is maintained for 10 days after sterility of CSF. Subsequently, cefotaxime can be continued alone to complete 21 days of therapy. There is an emerging problem with multidrug-resistant enteric microorganisms (especially *E coli*, *Klebsiella pneumoniae*); for this situation, the drug of choice is **meropenem**. (See Chapter 155.) Studies have shown no advantage for intrathecal or intraventricular gentamicin.
 - 5. Repeat lumbar puncture 48 to 72 hours into antibiotic therapy** is recommended to document CSF sterilization. Persistence of infection may indicate a focus, such as obstructive ventriculitis, subdural empyema, or multiple small-vessel thrombi. Infants with repeat positive CSF cultures after initiation of appropriate antibiotics are at risk for complications as well as a poor outcome. In general, approximately 3 days are required to sterilize the CSF in infants with gram-negative meningitis, whereas in gram-positive meningitis, sterilization usually occurs within 36 to 48 hours. External ventricular drainage may be indicated in certain cases complicated by ventriculitis. Treatment should continue until 14 days after cultures are negative or for 21 days, whichever is longer.
 - 6. Adjunctive therapy.** Contrary to childhood meningitis, dexamethasone does not seem to improve the outcome of neonatal meningitis. Other therapies focusing on enhancing the immune system in the newborn, such as hematopoietic growth factors or intravenous immune globulins, do not seem to help either.
- B. Supportive measures and monitoring for complications.** Head circumference should be measured daily, and neurologic examination should be performed

frequently. Electroencephalogram (EEG) is important to detect seizures and to assess background cerebral function. Imaging studies (especially MRI) are helpful for prognosis and guiding the length of therapy. Hearing and vision evaluation should be done in all neonates who develop meningitis. All of them should undergo long-term neurodevelopmental follow-up.

- VIII. Prognosis.** The **mortality rate** has decreased recently to 3% to 13%, compared with 25% to 30% from earlier decades. There is a high incidence (~20%–40%) of neurodevelopmental sequelae in survivors, and this figure has not changed much over the years. Major neurologic sequelae include cerebral palsy, hypertonia, hypotonia, shunt-dependent hydrocephalus, blindness, deafness, and mental retardation. Factors predictive of death or serious sequelae include preterm birth, gram-negative etiology (as opposed to gram positive), neutropenia, seizures persisting >72 hours after hospitalization, focal neurologic deficits, initial inotropic support, delayed sterilization of the CSF, low-voltage background on EEG, and parenchymal lesions (abscess, thrombi, infarcts, and encephalomalacia) on neuroimaging studies.

141 Methicillin-Resistant *Staphylococcus aureus* Infections

- I. Definition.** Infection with methicillin-resistant *Staphylococcus aureus* (MRSA) (**clustered gram-positive cocci**) causes a variety of localized and invasive purulent infections and toxin-mediated syndromes such as toxic shock syndrome and staphylococcal scalded skin syndrome (SSSS). MRSA infections used to be limited to healthcare facilities and were strictly nosocomial; however, a significant increase in community-acquired MRSA (CA-MRSA) has been seen in the past 10 to 15 years. The separation between healthcare-related MRSA and CA-MRSA is becoming less distinct, as CA-MRSA is becoming more virulent and causing significantly more healthcare-associated infections.
- II. Incidence.** The methicillin-sensitive *S aureus* normally colonizes the nose, umbilicus, and groin area by 1 week of age, with a colonization rate of 30% to 70%. Maternal anogenital colonization with MRSA ranges from 0.5% to 10.4%, with small risk for early-onset disease in the newborn. Case reports have described maternal vertical transmission of MRSA from maternal chorioamnionitis, by nasal colonization, and through breast feeding. Horizontal transmission from siblings and other family members has been documented as well. There are several documented outbreaks of invasive CA-MRSA that developed in healthy newborn infants discharged from normal newborn nurseries as well as neonatal intensive care units (NICUs). **The majority of MRSA infections in the NICU are of late onset.** According to neonatal data reported from the National Nosocomial Infections Surveillance System for the years 1995 to 2004, MRSA accounted for 23% of all hospital-associated *S aureus* infections. The incidence of MRSA infections increased by 308% during the study period (from 0.7 per 100,000 patient-days in 1995 to 3.1 in 2004). In a recent meta-analysis of 18 studies reporting data from 1999 to 2011, the prevalence of MRSA colonization at admission to a NICU or pediatric intensive care unit was 1.9%, and the acquisition rate was 4.1%. Neonates who were admitted to the NICU after discharge from the birth hospitalization were more likely to be colonized than those who had never left the NICU (5.8% vs 0.2%). The risk of MRSA infection during

hospitalization is increased 24-fold among colonized versus noncolonized patients. Another study that involved 1320 NICU patients found a MRSA colonization rate of 4% within 7 days of NICU discharge. Hand carriage of MRSA in healthcare personnel working in NICUs is estimated at 8%.

- III. Pathophysiology.** If the newborn infant is exposed to MRSA, whether from the community or the hospital, then he or she will be colonized with more virulent strains that are more likely to cause invasive disease. MRSA has specific virulence factors that make it more invasive than methicillin-sensitive *S aureus*. These include staphylococcal chromosome cassette (SCC) *mecA*, Panton-Valentine leukocidin (PVL), and staphylococcal enterotoxins. The SCC *mecA* has the genes that encode antibiotic resistance. PVL genes lead to the production of cytotoxins that form pores in the cellular membrane and cause tissue necrosis and cell lysis. Exfoliative toxins A and B secreted by *S aureus* are implicated in SSSS.
- IV. Risk factors.** Include overcrowding, inconsistent hand washing, invasive procedures (eg, central lines, endotracheal intubations, nasogastric tubes), prematurity, low birth-weight and very low birthweight (VLBW), multiple gestation, the practice of kangaroo (skin-to-skin) mother care, a high MRSA colonization rate, and prolonged hospital stay. Interestingly, a recent study from Brazil showed maternal skin-to-skin contact for 60 minutes twice daily for 7 days between MRSA-colonized NICU infants and their mothers (MRSA negative) resulted in a 53.8% decolonization rate compared to a rate of 22.4% in the control group (risk ratio = 2.27; number needed to treat = 4). The decolonization presumably occurred due to “bacterial interference,” through which the mother’s sensitive and nonpathogenic bacteria replaced the infant’s MRSA.
- V. Clinical presentations.** Invasive MRSA disease is likely to be preceded by colonization (skin, umbilicus, and nasopharynx). The source of the bacteria could be a healthcare worker, another patient, equipment, or a family member.
- A. Bloodstream infections.** These are usually catheter related. Common clinical signs are nonspecific and include apnea or hypoxia, fever, elevated C-reactive protein, and leukocytosis. The infant needs to be examined repeatedly and meticulously for subtle clues of focal infection (eg, phlebitis, pustulosis).
- B. Septic arthritis and osteomyelitis.** *S aureus* is the primary cause of septic arthritis and osteomyelitis in the neonate. Symptoms are nonspecific, such as poor feeding or increased irritability. Signs include soft tissue swelling and erythema.
- C. Endocarditis.** Neonates with congenital heart disease and percutaneous central catheters are at a higher risk for endocarditis.
- D. Skin and soft tissue infections.** *S aureus* is the most common pathogen causing pustulosis and cellulitis in the neonate. MRSA has virulence factors that contribute to the pathogen’s ability to damage the neonatal skin that is already compromised.
- E. Conjunctivitis.** See Chapter 58.
- F. Pneumonia.** Pneumonia can be primary or associated with ventilator therapy. The course is frequently complicated by alveolar necrosis, pneumatocele formation, and pleural empyema.
- G. Surgical site infections.**
- H. Meningitis and brain abscesses.** Uncommon but have been reported.
- I. Staphylococcal scalded skin syndrome, also known as Ritter disease** in newborns, is a very rare complication of methicillin-sensitive *S aureus* or MRSA infection. It is characterized by rash all over the body and peeling off of the skin, which resolves without scarring within 10 days of treatment. Epidermolytic lesions in pressure zones, with a positive Nikolsky sign, and palmoplantar exfoliative erythema are characteristic signs of SSSS.
- VI. Diagnosis.** The **gold standard for diagnosing bloodstream infection is a positive blood culture.** Diagnosing arthritis and osteomyelitis can be challenging. In addition to a blood culture, the workup should include a joint aspirate, bone culture (if surgical debridement is done), radiography, and possibly magnetic resonance imaging. Echocardiography (to diagnose endocarditis) is strongly recommended in

infants with >1 positive blood culture. For skin and soft tissue infections, incision and drainage, with subsequent Gram stain and culture of aspirated fluid, is recommended. Molecular typing is important in the identification and management of MRSA NICU outbreaks.

VII. Management

A. Eradication of colonization. Adult intensive care unit studies demonstrated that eradication of MRSA colonization using a combination of 5 days of intranasal mupirocin and 3 daily chlorhexidine baths resulted in reducing MRSA infections. There are no randomized studies in neonates showing similar efficacy; however, mupirocin (+/- chlorhexidine) has been used effectively in controlling outbreaks of MRSA in NICU populations. Mupirocin resistance is an increasing problem; routine mupirocin testing is an important factor for MRSA decolonization strategies. In cases of mupirocin resistance, retapamulin ointment 1% has been used for nasal decolonization.

B. Antibiotic therapy. Vancomycin is the first-line therapy for MRSA, and many NICUs with endemic MRSA use vancomycin as an empirical therapy for late-onset sepsis while awaiting culture results. In cases of vancomycin-intermediate *S aureus* (VISA) or vancomycin allergy, linezolid and clindamycin have been used effectively. Daptomycin is another antibiotic that could be used. Treatment duration depends on the specific infection. For **skin and soft tissue infections** and **bacteremia**, a 7- to 10-day course is generally appropriate. In cases of **endocarditis** and **osteomyelitis**, 6 to 8 weeks of treatment are necessary. In patients with **extensive disease with persistently positive blood cultures** despite therapeutic doses of vancomycin, both rifampin and gentamicin can be used for synergy. Mupirocin may be adequate for mild cases of localized neonatal pustulosis in the well-appearing full-term infant.

VIII. Prevention

A. Hand hygiene. The Centers for Disease Control and Prevention recommend using an alcohol-based hand sanitizer before touching patients, after touching patients, after removing gloves, and after touching the patient care environment and equipment due to the ability of MRSA to survive on inanimate objects. Alcohol-based hand sanitizers greatly improve compliance with hand hygiene policies (see Chapter 25).

B. Controlling outbreaks (see Table 141-1). During an outbreak, many measures are instituted concurrently. Hand hygiene should be emphasized to all personnel and visitors. Chlorhexidine 4% may be used for cleansing of the umbilical stump (has been reported to reduce the risk of omphalitis in resource-limited countries). Other measures recommended include reinforcement and monitoring of hand hygiene, alleviating overcrowding and understaffing, colonization surveillance cultures of newborn infants at admission and periodically thereafter, use of contact precautions for colonized or infected infants, and cohorting of colonized or infected infants and their caregivers. For hand hygiene, soaps containing chlorhexidine or alcohol-based hand rubs are preferred during an outbreak. Decolonization of colonized/infected patients with mupirocin and chlorhexidine baths may reduce patient-to-patient transmission. Colonized healthcare professionals epidemiologically implicated in transmission should receive decolonization therapy, but eradication of colonization may not occur. Use of molecular typing is an integral part of control because it can determine the ongoing transmission of a particular clone. Passive protection of neonates by using monoclonal antibodies or pooled human immunoglobulin G has been studied but does not seem to be efficacious. Efforts to develop an effective *S aureus* vaccine are ongoing.

IX. Outcome. Mortality from invasive MRSA infection (eg, bacteremia, meningitis) ranges from 11.9% for all NICU patients to 26.1% for VLBW infants. Survivors are at risk for neurodevelopmental impairment.

Table 141–1. GUIDELINES FOR OUTBREAKS OF METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS IN THE NICU

Recommendation Type, Rating Category ^a	Consensus Recommendation
Hand hygiene	
IA	A waterless, alcohol-based hand hygiene product should be made available and easily accessible; soap and water should be used if hands are visibly soiled.
IA	Monitoring of hand hygiene is a key component in preventing MRSA transmission in the NICU. Direct observations of hand hygiene practices on a regular basis, or consistent enforcement of proper hand hygiene (eg, use of a unit guard, providing feedback), contribute to increased rates of compliance.
Cohorting and isolation	
IA	MRSA-positive infants should be placed under contact precautions and cohorted (placed in a designated room or area), as should the supplies used in the care of these infants.
IA	Gloves and gowns should be worn when caring for or visiting infants known or suspected to be MRSA positive.
IA	Masks should be worn for aerosol-generating procedures, such as suctioning. The environment in the area of the infant should be kept clean and neat at all times.
NR/UI	Disposal of infant supplies used in the care of the MRSA-positive cohort should be decided by the institution's infection control experts.
IA	Whenever possible, nurses should be cohorted (designated exclusively) for care of MRSA-positive infants. Other HCWs should also be cohorted to the maximum extent allowed by the institution's resources.
II	If cohorting of nurses is not possible, nurses should care for the noncohorted patients before working with the cohorted neonates, when feasible.
II	The number of people (including HCWs and visitors) who enter a room or area designated for MRSA-positive infants should be limited to the minimum possible.
II	Cohorting of infants should be maintained until the last infected or colonized infant has been discharged from the NICU.
Neonatal surveillance cultures	
IB	Infants in the NICU should be screened periodically to detect MRSA colonization. The frequency of screening should increase (eg, to once per week) when clusters of colonization are detected; after evidence suggests a halt in transmission, it may decrease to a lower frequency (eg, to once per month) until the investigation is over.
IA	Although cultures of swab specimens from multiple body sites, including nares, throat, rectum, and umbilicus, have been used to detect MRSA colonization, culture of nasal or nasopharyngeal specimens alone is sufficiently sensitive to detect MRSA colonization in neonates.

(Continued)

Table 141–1. GUIDELINES FOR OUTBREAKS OF METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* IN THE NICU (CONTINUED)

Recommendation Type, Rating Category ^a	Consensus Recommendation
Screening of HCWs	
IB	Screening of HCWs in response to a cluster of MRSA colonization or infection in the NICU should be performed only to corroborate or refute epidemiologic data that link an HCW to transmission.
Decolonization	
IB	Mupirocin may be used for decolonization of neonates and/or HCWs if deemed necessary by the affected institution (off-label use).
Environmental cultures	
IA	Environmental cultures should be performed in response to a cluster of MRSA colonization or infection in the NICU only to corroborate or refute epidemiologic data that link an environmental source to transmission.
Molecular analysis	
IA	When investigating an outbreak, molecular analysis with pulsed-field gel electrophoresis or a comparable molecular epidemiologic tool should be performed to assess the relatedness of strains found in NICU patients, HCWs, and the environment.
IB	If the hospital cannot perform genotyping in-house, then the isolates should be sent to a suitable laboratory for molecular analysis.
Communication	
II	Open communication between regional NICUs is essential to prevent spread between NICUs at different institutions, particularly when an infant is transferred from one NICU to another.
II	In the intake of a transferred patient, the receiving facility should be able to determine whether the infant has been screened previously for MRSA, and if so, the date, specimen source, and result of the culture.
II	In the intake of a transferred patient, the receiving facility should be able to determine whether the transferring institution currently knows of any MRSA-positive infants in its NICU.
IB	The receiving facility should consider isolation and screening of any infant transferred from another NICU, regardless of the transferring institution's MRSA status.
II	Standardized instruction sheets describing methods to prevent transmission of MRSA should be developed as a resource for parents and visitors of infants in NICUs in which MRSA has been detected.
Regulation	
IA	Overcrowding increases the likelihood of MRSA transmission in the NICU; institutions should adhere to all appropriate licensing requirements.
IA	Agency HCWs should be oriented to and monitored periodically for compliance with the institution's infection control and hand hygiene procedures.

(Continued)

Table 141–1. GUIDELINES FOR OUTBREAKS OF METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* IN THE NICU (CONTINUED)

Recommendation Type, Rating Category ^a	Consensus Recommendation
Regulation (cont.)	
II	Logs of shifts worked by agency HCWs should be updated frequently to ensure that, in the case of an epidemiologic investigation, transmission links to these staff may be evaluated.
IC	Hospitals must comply with all local and state regulations regarding the reporting of MRSA in NICUs.
Hospital and public health collaboration	
II	Hospital officials should collaborate with state and local public health officials to conduct surveillance for MRSA in NICUs, facilitate inter-institutional communication and coordination of prevention activities, and provide laboratory support to allow detection of shared MRSA clones among NICUs in multiple institutions.

MRSA, methicillin-resistant *Staphylococcus aureus*; NICU, neonatal intensive care unit; HCW, health care worker.

^aRating categories are defined as follows. **IA:** Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies. **IB:** Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale. **IC:** Required by state or federal regulations, rules, or standards. **II:** Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale. **NR/UI:** No recommendation or unresolved issue for which evidence is insufficient or no consensus regarding efficacy exists. Definitions from Boyce et al.

Reproduced with permission from Gerber SI, Jones RC, Scott MV, et al: Management of outbreaks of methicillin-resistant *Staphylococcus aureus* infection in the neonatal intensive care unit: a consensus statement, *Infect Control Hosp Epidemiol.* 2006 Feb;27(2):139-145.

142 Parvovirus B19 Infection

- I. Definition.** Human parvovirus B19 (B19V) is a small, single-stranded, nonenveloped DNA virus in the family Parvoviridae, genus *Erythrovirus*.
- II. Incidence.** Infection with B19V is common worldwide. Infection occurs mostly among school-aged children where the major manifestation is **erythema infectiosum** (also called **fifth disease**). Infection in adults can be entirely asymptomatic or may result in **polyarthropathy syndrome** and/or **petechial, papular-purpuric gloves-and-socks syndrome**. The prevalence of immunoglobulin G (IgG) antibodies directed against B19V ranges from 15% to 60% in children 6 to 19 years old. About 35% to 45% of women of childbearing age do not possess protective IgG antibodies against B19V and therefore are susceptible to primary infection. The incidence of acute B19V infection in pregnancy is 3.3% to 3.8%. Annual seroconversion rates in pregnant women in the United States range from 1% to 1.5%. The incubation period is between 4 and 14 days but can be as long as 21 days.

- III. Pathophysiology.** The pathogenesis of B19V infection is related to its tropism for erythroid progenitor cells. Infection and lysis of these cells make **B19V a potent inhibitor of hematopoiesis**. The cellular receptor for B19V is globoside or P-antigen, which is found on erythrocyte progenitor cells, synovium, placental tissue, fetal myocardium, and endothelial cells. The B19V-associated red blood cell aplasia is related to caspase-mediated apoptosis of erythrocyte precursors. Infection with B19V is usually acquired through respiratory droplets, but the virus can also be transmitted by blood or blood products and vertically from mother to fetus. In children and adults, viremia develops 2 days after exposure and reaches its peak at approximately 1 week. During the phase of viral replication and shedding, the patient is generally asymptomatic. When the typical rash (characterized by a “slapped cheek” appearance on the face and a “lace-like” erythematous rash on the trunk and extremities) or arthralgias develop, the patient is no longer infectious to others. Symptoms of the papular-purpuric gloves-and-socks syndrome can occur in association with viremia and before development of antibody response, and affected patients should be considered infectious. Symptoms during pregnancy are nonspecific and include a flulike syndrome with a low-grade fever, sore throat, generalized malaise, and headache. The fetus may become infected during the maternal viremic stage. Because of active erythropoiesis in the fetus with a shortened red cell life span, marked fetal anemia, high-output cardiac failure, and fetal hydrops may develop. Myocarditis, and less often fetal hepatic infection, may contribute to fetal cardiac failure. Teratogenicity from B19V has been described in case reports; also, one study found high prevalence of trisomy in pregnancy loss ascribable to B19V/erythrovirus infection. Despite that, B19V is considered nonteratogenic based on large epidemiologic studies.
- IV. Risk factors.** The risk of acquiring B19V infection during pregnancy is highest in schoolteachers, daycare workers, and women who have school-aged children at home.
- V. Clinical presentation**
- A. During pregnancy.** The mother may report a history of exposure to a child with **erythema infectiosum**. More commonly, the mother does not recall such exposure and the diagnosis is made based on ultrasound findings. Fortunately, most maternal infections are associated with normal pregnancy outcomes. The overall risk of adverse outcomes after primary infection is probably <10% despite a transplacental transmission rate of 32% to 50%. Adverse outcomes include the following:
- 1. Fetal death.** Infection in the first trimester may result in fetal loss or miscarriage. A large prospective study of B19V infection in pregnant women reported fetal death in 6.3% of pregnancies (up to 10.2% in other smaller studies). All deaths were limited to B19V infections diagnosed in the first half of pregnancy (13% for first-trimester infections, 9% for infections diagnosed between 13 and 20 weeks of gestation). Fetal death in the third trimester is exceedingly rare (<1%), and those fetuses (stillborn) are usually nonhydropic.
 - 2. Nonimmune hydrops fetalis.** The observed risk of B19V-induced hydrops fetalis is approximately 4% after maternal infection throughout pregnancy, with a maximum rate of approximately 10% when infection occurs between 9 and 20 weeks' gestation. The median interval between diagnosis of maternal infection and hydrops is 3 weeks. Hydrops can progress rapidly to fetal death (days to weeks) or can resolve spontaneously with an apparently normal infant at delivery. The spontaneous resolution is estimated at 34%. Severe thrombocytopenia can develop in 37% of parvovirus-infected fetuses with hydrops. This can lead to significant blood loss and exsanguination at the time of periumbilical blood sampling (PUBS) or other fetal procedures; for this reason, the platelet count should be determined and platelets should be available for transfusion if needed.
- B. Neonatal period.** The newborn infant may present with anemia and thrombocytopenia, especially if maternal infection occurred in the third trimester. Few cases of encephalopathy, meningitis, and severe central nervous system abnormalities following intrauterine B19V infection have been reported.

VI. Diagnosis

A. Laboratory studies

- 1. Serologic tests.** B19V IgG and IgM antibodies are first ordered when B19V infection is suspected. B19V-specific IgM antibodies become detectable in maternal serum within 7 to 10 days after infection, sharply peak at 10 to 14 days, and then rapidly decrease within 2 or 3 months. IgG antibodies rise considerably more slowly and reach a plateau at 4 weeks after infection. Measurement of maternal IgM is sensitive and detects approximately 90% of patients with clinical B19V infection. However, at the time of clinically overt hydrops fetalis, IgM levels may already have become low or (rarely) even undetectable. In such cases, detection of B19V DNA in maternal blood/serum by polymerase chain reaction (PCR) can be useful. In contrast to maternal testing, serologic examination of fetal and neonatal blood samples is highly unreliable.
- 2. Polymerase chain reaction** to detect B19V DNA is extremely sensitive. This method is especially useful in patients lacking an adequate antibody-mediated immune response, in immunocompromised individuals, and in fetuses. Using standard procedures, detection of B19V-specific IgM in fetal blood has a sensitivity of 29% compared with almost 100% for PCR. Use of PCR on amniotic fluid is particularly helpful when attempting to determine the cause of hydrops and is the method of choice to diagnose fetal B19V infection. However, low viral DNA levels may persist for years after acute infection in children and adults, and therefore, low-positive PCR results do not prove recent infection. The World Health Organization published a standard for B19V DNA amplification technology so that assay results can be reported in international units per milliliter (IU/mL) to allow for straightforward comparison across assays.

- B. Ultrasound and Doppler velocimetry** are very useful noninvasive measures to monitor the pregnant woman who is exposed to B19V. Ultrasound is used to monitor for hydrops and fluid accumulation in fetal body cavities. **Doppler velocimetry is used to detect blood flow pattern in the fetal middle cerebral artery (MCA).** An increase in the MCA peak systolic velocity (MCA-PSV) is a very sensitive measure of fetal anemia.

VII. Management.

Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

- A. Monitoring of the exposed pregnant woman.** Women who have been exposed or symptomatic should be assessed by determining their B19V IgG and IgM status. Blood PCR is recommended when the fetus is hydropic. If the woman is immune to B19V (IgG positive, IgM negative), she can be reassured that recent exposure will not result in adverse consequences in her pregnancy. If there is no immunity to the virus and seroconversion has not taken place after 2 weeks, the woman is not infected but remains at risk. If the woman has been infected with B19V (IgM positive), the fetus should be monitored for the development of hydrops fetalis by ultrasound examination and Doppler assessment of MCA-PSV, preferably weekly until 8 to 10 weeks after exposure.
- B. Intrauterine blood transfusion.** If the fetus subsequently develops hydrops and/or anemia (increase in MCA-PSV), PUBS and intrauterine blood transfusion (PUBS-IUT) should be considered. PUBS-IUT is an invasive procedure and carries a complication rate of 2% to 6% but can be lifesaving. It should be considered only for fetuses who are symptomatic. In most cases, 1 transfusion is sufficient for fetal recovery. When preparing for fetal transfusion, both packed red blood cells (PRBCs) and platelets must be available because some fetuses have severe thrombocytopenia in addition to anemia. Platelet transfusion may help if the fetus develops a hemorrhagic complication secondary to the procedure.
- C. Packed red blood cell transfusion.** PRBC transfusion may be indicated for the symptomatic anemic newborn patient.

- D. Intravenous immunoglobulin.** Intravenous immunoglobulin (IVIG) has been used to treat acute B19V infection in immunodeficient adults and human immunodeficiency virus-infected children with aplastic crisis. However, there are only limited case reports on its use during pregnancy; as such, the use of IVIG cannot be recommended.
- E. Antiviral agents.** No antiviral agents are effective against B19V.
- VIII. Prognosis.** Mortality with parvovirus-related fetal hydrops is better than the generally reported mortality for nonimmune fetal hydrops (40%–90%). Children who survive fetal hydrops caused by B19V may have an increased risk of neurodevelopmental impairments. However, large population-based studies show B19V infection during pregnancy is not associated with overall morbidity or mortality in infancy and childhood.

143 Pertussis

- I. Definition.** Pertussis (whooping cough) is a highly contagious respiratory tract infection caused by the gram-negative bacteria *Bordetella pertussis*. While children may present with the classic whooping cough, neonates often present with an atypical and severe disease course.
- II. Incidence.** The Centers for Disease Control and Prevention (CDC) reported a national incidence rate of 6.5 cases per 100,000 in 2015, and despite vaccination, the incidence has been rising. The overall pertussis incidence rate among infants <12 months of age is approximately 118 per 100,000 person-years (infants <3 months of age have the highest incidence rate of ~248 per 100,000 person-years). Outbreaks in neonatal units with serious morbidity have been reported.
- III. Pathophysiology.** *B pertussis* is transmitted via close contact with respiratory secretions or aerosolized respiratory droplets. The source of pertussis infection in infants is unknown in about 50% of cases. In infants with a known origin of infection, the most commonly identified source has now shifted from mothers to siblings.
- B pertussis* is primarily a toxin-mediated disease. The organism produces multiple virulence factors including pertussis toxin, filamentous hemagglutinin, agglutinogens, adenylate cyclase, pertactin, and tracheal cytotoxin. Pertussis toxin leads to induction of lymphocytosis, and tracheal cytotoxin damages cilia in the respiratory epithelium via a nitric oxide synthase-dependent pathway. Lymphocytosis can lead to aggregation of leukocytes in the pulmonary circulation, causing severe pulmonary hypertension.
- IV. Risk factors.** Infants <6 months of age are at highest risk for severe pertussis and complications or death from pertussis, especially if they are unvaccinated. Other risk factors include prematurity and low birthweight.
- V. Clinical presentation.** The 3 phases of classic pertussis, namely **catarrhal** (1–2 weeks), **paroxysmal** (2–6 weeks), and **convalescent** (2–6 weeks), are not typically observed in young infants. Neonatal cases tend to present with paroxysmal cough, gagging, bradycardia, gasping, apnea (67%), and cyanotic spells, but not fever or tachypnea. They do not have the characteristic “whoop” due to lack of prolonged inspiratory effort at the end of a paroxysm. Infants <6 months of age tend to have a short or absent catarrhal phase. The following complications may be observed in neonates and young infants with pertussis:
- A. Secondary infections.** Pertussis can be complicated by secondary infections such as pneumonia (23%), meningoencephalitis, and otitis media.

- B. Ophthalmologic complications.** The forceful coughing paroxysms characteristic of pertussis can result in eye bulging and subconjunctival, scleral, or rarely retinal hemorrhages.
- C. Central nervous system manifestations.** Subdural bleeding may result from increased intracranial pressure secondary to the Valsalva effect of paroxysmal coughing. Seizures (2%) are attributed to hypoxemia from apnea or relentless coughing, but may also be due to hyponatremia secondary to pneumonia-induced syndrome of inappropriate antidiuretic hormone secretion. Encephalopathy (<0.5%) can also present with fever, convulsions, focal neurologic signs, and altered mental status.
- D. Respiratory complications.** Infants with pertussis are at increased risk for severe pulmonary hypertension due to pulmonary vasoconstriction from hypoxia and acidosis secondary to recurrent prolonged apnea, as well as restriction of pulmonary blood flow from leukocyte aggregates. Neonates with pertussis have a greater need for mechanical ventilation due to frequent apnea, respiratory compromise during paroxysms of coughing, and pulmonary hypertension.
- E. Miscellaneous.** The increased intrathoracic and intra-abdominal pressures associated with paroxysmal coughing can result in other physical sequelae such as epistaxis, petechiae, pneumothorax, and umbilical and inguinal hernias. Posttussive emesis can lead to alkalosis, dehydration, and malnutrition.

VI. Diagnosis. Pertussis should be differentiated from other infectious causes of respiratory distress in neonates. Adenoviral infections can produce apnea and intractable coughing but usually present with fever, lethargy, maculopapular rash, pharyngitis, conjunctivitis, and coagulopathy. *Mycoplasma pneumoniae* can present with protracted cough and pneumonia. *Chlamydia trachomatis* infections may present with conjunctivitis, nasal congestion, pneumonia, and a staccato cough in afebrile patients. Respiratory syncytial virus (RSV) can present with apnea and lower respiratory tract infection. Pertussis and RSV, as coexisting infections, are not infrequent. Other viral respiratory pathogens, such as influenza A and B viruses, parainfluenza viruses, rhinovirus, and human metapneumovirus, need to be considered in the differential diagnosis.

A. Laboratory studies

- 1. Complete blood count with differential.** Leukocytosis (white blood cell [WBC] count of $>20,000$ cells/mm³) with lymphocytosis ($>50\%$ lymphocytes) is very strongly associated with pertussis. Marked leukocytosis (WBC $\geq 30,000$ cells/mm³) has been associated with increased disease severity (pulmonary hypertension) and death.
- 2. Bacterial culture.** The gold standard for diagnosis is bacterial culture of a nasopharyngeal specimen placed in a special transport medium (Regan-Lowe). While this method is 100% specific, false-negative cultures can occur if the specimen is obtained >2 weeks after onset of cough or in pretreated or vaccinated patients.
- 3. Polymerase chain reaction.** Testing for pertussis by polymerase chain reaction (PCR) has increased sensitivity over bacterial culture. PCR is widely used due to its increased sensitivity and rapid turnaround time; however, false-positive cases have been reported. PCR is more reliable during the first 3 weeks of illness.

B. Imaging studies

- 1. Chest radiograph.** Infants with uncomplicated pertussis usually have normal findings. Radiographic evidence of pneumonia may be seen in severe or complicated cases.

VII. Management

- A. Antimicrobial therapy.** Macrolide antibiotics alleviate disease severity if given during the initial catarrhal stage. Treatment after cough is established does not affect the disease course but is recommended to reduce the risk of contagion. Azithromycin (10 mg/kg/d as a single daily dose for 5 days) is the current drug of choice for treatment and postexposure prophylaxis of pertussis in infants <1 month of age. Azithromycin should be used with caution in people with prolonged QT interval

and proarrhythmic conditions. Neonates who receive macrolides (erythromycin and azithromycin, especially during the first 2 weeks of life) should be monitored for the development of infantile hypertrophic pyloric stenosis.

B. Respiratory support

- 1. Mechanical ventilation.** Intubation and mechanical ventilation are often necessary due to frequent apnea or respiratory failure.
- 2. Airway therapies.** Bronchodilators, inhaled steroids, and cough suppressants are not routinely recommended.
- 3. Inhaled nitric oxide.** Vasodilator therapy with inhaled nitric oxide (iNO) does not address the issues of pertussis-associated pulmonary hypertension secondary to leukocyte thrombi in the pulmonary vasculature. Moreover, although there are some published reports of successful resolution of pertussis-related pulmonary hypertension with iNO, recent literature suggests that iNO might actually be detrimental in the setting of pertussis.
- 4. Double-volume exchange transfusion** is suggested for high and rapidly rising WBC count and is thought to work by both leukodepletion and removal of the pertussis toxin. In case series, hypoxemia, pulmonary hypertension, and cardiac failure that were unresponsive to other measures improved after exchange transfusion.
- 5. Extracorporeal life support (ECLS)** has been used for pertussis cases with refractory respiratory failure and pulmonary hypertension, but the mortality rate is significantly higher than that of infants on ECMO for other reasons.

C. Prevention/control measures

- 1. Isolation.** Standard precautions are recommended for the entire course of illness. Droplet precaution is recommended for 5 days after initiation of effective therapy.
- 2. Postexposure prophylaxis.** Early chemoprophylaxis (typically with azithromycin for 5 days) is recommended for all household contacts of the index case and other close contacts, including children in childcare, regardless of immunization status. Due to limited efficacy, late chemoprophylaxis (after 21 days) is only recommended for high-risk contacts (pregnant women and young infants or their contacts). The agents, doses, and duration of postexposure prophylaxis (PEP) are the same as for treatment of pertussis. Healthcare facilities should maximize efforts to immunize all healthcare personnel with tetanus, diphtheria, and pertussis (Tdap). PEP is recommended for all healthcare personnel (even if immunized with Tdap) who have been exposed to pertussis and are likely to expose other patients at risk of severe pertussis (eg, hospitalized neonates and pregnant women).
- 3. Immunizations.** Six doses of pertussis vaccine are recommended during childhood. Preterm birth is not a contraindication to the pertussis vaccine.
- 4. Newborn exposure.** Due to the drastic increase in pertussis cases, the CDC updated vaccine guidelines in 2013 to recommend that a dose of Tdap be administered during each pregnancy regardless of prior Tdap immunizations. Tdap should be administered preferably early in the interval between 27 and 36 weeks' gestation, although Tdap may be administered at any time during pregnancy. Current evidence suggests that immunization early in the interval between 27 and 36 weeks' gestation will maximize passive antibody transfer to the infant; this strategy has been shown to be highly protective against infant pertussis, especially in the first 2 months of life. In addition, the CDC, American Academy of Pediatrics, and American College of Obstetricians and Gynecologists advocate "cocooning" of newborns by providing postpartum immunization to all close contacts of the infant.

VIII. Prognosis. Factors associated with adverse outcomes in infants include low birth-weight, younger gestational age, younger age at time of cough onset, higher peak WBC count, intubation, and use of nitric oxide.

144 Respiratory Syncytial Virus

- I. **Definition.** Respiratory syncytial virus (RSV) is a large, enveloped, nonsegmented, negative-strand RNA virus of the genus *Pneumovirus* of the family Paramyxoviridae. The virus uses attachment (G) and fusion (F) surface glycoproteins for virus entry. Two major strains (groups A and B) have been identified and often circulate concurrently.
- II. **Incidence.** Almost all children are infected at least once by 2 years of age. Humans are the only source of infection. Initial infection occurs most commonly during the child's first year. Reinfection throughout life is common. In the United States, RSV occurs in annual epidemics during winter and early spring (predominantly November through March). Communities in the southern United States, particularly some communities in the state of Florida, tend to experience the earliest onset of RSV activity (as early as July). In the southern hemisphere, wintertime epidemics occur from May to September, with a peak in May, June, or July. RSV is the most common cause of acute lower respiratory tract infection (ALRI) in children <1 year of age. **RSV is associated with up to 120,000 pediatric hospitalizations (1%–3% of children in the first 12 months of life) each year in the United States.** Globally, the annual rate of RSV hospitalization among children <5 years is approximately 4.4 per 1000; hospitalization rates are highest among children <6 months old (2%) and premature infants <1 year old (6.4%). In addition, RSV is a common cause of nosocomial infection in the neonatal intensive care unit (NICU). It can persist on environmental surfaces for several hours and for a half-hour or more on hands. Infection among hospital personnel and others may occur by hand-to-eye or hand-to-nasal epithelium self-inoculation with contaminated secretions.
- III. **Pathophysiology.** The disease is generally limited to the respiratory tract. RSV usually is transmitted by direct or close contact with contaminated secretions, which may occur from exposure to large-particle droplets at short distances (typically <6 feet) or from fomites. The inoculation of the virus occurs in nasopharyngeal or ocular mucous membranes after contact with virus-containing secretions or fomites. The virus replicates in the nasopharynx and spreads to the small bronchiolar epithelium, sparing the basal cells. Subsequently, the virus extends to type 1 and 2 alveolar pneumocytes in the lung, presumably by cell-to-cell spread or via aspiration of secretions. In infants, the disease manifests itself as bronchiolitis or pneumonia. In very rare cases, RSV may be recovered from extrapulmonary tissues, such as liver, spinal, or pericardial fluid. Up to 30% of children with RSV bronchiolitis may be **coinfected** with another respiratory tract virus, such as human metapneumovirus, rhinovirus, bocavirus, adenovirus, coronavirus, influenza virus, or parainfluenza virus.
- IV. **Risk factors.** Risk factors for RSV ALRI include infants <6 months of age, premature infants born <35 weeks' gestation, infants with underlying lung disease such as chronic lung disease (CLD) of prematurity, infants <2 years of age with heart disease, infants with school-aged siblings, infants who attend daycare, family history of asthma, regular exposure to secondhand smoke or air pollution, multiple birth babies, peak RSV season (fall to end of spring), being male, immunocompromised patients (eg, severe combined immunodeficiency, leukemia, or undergoing organ transplant), <1 month of or no breast feeding, and others sharing the bedroom with the infant. High altitude increases the risk of RSV hospitalization. Children with Down syndrome are at increased risk for severe RSV disease.
- V. **Clinical presentation.** The incubation period ranges from 2 to 8 days. RSV usually begins in the nasopharynx with coryza and congestion. During the first 2 to 5 days, it may progress to the lower respiratory tract (20%–30%) with development of cough, dyspnea, and wheezing. RSV is the most common cause of bronchiolitis and pneumonia in infants <2 years old. Lethargy, irritability, and poor feeding are commonly

present in young infants. **Apnea** may be the presenting symptom in approximately 20% of infants hospitalized with RSV and may be the cause of sudden, unexpected death. Most previously healthy infants infected with RSV do not require hospitalization. Most RSV hospitalizations occur in the first 3 months of life. RSV infection may predispose to reactive airway disease and recurrent wheezing during the first decade of life; the association between RSV bronchiolitis early in life and subsequent asthma remains poorly understood.

VI. Diagnosis

A. Enzyme-linked immunosorbent assay and direct fluorescent antibody tests use antigen capture technology that can be performed in <30 minutes on nasal wash or tracheal aspirate. Their sensitivity is approximately 80%, and specificity is approximately 95% (in comparison with culture). False-positive test results are more likely to occur when the incidence of disease is low. Multiplex assays or viral respiratory panels (which test for multiple respiratory viruses with 1 test) may be preferred in many clinical settings because they are able to identify co-infection. Viral isolation from nasopharyngeal secretions in cell culture requires 1 to 5 days (shell vial techniques can produce results within 24–48 hours). Molecular diagnostic tests using reverse transcriptase–polymerase chain reaction (RT-PCR) are cleared by the US Food and Drug Administration and available widely; they increase RSV detection rates over viral isolation or antigen detection assays. RT-PCR is an alternative to culture for confirming the result of rapid antigen detection assay, which is rarely needed except to mark the start of the RSV season. Additionally, palivizumab exposure (see Section VII on management) may interfere with immunologic-based antigen detection assays (enzyme-linked immunosorbent assay and direct fluorescent antibody) as well cell culture, but it does not interfere with RT-PCR. Diagnostic serology is not helpful in infants because of the passive transplacental transfer of maternal antibody.

B. Chest radiograph usually reveals infiltrates or hyperinflation.

C. Blood gas analysis may show hypoxemia and occasionally hypercarbia. Development of hypercarbia is an ominous sign of impending respiratory failure.

VII. Management. Primary treatment of young infants hospitalized with RSV bronchiolitis is supportive and should include hydration, careful assessment of respiratory status, measurement of oxygen saturation, suction of the upper airway, use of a nasal continuous positive airway pressure or high-flow nasal cannula therapy, and if necessary, intubation and mechanical ventilation. Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

A. Immunization

1. Passive

a. Palivizumab (Synagis) provides passive immunity. It is a humanized RSV monoclonal antibody administered intramuscularly (15 mg/kg) monthly during RSV season. It is well tolerated with infrequent or minimal side effects. According to the American Academy of Pediatrics guidelines, palivizumab should be considered for:

i. Infants with chronic lung disease of prematurity, defined as having a gestational age <32 weeks, 0 days and a requirement for >21% oxygen for at least the first 28 days after birth. Prophylaxis may be given during the first RSV season (first year of life). During the second year of life, palivizumab is recommended only for CLD infants who continue to require medical support (chronic corticosteroid therapy, diuretic therapy, or supplemental oxygen) during the 6-month period before the start of the second RSV season.

ii. Infants with hemodynamically significant congenital heart disease. Defined as acyanotic heart disease requiring medication to control congestive heart failure (CHF) and that will require cardiac surgical

both at the preclinical and clinical stages. RSV maternal immunization is a strategy that is being studied for the prevention of RSV in neonates and young infants.

- B. **Nebulized hypertonic saline (3%)** may be safe and effective at improving the symptoms of mild to moderate bronchiolitis after 24 hours of use and in reducing hospital length of stay in settings where the duration of stay is likely to exceed 3 days. Hypertonic saline has not been studied in NICU settings.
 - C. **Ribavirin** has in vitro antiviral activity against RSV, but ribavirin aerosol treatment for RSV is not recommended routinely.
 - D. **Surfactant.** Two small, randomized studies showed that surfactant therapy improves gas exchange and decreases mechanical ventilation days and intensive care unit stay in infants with severe RSV-induced respiratory failure.
 - E. **α -Adrenergic and β -adrenergic agents are not recommended** for care of first-time wheezing associated with RSV bronchiolitis based on randomized clinical trial findings.
 - F. **Antibiotics, theophylline, and corticosteroids** have not been shown to be helpful in the treatment of RSV.
 - G. **Isolation.** Contact precautions are recommended for the duration of the illness. RSV present in secretions remains viable for up to 6 hours on countertops. Gowns, gloves, and scrupulous hand-washing practices are required. Patients with RSV infection should be cared for in a single room or placed in a cohort. High-risk infants should be kept away from crowds and from situations in which exposure to infected people cannot be controlled. Participation in group childcare should be restricted during the RSV season for high-risk infants whenever feasible.
- VIII. **Prognosis.** Globally, RSV is estimated to cause as many as 2.3% of deaths among neonates 0 to 27 days of age and 6.7% of deaths among infants 28 to 364 days of age. In the United States, estimated mortality is approximately 3.1 per 100,000 person-years in children <1 year old, mostly in children born prematurely and those with underlying cardiopulmonary disease or other chronic conditions. In prematurely born infants with CLD who are hospitalized because of RSV in the first 2 years of life, there is a reduced airway caliber at school age. Even in normal infants, RSV infection in the first 3 years of life predisposes them to recurrent wheezing up to 11 years of age. Palivizumab prophylaxis administered to preterm infants does not suppress the onset of atopic asthma but results in a significantly lower incidence of recurrent wheezing during the first 6 years.

145 Rubella

- I. **Definition.** Rubella virus is an enveloped, positive-stranded RNA virus classified as a *Rubivirus* in the *Togaviridae* family. It is capable of causing chronic intrauterine infection and damage to the developing fetus (**congenital rubella syndrome [CRS]**).
- II. **Incidence.** The incidence of rubella in the United States has decreased by >99% from the prevaccine era. In 2004, the United States was determined to no longer have endemic rubella, and from 2004 through 2014, 94 cases of rubella and 9 cases of CRS, including 3 cases in 2012, were reported; all of them were associated with individuals outside the United States or from unknown sources. Of childbearing women, 92% are estimated to be seropositive (rubella immune). Endemic transmission of rubella was declared eliminated from the Americas in 2015. However, rubella continues to be endemic in other parts of the world. It is estimated that >100,000 infants worldwide are born with CRS each year.

III. Pathophysiology. Rubella typically has an epidemic seasonal pattern of increased frequency in the spring. In developing countries with no vaccination programs, epidemics have occurred at 4- to 7-year intervals, with major pandemics every 10 to 30 years. Humans are the only known hosts, with an incubation period of 14 to 21 days after contact. Virus is spread by respiratory secretions and also from stool, urine, and cervical secretions. A live virus vaccine has been available since 1969. In places with no vaccination, 15% to 20% of women of childbearing age are susceptible to rubella. There is a high incidence of subclinical infections. Maternal viremia is a prerequisite for placental infection, which may or may not spread to the fetus. Most cases occur after primary disease, although few cases (2%) have been described after reinfection.

Rubella infection can have catastrophic effects on the developing fetus, resulting in spontaneous abortion, fetal infection, stillbirth, or intrauterine growth restriction. The fetal infection rate varies according to the timing of maternal infection during pregnancy. If infection occurs at 1 to 12 weeks and is associated with maternal rash, there is an 81% risk of fetal infection; at 13 to 16 weeks, 54%; at 17 to 22 weeks, 36%; at 23 to 30 weeks, 30%. There is a rise to 60% at 31 to 36 weeks and to 100% in the last month of pregnancy, but late infection is not associated with CRS. No correlation exists between the severity of maternal rubella and teratogenicity. However, the incidence of fetal effects is greater the earlier in gestation that infection occurs, especially at 1 to 12 weeks, when 85% of infected fetuses will have congenital defects. Infection during weeks 13 to 16 results in 35% of fetuses having congenital defects; infection at later gestational ages rarely causes deafness or congenital malformations. Spontaneous abortion may occur in up to 20% of cases when rubella occurs in the first 8 weeks of pregnancy. The disease involves angiopathy as well as cytolytic changes. Other viral effects include chromosome breakage, decreased cell multiplication time, induction of programmed cell death (apoptosis), and mitotic arrest in certain cell types. There is little inflammatory reaction.

IV. Risk factors. Women of childbearing age who are rubella nonimmune or foreign born are at risk.

V. Clinical presentation. Congenital rubella infection has a wide spectrum of presentations, ranging from asymptomatic infection to acute disseminated infection to deficits not evident at birth.

A. Systemic transient manifestations include low birthweight, hepatosplenomegaly, meningoencephalitis, thrombocytopenia with or without purpura, and bony radiolucencies. These are probably a consequence of extensive viral infection and usually resolve spontaneously within days or weeks. Infants with these abnormalities usually fail to thrive during infancy.

B. Systemic permanent manifestations include heart defects (eg, patent ductus arteriosus [PDA], pulmonary artery stenosis or hypoplasia), eye defects (eg, cataracts, iris hypoplasia, microphthalmos, and retinopathy), central nervous system (CNS) problems (eg, intellectual disability and psychomotor developmental delay, speech and language delay), microcephaly, and sensorineural deafness (unilateral or bilateral). More than half of children infected during the first 8 weeks of gestation have heart defects; **branch pulmonary artery stenosis** (78%) and **PDA** (62%) are the most common. Of the eye defects, a “**salt and pepper**” retinopathy is the most common. **Cataract** occurs in approximately 30% of cases of CRS (~50% bilateral); rubella virus is recovered in high titer from lens aspirates in children with congenital cataracts for several years. **Deafness** is a major disabling abnormality and may occur alone.

C. Developmental and late-onset abnormalities. Rubella is a progressive disease due to the persistence of the viral infection and the defective immune response to the virus. Existing manifestations, such as deafness and CNS disease, may progress, and some abnormalities may not be detected until the second year of life or later. These include hearing, developmental and eye defects, diabetes mellitus (DM), thyroid disorders, behavioral and educational difficulties, and progressive panencephalitis. Insulin-dependent DM is the most frequent endocrine abnormality, occurring in approximately 20% of cases.

VI. Diagnosis. Timely diagnosis of congenital rubella infection is important both for management of the individual patient and for prevention of secondary infection because these infants may remain infectious for 1 year. The diagnosis may be suspected clinically but needs to be confirmed with laboratory tests. The Centers for Disease Control and Prevention (CDC) has published an elaborate case definition for congenital rubella infection that is updated regularly (<https://wwwn.cdc.gov/nndss/conditions/rubella-congenital-syndrome/>; accessed September 6, 2018). According to the most recent update available at the time of publication (2010), cases of CRS are classified as suspected, probable, confirmed, or infection only, depending on clinical findings and laboratory criteria for diagnosis.

A. Centers for Disease Control and Prevention case definition

1. **Suspected.** An infant who has 1 or more of the following findings (but does not meet the criteria for a confirmed or probable case): cataracts or congenital glaucoma, congenital heart disease (most commonly PDA or peripheral pulmonary artery stenosis), hearing impairment, pigmentary retinopathy, purpura, hepatosplenomegaly, jaundice, microcephaly, developmental delay, meningoencephalitis, or radiolucent bone disease.
2. **Probable.** An infant who has at least 2 of the following findings (but does not have laboratory confirmation of rubella infection or a more plausible etiology): either cataracts or congenital glaucoma or both (counts as 1), congenital heart disease (most commonly PDA or peripheral pulmonary artery stenosis), hearing impairment, or pigmentary retinopathy.

OR

An infant who has at least 1 or more of the following (but does not have laboratory confirmation or an alternative more plausible etiology): either cataracts or congenital glaucoma or both (counts as 1), congenital heart disease (PDA or peripheral pulmonary artery stenosis), hearing impairment, or pigmentary retinopathy

AND

1 or more of the following of the following: purpura, hepatosplenomegaly, microcephaly, developmental delay, meningoencephalitis, or radiolucent bone disease.

3. **Confirmed.** An infant with at least 1 symptom (listed previously) that is clinically consistent with CRS and laboratory evidence of congenital rubella infection as demonstrated by: isolation of rubella virus, or detection of rubella-specific immunoglobulin (Ig) M antibody, or infant rubella antibody level that persists at a higher level and for a longer period than expected from passive transfer of maternal antibody (ie, rubella titer that does not drop at the expected rate of a 2-fold dilution per month), or a specimen that is polymerase chain reaction (PCR) positive for rubella virus.
4. **Infection only.** An infant with laboratory evidence of infection but with no clinical symptoms or signs. Laboratory evidence is as shown in Section VI.A.3. If any signs or symptoms are identified later such as hearing loss, then the diagnosis is reclassified as confirmed.
5. **Congenital rubella syndrome cases are further classified epidemiologically as internationally imported or United States acquired,** according to the source of infection in the mother.

B. Laboratory studies

1. **Open cultures.** The virus can be cultured for up to 1 year despite measurable antibody titer. The best specimens for viral recovery are from nasopharyngeal swabs, conjunctival scrapings, urine, and cerebrospinal fluid (CSF), in decreasing order of usefulness.
2. **Serologic studies.** These are the mainstay of rubella diagnosis. CRS is diagnosed by the detection of **rubella-specific IgM in a serum or oral fluid taken before 3 months of age.** IgM testing is less reliable after 3 months of age as levels of

specific IgM decline. However, if sensitive assays are used, specific IgM may be detected in 85% of symptomatic infants at 3 to 6 months and >30% at 6 to 12 months of age. A negative result by IgM-capture enzyme immunosorbent assay in the first 3 months of age virtually excludes congenital infection. It is also possible to make a diagnosis by demonstrating persistence of rubella IgG in sera taken between 6 and 12 months of age. It is difficult to make a serologic diagnosis of congenital rubella after rubella vaccination. Testing of oral fluid samples (IgM, IgG, and PCR) as an alternative to serum has been used and standardized. It offers many advantages for surveillance of CRS in developing countries. A false-positive IgM test result may rarely occur; this is caused by a number of factors including rheumatoid factor, parvovirus IgM, and heterophile antibodies. If false-positive IgM results are suspected, IgG avidity assay in a reference laboratory (eg, CDC) can be used to confirm or refute the diagnosis. IgG avidity and IgG response to the 3 viral structural proteins (E1, E2, and C), reflected by immunoblot fluorescent signals may help to establish the diagnosis of CRS in older school-aged children.

3. Rubella virus polymerase chain reaction. CRS may also be diagnosed by detection of viral RNA by nested reverse transcriptase (RT)-PCR in nasopharyngeal swabs, urine, oral fluid, CSF, lens aspirate, and ethylenediaminetetraacetic acid (EDTA)-blood.

4. Cerebrospinal fluid examination. This may reveal encephalitis with an increased protein and cell count.

C. Imaging studies. Long-bone films may show metaphyseal radiolucencies that correlate with metaphyseal osteoporosis.

VII. Management. Prenatal serologic screening for rubella immunity should be undertaken for all pregnant women. Those without antibody concentrations above the standard positive cutoff or those with equivocal test results **should receive rubella vaccine during the immediate postpartum period before discharge.** Cases of CRS (suspected or confirmed) in the United States should be reported to the CDC through local and state health departments. All newborns who fail hearing screening and born to mothers who are rubella nonimmune should undergo evaluation for rubella (measurement of rubella-specific IgM antibodies) and other intrauterine infections. There is no specific treatment for rubella. Long-term follow-up is needed secondary to late-onset symptoms. Prevention consists of vaccination of the susceptible population (especially young children). **Vaccine should not be given to pregnant women.** Pregnancy should be avoided for 28 days after vaccination. Inadvertent vaccination of pregnant women does not cause CRS, although there is a 3% chance of congenital infection. Passive immunization (with immune globulin [IG]) does not prevent rubella infection after exposure and is not recommended. Administration of IG should be considered only if a pregnant woman who has been exposed to rubella will not consider termination of pregnancy under any circumstance. Administration of IG eliminates the value of IgG antibody testing to detect maternal infection; however, IgM antibody can still be used to detect maternal infection after exposure. Children with congenital rubella should be considered contagious until they are at least 1 year of age, unless 2 cultures of clinical specimens (nasopharyngeal and urine cultures) obtained 1 month apart are negative for rubella virus after 3 months of age. Rubella vaccine virus can be isolated from breast milk in lactating women who have received the vaccine. However, **breast feeding is not a contraindication to vaccination** because no evidence indicates that the vaccine virus is in any way harmful to the infant.

VIII. Prognosis. Infection in the first or second trimester can cause growth restriction, deafness, and other congenital malformations (CRS, discussed earlier). Congenital rubella is a progressive disease, some of its consequences may not present until the second decade of life (motor and mental retardation, hearing and communication disorders, DM). Natural rubella infection in pregnancy is 1 of the few known causes of autism.

146 Sepsis

Neonatal sepsis is a clinical syndrome of systemic illness accompanied by bacteremia occurring in the first month of life. It can be classified into 2 relatively distinct syndromes based on the age of presentation: early-onset and late-onset sepsis. These 2 entities will be discussed separately.

NEONATAL EARLY ONSET SEPSIS

- I. **Definition.** Early-onset sepsis (EOS) is defined by the Centers for Disease Control and Prevention (CDC) as blood and/or cerebrospinal fluid (CSF) culture-proven infection occurring in the newborn at <7 days of age. For the continuously hospitalized very low birthweight (VLBW; <1500 g) infant, EOS is defined as culture-proven infection occurring at <72 hours of age.
- II. **Incidence.** The overall incidence of EOS in the United States is estimated at 0.77 to 0.98 per 1000 live births. Incidence is strongly influenced by gestational age (GA) at birth. Among infants born at ≥ 37 weeks' gestation, the incidence is around 0.53 per 1000 live births, whereas in the preterm population, the incidence is 3.7 per 1000 live births (7 times higher), and among VLBW infants, it is approximately 11 per 1000 live births (20 times higher).
- III. **Pathophysiology**
 - A. **Infants usually present with a multisystem, sometimes fulminant, illness with prominent respiratory symptoms.** Typically, the infant has acquired the organism during the antepartum or intrapartum period from the maternal genital tract. Several infectious agents, notably treponemes, viruses (eg, herpes simplex virus, enteroviruses, and parechoviruses), *Listeria*, and probably *Candida*, can be acquired transplacentally via hematogenous routes. Acquisition of other organisms is associated with the birth process. With rupture of membranes, vaginal flora or other bacterial pathogens may ascend to reach the amniotic fluid and the fetus. Chorioamnionitis develops, leading to fetal colonization and infection. Aspiration of infected amniotic fluid by the fetus or neonate may play a role in the resultant respiratory symptoms. Finally, the infant may be exposed to vaginal flora as it passes through the birth canal. The primary sites of colonization tend to be the skin, nasopharynx, oropharynx, conjunctiva, and umbilical cord. Trauma to these mucosal surfaces may lead to infection. The disease may present suddenly with a fulminant course that can progress rapidly to septic shock and death.
 - B. **Microbiology.** The principal pathogens involved in EOS have tended to change with time. Before 1965, *Staphylococcus aureus* and *Escherichia coli* used to be the most commonly isolated organisms. In the late 1960s and early 1970s, **group B Streptococcus (GBS)** emerged as the most common microorganism. Currently, most centers continue to report GBS as the most common microorganism, even though the incidence has decreased considerably after the widespread adoption of universal antenatal screening for GBS colonization at 35 to 37 weeks' gestation and intrapartum antibiotic prophylaxis (IAP) with penicillin or ampicillin for colonized women. **The incidence of EOS secondary to GBS decreased from 1.7 per 1000 live births in 1993 to 0.22 per 1000 in 2016 (>85% reduction).** The second most common bacteria are gram-negative enteric organisms, especially *E coli*. An increase in the incidence of *E coli* has been noted in EOS in VLBW infants to the extent that *E coli* is currently the predominant microorganism in this group of patients. GBS and *E coli* account for two-thirds of all cases of EOS. Other pathogens causing EOS include *Listeria monocytogenes*, *S aureus*, enterococci, other gram-negative bacteria (*Klebsiella*, *Citrobacter*, *Serratia*, and *Enterobacter*), anaerobes (especially *Bacteroides fragilis*), *Haemophilus influenzae*, and *Streptococcus pneumoniae*.

IV. Risk factors for neonatal early-onset sepsis

- A. **Prematurity and low birthweight.** Prematurity (especially if <35 weeks' gestation) is the single most significant factor correlated with sepsis. The risk increases in proportion to the decrease in birthweight and GA.
 - B. **Rupture of membranes ≥ 18 hours.** The risk for proven sepsis increases 10-fold.
 - C. **Maternal peripartum infection.** Infections such as **chorioamnionitis** manifesting as **maternal fever**, urinary tract infection (UTI) especially **GBS bacteriuria**, **rectovaginal colonization with GBS**, and perineal colonization with *E coli* are well-recognized risk factors for EOS. Chorioamnionitis is an imprecise and heterogeneous disorder; the National Institute of Child Health and Human Development (NICHD) convened a group of experts in 2015 to a workshop that issued evidence-based recommendations with regard to this issue. The group proposed to replace the term *chorioamnionitis* with a more general descriptive term: "**intrauterine inflammation or infection or both**," abbreviated as "**triple I**." However, this terminology has not been widely accepted yet. The American College of Obstetricians and Gynecologists (ACOG) endorsed the recommendations of the NICHD workshop but chose to use the term "intraamniotic infection" instead.
 - D. **Previous delivery of a neonate with group B streptococcal disease.**
 - E. **Fetal and intrapartum distress.** Infants who had intrapartum fetal tachycardia, meconium-stained amniotic fluid, were born by traumatic delivery, or were severely depressed at birth and required intubation and resuscitation are either infected in utero or at significant risk for EOS.
 - F. **Multiple gestation.**
 - G. **Metabolic factors.** Hypoxia, acidosis, inherited metabolic disorders (eg, galactosemia predisposing to *E coli* sepsis), and immune defects (eg, asplenia) are factors that predispose to, as well as increase the severity of, sepsis.
 - H. **Other factors.** Males are affected 4 times more often than females, and the possibility of a sex-linked genetic basis for host susceptibility is postulated. **Black African descent** is an independent risk factor for EOS with GBS. Reasons for the disproportionately high disease burden among black populations cannot be fully explained by prematurity or socioeconomic status. However, Black African descent is known to be associated with higher rates of GBS colonization.
- V. **Clinical presentation of neonatal early-onset sepsis.** Because the initial diagnosis of sepsis is, by necessity, a clinical one, it is crucial to begin treatment before the results of cultures are available. Clinical signs and symptoms of sepsis are nonspecific, and the differential diagnosis is broad. Some signs are subtle or insidious, and therefore, a high index of suspicion is required to identify and evaluate infected neonates. Clinical signs and symptoms most often mentioned include the following:
- A. **Temperature irregularity.** Hypothermia is more common than fever as a presenting sign for bacterial sepsis in premature infants. Hyperthermia is more common in full-term infants beyond the first 24 hours of life and if viral agents (eg, herpes) are involved.
 - B. **Change in behavior.** Lethargy, irritability, seizures, or change in tone.
 - C. **Skin.** Poor peripheral perfusion, cyanosis, mottling, pallor, petechiae, rashes, sclerema, and jaundice singularly or in combinations are known signs of sepsis.
 - D. **Cardiopulmonary.** Tachypnea, respiratory distress (grunting, flaring, and retractions), apnea within the first 24 hours of birth, tachycardia, and hypotension singularly or in combinations should suggest sepsis. Hypotension tends to be a late sign.
 - E. **Metabolic.** Metabolic findings include hyperkalemia, hyponatremia, hyperglycemia, or metabolic acidosis. There is no evidence that hypoglycemia occurring in isolation is a risk factor or manifestation of EOS.

VI. Diagnosis

- A. **Differential diagnosis.** Because signs and symptoms of neonatal sepsis are nonspecific, noninfectious etiologies need to be considered. If the infant is presenting with respiratory symptoms, respiratory distress syndrome, transient tachypnea of the newborn, meconium aspiration, and aspiration pneumonia are considered. If the

infant is showing central nervous system (CNS) symptoms, then meningitis, intracranial hemorrhage, drug withdrawal, and inborn errors of metabolism are considered.

B. Laboratory studies

1. **Cultures.** Blood and other normally sterile body fluids (eg, tracheal aspirate and CSF) should be obtained for culture. Body surface cultures are not recommended.
 - a. **Blood cultures.** Modern, computer-assisted automated blood culture systems use optimized enriched culture media with antimicrobial neutralization properties; they provide continuous-read detection and are able to identify up to 94% to 96% of all microorganisms by 36 hours of incubation. Results may vary because of a number of factors, including maternal antibiotics administered before birth, organisms that are difficult to grow and isolate (ie, anaerobes), and sampling error with small sample volumes (**the minimum volume for blood culture is 1 mL**). The concerns about low-level bacteremia and the effect of intrapartum antibiotic administration are not substantiated as these systems have been shown to reliably detect bacteremia at a level of 1 to 10 colony-forming units per mL if a minimum blood volume of 1 mL is inoculated. Additionally, several studies have reported no effect of intrapartum antibiotic therapy on time to positivity since the culture media contains antimicrobial neutralization elements that efficiently neutralize β -lactam antibiotic agents as well as gentamicin. One aerobic blood culture is typically obtained in cases of EOS, however, the use of 2 separate culture bottles (1 aerobic and 1 anaerobic) may provide the opportunity to determine if commensal species are true infections by comparing growth in the 2 cultures. In some clinical situations where the infant is critically ill, it may be appropriate to treat for “presumed” sepsis despite negative cultures.
 - b. **Lumbar puncture.** Some *controversy* currently exists regarding whether a lumbar puncture (LP) is needed in asymptomatic newborns being worked up for presumptive EOS. Many institutions perform LPs only on infants who are clinically ill, infants who have CNS symptoms such as apnea or seizures, or in cases of documented positive blood cultures or if the decision is made to extend antibiotics beyond 48 hours for presumptive clinical sepsis.
 - c. **Urine cultures.** In neonates <24 hours of age, a sterile urine specimen is **not recommended** given that the occurrence of UTIs is exceedingly rare in this age group.
 - d. **Tracheal cultures** may be obtained shortly after intubation (within 3 hours) in ill neonates with a clinical picture suggestive of early-onset pneumonia or if the mother developed intraamniotic infection with overwhelming EOS of the newborn. Tracheal aspirates done after several hours or days of intubation are of limited value.
2. **Gram stain.** Gram staining is especially helpful for the study of CSF. Gram-stained smears and cultures of amniotic fluid are helpful in diagnosing intraamniotic infection. A Gram stain of tracheal aspirate can show the infecting microorganism in EOS/pneumonia.
3. **Molecular testing.** Molecular methods for detection of neonatal sepsis in blood include polymerase chain reaction (PCR) and DNA microarray–based methods. Most of these tests hold the promise of rapid detection directly from blood without prior culture combined with high sensitivity and specificity in relation to cultures and with using small volume of blood. A recent Cochrane review that evaluated 35 studies found a summary estimate of sensitivity of 0.90 and specificity of 0.93 and concluded that molecular assays have the advantage of producing rapid results and may perform well as add-on tests.
4. **Other laboratory tests**
 - a. **Complete blood count with differential.** These values alone are very non-specific. There are reference values for total white blood cell (WBC) count and absolute neutrophil counts as a function of postnatal age in hours

(they peak during the first 12–14 hours of age; see Chapter 78, particularly Tables 78–1 and 78–2). Neutropenia may be a significant finding with an ominous prognosis when associated with EOS. The presence of immature forms is more specific but still rather insensitive. Ratio of immature to total polymorphonuclear cells (I/T) >0.2 has good predictive value, if present. The diagnostic yield of WBC count improves when testing is done **after 6 hours of age**. A variety of conditions other than sepsis can alter neutrophil counts and ratios, including maternal hypertension and fever, neonatal asphyxia, maternal intrapartum oxytocin, hypoglycemia, stressful labor, meconium aspiration syndrome, pneumothorax, and even prolonged crying. Serial WBC counts obtained several hours apart may be helpful in establishing a trend. **Decreased platelet count** can be associated with EOS; however, this is usually a late sign and very nonspecific.

- b. Acute-phase reactants (APRs).** APRs are complex multifunctional group comprising complement components, coagulation proteins, protease inhibitors, C-reactive protein (CRP), and others that rise in concentration in the serum in response to inflammation. The inflammation may be secondary to infection, trauma, or other processes of cellular destruction. An elevated APR does not distinguish between infectious and noninfectious causes of inflammation. Except for CRP and procalcitonin (PCT), most APRs are not commercially available for routine testing.

i. C-reactive protein is an APR that increases the most in the presence of inflammation caused by infection or tissue injury. The highest concentrations of CRP are reported in patients with bacterial infections, whereas moderate elevations typify chronic inflammatory conditions. Synthesis of CRP by hepatocytes is modulated by cytokines. Interleukin (IL)-1 β , IL-6, IL-8, and tumor necrosis factor (TNF) are the most important regulators of CRP synthesis. CRP secretion starts within 4 to 6 hours after the inflammatory stimulus and peaks at approximately 36 to 48 hours. The biologic half-life of CRP is 19 hours, with a 50% reduction daily after the acute-phase stimulus resolves. A single normal value (<1 mg/dL) cannot rule out infection because the sampling may have preceded the rise in CRP; if a single value is obtained, it needs to be done after 18 hours of age. If CRP is obtained, serial determinations are better than a single value. Two normal CRP determinations (8–24 hours after birth and 24 hours later) have been shown to have a negative predictive value of 99.7% for proven neonatal sepsis. CRP elevations in noninfected neonates have been seen with fetal hypoxia, respiratory distress syndrome (RDS), and meconium aspiration; after trauma/surgery; and after immunizations. Serial abnormal CRP values alone should not be used to decide whether to administer antibiotics in the absence of a culture-confirmed infection. A false-positive rate of 8% has been found in healthy neonates. Nonetheless, CRP is a valuable adjunct in the diagnosis of sepsis (ruling it out when serial CRPs are low), monitoring the response to treatment, and guiding duration of treatment.

ii. Procalcitonin is a propeptide of calcitonin that is released by parenchymal cells in response to bacterial toxins. A recent systematic review showed a sensitivity of 0.85 and specificity of 0.54 for detection of neonatal sepsis (EOS and late-onset sepsis [LOS]) at the PCT cutoff of 2.0 to 2.5 ng/mL. A recent multicenter randomized controlled trial showed that PCT seems to have some utility in guiding the duration of antibiotic therapy in neonates with suspected EOS. A physiologic increase in the PCT concentration occurs within the first 24 hours of birth.

iii. Cytokines interleukin-6, interleukin-8, and tumor necrosis factor are produced primarily by activated monocytes and macrophages and are major mediators of the systemic response to infection. Studies have shown that combining cytokines with CRP may be better than using CRP alone.

- iv. **Neutrophil surface antigens CD11, CD14, and CD64** are promising markers of early infection that correlate well with CRP but peak earlier. **Presepsin** (soluble CD14 subtype) has attracted recent attention because of its utility as a sepsis marker in adults. Preliminary studies in neonates have shown that most variables commonly affecting CRP and PCT values do not affect presepsin levels, which suggests that presepsin could become an effective sepsis marker in neonates.
- C. **Imaging studies.** **Chest radiograph** should be obtained in cases with respiratory symptoms, although it is often impossible to distinguish GBS or *Listeria pneumonia* from uncomplicated RDS. One distinguishing feature is the presence of pleural effusion, which occurs in 67% of cases of pneumonia.
- D. **Other studies.** Examination of the placenta and fetal membranes may disclose evidence of chorioamnionitis and thus an increased potential for neonatal infection.
- VII. **Management.** Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F. Chapter 78 (on call problem “Post-delivery Antibiotics”) discusses which infants should be considered for antibiotics.
- A. **Prevention: group B *Streptococcus* prophylaxis.** Because of the widespread use of IAP, EOS secondary to GBS has been reduced by >85%. Fortunately, GBS prevention efforts have not led to an increasing burden of early-onset *E coli* infections. Approximately 20% to 30% of pregnant women are colonized with GBS in the vaginal or rectal area. Consensus guidelines regarding management of GBS were published by the CDC in 1996 and were later revised in 2002 and in 2010. In 2017, representatives from the CDC, AAP, ACOG, and other stakeholder organizations agreed to review and revise the 2010 GBS guidelines. It was decided that the AAP would revise neonatal care recommendations and ACOG would revise obstetric care guidelines. These separate but congruent clinical reports were published in July 2019 and replaced the CDC 2010 GBS perinatal guidelines. They recommend that all pregnant women should be screened at **36 0/7 to 37 6/7 weeks’ gestation** for vaginal and rectal GBS colonization. At the time of labor or rupture of membranes, IAP should be given to all pregnant women identified as GBS carriers. Women with GBS isolated from the urine (**GBS bacteriuria, any colony count**) during their current pregnancy should receive IAP because such women usually are heavily colonized with GBS and are at increased risk of delivering an infant with EOS. Women who have **previously given birth to an infant with invasive GBS disease** should receive IAP as well. Additionally, women who were **GBS colonized during a previous pregnancy have a 50% likelihood of GBS carriage in the current pregnancy**, therefore, ACOG guidelines recommend that if a woman with unknown GBS status presents in labor and is known to have had GBS colonization in a previous pregnancy, IAP should be considered for such woman. **Penicillin is the drug of choice**, but ampicillin is an acceptable alternative. First generation cephalosporins (ie, cefazolin) are recommended for women whose reported penicillin allergy indicates a low risk of anaphylaxis or is of uncertain severity. Penicillin allergy skin testing, if available, is safe during pregnancy and can be recommended to “penicillin-allergic” women to ascertain their true risk of anaphylaxis. Clindamycin is the recommended alternative to penicillin only if the GBS isolate is known to be susceptible to clindamycin. Vancomycin is used when there is a high-risk penicillin allergy and when GBS isolate is not susceptible to clindamycin. The risk-based approach is not acceptable except for circumstances in which screening results are not available before labor and delivery. In these circumstances, IAP should be given to women <37 weeks’ gestation, those with rupture of membranes ≥ 18 hours, and women who have a fever $\geq 38^{\circ}\text{C}$ (100.4°F). Women with GBS colonization in one pregnancy have an estimated 50% risk of colonization in a subsequent pregnancy, therefore GBS IAP may be considered for such women. The guidelines recognize the availability of commercial **nucleic acid amplification tests (NAAT) such as PCR for rapid detection of GBS**. If available, NAAT intrapartum rectovaginal testing can

be performed on women with unknown GBS status and no intrapartum GBS risk factors. IAP should be given if the NAAT testing returns positive or an intrapartum risk factor develops regardless of NAAT results. In addition, the guidelines specifically addressed **threatened preterm labor (PTL) and preterm prelabor rupture of membranes (pPROM) with detailed algorithms**. Briefly, women with threatened PTL or pPROM should be screened for GBS colonization on admission unless a GBS culture was obtained within the preceding 5 weeks. In both of these situations, women should receive GBS prophylaxis (typically for 48 hours) unless the screening results are negative. The recommendations also provide clarification on optimal GBS culturing methods. On the neonatal side, the GBS guidelines (published by AAP) review the epidemiology of neonatal GBS disease and provide specific algorithms for neonatal management based on risk assessment and gestational age (see next sections).

B. Neonatal risk assessment for infants born at ≥ 35 weeks' gestation. The AAP report acknowledges and endorses 3 commonly used approaches to risk assessment among infants born at ≥ 35 weeks' gestation as follows:

1. Categorical risk assessment. This approach uses risk factor (mainly maternal intrapartum fever—oral temperature $>38^{\circ}\text{C}$) to identify infants at increased risk for EOS due to GBS (Figure 146–1A). Different versions of this approach

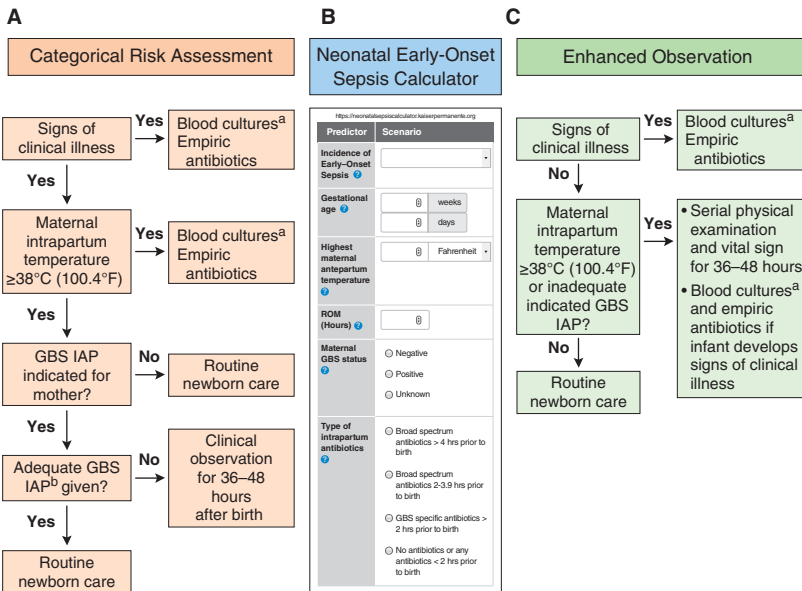

FIGURE 146–1. Options for EOS risk assessment among infants born ≥ 35 weeks' gestation. (A) Categorical risk assessment. (B) Neonatal Early-Onset Sepsis Calculator. (The screenshot of the Neonatal Early-Onset Sepsis Calculator [https://neonatalesepsiscalculator.kaiserpermanente.org/] was used with permission from Kaiser-Permanente Division of Research.) (C) Enhanced observation. ^aConsider lumbar puncture and CSF culture before initiation of empiric antibiotics for infants who are at the highest risk of infection, especially those with critical illness. Lumbar puncture should not be performed if the infant's clinical condition would be compromised, and antibiotics should be administered promptly and not deferred because of procedure delays. ^bAdequate GBS IAP is defined as the administration of penicillin G, ampicillin, or cefazolin ≥ 4 hours before delivery. (Reproduced with permission from Puopolo KM, Lynfield R, Cummings JJ, et al: *Management of Infants at Risk for Group B Streptococcal Disease*, Pediatrics. 2019 Aug;144(2). pii: e20191881.)

have been published previously including the algorithm published by CDC in 2010. For the purpose of categorical risk assessment, maternal intrapartum temperature $>38^{\circ}\text{C}$ is used as a surrogate for intraamniotic infection (called chorioamnionitis in the 2010 CDC algorithm). The administration of penicillin G, ampicillin, or cefazolin >4 hours before delivery is considered adequate GBS IAP; other antibiotics or other durations of treatment <4 hours are considered inadequate for this approach. It has been recognized that the risk of EOS is highly variable when maternal fever (any degree) is used alone as the principal categorical risk. Other important factors that modify the risk substantially include gestational age, duration of ROM, and timing and content of administered intrapartum antibiotics. Adopting this approach may result in many relatively low risk infants receiving empirical antibiotic treatment unnecessarily, especially if their only risk is exposure to low-grade maternal fever.

2. Multivariate risk assessment (the Neonatal Early-Onset Sepsis Calculator):

Multivariate risk assessment integrates the individual infant's combination of objective quantifiable risk factors and his/her clinical examination to estimate the individual infant's risk of EOS (including EOS secondary to GBS). Predictive models based on gestational age at birth (weeks and days), highest maternal intrapartum temperature (centigrade or Fahrenheit), maternal GBS colonization status (positive, negative, uncertain), duration of ROM (hours), and type and duration of intrapartum antibiotic therapies (1 of 4 categories) have been developed and validated. The models are available as web-based Neonatal Early-Onset Sepsis Calculator (Figure 146-1B) (**neonatalesepsiscalculator.kaiserpermanente.org**). The calculator begins with the previous probability of EOS (typically of 0.5/1000 in the United States, unless local incidence of EOS is known to differ). When using the calculator, only penicillin, ampicillin, or cefazolin should be considered as "GBS-specific antibiotics." The administration of clindamycin or vancomycin alone for intrapartum GBS prophylaxis for any duration is currently recommended to be entered as "no antibiotics." Entering the data listed above in the calculator produces risk estimate of EOS per 1000 births and recommends further action based on infant's examination ranging from enhanced clinical observation to blood culture and empirical antibiotic therapy. Using the original dataset, if the hypothetical risk of sepsis ranged from 0.65 to 1.54 per 1000 live births (based solely on objective risk factors), 823 well-appearing neonates born to women with maternal fever/possible intraamniotic infection would need treatment to capture the one truly infected neonate (the number needed to treat). Such newborns account for 11% of all live births. For example, if a well-appearing newborn infant is born at 39 2/7 weeks' gestation to a GBS positive mother with maximum intrapartum temperature of 38.5°C (called by obstetricians as chorioamnionitis), with ROM for 18 hours and IAP with Penicillin G, one dose 3 hours prior to delivery, this infant's sepsis risk score is calculated at 1.13. The management of the infant in this scenario would be different if categorical risk assessment is used (blood culture followed by empirical antibiotics) compared to Neonatal Sepsis Calculator (no culture, no antibiotics; vitals every 4 hours for 24 hours). Several retrospective and prospective studies have demonstrated the utility of the sepsis calculator in substantially reducing laboratory testing and exposure to antimicrobial agents (compared to categorical risk strategy) in populations of well-appearing neonates with gestational age ≥ 35 weeks without missing EOS, provided that these neonates receive continued observation for 48 hours after birth. Centers that opt for this approach will need to develop a structured method for close clinical observation of infants at specific levels of estimated risk.

3. Risk assessment based on clinical condition (enhanced observation): This approach relies on clinical signs of illness to identify infants with EOS (including that secondary to GBS) regardless of neonatal or maternal

risk factors (Figure 146–1C). Infants who appear ill at birth and those who develop signs of illness over the first 48 hours after birth are treated empirically with antibiotic agents (after blood culture is obtained). Among term infants, “good clinical condition” at birth is associated with a reduction in risk for EOS of approximately 60% to 70%. Researchers at 1 center in Italy reported a cohort of 7628 term infants who were managed with a categorical approach to risk identification and compared the outcomes with a cohort of 7611 infants who were managed with serial physical examinations every 4 to 6 hours through 48 hours of age. Significant decreases in the use of laboratory tests, blood cultures, and empirical antibiotic agents were observed in the second cohort. Two infants who developed EOS in the second cohort were identified as they developed signs of illness. This approach is embraced by the NICHD workshop on chorioamnionitis. Centers that adopt this approach need to establish processes to ensure serial, structured, documented physical assessments and develop clear criteria for additional evaluation and empirical antibiotic administration. Physicians and families must understand that the identification of initially well-appearing infants who develop clinical illness is not a failure of care, but rather an anticipated outcome of this approach to EOS (including EOS due to GBS). Additionally, it may be reasonable to consider supplementing the structured clinical examination with a limited evaluation (eg, CBC, CRP) at 6 hours of age.

The AAP guidelines stop short of recommending one approach over the other. Instead, they recommend that birth centers consider the development of locally tailored, documented guidelines for EOS risk assessment and clinical management. They also recommend ongoing surveillance once guidelines are implemented.

C. Neonatal risk assessment for infants born at $\leq 34\ 6/7$ weeks’ gestation. The AAP report on GBS addresses infants born at $\leq 34\ 6/7$ weeks’ gestation at risk for GBS in a similar fashion to infants at risk from all other causes of EOS. It indicates that those infants can be categorized by level of risk for EOS by the circumstances of their preterm birth as follows (Figure 146–2):

- 1. Preterm infants at highest risk for EOS.** Infants born preterm because of maternal cervical incompetence, preterm labor, pPROM, clinical concern for intraamniotic infection, and/or acute onset of unexplained nonreassuring fetal status are at the highest risk for EOS. Such neonates should undergo EOS evaluation with a blood culture and empiric antibiotic treatment.
- 2. Preterm infants at lowest risk for EOS.** Preterm infants at lowest risk for EOS (including EOS due to GBS) are those born under circumstances that include **all** of these criteria: (1) maternal and/or fetal indications for preterm birth (such as maternal preeclampsia or other noninfectious medical illness, placental insufficiency, or fetal growth restriction), (2) birth by cesarean delivery, and (3) absence of labor, attempts to induce labor, or any ROM before delivery. Acceptable initial approaches to these infants include (1) no laboratory evaluation and no empirical antibiotic therapy or (2) blood culture and clinical monitoring. For infants who do not improve after initial stabilization and/or those who have severe systemic instability, the administration of empirical antibiotics may be reasonable but is not mandatory.
- 3. Preterm infants delivered for maternal and/or fetal indications but who are ultimately born by vaginal or cesarean delivery after efforts to induce labor and/or with ROM before delivery.** Those infants are subject to factors associated with the pathogenesis of EOS due to GBS or other bacteria. If the mother has an indication for GBS prophylaxis and appropriate treatment (penicillin, ampicillin, or cefazolin >4 hours before delivery) is not given or if any other concern for infection arises during the process of delivery, the infant should be managed as recommended above for preterm infants at higher risk for EOS

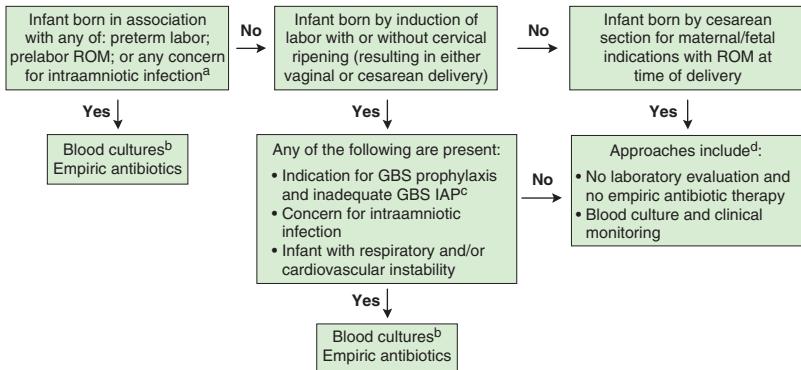

FIGURE 146–2. EOS risk assessment among infants born ≤ 34 weeks' gestation. ^aIntraamniotic infection should be considered when a pregnant woman presents with unexplained decreased fetal movement and/or there is sudden and unexplained poor fetal testing. ^bLumbar puncture and CSF culture should be performed before initiation of empiric antibiotics for infants who are at the highest risk of infection unless the procedure would compromise the infant's clinical condition. Antibiotics should be administered promptly and not deferred because of procedural delays. ^cAdequate GBS IAP is defined as the administration of penicillin G, ampicillin, or cefazolin ≥ 4 hours before delivery. ^dFor infants who do not improve after initial stabilization and/or those who have severe systemic instability, the administration of empiric antibiotics may be reasonable but is not mandatory. (Reproduced with permission from Puopolo KM, Lynfield R, Cummings JJ, et al: *Management of Infants at Risk for Group B Streptococcal Disease*, Pediatrics. 2019 Aug;144(2). pii: e20191881.)

(Section VII.C.1). Otherwise, an acceptable approach to these infants is close observation for those infants who are well appearing at birth and to obtain a blood culture and initiate antibiotic therapy for infants with respiratory and/or cardiovascular instability after birth.

D. Empiric antibiotic therapy. Treatment for EOS is often begun before a definite causative agent is identified. It usually consists of **ampicillin** and **gentamicin**. (Dosages are presented in Chapter 155.) This empirical regimen covers the most commonly encountered microorganisms, namely GBS and *E coli*, and has proved to be efficacious over the years. Third-generation cephalosporins should be avoided as an empirical therapy for EOS because they are associated with increased risk for antibiotic resistance and invasive fungal infections. Third-generation cephalosporins may be considered for infants suspected to have meningitis or who have renal impairment. According to recent CDC surveillance studies, approximately 1.7% of all *E coli* EOS cases were resistant to both ampicillin and gentamicin; therefore, the empirical addition of broader spectrum antibiotics should be considered in critically ill newborns who deteriorate despite being on ampicillin and gentamicin, or in preterm infants exposed to prolonged antepartum maternal antibiotic treatment. When blood cultures are sterile, antibiotic therapy should be discontinued by 36 to 48 hours of incubation, unless there is clear evidence of site-specific infection or unexplained persistent cardiorespiratory instability. Laboratory test abnormalities alone rarely justify prolonged empirical antibiotic administration, particularly among preterm infants at a lower risk for EOS.

E. Continuing therapy is based on culture and sensitivity results, clinical course, and occasionally other serial laboratory studies (eg, CRP and PCT). Monitoring for

antibiotic toxicity is important, as is monitoring levels of aminoglycosides. When GBS is documented as the causative agent, penicillin G is the drug of choice; however, an aminoglycoside is often added for a few days because of documented synergism *in vitro*.

F. Complications and supportive therapy

1. **Respiratory.** Ensure adequate oxygenation with blood gas monitoring, and initiate oxygen therapy or ventilator support if needed.
2. **Cardiovascular.** Support blood pressure and perfusion to prevent shock. Use volume expanders such as normal saline, and monitor the intake and output of fluids. Inotropes such as dopamine or dobutamine may be needed (see Chapter 70).
3. **Hematologic**
 - a. **Disseminated intravascular coagulation.** With disseminated intravascular coagulation (DIC), one may observe generalized bleeding at puncture sites, the gastrointestinal tract, or CNS. In the skin, large-vessel thrombosis may cause gangrene. Laboratory parameters consistent with DIC include thrombocytopenia, increased prothrombin time, and increased partial thromboplastin time. There is an increase in fibrin split products or d-dimers. Treatment options include fresh-frozen plasma, 10 mL/kg; vitamin K (see Chapter 155); platelet infusion; and possible exchange transfusion (see Chapter 34).
 - b. **Neutropenia.** Multiple factors contribute to the increased susceptibility of neonates to infection, including developmental quantitative and qualitative neutrophil defects. Colony-stimulating factors comprise a group of cytokines that are central to the hematopoiesis of blood cells, as well as to the maintenance of homeostasis and overall immune competence. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have been used in neonates with established sepsis associated with neutropenia, in neutropenic infants without sepsis, and prophylactically in neonates at risk for sepsis. Limited data suggest that colony-stimulating factor administration may reduce mortality when systemic infection is accompanied by severe neutropenia. Intravenous immunoglobulin does not appear useful either as a prophylactic agent or as an adjunct to antibiotic therapy in serious neonatal infection.
4. **Central nervous system.** Implement seizure control measures using phenobarbital, and monitor for the syndrome of inappropriate antidiuretic hormone (decreased urine output, hyponatremia, decreased serum osmolarity, and increased urine specific gravity and osmolarity).
5. **Metabolic.** Monitor for and treat hypoglycemia or hyperglycemia. Metabolic acidosis may accompany sepsis and is treated with bicarbonate and fluid replacement.

- G. Future developments.** Intensive research continues in the development of vaccines (especially for GBS). Research is also ongoing into blocking some of the body's own inflammatory mediators that result in significant tissue injury, including endotoxin inhibitors, cytokine inhibitors, nitric oxide synthetase inhibitors, and neutrophil adhesion inhibitors.

VIII. Prognosis. With early diagnosis and treatment, most infants will recover and not have long-term complications. However, the mortality rate is still significant for EOS, especially in VLBW infants. For term and late preterm infants, the reported mortality is approximately 3%, whereas EOS mortality for VLBW infants is approximately 16%. Neonatal EOS is a risk factor for long-term neurodevelopmental impairment in premature infants.

NEONATAL LATE-ONSET SEPSIS

- I. Definition.** Neonatal LOS is defined by the CDC as blood and/or CSF culture-proven infection occurring in the newborn after 7 days of age caused by a postnatal acquisition (nosocomial or community sources). For the continuously hospitalized VLBW infant, LOS is defined as culture-proven infection occurring at >72 hours of age.

- II. Incidence of neonatal late-onset sepsis.** The overall incidence of primary sepsis (EOS and LOS) is 1 to 2 per 1000 live births. The incidence of LOS in term infants is hard to know; however, a study that looked at late preterm infants hospitalized in the first 3 months of life identified LOS in 6.3 per 1000 admissions. According to the CDC, late-onset GBS infection rates have remained relatively stable over the past 20 years and are not impacted by intrapartum antibiotics prophylaxis (0.32 per 1000 live births in 2015). Incidence of LOS is much higher for VLBW infants; according to data from the NICHD Neonatal Research Network (NICHD-NRN), the incidence is 32% and appears to be decreasing in recent years (37% in 2005, 27% in 2012).
- III. Pathophysiology of neonatal late-onset sepsis.** LOS is usually more insidious (compared to EOS), but it can be fulminant at times. It is usually not associated with early obstetric complications. In addition to bacteremia, these infants may have an identifiable focus, most often meningitis in addition to sepsis. Bacteria responsible for LOS and meningitis include those acquired after birth from the maternal genital tract (vertical transmission) as well as organisms acquired after birth from human contact or from contaminated equipment/environment (nosocomial). Therefore, horizontal transmission appears to play a significant role in LOS. The reasons for the delay in development of clinical illness, the predilection for CNS disease, and the less severe systemic and cardiorespiratory symptoms are unclear. Transplacental transfer of maternal antibodies (also in breastmilk) to the mother's own vaginal flora may play a role in determining which exposed infants become infected, especially in the case of GBS infections. In case of nosocomial spread, the pathogenesis is related to the underlying illness and debilitation of the infant, the flora in the neonatal intensive care (NICU) environment, and invasive monitoring and other techniques used in the NICU, especially the use of peripherally inserted central catheters (PICCs). Breaks in the natural barrier function of the skin and intestine allow opportunistic organisms to invade and overwhelm the neonate. Infants, especially the premature, have an increased susceptibility to infection because of underlying illnesses and immature immune defenses that are less efficient at localizing and clearing bacterial invasion.
- A. Microbiology.** The pathogens that cause LOS or nosocomial sepsis tend to vary in each nursery; however, coagulase-negative staphylococci (CONS), especially *Staphylococcus epidermidis*, are the most predominant (53% of cases in NICHD-NRN). Other microorganisms causing LOS include gram-negative rods (including *Pseudomonas*, *Klebsiella*, *Serratia*, *E coli*, and *Proteus*), *S aureus* (both methicillin-susceptible and methicillin-resistant), GBS, and fungal microorganisms.
- B. Antibiotic resistance.** Antibiotics resistance, especially to Enterobacteriaceae such as *E coli*, is an emerging problem in many NICUs. Multiple mechanisms of resistance may be present simultaneously. Resistance resulting from production of chromosomally encoded or plasmid-derived AmpC β -lactamases or from plasmid-mediated extended-spectrum β -lactamases (ESBLs) occurs primarily in *E coli*, *Klebsiella* species, and *Enterobacter* species but has been reported in many other gram-negative species. Resistant gram-negative infections have been associated with nursery outbreaks, especially in VLBW infants. Organisms that produce ESBLs typically are resistant to penicillins, cephalosporins, and monobactams and can be resistant to aminoglycosides. Carbapenemase-producing Enterobacteriaceae (CPE) also have emerged, especially *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Acinetobacter* species. ESBL- and carbapenemase-producing bacteria often carry additional plasmid-borne genes that encode for high-level resistance to aminoglycosides, fluoroquinolones, and trimethoprim-sulfamethoxazole.
- IV. Risk factors of neonatal late-onset sepsis**
- A. Prematurity and low birthweight.** Prematurity (<37 weeks' gestation) is the single most significant factor correlated with sepsis. The risk increases in proportion to the decrease in birthweight and GA (GA <25 weeks: 41%; GA 25–28 weeks: 21%; GA 29–32 weeks: 10%). Being small for gestational age increases the risk further.

- B. Invasive procedures/devices.** Intravascular catheterization (PICC and umbilical catheters) and respiratory (endotracheal intubation) or metabolic support (total parenteral nutrition) are important risk factors for LOS. Mechanical ventilation and continuous positive airway pressure have been associated with an increased risk of LOS in VLBW infants.
- C. Risk factors for extended-spectrum β -lactamase infection and carbapenemase-producing Enterobacteriaceae.** Additional risk factors associated with neonatal ESBL infection include prolonged mechanical ventilation, extended hospital stay, use of invasive devices, and use of antimicrobial agents. Infants born to mothers colonized with ESBL-producing *E coli* are themselves at an increased risk of acquiring colonization with ESBL-producing *E coli*.
- D. Other factors.** Bottle feeding (as opposed to breast feeding) predisposes to infection. Black African descent has been found as an independent risk factor for GBS sepsis (both EOS and LOS). Reasons for the disproportionately high disease burden among black populations cannot be fully explained by prematurity or socioeconomic status. NICU staff and family members are often vectors for the spread of microorganisms, primarily as a result of improper or lack of hand washing. The risk of infection correlates with length of stay in the NICU.
- V. Clinical presentation of neonatal late-onset sepsis.** Because the initial diagnosis of sepsis is, by necessity, a clinical one, it is crucial to begin treatment before the results of cultures are available. Clinical signs and symptoms of sepsis are nonspecific, and the differential diagnosis is broad. Some signs are subtle or insidious, and therefore, a high index of suspicion is required to identify and evaluate infected neonates. Clinical signs and symptoms most often mentioned include the following:
- A. Temperature irregularity.** Hypothermia is more common than fever as a presenting sign for bacterial sepsis in premature infants. Hyperthermia is more common in full-term infants beyond the first 24 hours of life and if viral agents (eg, herpes) are involved.
- B. Change in behavior.** Lethargy, irritability, or change in tone.
- C. Skin.** Poor peripheral perfusion, cyanosis, mottling, pallor, petechiae, rashes, sclerema, and jaundice singularly or in combinations are known signs of sepsis.
- D. Feeding problems.** Feeding intolerance, vomiting, diarrhea, or abdominal distention with or without visible bowel loops.
- E. Cardiopulmonary.** Tachypnea, respiratory distress (grunting, flaring, and retractions), new onset of apnea, bradycardia and desaturation episodes (ABD [apnea, bradycardia, desaturation] spells), tachycardia, and hypotension singularly or in combinations should suggest sepsis. Hypotension tends to be a late sign.
- Reduced variability and transient decelerations in heart rate (HR) may be present in the hours to days before diagnosis of LOS. These **abnormal HR characteristics (HRC)** in response to systemic infection and inflammation have been characterized mathematically, and the resulting **HRC index** can be computed in real time and displayed continuously at the bedside. Some studies suggest that monitoring the HRC index in high-risk premature infants may result in improved outcomes and decreased mortality (through early warning with diagnosing early sepsis and prompt treatment with antibiotics).
- F. Metabolic.** Metabolic findings include hypoglycemia, hyperglycemia, or metabolic acidosis.
- G. Focal infections.** These may precede or accompany LOS. Look for cellulitis, impetigo, soft tissue abscesses, omphalitis, conjunctivitis, otitis media, meningitis, or osteomyelitis.
- VI. Diagnosis of neonatal late-onset sepsis**
- A. Differential diagnosis.** Because signs and symptoms of neonatal sepsis are nonspecific, noninfectious etiologies need to be considered. If the infant is presenting with cardiorespiratory symptoms, aspiration pneumonia, patent ductus arteriosus, or other congenital heart diseases need to be considered. If the infant is showing CNS

symptoms, then intracranial hemorrhage, drug withdrawal, and inborn errors of metabolism are considered. Patients with feeding intolerance and bloody stool may have necrotizing enterocolitis (NEC), gastrointestinal perforation, or obstruction. Some nonbacterial infections such as disseminated herpes simplex virus can be indistinguishable from bacterial sepsis and should be considered in the differential diagnosis, especially if the infant has fever. **Postnatal cytomegalovirus** (acquired through breast milk or blood transfusion) is another agent that is increasingly being recognized as a cause of sepsis-like illness in extremely low birth weight infants beyond the first week of life. Other viral agents that need to be considered include respiratory syncytial virus (RSV) and *Enterovirus/Parechovirus*.

B. Laboratory studies of neonatal late-onset sepsis

1. **Cultures.** Blood and other normally sterile body fluids (urine, spinal fluid, and occasionally tracheal aspirate) should be obtained for culture. Body surface cultures are not recommended unless the infant has pustules or a characteristic rash (eg, candida).

a. **Blood cultures.** Computer-assisted automated blood culture systems identify up to 94% to 96% of all microorganisms by 36 to 48 hours of incubation. The minimum volume for blood culture is 1 mL (some have suggested weight-based criteria; 1 mL for infants weighing <1.5 kg, 2 mL for infants weighing 1.5–3 kg, and 3 mL for infants >3 kg). **Two blood cultures (1 from PICC and 1 peripheral) are recommended.** In many clinical situations, infants are treated for “presumed” sepsis despite negative cultures, if clinical and laboratory findings are suggestive of infection and no other etiology is found to explain the clinical deterioration.

b. **Lumbar puncture.** LP should be part of the routine evaluation for LOS. Meningitis is likely to happen without sepsis in VLBW infants, and therefore, LP is mandatory.

c. **Urine culture** must be obtained as part of evaluation for LOS. Urine specimen should be obtained by either a suprapubic tap (see Chapter 29) or catheterized specimen (see Chapter 30). Bag urine samples should not be used to diagnose UTI in neonates.

d. **Tracheal cultures** may be considered in intubated neonates with a clinical picture suggestive of pneumonia, especially when the quality and volume of tracheal secretions change substantially. However, it is often hard to differentiate tube colonization from true infection.

2. **Gram stain of various fluids.** Gram staining is especially helpful for the study of CSF. A Gram stain of tracheal aspirate fluid may suggest an inflammatory process if numerous WBCs, together with bacteria, are identified.

3. **Molecular testing.** See prior discussion under EOS of this chapter (page 1177).

4. **Other laboratory tests**

a. **Complete blood count with differential.** See prior discussion under EOS of this chapter. LOS is associated with both low and high WBC (<1000/mm³ and >50,000/mm³), high absolute neutrophil count (>17,670/mm³), elevated I/T ratio (>0.2), and low platelet count (<50,000/mm³). It is also important to note that neutropenia has been described commonly as an incidental finding in otherwise healthy growing VLBW infants.

b. **Acute-phase reactants.** See prior discussion under EOS section of this chapter. **Serial CRP determinations** are helpful in ruling out infection when normal (high negative predictive value). **PCT** may be better than CRP in the diagnosis and follow-up of neonatal sepsis secondary to **CONS**.

C. Imaging and other studies

1. **Chest radiograph.** A chest radiograph should be obtained in cases with respiratory symptoms, although it is often difficult to differentiate changes associated with true bacterial pneumonia from those associated with bronchopulmonary dysplasia, simple aspiration, or atelectasis.

2. **Urinary tract imaging.** Imaging with renal ultrasound, renal scan, and possibly voiding cystourethrogram should be considered when UTI accompanies sepsis.

VII. Management of neonatal late-onset sepsis. Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

A. Prevention of neonatal nosocomial late-onset sepsis. A subset of nosocomial sepsis is **central line–associated bloodstream infections (CLABSIs)**. Although primary prevention of CLABSI relies on minimizing the use of central lines, novel technologies such as antiseptic- and antimicrobial-impregnated catheters in addition to meticulous care during PICC insertion and maintenance are key factors in preventing CLABSIs. Quality improvement initiatives that focus on adherence to best practices of catheter insertion and maintenance (NICU Central Catheter Bundles) have resulted in widespread reduction in CLABSIs across different NICUs. Some of those bundles were adopted and disseminated through statewide collaboratives such as the California Perinatal Quality Care Collaborative (CPQCC). **Hand hygiene is the single most important strategy** for avoiding transmission of contagions in the NICU. Fresh maternal milk contains a number of substances responsible for innate immune and humoral responses against pathogens; therefore, promotion of **breast feeding** is considered a key step in the prevention of NICU infections. Medical stewardship of antibiotics, steroids, and H₂ blockers is mandatory; indiscriminate use of these agents has been associated with increased nosocomial sepsis. Enhancement of the enteric microbiome composition with the possible use of **probiotics** may restore gut immune function and help prevent NEC and sepsis. In a recent meta-analysis of 37 trials, probiotics were associated with a small, but statistically significant, reduction in the risk of LOS compared with placebo or no treatment. Use of bioactive substances with known anti-infective properties such as **lactoferrin** may be helpful. **A recently published Cochrane review that included 6 trials suggested that lactoferrin supplementation to enteral feeds with or without probiotics may decrease LOS and NEC in preterm infants.** However, no recommendations can be made until ongoing trials that enrolled >6000 preterm neonates are completed. Finally, specific and targeted pharmacologic prophylactic interventions have been used with some success. For example, specific antifungal prophylaxis with fluconazole has been associated with significant reduction in invasive fungal infection; it is recommended in NICUs that experience high rates of invasive candidiasis. However, the use of pagibaximab, a recombinant monoclonal antibody targeting staphylococcal sepsis, does not appear to offer protection against gram-positive CLABSIs in the NICU.

B. Empiric antibiotic therapy. Treatment is most often begun before a definite causative agent is identified. In nosocomial sepsis, the flora of the NICU must be considered in choosing antibiotics; however, staphylococcal coverage with **vancomycin plus an aminoglycoside** such as gentamicin or amikacin is usually begun. Some NICUs use a **cefazolin** or **nafcillin** for staphylococcal coverage instead of vancomycin. The empirical treatment for suspected LOS in a neonate admitted from the community is ampicillin and gentamicin; cefotaxime can be added only when there is a concern for meningitis. Dosages are presented in Chapter 155.

C. Continuing therapy is based on culture and sensitivity results, clinical course, and other serial laboratory studies (eg, CRP or PCT). If an **ESBL-producing organism**, such as *K pneumoniae*, is suspected or identified, then **carbapenem** is the drug of choice (with aminoglycoside for double coverage). Of the aminoglycosides, **amikacin** retains the most activity against ESBL-producing strains. An aminoglycoside or cephepime can be used if the organism is susceptible, because **cefepime** does not induce chromosomal AmpC enzymes. Monitoring for antibiotic toxicity is important, as well as monitoring levels of aminoglycosides and vancomycin.

D. Complications and supportive therapy are reviewed under the EOS section of this chapter (page 1184). In particular, administration of **intravenous immunoglobulin** to neonates with suspected or proven LOS does not result in reduction in mortality

during hospital stay or major disability at 2 years of age. Similarly, administration of colony-stimulating factors, namely **G-CSF** and **GM-CSF**, does not result in reduced mortality or better neurodevelopmental outcome at 2 and 5 years. However, there might be a place for using **G-CSF** in cases of severe infection complicated by **severe neutropenia (absolute neutrophil count <500/mm³)** and/or in the presence of specific hematologic diseases causing severe neutropenia.

E. Future developments. Intensive research continues in the development of vaccines as well as synthetic monoclonal antibodies to the specific pathogens causing neonatal LOS. Research is also ongoing into blocking some of the body's own inflammatory mediators that result in significant tissue injury, including endotoxin inhibitors, cytokine inhibitors, nitric oxide synthetase inhibitors, and neutrophil adhesion inhibitors. Finally, recent research is showing prebiotics, probiotics, and lactoferrin to be promising agents in the prevention of LOS and NEC.

VIII. Prognosis. Neonatal LOS remains a major cause of death in VLBW infants, with a reported mortality rate of approximately 18%. Mortality due to gram-negative infections is higher than that due to gram-positive infections. Risk factors for LOS mortality include endotracheal intubation, administration of vasopressors, hypoglycemia, thrombocytopenia, and development of NEC. VLBW infants who survive LOS are at risk for long term neurodevelopmental impairment including cerebral palsy.

147 Syphilis

I. Definition. Syphilis is a sexually transmitted infection caused by *Treponema pallidum*, which is a thin, motile spirochete that is extremely fastidious, surviving only briefly outside the host. The Centers for Disease Control and Prevention (CDC) issued a case definition of **congenital syphilis (CS)** in 2018 as follows: a condition caused by infection in utero with *T pallidum*. A wide spectrum of severity exists, from inapparent infection to severe cases that are clinically apparent at birth. **Laboratory criteria for diagnosis** entail demonstration of *T pallidum* by: (1) darkfield microscopy of lesions, body fluids, or neonatal nasal discharge; **or** (2) polymerase chain reaction (PCR) or other equivalent direct molecular methods of lesions, neonatal nasal discharge, placenta, umbilical cord, or autopsy material; **or** (3) immunohistochemistry or special stains (eg, silver staining) of specimens from lesions, placenta, umbilical cord, or autopsy material. **Cases are classified as confirmed (by laboratory diagnosis) or probable.** **Probable CS** is a condition affecting an infant whose mother had untreated or inadequately treated syphilis at delivery, regardless of signs in the infant, **or** an infant or child who has a reactive nontreponemal test for syphilis (Venereal Disease Research Laboratory [VDRL], rapid plasma reagin [RPR], or equivalent serologic methods) **and** any 1 of the following: (1) any evidence of CS on physical examination; (2) any evidence of CS on radiographs of long bones; (3) a reactive cerebrospinal fluid (CSF) VDRL test; (4) an elevated CSF leukocyte (white blood cell [WBC]) count or protein (without other cause) in a nontraumatic lumbar puncture. Suggested parameters for **abnormal CSF WBC and protein** values include the following: during the first 30 days of life, a CSF WBC count of >15 WBC/mm³ or a CSF protein >120 mg/dL is abnormal; after the first 30 days of life, a CSF WBC count of >5 WBC/mm³ or a CSF protein >40 mg/dL is abnormal, regardless of CSF serology. **Adequate treatment** is defined as completion of a penicillin-based regimen, in accordance with CDC treatment guidelines, appropriate for stage of infection, initiated ≥30 days before delivery.

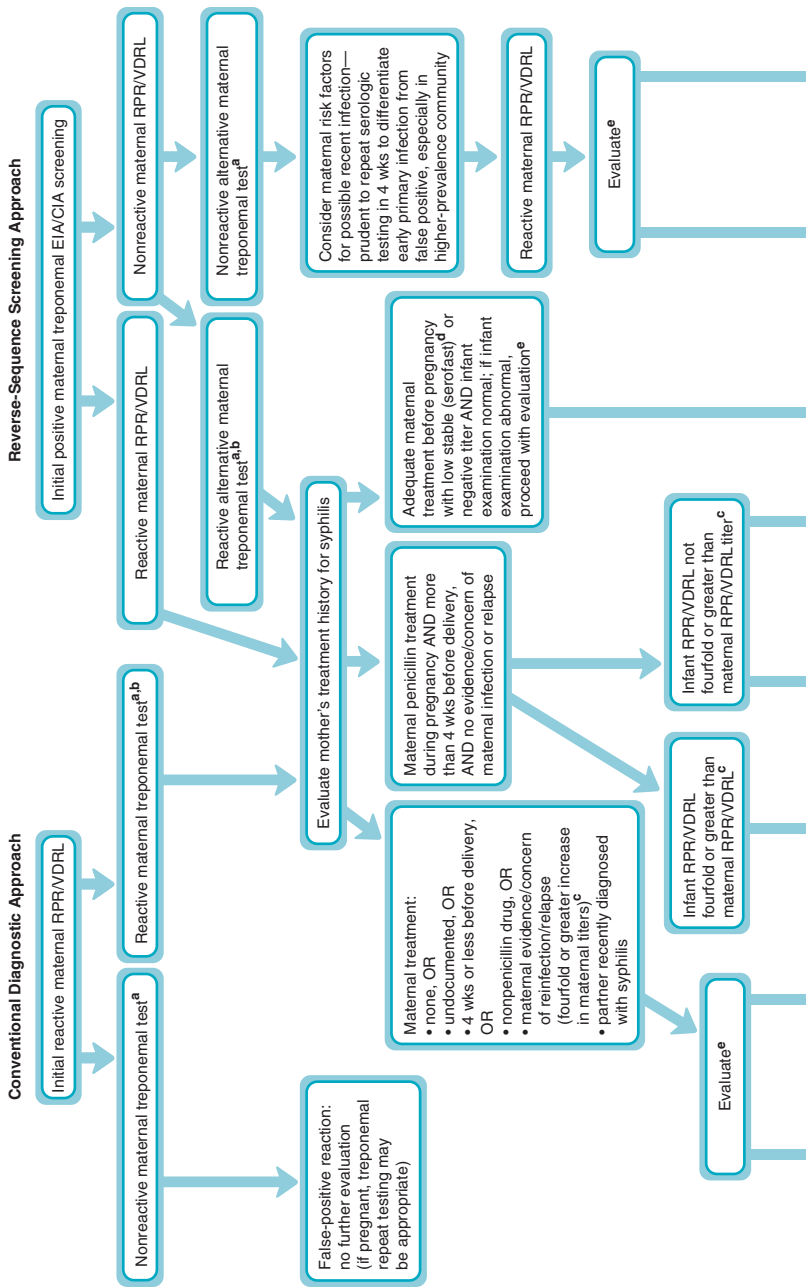

- II. Incidence.** According to the CDC, from 2013 through 2017, there was a 76% increase in cases of syphilis in the United States (from 17,375 to 30,644 cases). The incidence of CS parallels that of primary and secondary syphilis in the general population. In the United States, in 2016, there were a total of 628 reported cases of CS, including 41 syphilitic stillbirths, with a national rate of 15.7 cases per 100,000 live births. This rate represents an increase of 86.9% relative to 2012. Worldwide, syphilis continues to represent a serious public health problem; a World Health Organization analysis showed that in 2012, an estimated 930,000 maternal syphilis infections caused 350,000 adverse pregnancy outcomes including 143,000 early fetal deaths and stillbirths, 62,000 neonatal deaths, 44,000 preterm or low-weight births, and 102,000 infected infants worldwide. The rate of CS is increased among infants born to mothers with human immunodeficiency virus (HIV) infection.
- III. Pathophysiology.** Treponemes are able to cross the placenta at any time during pregnancy, thereby infecting the fetus. **Syphilis can cause stillbirth (30% to 40% of fetuses with CS are stillborn), preterm delivery, congenital infection, or neonatal death,** depending on the stage of maternal infection and duration of fetal infection before delivery. Untreated infection in the first and second trimesters often leads to significant fetal morbidity, whereas with third-trimester infection, many infants are asymptomatic. The most common cause of fetal death is placental infection associated with decreasing blood flow to the fetus, although direct fetal infection also plays a role. Infection can also be acquired by the neonate via contact with infectious lesions during passage through the birth canal. Kassowitz's law states that the risk of vertical transmission of syphilis from an infected, untreated mother decreases as maternal disease progresses. Thus, transmission ranges from 70% to 90% in primary and secondary syphilis, to 40% for early latent syphilis, and to 8% for late latent disease. CS can cause placentomegaly and congenital hydrops. *T pallidum* is not transferred in breast milk, but transmission may occur if the mother has an infectious lesion (eg, chancre) on her breast.
- IV. Risk factors.** At-risk group include infants whose mothers received no or inadequate treatment (dose was unknown, inadequate, or undocumented), whose mother received a nonpenicillin treatment during pregnancy for syphilis, or whose mother was treated within 30 days of the infant's birth. Infants of high-risk mothers (drug use, especially cocaine use; low socioeconomic levels; HIV infection; teen pregnancy; commercial sex work; and lack of prenatal care) are at increased risk for syphilis. **Lack of early prenatal care is the strongest predictor of CS.**
- V. Clinical presentation.** CS is a multiorgan infection that may cause neurologic or skeletal disabilities or death in the fetus or newborn. However, when mothers with syphilis are treated early in pregnancy, the disease is almost entirely preventable. The risk of fetal infection increases with advancing gestation. Approximately two-thirds of live-born neonates with CS are asymptomatic at birth but have low birthweight. Clinical manifestations after birth are arbitrarily divided into **early CS** (<2 years of age) and **late CS** (>2 years of age).
- A. Early manifestations** include nasal discharge (snuffles) and maculopapular or vesiculobullous rash that appears on the palms and soles. The rash may be associated with desquamation. Other early stigmata include fever, abnormal bone radiographs, hepatosplenomegaly, petechiae, lymphadenopathy, jaundice, pneumonia, osteochondritis, pseudoparalysis, hemolytic anemia, leukocytosis, thrombocytopenia, and central nervous system (CNS) involvement. Skin lesions and moist nasal secretions in infected babies are highly contagious. However, organisms are rarely found in lesions >24 hours after treatment has begun.
- B. Late manifestations** develop in untreated infants and are characterized by chronic granulomatous inflammation. The sites most often involved include bones and joints, teeth, eyes, and the nervous system. **Hutchinson triad** (blunted upper incisors, interstitial keratitis, and eighth nerve deafness) and saddle nose are distinct complications. Some of these consequences may not become apparent until many years after birth, such as interstitial keratitis (5–20 years of age) and eighth cranial nerve deafness (10–40 years of age). A poor response to antibiotic treatment is often noted.

VI. Diagnosis. Diagnosis relies on active surveillance and laboratory studies. Maternal testing during pregnancy to treat the mother and identify the at-risk newborn is crucial. Most infants are asymptomatic at birth. Besides testing for syphilis, these infants should be tested for HIV infection as well.

A. Laboratory studies. Patients with congenital or acquired syphilis produce several different antibodies that can be tested in the laboratory. These are grouped as **non-specific nontreponemal antibody (NTA) tests** and **specific treponemal antibody (STA) tests**. NTA tests (including VDRL, RPR, and automated reagin test) are inexpensive, rapid, and convenient screening tests that may indicate disease activity. These tests measure the antibody directed against lipoidal antigen from *T pallidum*, antibody interaction with host tissues, or both. They are used as initial screening tests and quantitatively to monitor a patient's response to treatment and to detect reinfection and relapse. False-positive reactions can be secondary to autoimmune disease, intravenous drug addiction, aging, pregnancy, and many infections, such as hepatitis, mononucleosis, measles, and endocarditis. The interpretation of NTA and STA tests can be confounded by maternal immunoglobulin (Ig) G antibodies that are passed transplacentally to the fetus.

1. Nonspecific nontreponemal antibody tests. The 2 most often used of these nonspecific screening tests are **VDRL** and **RPR**. A titer of at least 2 dilutions (4-fold) higher in the infant than in the mother signifies probable active infection. Titers should be monitored and repeated every 2 to 3 months after therapy. A sustained 4-fold decrease in titer, equivalent to a change of 2 dilutions (eg, from 1:16 to 1:4), of the NTA test result after treatment usually demonstrates adequate therapy, whereas a sustained 4-fold increase in titer (eg, from 1:8 to 1:32) after treatment suggests reinfection or relapse. The NTA test titer usually decreases 4-fold within 6 to 12 months after therapy for primary or secondary syphilis and usually becomes nonreactive within 1 year. **VDRL (not RPR) should be used on CSF.** A normal test result is negative, and any positive test should be followed up with a specific treponemal test. When NTA tests are used to monitor treatment response, the same test (eg, VDRL or RPR) must be used throughout the follow-up period, preferably by the same laboratory, to ensure comparability of results.

2. Specific treponemal antibody tests. These tests verify a diagnosis of current or past infection and should be performed if NTA test results are positive. These antibody tests do not correlate with disease activity and are not usually quantified. They are useful for diagnosing a first episode of syphilis and for distinguishing a false-positive result of NTA tests. However, they have limited use for evaluating response to therapy and possible reinfections. Once the STA test is positive, it will stay positive for life. In addition, STA tests are not 100% specific for syphilis; positive reactions variably occur in patients with other spirochetal diseases, such as yaws, pinta, leptospirosis, rat-bite fever, relapsing fever, and Lyme disease. NTA tests can be used to differentiate Lyme disease from syphilis, because the **VDRL test is nonreactive in Lyme disease**. Examples of STA tests include the *T pallidum* particle agglutination (TP-PA) test, *T pallidum* enzyme immunoassay (TP-EIA), *T pallidum* chemiluminescent assay (TP-CLA), and fluorescent treponemal antibody absorption (FTA-Abs) test. ***T pallidum*-specific IgM immunoblot** testing in the newborn is able to identify infants with CS with high sensitivity; however, the test is not commercially available. Recently, some clinical laboratories and blood banks have begun to screen samples using **TP-EIA**, rather than beginning with an NTA test; the reasons for this change in sequence of the screening relate to cost and manpower issues. However, this “reverse sequence screening” approach is associated with high rates of false-positive results, and in 2011, the CDC recommended against adopting it. Despite that, an increasing number of laboratories are adopting it and the Committee on Infectious Diseases of the American Academy of Pediatrics modified its diagnostic algorithm to CS to include the “reverse sequence screening approach” (see Section VII, “Management,” and Figure 147-1).

RPR indicates rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

a *Treponema pallidum* particle agglutination (TP-PA) (which is the preferred treponemal antibody absorption (FTA-ABS), or microhemagglutination test for antibodies to *T. pallidum* (MHA-TP)).

b Test for human immunodeficiency virus (HIV) antibody. Infants of HIV-infected mothers do not require different evaluation or treatment for syphilis.

c A fourfold change in titer is the same as a change of 2 dilutions. For example, a titer of 1:64 is fourfold greater than a titer of 1:16, and a titer of 1:4 is fourfold lower than a titer of 1:16. When comparing titers, the same type of nontreponemal test should be used (eg, if the initial test was a RPR, the follow-up test should also be an RPR).

d Stable VDRL titers 1:2 or less or RPR 1:4 or less beyond 1 year after successful treatment are considered low serofast.

e Complete blood cell (CBC) and platelet count; cerebrospinal fluid (CSF) examination for cell count, protein, and quantitative VDRL; other tests as clinically indicated (eg, chest radiographs, long-bone radiographs, eye examination, liver function tests, neuroimaging, and auditory brainstem response).

FIGURE 147-1. Algorithm for diagnostic approach of infants born to mothers with reactive serologic tests for syphilis. (Reproduced with permission from Kimberlin DW, Long SS, Brady MT, et al: Red Book: 2018 Report of the Committee on Infectious Diseases, 31st ed. Elk Grove Village, IL: American Academy of Pediatrics; 2018.)

3. **Direct identification of *T pallidum*.** Microscopic **darkfield examination** can be performed on appropriate specimens (lesion exudate, nasal discharge, or tissue, such as placenta, umbilical cord, or autopsy specimens) to detect spirochetes. Specimens from mouth lesions can contain nonpathogenic treponemes that can be difficult to distinguish from *T pallidum* by darkfield microscopy. **Direct fluorescent antibody** tests are no longer available in the United States. *T pallidum* can be detected by PCR assay, but clinical diagnostic PCR assays cleared by the US Food and Drug Administration (FDA) are not yet available.

4. **Lumbar puncture.** CNS disease may be detected by examining CSF and finding positive serologic tests (VDRL or FTA-ABS), darkfield examination positive for spirochetes, positive syphilis PCR, elevated monocyte count, or elevated spinal fluid protein levels. VDRL is most commonly used, but some experts recommend the FTA-ABS test as well. FTA-ABS may be more sensitive but less specific than VDRL. Results from the VDRL test should be interpreted cautiously because a negative result on a VDRL test of CSF does not exclude a diagnosis of neurosyphilis. Alternatively, a reactive VDRL test in the CSF of neonates can be the result of nontreponemal IgG antibodies that cross the blood–brain barrier. PCR testing of CSF may prove very useful for the diagnosis of CNS syphilis. The CDC has included age-appropriate definitions of abnormal CSF cell count and protein levels in the 2018 case definition of CS (see Section I).

B. Histopathologic examination of the placenta and umbilical cord. The placenta of neonates with CS is often large, thick, and pale. The umbilical cord is edematous and may resemble a “barber’s pole” with spiral stripes of red and light blue discoloration alternating with streaks of chalky white. It may be significantly inflamed with micro-abscesses and necrotizing funisitis. The placenta and the cord should be carefully examined with darkfield microscopy and special stains looking for spirochetes.

C. Imaging studies. Radiographic abnormalities may be noted in 65% of the cases. These manifestations noted on long bones include periostitis, osteitis, and sclerotic metaphyseal changes. Infants may also present with pseudoparalysis or pathological fractures.

VII. Management. Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.

A. Maternal testing during pregnancy. CDC recommends serologic syphilis testing for all pregnant women at the first prenatal visit. In communities and populations in which the risk for CS is high, serologic testing and a sexual history also should be obtained at 28 to 32 weeks’ gestation and at delivery. **Any woman who delivers a stillborn infant after 20 weeks’ gestation should be tested for syphilis.** An NTA test (RPR or VDRL) is recommended for screening, followed by a treponemal (eg, TP-PA) test if the screening result is positive. If the reverse-sequence screening algorithm is used, pregnant women with reactive treponemal TP-EIA/TP-CIA screening test results should have confirmatory testing with a quantitative NTA test. If the NTA test result is negative (discordant result), a second treponemal test using a different *T pallidum* antigen should be obtained to determine whether the initial treponemal test result was a false positive. If the second treponemal test result is positive, it may be attributable to a prior infection adequately treated in the past or to untreated syphilis in a late stage. For women treated during pregnancy, follow-up serologic testing is necessary to assess the effectiveness of therapy. Treated pregnant women with syphilis should have quantitative NTA serologic tests repeated at 28 to 32 weeks of gestation, at delivery, and according to recommendations for the stage of disease. Serologic titers may be repeated monthly in women at high risk of reinfection or in geographic areas where the prevalence of syphilis is high. **Rapid**

point-of-care prenatal syphilis screening using an immunochromographic strip has been used in several resource-limited countries.

- B. Evaluation and treatment of infants.** No newborn infant should be discharged from the hospital without determination of the mother's serologic status for syphilis at least once during pregnancy and also at delivery in communities and populations in which the risk for CS is high. Testing of umbilical cord blood or an infant serum sample is inadequate for screening, because these can be nonreactive if the mother's serologic test result is of low titer or she was infected late in pregnancy. All infants born to seropositive mothers require a careful examination and a quantitative NTA test. The test performed on the infant should be the same as that performed on the mother to enable comparison of titer results. **The diagnostic and therapeutic approach to infants being evaluated for CS is summarized in Figure 147-1.**

- 1. Infants with proven or highly probable congenital syphilis** (abnormal physical examination consistent with CS or a serum quantitative NTA titer that is 4-fold higher than the mother's titer or a positive darkfield microscopy or PCR of a lesion or body fluid). The recommended treatment according to the CDC guidelines is **aqueous crystalline penicillin G** 50,000 U/kg/dose intravenously every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days (preferred treatment) *or* **procaine penicillin G** 50,000 U/kg/dose intramuscularly (IM) in a single daily dose for 10 days. If >1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding the use of other antimicrobial agents (eg, ampicillin). A full 10-day course of penicillin is needed, even if ampicillin was initially provided for possible sepsis. These patients always should be treated with penicillin, even if desensitization for penicillin allergy is necessary (extremely rare in the newborn period).
- 2. Asymptomatic infants who have normal physical examination and a serum quantitative nonspecific nontreponemal antibody titer \leq 4-fold the maternal titer** should be managed according to the status of maternal treatment:
 - a. Maternal treatment uncertain (possible congenital syphilis).** The mother was not treated, was inadequately treated, or has no documentation of having received treatment; the mother was treated with erythromycin or other nonpenicillin regimen; or the mother received treatment <4 weeks before delivery. These infants should be fully evaluated and treated as described in Section VII.B.1. Alternatively, **benzathine penicillin G**, 50,000 U/kg as a single **IM** dose, is acceptable provided that all components of the evaluation are obtained and are normal, including normal CSF results, and follow-up is ensured.
 - b. Maternal treatment during pregnancy is adequate (congenital syphilis less likely).** (Penicillin therapy given >4 weeks before delivery and the mother has no evidence of reinfection or relapse.) No evaluation is needed; however, a single **IM** dose of **benzathine penicillin G**, 50,000 U/kg, is recommended. Alternatively, infants whose mother's NTA titers decreased at least 4-fold after appropriate therapy for early syphilis or remained stable at low titer (eg, VDRL \leq 1:2; RPR \leq 1:4) may be followed every 2 to 3 months without treatment until the NTA test becomes nonreactive.
 - c. Maternal treatment before pregnancy is adequate, and mother's nonspecific nontreponemal antibody titer remained low and stable before and during pregnancy and at delivery (eg, VDRL <1:2; RPR <1:4; congenital syphilis is unlikely).** No evaluation or therapy is needed for the infant. Infants with reactive NTA tests should be followed serologically to ensure test result returns to negative. Benzathine penicillin G, 50,000 U/kg IM as single dose, can be considered if follow-up is uncertain and infant

has a reactive test. Neonates with a negative NTA test result at birth and whose mothers were seroreactive at delivery should be retested at 3 months to rule out serologically negative incubating CS at the time of birth.

C. Isolation procedures. Precautions regarding drainage, secretions, and blood and body fluids are indicated for all infants with suspected or proven CS until therapy has been given for 24 hours.

D. Follow-up care. The infant should have repeated quantitative NTA tests at 3, 6, and 12 months. Most infants will have a negative titer with adequate treatment. A rising titer requires further investigation and retreatment.

VIII. Prognosis. Infants infected early in the pregnancy are usually stillborn. Infants infected in the second and third trimesters are at risk for premature delivery, low birthweight, neonatal death, and symptomatic congenital infection. In the United States, the case fatality rate for CS is 6% to 8%. Late manifestations of CS such as interstitial keratitis and anterior tibial bowing (“saber shins”) may occur despite appropriate treatment. Infants infected through the birth canal and treated early have excellent prognosis.

148 TORCH (TORCHZ) Infections

TORCH is an acronym that denotes a chronic nonbacterial perinatal infection. It stands for *toxoplasmosis*, *o*ther infections, *r*ubella virus, *c*ytomegalovirus (CMV), *h*erpes simplex virus (HSV). The Zika virus (ZIKV) infection during pregnancy results in a congenital infection syndrome in the fetus and the newborn similar to other TORCH infections; manifestations include fetal growth restriction (FGR), microcephaly, craniofacial disproportion, ventriculomegaly, intracranial calcification, optic nerve hypoplasia, and chorioretinal atrophy, among others. Thus, it has been suggested that ZIKV be added to the TORCH acronym to become **TORCHZ**. “Other” infections include syphilis, hepatitis B, coxsackievirus, Epstein-Barr virus, varicella-zoster virus (VZV), *Enterovirus/Parechovirus*, human immunodeficiency virus (HIV), tuberculosis, and parvovirus B19. HSV disease in the neonate does not fit the pattern of chronic intrauterine infection but is traditionally grouped with TORCH. This group of infections may present in the neonate with similar clinical and laboratory findings (ie, IUGR, hepatosplenomegaly, rash, central nervous system [CNS] manifestations including calcifications, early jaundice, and low platelets), hence the usefulness of the TORCHZ concept. However, because the “other infections” category of responsible pathogens is growing and becoming diverse, the validity of indiscriminate screening of neonates presenting with findings compatible with congenital infection using “TORCH titers” has been questioned. Additionally, some of this serologic testing yields both false-positive and false-negative results. An alternative approach involves testing of infants with suspected congenital infections for specific pathogens based on their clinical presentation (see Table 148–1 and individual chapters on each pathogen). A high index of suspicion for congenital infection and awareness of the prominent features of the most common congenital infections help to facilitate early diagnosis and possible therapy. Clinicians are getting away from the acronym TORCHZ; therefore, each of these chapters has been separated and listed as a single chapter. See Chapter 149 for toxoplasmosis, Chapter 145 for rubella, Chapter 132 for cytomegalovirus, Chapter 137 for herpes simplex viruses, Chapter 154 for ZIKV, and other disease-specific chapters. See Appendix F for isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues.

Table 148–1. SIGNS SUGGESTIVE OF A SPECIFIC CONGENITAL INFECTION IN THE NEONATE

Toxoplasmosis	Intracranial calcifications (diffuse), hydrocephalus, chorioretinitis
Syphilis	Snuffles, maculopapular rash (on palms and soles), skeletal abnormalities (osteochondritis and periostitis)
Rubella	Blueberry muffin lesions, ^a eye findings (cataracts, congenital glaucoma, pigmentary retinopathy), congenital heart disease (most commonly patent ductus arteriosus), radiolucent bone disease
Cytomegalovirus	Periventricular intracranial calcifications, microcephaly
Herpes simplex virus	Mucocutaneous vesicles or scarring, conjunctivitis or keratoconjunctivitis, elevated liver transaminases
Zika virus	Microcephaly, craniofacial disproportion, ventriculomegaly, intracranial calcification, optic nerve hypoplasia

^aSee Figure 80–18.

149 Toxoplasmosis

- I. **Definition.** Toxoplasmosis is caused by *Toxoplasma gondii*, a protozoan and obligate intracellular parasite capable of causing intrauterine infection (part of TORCH [toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus] infections; see Chapter 148).
- II. **Incidence.** The incidence of congenital toxoplasmosis (CT) is 0.23 to 0.91 per 10,000 live births based on published data from the New England Newborn Screening Program; the true incidence might be higher, because the sensitivity of the newborn screening test (blot-spot immunoglobulin [Ig] M test) is approximately 50% to 75%, and fetal losses attributable to severe CT are not counted. Seroprevalence of *T gondii* among women of childbearing age (15–44 years) has declined over time (15%, 11%, and 9% in 1988–1994, 1999–2004, and 2009–2010, respectively).
- III. **Pathophysiology.** *T gondii* is a coccidian parasite ubiquitous in nature. Members of the feline family are the definitive hosts. The organism exists in 3 forms: **oocyst**, **tachyzoite**, and **tissue cyst** (bradyzoites). Cats generally acquire the infection by feeding on infected animals such as mice or uncooked household meats. The parasite replicates sexually in the feline intestine. Cats may begin to excrete **oocysts** in their stool for 7 to 14 days after infection. During this phase, the cat can shed millions of oocysts daily for 2 weeks. After excretion, oocysts require a maturation phase (sporulation) of 24 to 48 hours before they become infective by the oral route. Intermediate hosts (sheep, cattle, and pigs) can have tissue cysts within organs and skeletal muscle. These cysts can remain viable for the lifetime of the host. The pregnant woman usually becomes infected by consumption of raw or undercooked meat that contains cysts or by the accidental ingestion of sporulated oocysts from soil or contaminated food. Ingestion of oocysts (and cysts) releases sporozoites that penetrate the gastrointestinal mucosa and later differentiate into **tachyzoites**. Tachyzoites are ovoid unicellular organisms characteristic of the acute infection. Tachyzoites spread throughout the body via the bloodstream and lymphatics. It is during this stage that vertical transmission from mother to the child (MTCT) occurs. In the immunocompetent host, the tachyzoites

are sequestered in **tissue cysts** and form bradyzoites. Bradyzoites are indicative of the chronic stage of infection and can persist in the brain, liver, and skeletal tissue for the life of the individual. There are reports of transmission of toxoplasmosis through contaminated municipal water, blood transfusion, organ donation, and occasionally as a result of a laboratory accident.

Acute infection in the pregnant woman is often **subclinical** (90% of the cases). If symptoms are present, they are generally nonspecific: mononucleosis-like illness with fever, painless lymphadenopathy, fatigue, malaise, myalgia, fever, skin rash, and splenomegaly. Placental infection occurs and persists throughout pregnancy. The infection may or may not be transmitted to the fetus. The later in pregnancy that infection is acquired, the more likely is MTCT (**first trimester, 17%; second trimester, 25%; and third trimester, 65% transmission**). In women who are screened routinely during pregnancy and treated once primary infection is diagnosed, the MTCT rate is <5%. Infections transmitted earlier in gestation are likely to cause more severe fetal effects (abortion, stillbirth, or severe disease with teratogenesis). Those transmitted later are more likely to be subclinical. Factors associated with an increased risk of MTCT are as follows: (1) acute *T gondii* infection during pregnancy, (2) immunocompromising conditions, (3) lack of antepartum treatment, (4) high *T gondii* strain virulence, and (5) high parasite load. Infection in the fetus or neonate usually involves the central nervous system (CNS) or the eyes with or without disseminated systemic infection. Approximately 60% to 80% of infants with congenital infection are asymptomatic at birth; however, visual impairment, learning disabilities, or mental impairment becomes apparent in a large percentage of children months to several years later.

IV. Risk factors. Epidemiologic risk factors for acquiring toxoplasmosis during pregnancy include eating or contact with raw or undercooked meat, cleaning the cat litter box, eating unwashed raw vegetables or fruits, exposure to soil, and travel outside the United States, Europe, or Canada. Interestingly, cat ownership by itself is not linked to toxoplasmosis (except having ≥ 3 kittens). One study found that eating raw oysters, clams, or mussels was a novel risk factor for acquiring toxoplasmosis. Premature infants have a higher incidence of CT than term infants (25%–50% of cases in most series).

V. Clinical presentation

A. Antenatal detection. Fetuses that are infected early in pregnancy may become symptomatic in utero with abnormalities detected on fetal ultrasound. These include intracranial hyperechogenic foci or calcifications and ventricular dilatation. Other abnormalities include anemia, hydrops, and ascites.

B. Subclinical neonatal infection. Occurs in **60% to 80% of infected newborns**, where no manifestations are found on routine physical examination. These infants are typically identified by routine maternal or newborn screening. When more specific tests are performed (eg, cerebrospinal fluid [CSF] tap, CNS imaging, and retinal eye examinations), up to 40% have abnormalities such as macular retinal scars, focal cerebral calcifications, and elevations of CSF protein and mononuclear cell count. Infants born to mothers known to be infected with both human immunodeficiency virus (HIV) and *T gondii* should be tested for CT. There is an increased risk for intrauterine reinfection after maternal reactivated *T gondii* disease.

C. Clinical neonatal disease. Those with evident clinical disease may have disseminated illness or isolated CNS or ocular disease. Late sequelae are primarily related to ocular or CNS disease. **Obstructive hydrocephalus, chorioretinitis, and diffuse intracranial calcifications** form the **classic triad of toxoplasmosis**, which is found in <10% of the cases. Beside the classic triad, other prominent features in symptomatic infants include abnormalities of CSF (high protein), anemia, seizures, direct hyperbilirubinemia, fever, hepatosplenomegaly, lymphadenopathy, eosinophilia, bleeding diathesis, hypothermia, rash, and pneumonitis. Some of these symptoms may develop in the first few months of life.

D. Late manifestations may develop in congenitally infected infants, especially in those who do not receive extended antiparasitic therapy. **Chorioretinitis** is the most common late manifestation. The lifetime incidence for untreated infants **approaches 90%**, and the risk extends into adulthood. Treated patients may have episodic recurrences of chorioretinitis. Associated ophthalmologic findings may include microphthalmia, strabismus, cataract, glaucoma, and nystagmus. These complications can lead to vision loss and retinal detachment. Other late CNS manifestations include microcephaly, seizures, motor and cerebellar dysfunction, mental retardation, and sensorineural hearing loss.

VI. Diagnosis. CT should be suspected in infants born to mothers who had primary infection during pregnancy, infants born to women who are immunosuppressed, infants who have suggestive clinical findings, and infants who test positive (toxoplasma IgM) through universal newborn screening (in regions where it is done). Infants suspected of the disease should undergo detailed evaluation that includes eye examination, CNS imaging, spinal tap, and detailed laboratory evaluation. In early 2017, the American Academy of Pediatrics issued an elaborate report discussing the diagnosis, treatment, and prevention of CT in the United States (Maldonado et al. *Pediatrics* 2017;139[2]:e20163860).

A. Laboratory studies. Laboratory tools for the diagnosis of *T gondii* infection include serologic tests, such as the *Toxoplasma* IgG, IgM, IgA, IgE, or IgG avidity and differential agglutination (AC/HS) tests; polymerase chain reaction (PCR) assays; histologic and cytologic examination of tissue and body fluids; and attempts to isolate the parasite with mice subinoculation (this test is only performed in reference laboratories). Commercial laboratories in the United States usually offer *Toxoplasma* IgG and IgM testing; some of them also offer *Toxoplasma* IgA and IgG avidity tests (approved by the US Food and Drug Administration [FDA] since 2011) and PCR assays. In reference laboratories for toxoplasmosis, like the one at Palo Alto Medical Foundation (Palo Alto Medical Foundation Toxoplasma Serology Laboratory [PAMF-TSL], <http://www.pamf.org/serology/>; phone: 650-853-4828; fax: 650-614-3292; e-mail: toxolab@pamf.org), panels of serologic tests are offered. The majority of the tests in those panels are not available in nonreference laboratories (NRL), including the *Toxoplasma* IgG dye test, the *Toxoplasma* IgM immunosorbent agglutination assay (ISAGA), the *Toxoplasma* IgE enzyme-linked immunosorbent assay, and the AC/HS differential agglutination test. The reference laboratories offer expert advice on the interpretation of these results.

1. Diagnosis of *T gondii* infection during pregnancy. When there is clinical suspicion of acute toxoplasmosis during pregnancy, serologic samples should be sent to a reference laboratory to avoid any unnecessary delays in the establishment of diagnosis and initiation of prenatal treatment. Prompt initiation of prenatal treatment has been recently shown to decrease MTCT and ameliorate the severity of clinical manifestations. In a recent publication from PAMF-TSL involving 451 patients with positive toxoplasmosis IgM and IgG from NRL, 335 of patients (74%) had a chronic infection, 100 (22%) had an acute infection, and 7 (2%) were not infected, and for 9 patients (2%), results were indeterminate. Positive *Toxoplasma* IgM and IgG test results obtained at NRLs cannot accurately distinguish between acute and chronic infections. To do so, testing at reference laboratories is required, as mandated by a 1997 letter from the FDA to clinicians and laboratories in the United States.

2. Prenatal diagnosis of congenital *T gondii* infection in the fetus. CT can occur in 3 ways: (1) transmission of *T gondii* infection to the fetus from a mother who acquired acute primary infection during pregnancy or shortly before conception; (2) reactivation of a *Toxoplasma* infection in an immune woman who became immunocompromised during gestation (eg, due to HIV infection or immunosuppressive medications); and (3) reinfection of a previously immune mother with a new, more virulent strain (eg, after international travel). Amplification of *Toxoplasma* DNA by PCR assay in amniotic fluid sample (AF PCR) is the

preferred method to diagnose fetal infection. The sensitivity and negative predictive value (NPV) for AF PCR is influenced by the gestational age at which infection is acquired. NPV of AF PCR assay for early maternal primary infections (first or second trimester) is very high (92%–99%). However, for infections acquired in the third trimester, the NPV is lower. Explanations for poor NPV include a dilution effect attributable to a larger amount of AF in the third trimester and/or maternal treatment before AF PCR testing. Moreover, it probably takes several weeks for the infection to cross the placenta from the mother to the fetus in large enough quantities to spill into the AF. The positive predictive value of an AF PCR at any time during pregnancy is very high (95%–100%). In general, AF PCR assay should be performed at least 4 weeks after acute primary maternal infection and at ≥ 18 weeks of gestation.

3. **Diagnosis of *T gondii* infection in the infant. Persistence of positive *Toxoplasma* IgG in the child beyond 12 months of age is considered as the gold standard for the diagnosis of CT.** In general, any maternal *Toxoplasma* IgG antibodies transferred transplacentally are expected to decrease by 50% per month after birth and usually disappear by 6 to 12 months of age. Maternal treatment during pregnancy and/or postnatal treatment of the infant could affect the production and kinetics of *Toxoplasma* IgG antibodies in the infant. **A positive *Toxoplasma* IgM ISAGA result (at or after 5 days of age) and/or a positive *Toxoplasma* IgA test result (at or after 10 days of age) are considered diagnostic of CT in infants with a positive *Toxoplasma* IgG.** Because IgM and IgA antibodies do not cross the placenta, they reflect the infant's response to *T gondii* infection. Of note, positive results before 5 or 10 days of age could represent false-positive results from contamination of the infant's blood with maternal blood (maternal–fetal blood leak). Moreover, false-positive *Toxoplasma* IgG and IgM test results can occur after recent transfusion of blood products or receipt of immunoglobulin intravenously. False-negative results occur in 13% of patients with IgM ISAGA, 23% with IgA, and 7% with both IgM and IgA. Infants with negative *Toxoplasma* IgM and IgA antibodies but with positive neonatal *Toxoplasma* IgG, serologic evidence of acute maternal *T gondii* infection during pregnancy, and evidence of clinical manifestations suggestive of CT should be regarded as having CT and treated as such. **Positive PCR assay results from peripheral blood, CSF, urine, or other body fluid in symptomatic patients are also diagnostic of CT.** One study showed that the sensitivity is 29% for blood PCR assay, 46% for CSF PCR assay, and 50% for urine PCR assay. The CSF PCR assay result was positive in 71% of infants with CT and hydrocephalus, in 53% of infants with CT and intracranial calcifications, and in 51% of infants with CT eye disease. Placentas can be examined with PCR assay as well; however, a positive placental PCR assay result may suggest CT but is not diagnostic of CT per se.
- B. **Cerebrospinal fluid examination** should be performed in suspected cases. The most characteristic abnormalities are xanthochromia, mononuclear pleocytosis, and a very high protein level (sometimes >1 g/L). Tests for PCR and CSF IgM to toxoplasmosis should also be performed.
- C. **Imaging studies. Fetal ultrasound** every month until delivery is recommended in a mother with definite seroconversion during pregnancy. Postnatal imaging studies include:
 1. **Computed tomography of the head** should be considered when there is suspicion of CT to evaluate for the presence of intracranial calcifications, ventriculomegaly, hydrocephalus, and other findings. Computed tomography is superior to ultrasound or magnetic resonance imaging in identifying calcifications.
 2. **Abdominal ultrasonography** at birth for intrahepatic calcifications and/or hepatosplenomegaly is also indicated.
 3. **Long-bone films** may show abnormalities, specifically metaphyseal lucency and irregularity of the line of calcification at the epiphyseal plates without periosteal reaction.

- D. Ophthalmologic examination (preferably by retinal specialist)** characteristically shows chorioretinitis. It may also show other findings such as microphthalmia, cataract, macular scarring, and optic nerve atrophy.

VII. Management

- A. Antepartum management of pregnant women.** Initiating treatment of the pregnant woman as soon as possible after seroconversion helps to prevent MTCT. The odds of MTCT decrease by 52% when treatment is promptly initiated within 3 weeks after seroconversion. Additionally, antepartum treatment is associated with lower odds of severe neurologic sequelae in infants with CT. **Spiramycin** is recommended for women who acquire their infection at <18 weeks of pregnancy. It should be continued until delivery to prevent MTCT. Spiramycin is not teratogenic and is available in the United States only through the Investigational New Drug process at the FDA (phone: 301-796-1600). Spiramycin is not recommended when fetal infection is established (it should be stopped if AF PCR or fetal ultrasound is suggestive of CT). For established fetal infections (based on AF PCR or fetal ultrasound), maternal treatment with **pyrimethamine, sulfadiazine, and folinic acid should be instituted** after 18 weeks of gestation. Pyrimethamine is potentially teratogenic and should not be used before the 18th week of pregnancy.
- B. Postnatal management of the infant with congenital toxoplasmosis.** Antiparasitic therapy is indicated for infants in whom a diagnosis of CT is confirmed or probable based on serology, PCR, or clinical symptoms. The typical course consists of **sulfadiazine** (50 mg/kg, twice daily), **pyrimethamine** (2 mg/kg/d for 2 days, then 1 mg/kg/d for 2–6 months, then 1 mg/kg/d 3 times a week), and **folinic acid** (10 mg, 3 times weekly) for a minimum of 12 months. Serial follow-up to gauge the response of the infant to therapy should include neuroradiology, ophthalmologic examinations, and CSF analysis if indicated. Corticosteroids in the form of **prednisone** (1 mg/kg/d in 2 divided doses) should be given when **CSF protein is >1 g/dL and when active chorioretinitis threatens vision**. Prednisone is continued until resolution of CSF protein elevation and active chorioretinitis. Infants treated with pyrimethamine and sulfadiazine require weekly blood counts (complete blood count [CBC] including platelets) and urine microscopy to detect any adverse drug effects. CBC can be spaced to every 2 weeks if counts remain stable.
- C. Prevention**
- 1. Primary prevention** should be done through education. Pregnant women should be counseled that toxoplasma infection can be prevented in large part by cooking meat to a safe temperature (152°F); peeling or thoroughly washing fruits and vegetables before eating; avoiding drinking unfiltered water in any setting; cleaning cooking surfaces and utensils after they have contacted raw meat, poultry, seafood, or unwashed fruits or vegetables; avoiding ingestion of raw shellfish such as oysters, clams, and mussels; avoiding ingestion of raw goat milk; avoiding changing cat litter or, if necessary, using gloves, and then washing hands thoroughly; not feeding raw or undercooked meat to cats; and keeping cats inside to prevent acquisition of *Toxoplasma* by eating infected prey.
 - 2. Secondary prevention.** Only approximately 50% of mothers of infants with CT had clinical symptoms suggestive of acute toxoplasmosis during pregnancy or had reported risk factors for *T gondii* exposure (eg, exposure to undercooked meat or to cat feces). Therefore, only routine serologic screening during pregnancy would have identified the other 50%. Secondary prevention by routine serologic screening of the pregnant woman is done in some countries (France and Austria) but is not widely used in the United States.

- VIII. Prognosis.** Maternal toxoplasmosis acquired during the first and second trimesters is associated with stillbirth (35%) and perinatal death (7%). Infants with CT have a mortality rate as high as 12% and are at risk for many other problems later in life (seizures, visual impairment, learning disabilities, deafness, mental retardation, and spasticity). Adults who were treated as infants for CT appear to have reasonable quality of life and visual function.

150 Tuberculosis

- I. **Definition.** Tuberculosis (TB), an infection caused by the organism *Mycobacterium tuberculosis*, can be congenital or acquired in the postnatal period.
- II. **Incidence.** The World Health Organization (WHO) estimates an incidence of 10.4 million new TB cases and 1.3 million TB deaths in 2016. Although congenital TB is rare, with about 350 cases reported in the English literature, the mortality rate is as high as 50%.
- III. **Pathophysiology.** *M tuberculosis* transmission occurs via inhalation of airborne droplet nuclei, which are carried by alveolar macrophages through the lymphatic system to hilar lymph nodes. The infection can either be contained or lead to primary progressive TB. Infected macrophages interact with T lymphocytes to release cytokines that promote phagocytosis of *M tuberculosis*, leading to granuloma formation within 2 to 8 weeks in most individuals. Young children and immunosuppressed individuals lack host immunity and instead develop active primary progressive disease in the lung parenchyma and hilar lymph nodes. In these individuals, the characteristic fibrous granuloma capsule becomes disrupted, causing liquefactive necrosis of the central caseous material. The necrotic material can then flow into adjacent vasculature and disseminate systemically or to adjacent bronchi and spread externally via respiratory droplets. Immunosuppression and malnutrition are risk factors for reactivation of latent infection.

Vertical transmission causing **congenital TB** can occur due to hematogenous spread via the umbilical vein leading to a primary tuberculous lesion in the liver or lung. Alternatively, fetal aspiration or ingestion of infected amniotic fluid can lead to pulmonary or gastrointestinal TB.

- IV. **Risk factors.** The highest risk of transmission to newborns occurs via respiratory transmission from **untreated mothers** during the postnatal period. This is more common than congenital TB, and diagnosis of neonatal TB can lead to identification of previously unrecognized diagnosis of TB in the mother. Maternal extrapulmonary TB, such as miliary TB or tuberculous endometritis, increases the risk of congenital infection. Maternal treatment for 2 to 3 weeks in the antenatal period reduces the risk of postnatal infection. Human immunodeficiency virus (HIV) is a risk factor for maternal TB, which in turn increases the risk of mother-to-child transmission of HIV. Living in endemic areas or crowded conditions also increases the risk of TB.

V. Clinical presentation

- A. **Pregnancy.** Pregnant women with TB tend to have fewer of the typical symptoms associated with TB. Active TB symptoms and signs include fever, cough, night sweats, anorexia, weight loss, general malaise, and weakness. Extrapulmonary TB can affect the genitourinary tract, bones and joints, meninges, lymph nodes, pleural lining, and peritoneum. Extrapulmonary TB is more common when there is co-infection with HIV. The natural history of TB is thought to be unaffected by pregnancy. Maternal TB, especially extrapulmonary disease, does increase pregnancy and perinatal complications such as preeclampsia, vaginal bleeding, early pregnancy loss, preterm labor, and low birthweight.
- B. **Neonatal period.** Congenital TB can mimic neonatal sepsis, or the infant may present in the first 90 days of life with **bronchopneumonia** and/or **hepatosplenomegaly**. Symptoms are usually present by the second or third week of life. As neonates tend to present with atypical signs, the diagnosis of TB must be considered in the differential diagnosis of other congenital infections (syphilis, cytomegalovirus, and toxoplasmosis). Beside bronchopneumonia and/or hepatosplenomegaly, congenital TB can present with fever, lymphadenopathy, abdominal distention, lethargy or irritability, ear discharge, and papular skin lesions. Less common symptoms

include vomiting, apnea, cyanosis, jaundice, seizures, and petechiae. Respiratory signs include cough, wheezing, tachypnea, stridor, and crepitation, which is thought to result from obstruction of bronchi by enlarged hilar lymph nodes. Young infants are at increased risk for meningeal involvement and disseminated or miliary TB due to their immature immune systems. Meningeal presentations include meningoen- cephalitis, basal arachnoiditis, and intracranial tuberculomas. TB of the spine (Pott disease) has also been described in congenital infection. Clinical signs of congenital or postnatally acquired TB are typically occult and delayed in presentation because of the immaturity of the newborn and infant immune system.

VI. Diagnosis

- A. **Clinical criteria.** Congenital infection is diagnosed if the infant has the primary criterion and meets 1 of the secondary criteria for congenital TB (Cantwell criteria). Otherwise, postnatally acquired TB is diagnosed based on known exposure and a proven tuberculous lesion.
 1. **Primary criterion.** The infant must have proven tuberculous lesions.
 2. **Secondary criteria**
 - a. **Lesions in the first week of life.**
 - b. **A primary hepatic complex or caseating hepatic granulomas.**
 - c. **Tuberculous infection of the placenta or the maternal genital tract.**
 - d. **Exclusion of postnatal transmission by a thorough investigation.**
- B. **Acid-fast *Bacillus* smear and culture.** *M tuberculosis* can be identified by culture from the following specimens: gastric aspirates, sputum, bronchial washings, pleural fluid, cerebrospinal fluid (CSF), urine, or other body fluids. A biopsy specimen can also be obtained from lymph node, pleura, mesentery, liver, bone marrow, or other tissues. **The best specimen in neonates and infants who may have an absent or nonproductive cough is an early-morning gastric aspirate, obtained by a nasogastric tube before feeding.** Aspirates should be collected on 3 separate days. Gastric aspirates usually yield negative acid-fast *Bacillus* (AFB) smears, with an overall diagnostic yield of <50%. Fluorescent staining methods increase the sensitivity of gastric aspirates. The presence of nontuberculous mycobacteria can result in a false-positive smear. Liquid media culture facilitates growth of *M tuberculosis*, which can take between 3 and 6 weeks to grow.
- C. **Nucleic acid amplification test.** Nucleic acid amplification tests for rapid diagnosis of TB are available but have varying sensitivity and specificity. False-positive and false-negative results have also been reported.
- D. **Tuberculin skin testing. A negative tuberculin skin test (TST) result should be considered unreliable in infants <3 months of age.** The definition of a **positive** Mantoux skin test is as follows:
 1. **Reaction ≥ 5 mm**
 - a. **Infants in close contact with known or suspected infectious cases of TB.**
 - b. **Infants suspected to have tuberculous disease** based on clinical evidence or abnormal chest radiograph.
 - c. **Infants with an immunosuppressive condition**, including HIV, or receiving immunosuppressive therapy.
 2. **Reaction ≥ 10 mm**
 - a. **Age <4 years.**
 - b. **Medical risk factors such as chronic renal failure or malnutrition.**
 - c. **Increased environmental exposure.**
- E. **Interferon- γ release assays.** Interferon- γ release assays (IGRAs) measure interferon- γ production from T lymphocytes in response to antigens specific to *M tuberculosis*. Because these antigens are not found on *Mycobacterium bovis*-bacille Calmette-Guérin (BCG) vaccine or most nontuberculous mycobacteria, IGRAs are more specific tests than the TST, yielding fewer false-positive results. IGRAs may be used in conjunction with TST, but a negative test is unreliable in newborns due to low sensitivity.

- F. **Chest radiograph.** Chest imaging may initially be normal, but most infants present with abnormal findings, including miliary TB, multiple pulmonary nodules, lobar pneumonia, bronchopneumonia, interstitial pneumonia, pleural effusion, and mediastinal adenopathy. The upper lobes and posterior lung segments are thought to be the most common sites for TB in infants.
- G. **Imaging.** Other imaging modalities include abdominal sonography for hepatic involvement and thoracic computed tomography (CT) for adenopathies. Central nervous system (CNS) imaging includes ultrasonography, CT, and magnetic resonance imaging.
- H. **Laboratory markers.** Leukocytosis with neutrophil predominance and elevation of C-reactive protein has been reported in congenital TB due to the inflammatory response associated with *M tuberculosis*. Thrombocytopenia has also been observed, although it is a nonspecific finding.
- I. **Cerebrospinal fluid.** A lumbar puncture should promptly be performed when congenital or postnatally acquired TB is suspected. CSF findings can include lymphocytic pleocytosis, increased protein levels, and decreased CSF-to-serum glucose ratio.
- J. **Human immunodeficiency virus testing.** All individuals with TB should be evaluated for HIV infection due to the increased incidence of TB co-infection.
- K. **Placental pathology.** The placenta may demonstrate evidence of granulomas, and an AFB smear and culture should be sent from placental specimen.

VII. Management

A. Antimicrobial therapy during pregnancy

1. **Latent infection.** The Centers for Disease Control and Prevention (CDC) recommends deferring treatment of pregnant women with latent infection until the postpartum period except in high-risk situations. Isoniazid therapy for 9 months should be considered for latent TB (positive TST and normal chest radiographic findings) in pregnant women with HIV, recent contagious contact, and skin test conversion within the prior 2 years. Pyridoxine supplementation should be administered for the duration of pregnancy and breast feeding.
2. **Active infection.** The CDC recommends an initial treatment regimen with isoniazid, rifampin, and ethambutol for 2 months, followed by isoniazid and rifampin for a total of 9 months. Isoniazid, rifampin, and ethambutol are considered relatively safe for the fetus. Streptomycin should not be administered to the mother due to ototoxic effects in the fetus. Although pyrazinamide is used in some regimens, its safety during pregnancy has not been established.

B. Antimicrobial therapy during the neonatal period

1. **Active maternal and congenital or neonatal acquired infection.** In cases in which the maternal physical examination and chest radiographic findings are diagnostic of active TB, **the infant should be treated promptly with isoniazid, rifampin, pyrazinamide, and an aminoglycoside such as amikacin.** Pyridoxine (to prevent neurotoxicity) supplementation in infants receiving isoniazid therapy is recommended in the following instances: exclusively breast-fed infants, malnourished infants, and those with symptomatic HIV infection. Hepatotoxic effects of isoniazid therapy are rare but can be life threatening.
2. **Active maternal infection without congenital infection.** If the mother has active TB disease but the neonate is not affected, isoniazid should be given until 3 or 4 months of age. If a negative TST result is obtained at the end of therapy and the mother demonstrates successful response to therapy, the infant's isoniazid can be discontinued. A positive TST at 3 to 4 months of age necessitates a reevaluation for TB disease in the infant and continued isoniazid therapy for a total of 9 months with monthly evaluation.
3. **Latent maternal infection.** Neonatal evaluation and therapy are not required in cases where the mother is asymptomatic and is diagnosed with latent TB infection.

4. **Postnatal tuberculosis infection.** For infants with pulmonary disease, pulmonary disease with hilar adenopathy, and hilar adenopathy disease, a 6-month 4-drug regimen is recommended as follows: isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampin for 4 months. The duration of therapy is extended to 9 months if there is evidence of cavitory pulmonary lesions or sputum culture remains positive after 2 months of therapy. The risks and benefits of using ethambutol in infants need to be considered due to a dose- and duration-dependent risk of optic neuritis. An infectious disease consultation is essential for managing infants who are co-infected with HIV due to drug interactions and overlapping drug toxicities, especially between antiretrovirals and rifampin.
 5. **Extrapulmonary tuberculosis.** For tuberculous meningitis, treatment is initiated with isoniazid, rifampin, pyrazinamide, and ethionamide/aminoglycoside. Pyrazinamide is given for a total of 2 months, and isoniazid and rifampin are given for a total of 9 to 12 months. Ethionamide or aminoglycoside is discontinued after drug susceptibility is established. **Corticosteroids** should be added in confirmed cases of TB meningitis as they reduce mortality rates and long-term neurologic impairment. Corticosteroids can also be considered for pleural and pericardial effusions, severe miliary disease, endobronchial disease, and abdominal TB. Surgical therapy for lymphadenitis, bone and joint abscesses, and hydrocephalus complicating CNS disease may be indicated.
- C. **Isolation precautions/breast feeding**
1. **Maternal latent infection.** No separation or restrictions on breast feeding are required.
 2. **Maternal active disease.** In suspected or proven cases of maternal TB, the mother and infant should be separated pending evaluation and appropriate maternal and infant therapy. Separation is not necessary once the infant begins isoniazid and the mother adheres to treatment, wears a mask, and follows infection control measures. In cases of multidrug-resistant TB or maternal nonadherence to therapy, the infant should be separated, and BCG vaccine should be considered in consultation with an infectious disease specialist. Breast-feeding restrictions can be removed after the mother has been treated appropriately for ≥ 2 weeks and is not considered contagious.
- D. **Hospital control measures.** Restriction to an airborne infection isolation room is indicated in the following cases: neonates with congenital or acquired TB undergoing manipulation of the oropharyngeal airway, infants with cavitory lesions, positive sputum AFB smears, and laryngeal or extensive pulmonary involvement. Nosocomial transmission from infants to healthcare workers and between infants via contaminated respiratory equipment has been reported.
- E. **Prevention.** The BCG vaccine contains a live attenuated strain of *M bovis*. The WHO recommends that a single dose of BCG vaccine should be given to all infants soon after birth in countries with a high TB burden. BCG vaccine should not be given to symptomatic HIV-positive or immunosuppressed infants. If the neonate is exposed to smear-positive pulmonary TB shortly after birth, BCG vaccine should be delayed pending completion of isoniazid therapy. The CDC does not recommend routine use of BCG vaccine in the United States due to the low burden of disease and interference of the vaccine with TST reactivity.
- VIII. **Prognosis.** Information on prognostic factors is not well defined for infants with either congenital or acquired disease. Survival rate is not influenced by the following factors: specific signs or symptoms, birthweight, the nature or severity of maternal disease, timing of maternal diagnosis, prematurity, hepatic dysfunction, or thrombocytopenia. An improved survival rate has been seen in infants with the following: presentation of symptoms after 3 weeks of age, no CNS TB disease, appropriate anti-TB therapy, higher leukocyte count, and absence of miliary or multiple pulmonary nodules pattern on chest radiograph.

151 *Ureaplasma* Infection

- I. **Definition.** *Ureaplasma* belongs to the Mycoplasmataceae family. These are small pleomorphic bacteria that characteristically lack a cell wall. The genus *Ureaplasma* contains 2 species capable of causing human infection, *Ureaplasma urealyticum* and *Ureaplasma parvum*.
- II. **Incidence.** *Ureaplasma* species are frequently present in the lower genital tract of sexually active women with a colonization rate ranging between 40% and 80%. Vertical transmission to the newborn is high, especially in premature infants <1000 g birth-weight, in whom the transmission rate approaches 90%.
- III. **Pathophysiology.** *U. urealyticum* has been implicated in a variety of obstetric and neonatal diseases including **preterm labor, preterm premature rupture of membranes (pPROM), chorioamnionitis, postpartum fever and endometritis, congenital pneumonia, bacteremia, meningitis, intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), and bronchopulmonary dysplasia (BPD)**. The presumed mechanisms of infection include fetal exposure to ascending intrauterine infection, passage through an infected birth canal, and hematogenous dissemination through the placenta into umbilical vessels. This exposure leads to colonization of the skin, mucosal membranes, gastrointestinal and respiratory tract, and sometimes dissemination into the bloodstream and central nervous system (CNS). Phospholipases and cytokines produced through the inflammatory response can trigger uterine contractions and premature birth. *Ureaplasma* infection of the respiratory tract in the newborn promotes a proinflammatory cytokine cascade with increase in tumor necrosis factor- α , interleukin (IL)-1 β , and IL-8. These cytokines recruit neutrophils to the lungs and intensify the inflammatory cascade, which damages the premature lung and impairs future alveolar development. The same mechanisms may be involved in *Ureaplasma*-mediated intestinal injury and NEC.
- IV. **Risk factors.** *Ureaplasma* colonization is associated with preterm labor, chorioamnionitis, birthweight <1000 g, and gestational age (GA) <30 weeks. Respiratory colonization is inversely related to GA at birth (65% in infants <26 weeks vs 31% in infants \geq 26 weeks).
- V. **Clinical presentation**
 - A. **Preterm labor, preterm premature rupture of membranes, and chorioamnionitis.** *Ureaplasma* can invade the amniotic fluid early in pregnancy and are the single most common organisms that can be isolated from inflamed placentas. *Ureaplasma* can persist in the amniotic fluid subclinically for several weeks. Detection of *Ureaplasma* in second-trimester amniotic fluid by polymerase chain reaction (PCR) correlates with subsequent preterm labor and delivery (58.6% for those with positive PCR vs 4.4% for those with negative results). In addition, *Ureaplasma* cord blood infections (identified by cultures) are far more common in spontaneous than indicated preterm deliveries and are strongly associated with markers of acute placental inflammation. Positive cord cultures are also associated with neonatal systemic inflammatory response syndrome.
 - B. **Congenital pneumonia.** Evidence that suggests *Ureaplasma* as a cause of congenital pneumonia includes isolation of the organism in pure culture from amniotic fluid and tracheal aspirate of neonates <24 hours after birth with specific immunoglobulin M (IgM) response in the midst of an acute inflammatory reaction and radiographic changes. These infants develop early interstitial pulmonary infiltrates with cystic/dysplastic changes as early as 7 to 10 days of age.
 - C. **Meningitis and intraventricular hemorrhage.** Multiple studies have shown *Ureaplasma* to be isolated from cerebrospinal fluid (CSF) of premature infants with meningitis, IVH, and hydrocephalus. The contribution of *Ureaplasma* to the outcome of these newborns is uncertain.

- D. Association with necrotizing enterocolitis.** One study showed that the incidence of NEC was 3.3-fold higher in *Ureaplasma*-positive, ≤ 28 weeks preterm infants with higher cord blood IL-6 and IL-1 β .
- E. Predisposition to bronchopulmonary dysplasia.** Multiple cohort studies have linked the development of BPD with colonization of the airways with *Ureaplasma*.
- VI. Diagnosis**
- A. Laboratory studies**
- 1. Culture.** Specimens for culture require specific transport media with refrigeration at 4°C. Dacron or calcium alginate swabs should be used instead of cotton swabs.
 - 2. Other tests.** Several sensitive PCR assays have been developed, but they are not available routinely. Serologic assays are of limited value.
- VII. Management.** Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.
- A. Treatment of the colonized pregnant mother.** Treatment of pregnant women who present with pPROM with a 7-day course of **erythromycin** has been shown to prolong pregnancy, reduce neonatal treatment with surfactant, decrease infant oxygen dependency at ≥ 28 days of age, and result in fewer major cerebral abnormalities on ultrasonography before discharge. A recent study showed that a single oral dose of **azithromycin** (1 g) is comparable to a 7-day regimen of erythromycin. Those same benefits are not accrued if the mother presents with preterm labor but with intact membranes.
- B. Treatment of the colonized newborn infant is controversial.** For infants with congenital pneumonia with radiographic evidence of early interstitial pneumonitis and when *Ureaplasma* is the only microorganism isolated from the respiratory tract, some experts recommend treatment with a 3-day course of intravenous azithromycin (20 mg/kg/d). Treatment may also be considered when *Ureaplasma* is isolated from a normally sterile site such as the bloodstream or CSF. Azithromycin has both anti-inflammatory and anti-infective properties; limited evidence suggests that azithromycin significantly reduces the risk of BPD in preterm neonates irrespective of *Ureaplasma* colonization. However, given the limited information on pharmacokinetics and potential harmful effects including risk of pyloric stenosis, its routine use for the prevention of BPD cannot be recommended.
- VIII. Prognosis.** In utero exposure to *Ureaplasma* is associated with reactive airway disease and wheezing in the first 2 to 3 years of life. It is also associated with adverse neurodevelopmental outcome and cerebral palsy at 2 years of adjusted age in these infants.

152 Urinary Tract Infection

- I. Definition.** A urinary tract infection (UTI) is the presence of pathogenic bacteria or fungus in the urinary tract. It is the most common bacterial infection in febrile neonates, although it is very uncommon in the first few days of life.
- II. Incidence.** UTI incidence in all neonates is approximately 0.1% to 2%. However, in preterm and low birthweight infants, the incidence is as high as 20%. In infants younger than 3 months, boys have a higher prevalence of UTI than girls.
- III. Pathophysiology.** See Table 152–1 for the most common pathogens isolated in neonatal UTI. Nosocomial infections occur more often due to indwelling urinary catheters.
- A. Term infants.** Ascending infection through the urethra is the most common source of infection in term infants. *Escherichia coli* is the most common bacterial pathogen, followed by other gram-negative bacilli (*Klebsiella*, *Proteus*, *Enterobacter*).

Table 152–1. COMMON ORGANISMS ISOLATED IN NEWBORN AND NEONATAL UTI

Organism	Incidence (%)
Gram-negative rods	
<i>E. coli</i>	40–72
<i>Klebsiella</i> spp	7–40
<i>Enterobacter cloacae</i>	3–8
<i>Proteus vulgaris</i>	3
<i>Serratia marcescens</i>	1–7
<i>Pseudomonas aeruginosa</i>	1
Gram-positive cocci	
<i>Enterococcus</i> spp	10–16
<i>Staphylococcus aureus</i>	1–5
Group B streptococcus	1–3
<i>Staphylococcus</i> , coagulase negative	1
Viridans streptococcus	1
Yeast	
<i>Candida</i> spp	25–42

Reproduced with permission from Arshad M, Seed PC: Urinary tract infections in the infant, *Clin Perinatol*. 2015 Mar;42(1):17-28.

- B. Preterm infants.** Hematogenous spread of infection plays a bigger role in preterm infants. *Klebsiella* and coagulase-negative *Staphylococcus* are more commonly identified than *E. coli*. *Candida* UTIs are also common in this group.
- C. Fungal urinary tract infections.** Most often caused by *Candida* species and are more common in nosocomial infections. Fungal UTIs are also more common in extremely low birthweight babies.

IV. Risk factors

- A. Congenital anomalies of the kidney and urinary tract (CAKUT)** such as urinary tract dilatation (eg, ureteropelvic junction obstruction, ureterovesical junction obstructions, ureterocele, ectopic ureter), posterior urethral valves, and vesicoureteral reflux can predispose to UTIs.
- B. Alteration in normal bladder function** (eg, neurogenic bladder) predisposes the infant to UTI.
- C. Recent urinary tract instrumentation or indwelling catheters** are the most common risk factors for nosocomial infections.
- D. Uncircumcised males have a 10-fold increased risk for UTI** compared to circumcised males. This is presumably due to increased bacterial adherence to the mucosal surface of the foreskin and bacterial colonization under the foreskin.
- E. Prematurity is a risk factor for UTI** because premature infants are relatively immunocompromised compared to term infants. Risk increases with decreasing gestational age and birthweight.
- F. Prolonged unexplained jaundice can be a marker** for UTI in infants and warrants screening with a urinalysis and culture. Indirect (unconjugated) hyperbilirubinemia is thought to be secondary to hemolysis caused by *E. coli* infection. Direct (conjugated) hyperbilirubinemia-associated UTI is secondary to cholestasis, but the mechanism is not known.

- G. Maternal urinary tract infection during pregnancy and premature rupture of membranes** are potential risk factors for UTI. These were reported in 2 small case series. The increased incidence may be because these mothers harbor pathogens transmitted to the infant during birth.
- H. White race is risk factor for urinary tract infection.** Febrile white infants have a higher probability of being diagnosed with UTI compared to black infants or infants of other ethnic groups. This is especially the case in female white infants. In 1 study, African American infants were much less likely to be diagnosed with UTI than white or Hispanic infants.
- V. Clinical presentation.** Infants may appear acutely toxic, similar to neonatal sepsis, or present with nonspecific findings of fever, lethargy, irritability, poor feeding, vomiting, jaundice secondary to cholestasis, loose stools, or failure to thrive. Fever does not always occur. Newborns with UTI are at higher risk for bacteremia than older infants. Preterm infants have the same signs as term infants but can also have apnea, bradycardia, and hypoxia. Term infants usually present in the second to third week with a UTI.
- VI. Diagnosis**
- A. Laboratory studies**
- 1. Urinalysis.** Positive leukocyte esterase suggests inflammation in the urinary tract; it has a sensitivity of 84% and specificity of 78%. Positive nitrite suggests the presence of gram-negative bacteria and is 98% specific; sensitivity is only 50%. Detection of bacteria by microscopy adds specificity to other urine findings. Hemocytometer white blood cell (WBC) counts in the urine specimen may be of value in diagnosing UTI. A recent study stated that a minimum of 3 to 6 WBCs per high-power field depending on urine concentration is required for a presumptive diagnosis of UTI. Although no single finding on urinalysis is diagnostic of UTI, neonates without pyuria or bacteriuria have a very low likelihood of UTI.
 - 2. Urine culture.** A urine culture is no longer recommended in infants <72 hours of age in an early-onset sepsis workup and is more appropriately done for late-onset sepsis workup.
 - a. Suprapubic aspiration and bladder catheterizations** are the only truly reliable methods to obtain urine cultures in neonates (see Chapters 29 and 30). Cultures obtained from a suprapubic bladder aspiration that grow >1000 colony-forming units (CFU)/mL are significant. The optimal definition for UTI from catheter-obtained specimens in neonates has not been established. However, >50,000 CFU/mL or 10,000 to 50,000 CFU/mL with pyuria on the urinalysis are generally accepted definitions.
 - b. Clean-catch or collection bag specimens** often are inaccurate due to contamination and are only clinically reliable if the culture demonstrates no growth. **Due to high false-positive rates, this type of collection is not recommended.**
 - c. Rapid culture** techniques using reverse transcriptase–polymerase chain reaction and next-generation sequencing to identify organisms are available in many facilities.
 - 3. Serum tests.** Complete blood count, blood cultures, serum creatinine, C-reactive protein, and erythrocyte sedimentation rate may be clinically useful in guiding management.
 - 4. Sepsis evaluation** should be done in all infants suspected of a UTI (see Chapter 146). The risk of sepsis is about 4% to 7% in term newborns and young infants and is greater in preterm infants. Blood culture is mandatory in all infants with a suspected UTI and prior to starting antibiotics. The risk of bacterial meningitis is approximately 1% to 3% in infants with a UTI; therefore, the decision to perform a lumbar puncture depends on the severity of illness of the infant.
- VII. Management**
- A. Initial antibiotic treatment.** For the majority of neonatal cases, initial treatment with broad-spectrum intravenous (IV) antibiotics is appropriate (usually ampicillin and gentamicin). It is also important to consider maternal use of antibiotics prior to

delivery (which increases the risk of a neonatal UTI with β -lactamase-producing *E coli*) and local antibiotic resistance patterns. Antibiotics can be tailored according to susceptibility testing on urine culture. Ideal duration of therapy is not completely known but is usually 10 to 14 days. For an infant in the hospital who is older than 7 days, consider vancomycin and gentamicin. Oral antibiotics can be initiated for mature infants who are able to tolerate oral intake and who are not ill appearing. A delay in initiation of antibiotic treatment of 72 hours or more was a risk factor for permanent renal scars after the first febrile UTI. There is no difference in renal scarring between oral and IV antibiotic therapy.

B. Imaging after urinary tract infection

1. Renal ultrasound. Because of the high rate of congenital anomalies of the kidney and urinary tract, all neonates with a documented UTI should undergo **renal ultrasound**. The timing of this study remains under debate. Hydronephrosis or upper urinary tract dilatation is the most common finding.

2. Voiding cystourethrogram. Children younger than 2 months of age and any child with an *abnormal* renal ultrasound should also have a voiding cystourethrogram (VCUG) to look for vesicoureteral reflux, obstructive lesions (eg, ureterocele, posterior urethral valve), or signs of neurogenic bladder. VCUG for children older than 2 months of age with *normal* renal ultrasound after first febrile UTI is controversial and is currently not recommended by the American Academy of Pediatrics (AAP). Any child with a history of >1 febrile UTI should undergo a VCUG.

3. Watchful waiting without voiding cystourethrogram. In children 0 to 3 months of age with *E coli* UTI (first, febrile UTI) and normal renal ultrasound, watchful waiting without VCUG can be considered. This is based on evidence that the probability of high-grade vesicoureteral reflux was low in children with *E coli* UTIs and normal renal ultrasounds (1%). The presence of non-*E coli* UTI increased the probability of high-grade vesicoureteral reflux to 26%, and adding an abnormal renal ultrasound further increased the probability to 55%.

4. Other imaging studies. Ultrasound of the spine or magnetic resonance imaging (MRI) of the spine may be considered if there is evidence of neurogenic bladder. MRI of the urinary tract is rarely done but can provide excellent anatomic detail of the urinary tract. Diuretic renogram can be done to localize and quantify the degree of urinary tract obstruction.

C. Antibiotic prophylaxis. Use and efficacy of antibiotic prophylaxis are debated subjects in the fields of pediatrics and urology. Although prophylactic antibiotics may reduce the incidence of UTI, they may not reduce the risk of renal scarring. The use of prophylactic antibiotics may also increase the risk of acquiring pathogens with antibiotic resistance. The AAP Red Book states that “data do not support the use of antimicrobial prophylaxis to prevent febrile recurrent UTIs in infants without vesicoureteral reflux.” For neonates with vesicoureteral reflux, moderate to severe hydronephrosis, or other abnormalities such as posterior urethral valves, antibiotic prophylaxis should be considered. Amoxicillin (10 mg/kg/d) is the most commonly used. If vesicoureteral reflux is present, prophylaxis is continued. Trimethoprim-sulfamethoxazole is contraindicated because of liver and kidney immaturity in neonates.

D. Circumcision should be considered in uncircumcised males with a history of recurrent UTIs. Newborn circumcision is a common procedure with relatively few associated complications. Pathogenic bacteria may be more adherent to the mucosal surface of the foreskin than the keratinized surface of the penis after circumcision. In theory, circumcision also reduces the bacterial colonization of the periurethral area, thereby reducing the risk of UTIs. The AAP feels that the potential benefits of male circumcision outweigh the risks; therefore, the procedure should be accessible to families who choose it. There is insufficient evidence to recommend routine circumcision in all newborns. The risks and potential benefits of the procedure should be outlined to parents to help them make an informed decision.

- E. **American Academy of Pediatrics Urinary Tract Infection Guidelines.** In 2011, the AAP revised its practice parameters for diagnosis and management of initial UTI in febrile infants and children age 2 to 24 months. This report did not include infants younger than 2 months of age due to insufficient data in this age group. Therefore, there is no consensus on evaluation and management in infants <2 months old.

153 Varicella-Zoster Infections

Varicella-zoster virus (VZV) is a member of the herpesvirus family. Primary maternal VZV infection (chickenpox) can result in fetal or neonatal infection. Other rare complications include spontaneous abortion, fetal demise, and premature delivery. Reactivation infection (zoster, shingles) does not result in fetal infection. Primary maternal VZV infection during the last trimester can cause maternal pneumonia with significant morbidity and mortality. The overall incidence of maternal and neonatal varicella has decreased over the past 15 to 20 years, presumably due to varicella vaccination. Active surveillance among adults has shown that the incidence of varicella declined 74% during 1995 to 2005, despite vaccination rates among adults of only 3%. Herd immunity is the likely explanation for this phenomenon. As of 2013, more than 78% of 13- to 17-year-old adolescents have received 2 doses of varicella vaccine. Varicella immunization is recommended for all nonimmune women as part of prepregnancy and postpartum care. **Varicella vaccine should not be administered to pregnant women,** because the possible effects on fetal development are unknown, although no cases of congenital varicella syndrome or patterns of malformation have been identified after inadvertent immunization of pregnant women. When postpubertal females are immunized, pregnancy should be avoided for at least 1 month after immunization. Reporting of instances of inadvertent immunization to the US Food and Drug Administration with a varicella-zoster-containing vaccine during pregnancy is encouraged (1-877-888-4231).

There are 3 forms of varicella-zoster infections involving the fetus and neonate: **fetal, congenital (early neonatal), and postnatal.**

FETAL VARICELLA SYNDROME

- I. **Definition.** VZV is a teratogen that can cross the placenta and cause a pattern of congenital malformations called fetal varicella syndrome (FVS). This form occurs when the mother has her first exposure to VZV during the first half of pregnancy. The syndrome is also recognized in the literature as **congenital varicella syndrome (CVS)**.
- II. **Incidence.** Only approximately 5% of women of childbearing age are susceptible to VZV. The incidence of varicella during pregnancy is estimated at 1 to 5 cases per 10,000 pregnancies. The incidence of **embryopathy and fetopathy (FVS)** after maternal varicella infection in the first 20 weeks is 1% to 2%.
- III. **Pathophysiology.** Maternal acquisition of the virus probably occurs via respiratory droplets or direct contact with chickenpox or zoster lesions. The virus replicates in the oropharynx, and viremia results, before the onset of rash, with transplacental passage to the fetus. Almost all cases reported have involved exposure between the 8th and 20th weeks of pregnancy. The pathogenesis of FVS may reflect disseminated infection in utero or be a consequence of failure of the virus–host interaction to result in establishment of latency, as normally occurs in postnatal VZV infection. Because VZV is a lymphotropic virus, it has the potential to spread to all fetal organs by the

hematogenous route. Pathology specimens from aborted fetuses with VZV infection have shown the virus to be distributed throughout fetal tissues. Microcephaly can be attributed to VZV encephalitis and irreversible damage to the developing brain. Of interest, the virus does not appear to cause intrauterine damage to the lungs or liver in infants with FVS, as it does in perinatal varicella or in other immunocompromised hosts. Fulminant infection involving these organs may result in fetal demise, rather than birth of an infant with FVS. VZV is also a neurotropic virus; many of the defects have been postulated to be a direct result of spinal cord and ganglia infection, which causes destruction of the plexi during embryogenesis, leading to denervation of the limb bud and subsequent hypoplasia. Failure of muscle development has consequences for limb bone formation. The cutaneous defects are also likely to reflect VZV infection of sensory nerves. VZV infection of cells in developing optic tracts also explains the optic atrophy and chorioretinitis. From the pattern of dermatomal distribution of the skin defects seen in FVS, particularly the scarring and limb hypoplasia, it has been suggested that FVS is the result of intrauterine zoster. The extremely short latent period between fetal infection and reactivation, if latency is established at all, is the consequence of the lack of cell-mediated immunity in the fetus before 20 weeks' gestation. Infants exposed to VZV in utero also can develop zoster (shingles) early in life without having had extrauterine varicella (chickenpox).

- IV. **Risk factors.** A pregnant woman with no history of varicella infection or vaccination who becomes exposed to VZV between the 8th and 20th weeks of gestation is at risk.
- V. **Clinical presentation.** The main symptoms of FVS are:
 - A. **Skin lesions (60%–70%).** Cicatricial scars and skin loss.
 - B. **Central nervous system defects or disease (60%).** Microcephaly, seizures, encephalitis, cortical atrophy and spinal cord atrophy, mental retardation, and cerebral calcifications.
 - C. **Ocular abnormalities (60%).** Microphthalmia, chorioretinitis, cataracts, optic atrophy, nystagmus, and Horner syndrome (ptosis, miosis, and enophthalmos).
 - D. **Limb abnormalities, which often include hypoplasia of bone and muscle (50%).**
 - E. **Prematurity and intrauterine growth restriction (35%).**
- VI. **Diagnosis.** Alkalay et al proposed the following criteria for the diagnosis of FVS in the newborn:
 - A. **Appearance of maternal varicella during pregnancy.**
 - B. **Presence of congenital skin lesions** in dermatomal distribution and/or neurologic defects, eye disease, or limb hypoplasia.
 - C. **Proof of intrauterine varicella-zoster virus infection** by detection of viral DNA in the infant by polymerase chain reaction (PCR), presence of VZV-specific immunoglobulin (Ig) M, persistence of VZV IgG beyond 7 months of age, or appearance of zoster (shingles) during early infancy.

Prenatal diagnosis is most often done by detailed ultrasound, searching for typical anomalies and VZV-specific PCR in amniotic fluid. At least a 5-week interval is advised between onset of maternal rash and obtaining of the ultrasound. An initial ultrasound is recommended at 17 to 21 weeks of gestation with a follow-up study done 4 to 6 weeks later. The role of prenatal magnetic resonance imaging for assessment of the fetus after maternal varicella is only beginning to be delineated, but it may provide improved specificity, particularly for central nervous system damage.
- VII. **Management.** Isolation precautions for all infectious diseases, including maternal and neonatal precautions, breast feeding, and visiting issues, can be found in Appendix F.
 - A. **Mother.** If the mother is exposed to VZV infection in the first or second trimester, treat the mother with **varicella-zoster immune globulin (VariZIG)** if her past history of varicella infection or vaccination is negative or uncertain. For dosage, see Chapter 155. **VariZIG** should be given as soon as possible after exposure (preferably within 72 hours, but up to 10 days), and it appears to protect both mother and fetus. If VariZIG is not available, intravenous immunoglobulin (IVIg) can be used. If chickenpox is diagnosed during pregnancy, antiviral therapy with **acyclovir**

or **valacyclovir** should be strongly considered. Acyclovir and valacyclovir therapy during pregnancy appears to be safe; it has not been associated with increased congenital abnormalities compared with the general population.

B. Infant. Supportive care of the infant is required because there is usually profound neurologic impairment. Acyclovir therapy may be helpful to stop the progression of eye disease or to treat recurrent zoster (shingles), which is common in the first 2 years of life.

C. Isolation. Isolation is not necessary.

VIII. Prognosis. Approximately 30% of these infants with FVS die in the first months of life, often because of intractable gastroesophageal reflux, severe recurrent aspiration pneumonia, and respiratory failure. Survivors usually suffer profound mental retardation and major neurologic disabilities. These infants are also at risk for developing zoster (shingles) in the first 2 years of life.

CONGENITAL (EARLY NEONATAL) VARICELLA INFECTION

- I. Definition.** This is the form of the disease that occurs when a pregnant woman suffers chickenpox during the last 3 weeks of pregnancy or within the first few days postpartum. Disease begins in the neonate just before delivery or within the first 10 to 12 days of life.
- II. Incidence.** Although the congenital (early neonatal) form is more common than the teratogenic form, it is still rare, with recent estimates of 0.7 per 100,000 live births per annum. The introduction of varicella vaccination in 1995 greatly reduced the incidence of varicella infection in all age groups (herd immunity).
- III. Pathophysiology.** Maternal chickenpox near term or soon after delivery may cause severe or fatal illness in the newborn. Maternal varicella can affect the baby through transplacental viremia, ascending infection during birth, or respiratory droplet/direct contact with infectious lesions after birth. Neonatal chickenpox occurring in the first 10 to 12 days of life is typically caused by intrauterine transmission of VZV (incubation period 10–21 days). Chickenpox after the 12th day of life is most likely acquired by postnatal VZV exposure. If the onset of **maternal disease is between 5 days before delivery or 2 days postpartum**, there is a high attack rate (up to 50%) with significant associated mortality (up to 30%). Those babies present with the classic skin lesions, but can disseminate with pneumonia, hepatitis, meningoencephalitis, and severe coagulopathy (disseminated intravascular coagulation [DIC]) resulting from liver failure and thrombocytopenia. If the maternal rash happens >5 days before delivery, there is enough maternal anti-VZV IgG production with subsequent transplacental transfer to protect the newborn, which results in a milder case of chickenpox.
- IV. Risk factors.** Primarily a mother with chickenpox during the last 3 weeks of pregnancy or within the first few days postpartum. There is a higher risk of mortality if the onset of maternal disease is **5 days before delivery or 2 days postpartum**. Premature infants, especially those <28 weeks, are extremely susceptible.
- V. Clinical presentation** is variable. There may be only mild involvement of the infant, with vesicles on the skin, or the following may be seen:
 - A. Skin.** A centripetal rash (beginning on the trunk and spreading to the face and scalp, sparing the extremities) begins as red macules and progresses to vesicles and encrustation. Lesions are more common in the diaper area and skin folds. There may be 2 or 3 lesions or thousands of them. The differential diagnosis includes herpes simplex virus and enterovirus. The main complication is staphylococcal and streptococcal secondary skin infections.
 - B. Lungs.** Lung involvement is seen in all fatal cases. It usually appears 2 to 4 days after the onset of the rash but may be seen up to 10 days after. Signs include fever, cyanosis, rales, and hemoptysis. Chest radiograph shows a diffuse nodular-miliary pattern, especially in the perihilar region.

C. **Other organs.** Focal necrosis may be seen in the liver, adrenals, intestines, kidneys, and thymus. Glomerulonephritis, myocarditis, encephalitis, and cerebellar ataxia are sometimes seen.

VI. **Diagnosis.** The diagnosis of varicella usually is made clinically based on the characteristic appearance of skin lesions.

A. **Polymerase chain reaction** is the **most sensitive and specific method for detection** of VZV DNA in clinical specimens. This is the diagnostic method of choice for investigation of vesicular fluid or scabs, biopsies, and amniotic fluid. This testing also can be used to distinguish between wild-type and vaccine-strain VZV (genotyping). Viral culture and direct fluorescent antibody assay are less sensitive than PCR and are not usually recommended.

B. **Serum testing of varicella-zoster virus antibody.** Serologic tests may help to document acute infection in difficult cases. IgM antibody may be detected as soon as 3 days after the appearance of VZV symptoms, but the test may not be reliable.

VII. Management

A. **VariZIG.** Infants of mothers who develop VZV infection (rash) **within 5 days before or 2 days after** delivery should receive 125 U (62.5 U if <2 kg) of **VariZIG** as soon as possible and no later than 10 days. **IVIg** (400 mg/kg) should be used if VariZIG is not available. Infants treated with immune globulins should be placed in strict respiratory isolation for 28 days because immunoglobulin treatment may prolong the incubation period. VariZIG is not expected to reduce the clinical attack rate in treated newborns; however, these infants tend to develop milder infections than the untreated neonates. Prophylactic administration of oral **acyclovir** beginning 7 days after exposure also may prevent or attenuate varicella disease in exposed infants. Infants born to mothers with rash occurring **>5 days before delivery** do not need VZIG, unless they are born at <28 weeks' gestation; it is believed that these infants should have received protective transplacental antibodies.

B. **Acyclovir therapy** 15 mg/kg/dose every 8 hours for 7 days should be considered for postexposure prophylaxis as well as a treatment in symptomatic neonates.

C. **Antibiotics.** Use antibiotics if secondary bacterial skin infections occur.

D. **Breast feeding.** Neither wild-type VZV nor Oka vaccine strain virus has been shown to be transmitted by human milk; expressed/pumped milk from a mother with varicella or zoster can be given to the infant, provided no lesions are on the breast.

VIII. **Prognosis.** If the mother has onset of disease within 5 days before delivery or 2 days after, the infant is exposed with no antibodies and will be at risk for severe disease. Overwhelming sepsis and multiple organ failure can lead to a mortality rate as high as 30%. The usual causes of death are pneumonia, fulminant hepatitis, and DIC. With the use of VariZIG, the mortality rate is reduced to 7%. There is an increased risk of developing zoster (shingles) in the first 2 years of life.

POSTNATAL CHICKENPOX

I. **Definition.** This form of the disease presents after the 12th day of life. It does not represent transplacental infection from the mother.

II. **Incidence.** There has been a significant decline in the incidence since the introduction of the varicella vaccine in 1995 (by 90%). The incidence of neonatal varicella in the vaccine era is approximately 0.7 per 100,000 live births.

III. **Pathophysiology.** Postnatal VZV infection occurs by droplet transmission. This disease is usually mild because of passive protection from maternal antibodies. Placental antibody transfer is lower in preterm infants, which makes them more susceptible compared with term infants. Horizontal transmission in neonatal intensive care units has been well documented. Neonatal vaccine-strain VZV infection after maternal postpartum vaccination has been reported.

- IV. Risk factors.** Seronegative mother, delivery before 28 weeks, birthweight <1.5 kg, postnatal age >2 months (maternal transplacental immunity has waned), immunocompromised neonates (eg, sepsis, steroids).
- V. Clinical presentation.** The typical chickenpox rash is seen with centripetal spread, beginning on the trunk and spreading to the face and scalp and sparing the extremities. All stages of the rash may appear at the same time, from red macules to clear vesicles to crusting lesions. Complications of this form of the disease are rare but may include secondary infections and varicella pneumonia. In older children, necrotizing fasciitis secondary to group A streptococcal infections is particularly worrisome and may be associated with ibuprofen use (see Figure 80–11).
- VI. Diagnosis.** Same as for congenital varicella (see the previous section). Diagnosis is usually made based on clinical grounds.
- VII. Management.** For the full-term infant in the community setting, the disease is usually mild. Therefore, acyclovir therapy is *controversial*. For nosocomial chickenpox in the intensive care nursery (exposure):
- Varicella-zoster immune globulin.** Recommended for all exposed infants of <28 weeks' gestational age or weighing ≤ 1000 g regardless of their mothers' evidence of immunity to varicella. It is also recommended in older premature infants (28–36 weeks) whose mothers do not have a history of chickenpox or varicella vaccination (**seronegative**). Some experts recommend administration of VariZIG to term infants who have been exposed to varicella in the first 2 weeks after birth and whose mothers do not have evidence of immunity.
 - Infants ≥ 28 weeks' gestation born to seropositive (immune) mothers.** These infants should have sufficient transplacental antibodies to protect them from the risk of complications.
 - Isolation.** Exposed infants should be placed in strict isolation (airborne and contact precautions) from 8 until 21 days after the onset of the rash in the index case. Exposed infants who receive VariZIG/IVIG should be in strict respiratory isolation for 28 days.
 - Breast feeding.** Expressed/pumped milk from a mother with varicella or zoster can be given to the infant, provided no lesions are on the breast. Breast feeding is encouraged in infants exposed to or infected with varicella because antibody in breast milk may be protective.
 - Acyclovir.** Recommended for infants who develop breakthrough lesions or prophylactically beginning 7 days after exposure. Therapy should be continued for 7 days (if used prophylactically) or for 48 hours after the last new lesions have appeared.
- VIII. Prognosis.** This form of the disease is mild, and death is extremely rare. Normal term infants who develop postnatal chickenpox have the same risk of complications of chickenpox as older children. Premature infants are at increased risk for nosocomial acquisition of VZV. The risk of complications for infants <28 weeks who develop postnatal chickenpox is unknown.

154 Zika Virus (Congenital Zika Syndrome)

- I. Definition.** Congenital Zika syndrome (CZS) is a constellation of central nervous system (CNS), ocular, and neuromuscular abnormalities seen in newborns after in utero exposure to Zika virus, a member of the *Flaviviridae* virus family (which includes dengue, yellow fever, and West Nile viruses).

II. Incidence. As of late August 2017, the Pan American Health Organization reported 48 countries in the Americas with vector-borne transmission of Zika virus and 27 countries and territories in the Americas with confirmed cases of CZS. As of mid-April 2018, the Centers for Disease Control and Prevention (CDC) identified 2328 completed pregnancies in the United States (including the District of Columbia) in women with laboratory evidence of possible Zika virus infection. Of these pregnancies, 115 liveborn neonates and 9 pregnancy losses had documented birth defects. The prevalence of CZS-associated birth defects in infants of women in the US Zika Pregnancy Registry during the first 9 months of 2016 was 58.8 cases per 1000 live births, roughly 20-fold greater than a “pre-Zika” cohort in 2013 to 2014.

III. Pathophysiology. Zika virus is an arbovirus (arthropod-borne virus) first identified in the Zika Forest of Uganda in 1947. Mosquitoes of the *Aedes* genus (specifically, *Aedes aegypti* and *Aedes albopictus*) are the primary arthropod vectors and are endemic to regions of the continental United States and Hawaii, Puerto Rico, and the US Virgin Islands. In urban and suburban areas, the virus is transmitted from human to human via mosquito bites (“blood meals”) commonly during daylight hours. Sexual transmission of the virus can occur from an infected person to his or her partner and is of great concern to pregnant women or women attempting to conceive.

Human disease secondary to Zika virus had been noted sporadically worldwide until outbreaks in the State of Yap, Federated States of Micronesia in 2007 and multiple Pacific Islands from 2013 to 2016. In most cases, persons infected with Zika virus are asymptomatic. In symptomatic patients, acute Zika syndrome typically is a mild illness presenting in adults and children roughly 7 to 10 days after exposure with a pruritic, maculopapular rash, a low-grade fever, musculoskeletal discomfort (myalgia/arthritis/arthralgia), extremity edema, conjunctivitis, and headache. Zika infection and Guillain-Barré syndrome, an autoimmune-mediated peripheral neuropathy, first were associated during an outbreak in French Polynesia in 2013 to 2014; a strong link between the virus and the disease was confirmed in a later case-control study in that area.

The first outbreak of Zika infection in the Americas occurred in early 2015 in the Bahia state of Brazil, with an estimated 1.3 million cases throughout the country. Later that year, health officials in Brazil noted an increased incidence of anomalies in babies born in Zika-affected areas. Zika RNA and proteins subsequently were found in fetal and maternal tissues from microcephalic fetuses, infants, and early pregnancy losses of Brazilian mothers with symptoms of acute Zika infection in pregnancy. Additional research has demonstrated that the virus generates a placentitis and has a notable tropism for human neuronal tissue *in vitro* and *in vivo*, specifically for neural progenitor cells. Furthermore, clinical, imaging, and autopsy findings in affected fetuses and newborns documented significant cranial, CNS, and ophthalmologic abnormalities. Using criteria for teratogenicity and evidence of causation, the CDC concluded in May 2016 that a causal relationship may be inferred between antenatal maternal Zika virus infection and neonatal microcephaly and other brain anomalies.

IV. Risk factors. Risk factors for Zika virus infection include:

A. Residing in or travel to a Zika-endemic region. As of September 2017, the following countries have been designated by the CDC as areas with risks of acquiring Zika:

1. **Africa:** Angola, Benin, Burkina-Faso, Burundi, Cameroon, Cape Verde, Central African Republic, Chad, Congo (Congo-Brazzaville), Côte d’Ivoire, Democratic Republic of the Congo (Congo-Kinshasa), Equatorial Guinea, Gabon, Gambia, Ghana, Guinea, Guinea-Bissau, Kenya, Liberia, Mali, Niger, Nigeria, Rwanda, Senegal, Sierra Leone, South Sudan, Sudan, Tanzania, Togo, Uganda.
2. **Asia:** Bangladesh, Burma (Myanmar), Cambodia, India, Indonesia, Laos, Malaysia, Maldives, Pakistan, Philippines, Singapore, Thailand, Timor-Leste (East Timor), Vietnam.
3. **The Caribbean:** Anguilla, Antigua and Barbuda, Aruba, The Bahamas, Barbados, Bonaire, British Virgin Islands, Cuba, Curaçao, Dominica, Dominican Republic, Grenada, Haiti, Jamaica, Montserrat, Puerto Rico, Saba, Saint Kitts and Nevis,

Saint Lucia, Saint Martin, Saint Vincent and the Grenadines, Saint Eustatius, Saint Maarten, Trinidad and Tobago, Turks and Caicos Islands, US Virgin Islands.

4. **Central America:** Belize, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, Panama.
 5. **North America:** Mexico.
 6. **The Pacific Islands:** Fiji, Marshall Islands, Micronesia, Palau, Papua New Guinea, Samoa, Solomon Islands, Tonga.
 7. **South America:** Argentina, Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Paraguay, Peru, Suriname, Venezuela.
 8. **United States travel precautions:** Autochthonous infection (ie, infection caused by endemic mosquitoes) previously was documented in the United States in Miami-Dade County, Florida, and Brownsville, Texas, leading to Zika cautionary (yellow) designations. Pregnant women (or women wishing to conceive) were recommended to limit travel to these areas. As of August 2017, however, the CDC lifted these designations, although people residing in or traveling to these regions should take precautions to minimize the risk of mosquito bites. Up-to-date, worldwide travel recommendations may be obtained from the CDC's Zika virus (cdc.gov/Zika).
- B. Sex with a person who resides in or has traveled to a Zika-endemic region.** The Zika virus persists in human body fluids, even after resolution of the acute infection. Notably, Zika virus can persist in semen for up to 6 months after infection. Women who wish to conceive or who are pregnant should discuss with their health-care provider strategies to prevent Zika infection in this manner.
- C. Blood product transfusion.** To date, 4 suspected cases of transfusion-associated Zika virus transmission have been reported (all in Brazil). As of late 2016, however, blood banks in the United States test all donations for Zika virus or subject the samples to pathogen reduction techniques, with all positive blood products quarantined and removed from the blood supply.
- D. Breast milk.** Although Zika virus has been isolated from breast milk, cases of Zika transmission via breast feeding have not been reported. In the absence of other contraindications (eg, human immunodeficiency virus infection, medications), women with confirmed, probable, or suspected Zika exposure may breast feed their babies.
- V. Clinical presentation.** The clinical features of CZS are due to direct CNS injury and resultant calvarial abnormalities. These findings initially may be detected on antenatal imaging, recognized at the time of birth, or identified in childhood.
- A. Microcephaly and brain or spinal cord abnormalities.** CZS has been associated with the fetal brain disruption sequence (FBDS), a constellation of findings including severe microcephaly (occipitofrontal head circumference [OFC] <3 standard deviations below the mean for gestational age), overlapping cranial sutures, occipital prominence, craniofacial disproportion, and excessive scalp skin. In CZS, FBDS theoretically occurs secondary to loss of brain volume after Zika-induced neuronal death and impaired neuronal migration. Specific brain abnormalities include subcortical calcifications (in contrast to periventricular calcifications seen in congenital cytomegalovirus infection), cortical dysgenesis (heterotopias, pachygyria, lissencephaly), cortical thinning, ventriculomegaly, and callosal and cerebellar hypoplasia. Neural tube defects (eg, spina bifida, anencephaly) have been reported among babies in the US Zika Pregnancy Registry, although a causal relationship has not been established. Of note, microcephaly, postnatal hydrocephalus, and developmental delays not noted at birth may develop later as the infant grows (secondary to early neuronal injury).
- B. Ophthalmologic abnormalities.** As many as half of newborns with CZS and associated microcephaly have eye anomalies. Posterior segment abnormalities are the most common findings, including chorioretinal atrophy, retinal pigment mottling, and optic nerve findings (atrophy/hypoplasia or cupping). Acute chorioretinitis, often seen in other congenital infections (eg, *Toxoplasma*, cytomegalovirus), is not

present in neonates with Zika infection. Anterior segment abnormalities in CZS include iris coloboma, microphthalmia, lens subluxation, cataracts, glaucoma, and intraocular calcifications.

C. Neurologic/neuromuscular abnormalities. Abnormal neurologic findings in neonates with CZS may include hypotonia or hypertonia, hyperreflexia, seizures (or abnormal electroencephalography without clinical seizures), irritability, extraocular muscle paresis, dysphagia, and developmental delays. Congenital sensorineural hearing loss has been demonstrated, but delayed-onset hearing loss (as seen with congenital cytomegalovirus infection) has not been documented. Congenital neuromuscular abnormalities observed in CZS include contractures of ≥ 1 joint (arthrogryposis), club foot (talipes equinovarus), diaphragmatic paralysis, and hip and knee dislocation.

D. Laboratory markers of hepatic involvement (ie, elevated transaminases) are extremely rare in CZS, unlike in other congenital or perinatally acquired infections (eg, neonatal herpes simplex virus infection). However, autopsies of a small cohort of newborns with CZS demonstrated hepatic (steatosis, hepatocyte necrosis) and genitourinary (cystitis, focal glomerular sclerosis) injury.

VI. Diagnosis. Confirmative diagnosis of Zika virus infection in expectant mothers, fetuses, and neonates is challenging due to a paucity of data and a limited number of available tests. Diagnosis of CZS relies on identification of clinical signs and symptoms, laboratory analyses, and imaging modalities in the fetus and newborn in combination with maternal history and testing results. All pregnant women should be asked whether they have had possible Zika virus exposure during pregnancy. For infants with concern for CZS, coordination of care between healthcare facilities, local and regional health departments, and the CDC is important to ensure appropriate procurement and processing of samples and appropriate follow-up of neonates with suspected, probable, or confirmed CZS. See Figure 154–1 for the evaluation of infants with possible congenital Zika virus infection.

A. Laboratory studies. Currently available diagnostic tests for Zika virus include molecular nucleic acid amplification tests (NAATs) and serologic assays approved by the US Food and Drug Administration under an Emergency Use Authorization. Samples for neonatal testing should be obtained as early as possible (preferably within the first 2 days of age) because delayed testing may prevent clinicians from distinguishing congenital Zika infection from postnatally acquired Zika infection. **Cord blood should not be used for Zika testing**, because false-positive and/or false-negative results may occur.

1. Zika nucleic acid amplification testing (NAAT). Zika virus real-time reverse transcription polymerase chain reaction (rRT-PCR) is used to identify viral RNA. This assay may be used for serum or whole blood; urine; cerebrospinal, seminal, or amniotic fluid; and placental tissue specimens. Zika virus RNA has been detected in serum for up to 2 weeks after acute infection in nonpregnant individuals and up to 62 days in pregnant women. RNA may persist for longer in other specimens and has been documented in seminal fluid months after acute infection. A positive rRT-PCR test result in any specimen indicates active Zika virus infection. However, a negative Zika virus rRT-PCR test does not exclude infection because patient sampling may have occurred outside the acute phase of infection. Zika NAAT testing should be performed in tandem with serologic testing in patients with concern for Zika infection.

2. Zika serologic testing. Zika immunoglobulin (Ig) M antibody is the current first-line serologic test in the United States. IgM antibodies may be detectable within days of acute infection and persist for at least 4 months thereafter. However, Zika IgM testing has several limitations. False-negative results may occur if testing occurs outside the window of IgM detection or if the patient failed to generate an IgM antibody response. False-positive or equivocal results may occur in patients who have been infected with other arboviruses (eg, dengue or

chikungunya viruses) or vaccinated against Japanese encephalitis or yellow fever. Presently, there is no approved Zika IgG assay available in the United States.

All positive Zika IgM results should be confirmed with a plaque reduction neutralization test (PRNT), which measures virus-specific neutralizing antibodies that develop soon after infection and that may persist for years. PRNT testing may help confirm or rule out a prior infection (congenital or postnatal). However, a positive PRNT test alone cannot distinguish timing of infection, and the results of this test must be interpreted within the clinical context of the patient. In low-risk areas, postnatally acquired infections are unlikely; therefore, a positive PRNT test shortly after birth in a neonate is more likely to reflect a congenital infection. In addition, the PRNT assay cannot distinguish between maternal and infant antibodies in specimens collected from infants at or near birth. Because maternal Zika antibodies are expected to become undetectable by 18 months of age, repeat serologic testing in infants beyond this age may aid in confirming or ruling out congenital Zika virus infection.

3. **Interpretation and caveats of neonatal and infant Zika testing.** Interpretation of laboratory testing of neonatal and infant serum, urine, and/or CSF samples for Zika virus, per the CDC, is as follows:

- a. **Nucleic acid amplification test positive, any immunoglobulin M result.**

These results are consistent with **confirmed** congenital Zika virus infection in the infant. However, distinguishing congenital and postnatal Zika virus infection may be difficult if the infant is born in an area of ongoing Zika virus transmission and testing is not done soon after birth. If the timing of the infection cannot be determined, the infant should be evaluated as if she or he has a congenital Zika virus infection.

- b. **Nucleic acid amplification test negative, immunoglobulin M nonnegative.** These results are consistent with **probable** congenital Zika virus infection but should be interpreted within the context of timing of infection (or potential infection) in pregnancy, maternal laboratory results, and the infant's PRNT test results and clinical exam. *If the Zika PRNT test is negative, the infant's Zika IgM result likely is a false positive.*

- c. **Nucleic acid amplification test negative, immunoglobulin M negative.** These results are consistent with congenital Zika virus infection being **unlikely**, particularly if specimens collected soon after birth and the clinical evaluation are normal. Again, these results must be interpreted in light of the factors mentioned in **Section VI.A.3.b**. Furthermore, clinicians should remain vigilant for any signs or symptoms of CZS in infancy and childhood.

4. **Other laboratory tests**, including a complete blood count, metabolic panel, hepatic enzymes, and liver function tests, should be sent in children with high suspicion of CZS and may aid in diagnosis or exclusion of other congenital infectious, genetic, or metabolic conditions.

5. **Clinicians also should be aware** that cases of infants with **clinical findings consistent with possible CZS** but with **negative laboratory results** have been reported.

B. Imaging and other studies

1. **Ultrasound, computed tomography, or magnetic resonance imaging.** CNS imaging should be performed in all infants with suspicion of CZS within the first month of age. Ultrasound is the most convenient method to assess intracranial anatomy in neonates. Subtle abnormalities may be detected more readily by magnetic resonance imaging (MRI) or computed tomography (CT) scan. Therefore, particularly in children with restrictive anterior fontanelles or whose clinical findings strongly suggest CZS, MRI or CT should be considered.
2. **Ophthalmologic exam.** This should be performed by an ophthalmologist or retinal specialist, with specific attention to the retinae and optic nerves.

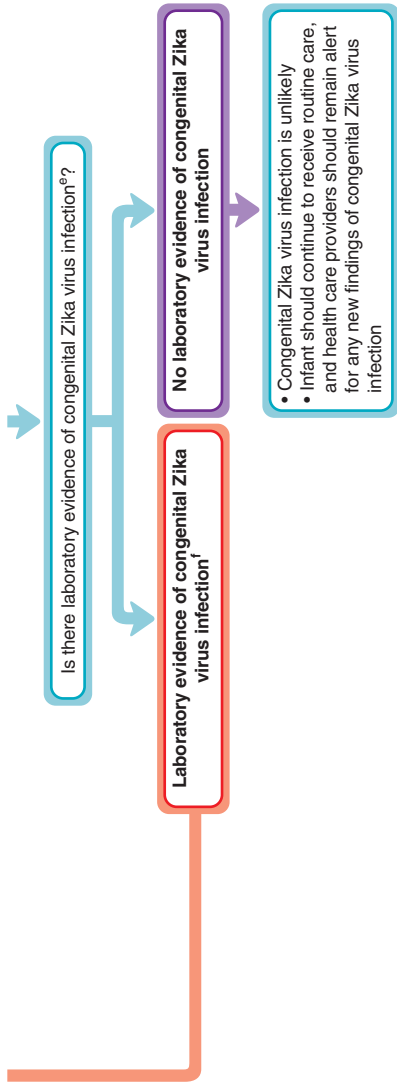

FIGURE 154–1. Recommendations for the evaluation of infants with possible congenital Zika virus infection based on infant clinical findings,^{a,b} maternal testing results,^{c,d} and infant testing results.^{e,f} United States October 2017. ABR, auditory brainstem response; CSF, cerebrospinal fluid; CZS, congenital Zika syndrome; IgM, immunoglobulin M; NAAT, nucleic acid amplification test; PRNT, plaque reduction neutralization test. ***All infants should receive a standard evaluation at birth** and at each subsequent well-child visit by their healthcare providers including (1) comprehensive physical examination, including growth parameters and (2) age-appropriate vision screening and developmental monitoring and screening using validated tools. Infants should receive a standard newborn hearing screen at birth, preferably using ABR. **^bAutomated ABR by age 1 month if newborn hearing screen passed** but performed with otoacoustic emission methodology. **†Laboratory evidence of possible Zika virus infection during pregnancy** is defined as (1) Zika virus infection detected by a Zika virus RNA NAAT on any maternal, placental, or fetal specimen (referred to as NAAT-confirmed), or (2) diagnosis of Zika virus infection, timing of infection cannot be determined by serologic tests on a maternal specimen (ie, positive/equivocal Zika virus IgM or unspecified flavivirus infection, timing of infection cannot be determined by serologic tests on a maternal specimen (ie, positive/equivocal Zika virus IgM and Zika virus PRNT titer ≥ 10 , regardless of dengue virus PRNT value; or negative Zika virus IgM, and positive or equivocal dengue virus IgM, and Zika virus PRNT titer ≥ 10 , regardless of dengue virus PRNT titer). The use of PRNT for confirmation of Zika virus infection, including in pregnant women, is not routinely recommended in Puerto Rico (<https://www.cdc.gov/zika/laboratories/lab-guidance.html>). **^dThis group includes women who were never tested during pregnancy as well as those whose test result was negative** because of issues related to timing or sensitivity and specificity of the test. Because the latter issues are not easily discerned, all mothers with possible exposure to Zika virus during pregnancy who do not have laboratory evidence of possible Zika virus infection, including those who tested negative with currently available technology, should be considered in this group. **†Laboratory testing of infants for Zika virus should be performed as early as possible**, preferably within the first few days after birth, and includes concurrent Zika virus NAAT in infant serum and urine, and Zika virus IgM testing in serum. If CSF is obtained for other purposes, Zika virus NAAT and Zika virus IgM testing should be performed on CSF. **†Laboratory evidence of congenital Zika virus infection** includes a positive Zika virus NAAT or a nonnegative Zika virus IgM with confirmatory neutralizing antibody testing, if PRNT confirmation is performed. (Reproduced with permission from Adebajojo T, Godfred-Cato S, Vicens L, et al: Update: Interim Guidance for the Diagnosis, Evaluation, and Management of Infants with Possible Congenital Zika Virus Infection—United States, October 2017, *MMWR Morb Mortal Wkly Rep*. 2017 Oct 20;66(41):1089-1099.)

- 3. Hearing screening.** In children with laboratory and clinical abnormalities consistent with CZS, automated auditory brainstem response should be performed by 1 month of age if the newborn screening test was passed (via otoacoustic emissions [OAE] testing). Automated auditory brainstem response will detect abnormalities along the auditory brainstem pathway or in the 8 cranial nerves not reflected in OAE testing.

VII. Management. During the recent Zika epidemic, guidelines for the evaluation and management of pregnant woman, fetuses, and newborns with possible, probable, or confirmed Zika virus infection have been published and updated regularly (by organizations such as the CDC, the American College of Obstetricians and Gynecologists, and the Society of Maternal-Fetal Medicine). Clinicians should remain vigilant for further updates as more information is learned about Zika virus infection in pregnancy and CZS.

A. Pregnant women. All pregnant women should be assessed for Zika virus exposure prior to pregnancy and at each prenatal visit, including a review of travel history (including her partner's history). As of July, 2017:

- 1. If a pregnant woman has possible exposure to Zika virus and symptoms consistent with infection,** she should be offered Zika NAAT and serologic testing **immediately and through 12 weeks after symptom onset.**
- 2. If a pregnant woman is asymptomatic but has ongoing possible Zika exposure (from residing in or traveling to an at-risk area),** she should be offered NAAT testing at initiation of prenatal care and twice more thereafter. IgM testing in these women is no longer recommended due to limitations of and difficulty in interpreting these tests. *Of note, the optimal timing and frequency of testing asymptomatic women with NAAT only are not known.*
- 3. If a pregnant woman is asymptomatic with recent possible exposure (ie, during the pregnancy, 8 weeks before conception, or 6 weeks before her last menstrual period) but no ongoing exposure,** routine testing is **not recommended** but can be considered using a shared decision-making model between the patient and provider. This recommendation may be adapted based on unique factors in the jurisdiction where the woman resides (eg, seasonality, mosquito control factors).

Pregnant women whose fetuses have anomalies concerning for CZS should have NAAT and serologic testing and be referred to a high-risk obstetrician and/or a tertiary care medical center for comprehensive maternal and neonatal care. Previously, the CDC suggested serial ultrasounds roughly every 4 weeks for women exposed in pregnancy and with laboratory evidence of Zika infection; however, there are no data specific to this infection to support this recommendation. If amniocentesis is performed for abnormal prenatal findings, Zika NAAT testing can be considered. However, a negative NAAT on amniotic fluid cannot rule out CZS.

B. Neonates and infants. Based on risk and findings of affected neonates evaluated to date, the CDC has recommended the following evaluation and management strategies for newborns and infants born to mothers with possible Zika virus infection during pregnancy:

- 1. Infants with clinical findings consistent with congenital Zika syndrome and maternal history with possible Zika virus exposure during pregnancy.** The initial evaluation and subspecialty involvement may be done prior to discharge or within the first month of life as deemed appropriate based on the clinical context, setting, and feasibility of outpatient care. The evaluation should include the following:
 - a. A standard evaluation, including a comprehensive physical exam** (with documentation of weight, length, and OFC) and age-appropriate vision, hearing, and developmental surveillance and screening.
 - b. Zika virus nucleic acid amplification testing and immunoglobulin M from serum or blood** and NAAT from urine.

- c. **Zika virus nucleic acid amplification testing and immunoglobulin M from cerebrospinal fluid (CSF)** if CSF is obtained for other diagnostic purposes. Clinicians should consider CSF testing if serum and urine Zika results are negative and other explanation for abnormalities are ruled out, given reports of CZS in infants where CSF testing yielded the only positive result. At our institution (Johns Hopkins), due to logistical considerations, we recommend obtaining CSF at initial evaluation if the clinician has a high suspicion of CZS in the patient, especially if the results of serum and urine assays are not available at the time of patient evaluation or discharge.
 - d. **Head ultrasound by age 1 month.** Consider additional neuroimaging as discussed earlier.
 - e. **Comprehensive ophthalmologic exam by age 1 month of age.**
 - f. **Automated auditory brainstem response hearing evaluation by 1 month of age,** even if OAE screening is completed in the newborn nursery or neonatal intensive care unit (NICU).
 - g. **Evaluation for other causes of congenital anomalies.**
 - h. **Referral to developmental specialists and early intervention service programs** for infants and toddlers.
 - i. **Psychosocial support to the family (via social work and/or psychology).**
 - j. **Consultation with additional specialists** (as appropriate) based on the patient's clinical findings, including:
 - i. **Genetics,** for confirmation of the phenotype and evaluation for chromosomal/genetic/metabolic causes of microcephaly (eg, trisomies).
 - ii. **Infectious diseases** for evaluation other congenital infections (eg, rubella, cytomegalovirus) and assistance with Zika diagnosis and testing.
 - iii. **Neurology and neuroradiology,** by 1 month of age, for a thorough neurologic examination, consideration of other disorders of neuronal development (eg, intrauterine intracranial hemorrhage, inhalant embryopathy), and guidance regarding additional testing (eg, electroencephalography).
 - iv. **Consultations with other pediatric specialists,** including **orthopedics, otolaryngology, pulmonology, gastroenterology, endocrinology, and speech and language pathology,** may be appropriate based on clinical findings to assess and manage sequelae of CZS (eg, joint contractures, aspiration risk, feeding problems, hypothalamic-pituitary axis abnormalities). Clinicians and families may wish to pursue palliative care in severely affected children.
2. **Infants without clinical findings consistent with CZS but maternal history of laboratory evidence of possible Zika virus infection during pregnancy.**
 - a. **Standard evaluation as noted earlier.**
 - b. **Zika virus nucleic acid amplification testing and immunoglobulin M** from serum or blood and NAAT from urine.
 - c. **Head ultrasound by age 1 month.** Consider more advanced neuroimaging as discussed earlier.
 - d. **Comprehensive ophthalmologic exam by age 1 month,** with follow-up as determined by the ophthalmologist.
 - e. **Automated auditory brainstem response hearing evaluation by 1 month of age,** even if OAE screening is completed in the newborn nursery or NICU. If the infant is found to have abnormalities consistent with CZS at any time (eg, vision impairment, hearing problems, developmental delay, or delayed head growth) **or** the infant remains asymptomatic but has positive Zika testing results (positive NAAT or nonnegative IgM with confirmatory positive PRNT), then the infant should undergo additional evaluations and subspecialist involvement as described in **Section VII.B.1**. If the infant remains asymptomatic and Zika virus testing is negative, CZS is unlikely. The child should continue to receive routine pediatric care, with clinicians remaining vigilant for findings consistent with CZS.

3. **Infants without clinical findings** consistent with CZS and mothers with possible Zika virus exposure in pregnancy but without maternal testing or negative maternal laboratory results.
 - a. **A standard evaluation as noted earlier.**
 - b. **No additional Zika-specific testing or evaluations.**
 - c. **These infants should continue to receive routine pediatric care**, and providers should remain alert to the possibility of CZS and development of its sequelae. In some cases, additional evaluations may be considered depending on the context of the risk of exposure, maternal history, and infant's exam or if abnormalities are identified as the infant grows and develops. Should a child in this category demonstrate abnormalities consistent with CZS, he or she should undergo a complete evaluation as noted in **Section VII.B.1.**
 - C. **Infants with congenital Zika syndrome or in utero Zika exposure** should receive ongoing pediatric care, including monitoring of growth and development, preventive care, and immunizations in a stable medical home. Subspecialty care and referrals should be based on initial and newly identified medical concerns.
- VIII. Primary prevention.** Primary prevention should focus on educating pregnant and periconceptual women and their partners on reducing exposure to the virus. Mechanisms include avoiding primary acquisition via mosquito bites (by using mosquito nets, insect repellent containing *N,N*-diethyl-meta-toluamide [DEET], and air conditioning in endemic areas), avoiding exposure (for up to 6 months) to semen of a man infected with Zika virus (via abstinence or barrier contraception), and avoidance or limited travel of women and their male sexual partners to Zika-endemic areas. As of October 2018, a Zika virus vaccine does not exist, although clinical trials are ongoing.
- IX. Prognosis.** CZS is a newly recognized syndrome, but the sequelae in neonates and infants can be striking. Mortality among the initial cohort of Brazilian infants with laboratory confirmed Zika virus infection was 41.1 per 1000 live births. Data from another group of CZS infants during their first year of life show striking decreases in weight, length, and OFC. These children also demonstrated irritability (85.4%), pyramidal and extrapyramidal abnormalities (56.3%), and seizures (50%). Continued surveillance is necessary among infants with documented Zika infection or in utero exposure but without neonatal manifestations of the disease based on experience with other congenital infections (eg, rubella) causing complications later in childhood.

155 Medications Used in the Neonatal Intensive Care Unit¹

This section provides a description of medications used in the contemporary care of sick newborn infants. It is not intended to be an exhaustive list of all drugs available for infants, nor is it intended to be an in-depth source of information about neonatal pharmacology. Readers are encouraged to consult with their institutional pharmacists regarding issues of pharmacokinetics, drug interactions, drug elimination and metabolism, and monitoring drug serum levels. Many of these medications may not have formal US Food and Drug Administration (FDA) approval for use in neonates but have become commonly used in this population. The chapter does not provide detailed information about the medication but rather focuses on the use in neonatal population. Information on medications and breast feeding and pregnancy can be found in Chapter 156.

When the designations of neonate/newborn or infant are used for medication doses, it refers to the following:

Neonate/Newborn: Birth to 28 days postnatal age (PNA).

Infant: >28 days (1 month) to 1 year of age.

ACETAMINOPHEN (APAP) (LIQUIPRIN, TEMPRA, TYLENOL)

INDICATIONS AND USE: Analgesic, antipyretic.

ACTIONS: Analgesic effect—inhibition of prostaglandin synthesis in the central nervous system (CNS) and peripherally, blocking pain impulse generation. Antipyretic effect—inhibition of hypothalamic heat-regulating center.

DOSAGE: oral (PO), per rectum (PR), intravenous (IV).

- **Preterm infants 28 to 32 weeks:** 10 to 12 mg/kg/dose PO every 6 to 8 hours or 20 mg/kg/dose PR every 12 hours. Maximum daily dose: 40 mg/kg. IV: 20 mg/kg IV loading dose; then 7.5 to 10 mg/kg/dose IV every 12 hours. Maximum daily dose: 22.5 mg/kg.
- **Preterm infants 33 to 37 weeks; term neonates <10 days:** 10 to 15 mg/kg/dose PO every 6 hours or 30 mg/kg PR loading dose; then 15 mg/kg/dose every 8 hours. Maximum daily dose: 60 mg/kg. IV: 20 mg/kg IV loading dose; then 7.5 to 10 mg/kg/dose IV every 8 hours. Maximum daily dose: 40 mg/kg.
- **Term infants ≥10 days:** 10 to 15 mg/kg/dose PO every 4 to 6 hours or 30 mg/kg PR loading dose; then 20 mg/kg/dose every 6 to 8 hours. Do not exceed 5 doses in 24 hours. Maximum daily dose: 75 mg/kg. IV: 20 mg/kg IV loading dose; then 10 mg/kg/dose IV every 6 hours. Maximum daily dose: 40 mg/kg.

ADVERSE EFFECTS: Rash, blood dyscrasias (neutropenia, leukopenia, and thrombocytopenia), and hepatic necrosis with overdose; renal injury may occur with chronic use.

PHARMACOLOGY: Extensively metabolized by the liver primarily by sulfonation, and by glucuronidation to a much lesser extent. Excretion by the kidney with elimination half-life: term infants—approximately 3 hours, preterm infants >32 weeks—5 hours, and in premature infants <32 weeks—up to 11 hours. Prolonged elimination with liver dysfunction.

¹Edited Black Box “Warnings” are provided for select medications. Readers should review the entire package insert for each medication. Selected common brand names are provided in addition to the generic name. Many of these drugs are available as generic medications.

COMMENTS: Rectal administration may result in inaccurate dosing. Prophylactic use during vaccination may result in potential reduction in antibody response. IV administration in premature infants <32 weeks postmenstrual age has not yet been studied, so some experts do not recommend use in this age group. Beginning 2011 into 2012—transition to 1 pediatric concentration 160 mg/5 mL and elimination of 80 mg/0.8 mL infant drops per FDA recommendations. *N*-Acetylcysteine is the antidote of choice for acetaminophen poisoning.

ACETAZOLAMIDE (DIAMOX)

INDICATIONS AND USE: Reduce intraocular pressure in glaucoma; an anticonvulsant in refractory neonatal seizures; decrease cerebrospinal fluid (CSF) production in posthemorrhagic hydrocephalus; treatment of renal tubular acidosis.

ACTIONS: Competitive, reversible, carbonic anhydrase inhibitor; increases renal excretion of sodium, potassium, bicarbonate, and water, resulting in the production of acidosis. Decreases the production of aqueous humor and reduces abnormal discharge from CNS neurons.

DOSAGE: IV, PO.

- **Glaucoma:** 8 to 30 mg/kg/day PO divided every 8 hours or IV 20 to 40 mg/kg/day divided every 6 hours; maximum 1 g/day.
- **Anticonvulsant:** 4 to 16 mg/kg/day PO divided every 6 to 8 hours not to exceed 30 mg/kg/day or 1 g/day.
- **Alkalinize urine:** 5 mg/kg/dose PO 2 to 3 times over 24 hours.
- **Decrease CSF production:** 5 mg/kg/dose IV/PO every 6 hours; increased by 25 mg/kg/day to a maximum of 100 mg/kg/day. Furosemide has been used in combination.

ADVERSE EFFECTS: Gastrointestinal irritation, transient hypokalemia, hyperchloremic metabolic acidosis, growth retardation, bone marrow suppression, thrombocytopenia, hemolytic anemia, pancytopenia, agranulocytosis, leukopenia, drowsiness, and paresthesia.

PHARMACOLOGY: Unchanged in urine. Half-life is 4 to 10 hours.

COMMENTS: Currently, rarely used in neonates; a 1998 study failed to show efficacy in slowing the progression of posthemorrhagic hydrocephalus in neonates and infants. In neonates, use is limited to the treatment of glaucoma. Used as an adjunct to other medications in refractory seizures. Tolerance to diuretic effect may occur with long-term use. Oral solution may be compounded by using tablets.

ACYCLOVIR (ZOVIRAX)

ACTION AND SPECTRUM: Treatment and prophylaxis of herpes simplex virus (HSV-1 and HSV-2) infections, herpes simplex encephalitis, herpes zoster infections, and varicella-zoster infections.

DOSAGE: PO, IV.

Herpes simplex (based on American Academy of Pediatrics [AAP] *Red Book*, 2018–2021):

- **Neonatal:** 20 mg/kg/dose IV every 8 hours for 14 to 21 days. Treat CNS infections for 21 days (more than 21 days if CSF PCR remains positive) and all other infections for 14 days. Reduce dosing interval to every 12 hours in neonates <30 weeks' gestational age.
- **Dosing in renal impairment:**
 - **Serum creatinine 0.8 to 1.1 mg/dL:** 20 mg/kg IV every 12 hours.
 - **Serum creatinine 1.2 to 1.5 mg/dL:** 20 mg/kg IV every 24 hours.
 - **Serum creatinine >1.5 mg/dL:** 10 mg/kg IV every 24 hours.

Herpes simplex: chronic suppression following any herpes simplex infection

- 300 mg/m²/dose PO every 8 hours for 6 months.

Herpes zoster (shingles):

- **Infants and children:** 10 mg/kg/dose IV every 8 hours for 7 to 10 days. In immunocompromised host, the acquired immunodeficiency syndrome (AIDS) information guidelines recommend duration of therapy of 10 to 14 days.

Varicella-zoster (chickenpox) in immunocompromised host:

- **Infants <2 years:** 10 mg/kg/dose IV every 8 hours for 7 to 10 days.

ADVERSE EFFECTS: Generally well tolerated. Thrombophlebitis and inflammation of injection site. Acute renal failure/acute kidney injury, increased blood urea nitrogen (BUN) and serum creatinine, nephrotoxicity. Increased liver transaminases. Neutropenia, thrombocytopenia, anemia, thrombocytosis, leukocytosis, and neutrophilia. Neutropenia may necessitate reduction in dose or treatment with granulocyte colony-stimulating factor (G-CSF) if absolute neutrophil count (ANC) remains $<500/\text{mm}^3$. Adequate hydration and infusion rate of at least 1 hour reduces risk of transient renal impairment and crystalluria.

PHARMACOLOGY: Inhibits DNA synthesis and viral replication. Oral absorption is 15% to 30%, CSF concentrations are 50% of serum, and primarily excreted by the kidneys.

COMMENTS: Infuse over at least 1 hour; concentration $<7 \text{ mg/mL}$, 5 mg/mL is preferred. Do not refrigerate. Monitor complete blood cell count (CBC) and renal and liver function.

ACYCLOVIR OPHTHALMIC

See Chapter 58.

ADENOSINE (ADENOCARD)

INDICATIONS AND USE: Acute treatment of sustained paroxysmal supraventricular tachycardia for conversion to normal sinus rhythm.

ACTIONS: A purine nucleoside that slows conduction time through the atrioventricular (AV) node and interrupts reentry pathways through the AV node to restore normal sinus rhythm. Effects are mediated by depression of calcium slow-channel conduction, an increase in potassium conductance, and possibly indirect antiadrenergic effects.

DOSAGE: IV.

- 0.05 to 0.1 mg/kg by rapid IV push over 1 to 2 seconds. Repeat bolus doses at 2-minute intervals by increasing increments of 0.05 to 0.1 mg/kg until sinus rhythm is achieved or until a maximum single dose of 0.3 mg/kg is reached. Infuse as close as possible to the patient's heart and immediately flush IV with saline to ensure dose enters circulation. For doses $<0.2 \text{ mL}$, prepare dilution using normal saline (NS) to final concentration of 300 mcg/mL.

ADVERSE EFFECTS: Contraindicated in heart block. Transient arrhythmias, flushing, dyspnea, and hypotension. May cause bronchoconstriction; use with caution in patients with history of bronchospasm.

PHARMACOLOGY: Rapid onset of action; half-life is <10 seconds; duration is 20 to 30 seconds.

COMMENTS: Methylxanthines (caffeine and theophylline) are competitive antagonists; larger adenosine doses may be required.

ALBUMIN, HUMAN

INDICATIONS AND USE: Treatment of hypovolemia, maintenance of cardiac output in shock, plasma volume expansion, hypoproteinemia associated with generalized edema or decreased intravascular volume; acute nephrotic syndrome in premature infants. Not recommended for initial volume expansion; use isotonic crystalloid solutions—0.9% sodium chloride or lactated Ringer's (per Pediatric Advanced Life Support [PALS] and Neonatal Resuscitation Program [NRP] guidelines).

ACTIONS: Increases intravascular oncotic pressure, which results in a mobilization of fluid from the interstitial spaces into the intravascular space.

DOSAGE: IV.

- **Neonates, infants, and children:** 0.5 to 1 g/kg IV (or 10–20 mL/kg of 5% IV bolus) repeated as necessary. Maximum: 6 g/kg/day. Five percent solutions should be used in hypovolemic or intravascularly depleted patients; 25% solutions should be used in cases of fluid or sodium restriction.
- **Hypoproteinemia in neonates:** Dose may be added to hyperalimentation solutions; however, may increase potential for growth of bacteria or fungi.

ADVERSE EFFECTS: Rapid infusion may cause vascular overload and precipitation of congestive heart failure or pulmonary edema. The 25% solution should be used with extreme caution in premature neonates due to increased risk of intraventricular hemorrhage.

PHARMACOLOGY: Duration of volume expansion is approximately 24 hours.

COMMENTS: Refer to individual product information for use of correct in-line IV filter. A 5% concentration is osmotically equivalent to equal volume of plasma, and 25% concentration is osmotically equivalent to 5 times its volume of plasma. If unavailable, 5% solutions can be prepared by diluting the 25% solution with normal saline (NS) or 5% dextrose in water (D5W). Do not use sterile water to prepare dilution; this may cause hypotonic-associated hemolysis, which can be fatal.

ALBUTEROL (PROVENTIL, VENTOLIN)

INDICATIONS AND USE: Prevention and treatment of bronchospasm; bronchodilator in respiratory distress syndrome (RDS) and bronchopulmonary dysplasia/chronic lung disease (BPD/CLD). Used for treatment of hyperkalemia.

ACTIONS: Primarily β_2 -adrenergic stimulation (bronchodilation and vasodilation) with minor β_1 stimulation (increased myocardial contractility and conduction).

DOSAGE: Inhalation, nebulization.

- **Nebulization:** 1.25 to 2.5 mg/dose every 2 to 6 hours as needed.
- **Inhalation:** Metered dose inhaler 90 mcg/spray: 1 to 2 puffs every 2 to 6 hours as needed.

ADVERSE EFFECTS: Tachycardia, tremors, CNS stimulation, hypokalemia, hyperglycemia, and hypertension.

COMMENTS: Duration of action is approximately 2 to 5 hours. Titrate dose according to the effect on heart rate and improvement in respiratory symptoms. Albuterol should not be used as the sole agent for treating severe hyperkalemia.

ALPROSTADIL (PROSTAGLANDIN E₁) (PROSTIN VR)

WARNING: Apnea is experienced by about 10% to 12% of neonates with congenital heart defects treated with alprostadil injection, US Pharmacopeia (USP). Apnea is most often seen in neonates weighing <2 kg at birth and usually appears during the first hour of drug infusion. Therefore, respiratory status should be monitored throughout treatment, and alprostadil should be used where ventilatory assistance is immediately available.

INDICATIONS AND USE: Any clinical condition in which blood flow must be maintained through the ductus arteriosus to sustain either pulmonary or systemic circulation until corrective or palliative surgery can be performed. Examples are pulmonary atresia, pulmonary stenosis, tricuspid atresia, transposition of the great arteries, aortic arch interruption, coarctation of the aorta, and severe tetralogy of Fallot (TOF).

ACTIONS: Causes vasodilation of all vascular smooth muscle including the ductus arteriosus.

DOSAGE: IV.

- **Initial:** 0.05 to 0.1 mcg/kg/min by continuous infusion. Gradually titrate to maintain acceptable oxygen levels without adverse effects. Use the lowest rate to maintain improved oxygenation response.
- **Maintenance:** 0.01 to 0.4 mcg/kg/min. Higher doses may be required in patients receiving ECLS.

ADVERSE EFFECTS: See Black Box warning. May cause gastric outlet obstruction and reversible cortical proliferation of the long bones after prolonged treatment. Hypotension, cutaneous vasodilation, bradycardia, inhibits platelet aggregation, hypoventilation, seizure-like activity, jitteriness, temperature elevation, hypocalcemia, hypoglycemia.

COMMENTS: Decreased response after 96 hours of infusion. Maximal improvement in PaO₂, usually within 30 minutes in cyanotic infants and 1.5 to 3 hours in acyanotic infants. Use cautiously in infants with bleeding tendencies.

ALTEPLASE, RECOMBINANT (ACTIVASE, CATHFLO ACTIVASE, TISSUE PLASMINOGEN ACTIVATOR [tPA])

INDICATIONS AND USE: Used to restore patency of occluded central venous catheters and for the dissolution of large-vessel thrombus (systemic use). (See also Chapters 84 and 92.)

ACTIONS: Alteplase is a thrombolytic. It enhances conversion of plasminogen to plasmin, which then cleaves fibrin, fibrinogen, factor V, and factor VIII, resulting in clot dissolution.

DOSAGE: IV.

Occluded central venous catheter:

- **Manufacturer's recommendations (CathFlo, Activase):** PNA ≥ 14 days, use 1 mg/mL; instill a volume equal to 110% of the internal lumen volume; do not exceed 2 mg in 2 mL; leave in lumen for up to 2 hours and then aspirate out of catheter. May repeat process if lumen is still occluded. Check the catheter product literature or manufacturer for catheter volume.
- **Chest, 2008 dosing recommendations (Monagle et al, 2008):** 0.5 mg diluted in a volume of normal saline (NS) equal to the catheter lumen internal volume; instill over 1 to 2 minutes; dwell time is 1 to 2 hours. Aspirate solution from catheter and then flush catheter with NS.

Dissolution of large-vessel thrombus (systemic use):

- **Dose is controversial,** and optimal dose has not been established. May consider fresh-frozen plasma (FFP) prior to administration of alteplase. *Chest*, 2012 recommends use only when major vessel occlusion is causing critical compromise of organs or limbs.
- **Chest, 2012 recommendations (Monagle et al, 2012):** 0.1 to 0.6 mg/kg/h for 6 hours. Dose must be titrated to effect; some patients require longer or shorter duration of therapy.

ADVERSE EFFECTS: The risk of complications increases at rates >0.4 mg/kg/h. Systemic use is not recommended with preexisting intraventricular hemorrhage or cerebral ischemic changes. Bleeding from venipuncture sites may occur. During the treatment of occluded central venous catheter, bleeding may occur if excess alteplase is inadvertently injected into the systemic circulation. Excessive pressure during instillation may force clot into systemic circulation.

COMMENTS: Increases risk of bleeding in infants concurrently on heparin, warfarin, or indomethacin. Monitor prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen, and fibrin split products prior to the initiation of therapy and at least daily through the duration of therapy. Fibrinogen levels should be maintained >100 mg/dL and platelets $>50,000/\text{mm}^3$.

AMIKACIN SULFATE (AMIKIN)

WARNING: May cause neurotoxicity, nephrotoxicity, and/or neuromuscular blockade and respiratory paralysis. Avoid concomitant use with potent diuretics since diuretics themselves may cause ototoxicity and may enhance aminoglycoside toxicity. Avoid concomitant or sequential use of other neurotoxic and/or nephrotoxic drugs (eg, amphotericin B, colistin, polymyxin B, vancomycin, other aminoglycosides).

ACTION AND SPECTRUM: Active against gram-negative bacteria, including most *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Proteus*, *Escherichia coli*, and *Serratia* spp. No activity against anaerobic organisms. Reserve for treatment of gram-negative organisms resistant to gentamicin and tobramycin. Treatment of susceptible mycobacterial organisms.

DOSAGE: Intramuscular (IM), IV. Infuse over 30 minutes. Dosage should be monitored and adjusted by use of pharmacokinetics. Initial empirical dosing based on body weight (*Red Book*, 2018–2021):

- **Neonates ≤ 28 PNA:**
- **GA < 30 weeks:**
 - PNA ≤ 14 days: 15 mg/kg every 48 hours.
 - PNA > 14 days: 15 mg/kg every 24 hours.

- **GA 30–34 weeks:**
 - **PNA ≤14 days:** 15 mg/kg every 36 hours.
 - **PNA >14 days:** 15 mg/kg every 24 hours.
- **GA ≥35 weeks:**
 - **PNA ≤7 days:** 15 mg/kg every 24 hours.
 - **PNA >7 days:** 18 mg/kg every 24 hours.
- **Infants and children:** 15 to 22.5 mg/kg/day divided in 2 to 3 doses or 1 dose; some patients may require higher doses (eg, cystitis fibrosis).
- **Treatment of nontuberculous mycobacterial infection:** 15 to 30 mg/kg/day divided every 12 to 24 hours as a part of a multidrug regimen.
- **Meningitis:**
 - **PNA ≤7 days:** 15 to 20 mg/kg/day divided every 12 hours.
 - **PNA >7 days:** 20 to 30 mg/kg/day divided every 8 hours.

PHARMACOLOGY: Displays concentration-dependent killing; bactericidal activity. Renal elimination (glomerular filtration); half-life is 4 to 8 hours; volume of distribution is 0.6 L/kg.

ADVERSE EFFECTS: Possible nephrotoxicity and ototoxicity. Toxicities may be potentiated when used with furosemide or vancomycin, and neuromuscular blockade is increased if used with pancuronium or with coexisting hypermagnesemia.

COMMENTS: Monitor serum levels when treating >48 hours, in patients with decreased or changing renal function, with signs of nephrotoxicity or ototoxicity, with concomitant use of other nephrotoxic agents, and in patients who may require higher doses. Adjust the dosage according to serum peak and trough levels. Desired serum neonate concentration 24 to 40 mg/L (peak), <7 mg/L (trough) for neonates ≤28 postnatal days of age. Nephrotoxicity is associated with serum trough concentrations >10 mcg/mL; ototoxicity, with serum peak concentrations >35 to 40 mg/mL (more cochlear damage than vestibular).

AMINOPHYLLINE/THEOPHYLLINE

INDICATIONS AND USE: To reduce frequency and severity of apnea of prematurity, following extubation or during alprostadil administration. A bronchodilator in the treatment of bronchopulmonary dysplasia/chronic lung disease. Caffeine is more effective and safer for the treatment of apnea of prematurity. Caffeine also has the advantage of once-a-day dosing. Aminophylline/theophylline has greater bronchodilator effects.

ACTIONS: Theophylline (the active component of aminophylline) causes relaxation of bronchial smooth muscle; increases the force of contraction of the diaphragmatic muscles; dilates the pulmonary, coronary, and renal arteries; causes mild diuretic action; causes increased sensitivity of the CNS medullary respiratory centers to carbon dioxide; stimulates central respiratory drive and peripheral chemoreceptors; and increases sensitivity to catecholamines, resulting in increased cardiac output and improved oxygenation. Aminophylline is approximately 80% theophylline. Neonates have a unique ability to convert theophylline to caffeine in a ratio of 1:0.3. Caffeine may account for as much as 50% of the theophylline level.

DOSAGE: PO, IV.

- **IV loading dose:** 5 to 8 mg/kg, slowly over 30 minutes. IV maintenance dosage is 2 to 6 mg/kg/day divided every 8 to 12 hours starting 8 to 12 hours after loading dose.
- **PO (use immediate-release dosage form) loading dose:** Same as IV. PO maintenance dose as theophylline is 2 to 6 mg/kg/day divided every 6 to 8 hours. Older infants may need higher doses as clearance rate increases with increased PNA, possibly up to 25 to 30 mg/kg/day.

ADVERSE EFFECTS: Hyperglycemia, dehydration, diuresis, and feeding intolerance. CNS effects include jitteriness, hyperreflexia, and seizures. Most common side effects are cardiovascular with tachycardia (heart rate ≥180 beats/min) and other tachyarrhythmias.

COMMENTS: Therapeutic levels: apnea 6 to 12 mcg/mL; bronchospasm 5 to 15 mcg/mL. Toxicity usually >20 mcg/mL. Monitor serum levels at a peak 1 hour after IV dosing or 1 hours after PO dosing. Take trough levels 30 minutes before next dose. Serum levels should be monitored any time toxicity is suspected or when apneic episodes are increased. Steady state expected to be reached after 48 to 72 hours of therapy.

AMIODARONE (CORDARONE)

INDICATIONS AND USE: Treatment of resistant life-threatening ventricular arrhythmias unresponsive to other agents; prevention and suppression of supraventricular arrhythmias (especially those associated with Wolff-Parkinson-White syndrome) and postoperative junctional ectopic tachycardia.

ACTIONS: An iodinated benzofuran that prolongs the action potential and increases the effective refractory period. It decreases afterload (causes peripheral and coronary vasodilation), and demonstrates α - and β -blocking properties and calcium channel inhibition. It slows the heart rate (decreases atrioventricular node and sinus node conduction—negative inotropic effects).

DOSAGE: IV. Limited data are available. Generally not first line due to high incidence of adverse effects. Recommend consultation with pediatric cardiologist prior to use.

- **IV loading dose:** 5 mg/kg over 60 minutes; do not exceed 0.25 mg/kg/min unless clinically indicated; central venous access is recommended. May repeat dose up to total loading dose of 15 mg/kg/day.
- **Continuous IV infusion:** 5 mcg/kg/min gradually increasing as needed to 15 mcg/kg/min.
- **PO loading dose:** 10 to 20 mg/kg/day divided into 2 doses per day for 7 to 10 days or until adequate control of arrhythmia is achieved or significant adverse effects occur. Reduce dose to 5 to 10 mg/kg/day given once daily for several weeks. Attempt to reduce dose to lowest possible without the recurrence of arrhythmia: 2.5 mg/kg/day.

ADVERSE EFFECTS: Bradycardia and hypotension (may be related to rate of infusion), proarrhythmias (including torsade de pointes), heart block, congestive heart failure (CHF), and paroxysmal ventricular tachycardia. Amiodarone may cause hypothyroidism or hyperthyroidism (may partially inhibit the peripheral conversion of thyroxine [T_4] to triiodothyronine [T_3]; serum T_4 and reverse T_3 concentrations may be increased, and serum T_3 may be decreased). Amiodarone hydrochloride contains 37% iodine by weight and is a potential source of iodine; approximately 3 mg of inorganic iodine/100 mg of amiodarone is released into the circulation. Elevated liver enzymes, elevated bilirubin. Phlebitis and local injection site irritation: avoid concentrations >2.5 mg/mL, administer through central vein.

PHARMACOLOGY: Adult data: onset of oral antiarrhythmic effects may take up to 3 to 6 weeks. Duration of antiarrhythmic effects may persist for 30 to 90 days or longer following discontinuation of therapy. Protein binding: 96%. Metabolized in liver.

COMMENTS: Potential drug interactions may occur. Amiodarone inhibits certain cytochrome P450 enzymes and may increase serum levels of digoxin, flecainide, lidocaine, theophylline, procainamide, quinidine, warfarin, and phenytoin. To avoid toxicities with these agents, dosage reduction and serum concentration monitoring is recommended. Dosage reductions of 30% to 50% have been recommended. Concurrent administration of amiodarone with β -blockers, digoxin, or calcium channel blockers may result in bradycardia, sinus arrest, and heart block.

AMPHOTERICIN B (AMPHOCIN); AMPHOTERICIN B, LIPOSOMAL (AMBISOME); AMPHOTERICIN B LIPID COMPLEX (ABELCET)

ACTION AND SPECTRUM: Antifungal agent that acts by binding to sterols and disrupting the fungal cell membrane permeability. Broad spectrum of activity against *Candida* spp. and other fungi.

DOSAGE: IV, intrathecal, intraventricular.

Conventional amphotericin B (amphotericin B deoxycholate):

- **IV:** 1 to 1.5 mg/kg IV every 24 hours for 2 to 6 weeks or longer, but a lower dose may suffice. Infuse over 2 to 6 hours, but infusion over 1 to 2 hours may be used if tolerated. Use a 0.1 mg/mL concentration in 5% dextrose in water (D5W), D10W, or D20W. May use maximum concentration of 0.25 mg/mL for infusion through central venous catheter. Incompatible with sodium chloride.

- **Intrathecal or intraventricular:** Reconstitute with sterile water at 0.25 mg/mL; dilute with CSF and reinfuse. Usual dose: 25 to 100 mcg every 48 to 72 hours; increase to 1000 mcg as tolerated.
- **Irrigation, bladder:** 50 mcg/mL solution, administered as continuous irrigation or as intermittent irrigation 3 times per day with a 60- to 90-minute dwell time.

Liposomal amphotericin B:

- Concentrates in liver and spleen, but penetrates the CNS, kidneys, urinary tract, and eyes less than conventional amphotericin B. Used when refractory to or intolerant of conventional amphotericin B.
- 5 to 7 mg/kg/dose IV infused over 2 hours. May be diluted with D5W, D10W, D20W, or D25W to a final concentration of 1 to 2 mg/mL; concentrations of 0.2 to 0.5 mg/mL may be needed to provide sufficient volume for infusion.

Amphotericin B lipid complex:

- Used when refractory to or intolerant of conventional amphotericin B. Less nephrotoxic.
- 3 to 5 mg/kg/dose IV every 24 hours infused over 2 hours. Dilute with D5W, D10W, or D15W to final concentration of 1 mg/mL; a maximum concentration of 2 mg/mL. Manufacturer recommends that an in-line filter should *not* be used.

PHARMACOKINETICS: Slow renal excretion.

ADVERSE EFFECTS: Fewer adverse effects in neonates as compared to adults. May cause fever, chills, vomiting, thrombophlebitis at injection sites, renal tubular acidosis, renal failure, hypomagnesemia, hypokalemia, bone marrow suppression with reversible decline in hematocrit, hypotension, hypertension, wheezing, and hypoxemia.

COMMENTS: Protect the solution from light. Monitor serum potassium, magnesium, blood urea nitrogen (BUN), creatinine, and urine output at least every other day until the dosage is stabilized, then every week. Monitor complete blood cell count (CBC) and liver function every week. Discontinue if BUN is >40 mg/dL, serum creatinine is >3 mg/dL, or liver function tests are abnormal.

AMPICILLIN (POLYICILLIN, OTHERS)

ACTION AND SPECTRUM: Semisynthetic penicillinase-sensitive penicillin that is bactericidal and acts by inhibiting the late stages of cell wall synthesis. Treatment of susceptible bacterial infections caused by streptococci, pneumococci, enterococci, non-penicillinase-producing staphylococci, *Listeria*, meningococci; some strains of *Haemophilus influenzae*, *Proteus mirabilis*, *Salmonella*, *Shigella*, *Escherichia coli*, *Enterobacter*, and *Klebsiella*; used in combination with an aminoglycoside or cefotaxime in neonates for prevention and treatment of infections due to group B streptococci, *Listeria*, and *E coli*.

DOSAGE: IM, IV (WEIGHT-DIRECTED DOSING [BRADLEY, 2019]).

Body weight ≤2 kg:

- PNA ≤7 days: 50 mg/kg/dose every 12 hours.
- PNA 8 to 28 days: 75 mg/kg/dose every 12 hours.
- PNA 29 to 60 days: 50 mg/kg/dose every 6 hours.

Body weight >2 kg:

- PNA ≤28 days: 50 mg/kg/dose every 8 hours.
- PNA 29 to 60 days: 50 mg/kg/dose every 6 hours.

Group B streptococcal meningitis:

- PNA ≤7 days: 200 to 300 mg/kg/day IV divided every 6 to 8 hours.
- PNA >7 days: 300 mg/kg/day IV divided every 6 hours.

Infants and children:

- 100 to 200 mg/kg/day IM, IV divided every 6 hours. Maximum dose: 4000 mg/day.
- Meningitis: 200 to 400 mg/kg/day IM, IV divided every 6 hours. Maximum dose: 12 g/day.

ADVERSE EFFECTS: Hypersensitivity, rash, abdominal discomfort, nausea, vomiting, diarrhea, hemolytic anemia, thrombocytopenia, neutropenia, prolongation of bleeding time, interstitial nephritis, and eosinophilia. Large doses may cause CNS excitation or seizures.

AMPICILLIN SODIUM/SULBACTAM SODIUM (UNASYN)

ACTION AND SPECTRUM: Combination β -lactamase inhibitor and β -lactam. The bactericidal spectrum of ampicillin that is extended by the addition of sulbactam, a β -lactamase inhibitor; includes organisms producing β -lactamases such as *Staphylococcus aureus*, *Haemophilus influenzae*, *Escherichia coli*, *Klebsiella*, *Acinetobacter*, *Enterobacter*, and anaerobes.

DOSEAGE: IV, IM. Dose based on ampicillin component.

Preterm infants and neonates during the first week of life (0–7 days):

- 100 mg ampicillin/kg/day IM/IV divided every 12 hours.

Neonates >7 days:

- 100 mg ampicillin/kg/day IM/IV divided every 6 to 8 hours.

Infants \geq 1 month:

- 100 to 200 mg ampicillin/kg/day IM/IV divided every 6 hours. Maximum dose: 1000 mg ampicillin/dose.

Severe infection:

- 200 to 300 mg ampicillin/kg/day IM/IV divided every 6 hours. Maximum dose: 2000 mg ampicillin/dose.

ADVERSE EFFECTS: Elevated blood urea nitrogen (BUN) and serum creatinine. See Ampicillin.

COMMENTS: Modify dosage in patients with renal impairment.

ANAKINRA (KINERET)

INDICATIONS AND USE: Neonatal-onset multisystem inflammatory disease or chronic infantile neurologic, cutaneous, and articular syndrome.

ACTIONS: Interleukin-1 (IL-1) receptor antagonist.

DOSEAGE: Subcutaneous.

- **Initial:** 1 to 2 mg/kg daily in 1 to 2 divided doses.
- **Usual maintenance dose:** 3 to 4 mg/kg daily; maximum dose 8 mg/kg/day.

ADVERSE EFFECTS: Skin rash, vomiting, injection site reaction, upper respiratory tract infection, thrombocytopenia.

PHARMACOLOGY: Half-life elimination 4 to 6 hours; time to peak 3 to 7 hours.

COMMENTS: Monitor complete blood count (CBC) with differential, liver function tests, and renal function at baseline. Monitor CBC with differential every 3 months for up to 1 year.

ARGININE HCL (R-GENE)

INDICATIONS AND USE: Treatment of severe metabolic alkalosis after other treatment has failed, pituitary function test (stimulant for the release of growth hormone), and treatment of certain neonatal-onset urea cycle disorders. Limited data available on potential role for necrotizing enterocolitis prevention.

ACTIONS: Corrects severe hypochloremic metabolic alkalosis resulting from the high chloride content of arginine. Arginine stimulates pituitary release of growth hormone and prolactin and the pancreatic release of glucagon and insulin.

DOSEAGE: IV.

Metabolic alkalosis in infants and children:

- Arginine HCl dose (mEq) = $0.5 \times \text{weight (kg)} \times [\text{HCO}_3^- - 24]$, where HCO_3^- = the patient's serum bicarbonate concentration in mEq/L; give one-half to two-thirds of calculated dose and reevaluate.

Correct hypochloremia in infants and children:

- Arginine HCl dose (mEq) = $0.2 \times \text{weight (kg)} \times [103 - \text{Cl}^-]$, where Cl^- = the patient's serum chloride concentration in mEq/L; give one-half to two-thirds of the calculated dose, then reevaluate.
- IV: May use undiluted (irritating to tissues) or dilute with normal saline (NS) or dextrose. Administer through a central line. Infuse over at least 30 minutes or over 24 hours in maintenance IV. Maximum: 1 g/kg/h (= 10 mL/kg/h of 10% solution). PO: May use the injectable form, diluted.

Pituitary function test:

- IV 500 mg/kg (= 5 mL/kg of the 10% solution) infused IV over 30 minutes. (Use only IV, not PO administration, for this test.) Maximum dose: 30 g dose.

Urea cycle disorders:

- Consult specialists in metabolic disorders if a urea cycle disorder is suspected.

Necrotizing enterocolitis prevention:

- 261 mg/kg/day added to enteral or parenteral nutrition beginning on day 2 to 5 of life and continuing for 28 consecutive days.

ADVERSE EFFECTS: Not a first-line treatment for metabolic alkalosis and should never be used as initial therapy; try sodium, potassium, or ammonium chlorides first. May be toxic in infants with arginase deficiency. Do not use in patients sensitive to arginine HCl or in those with hepatic or renal failure. May cause hyperchloremic metabolic acidosis; elevated gastrin, glucagon, and growth hormone; flushing and gastrointestinal upset with rapid IV administration; hyperglycemia, hypoglycemia, hyperkalemia; tissue necrosis on extravasation, vein irritation; allergic reactions; elevated blood urea nitrogen (BUN) and creatinine.

COMMENTS: Monitor IV site, blood glucose, chloride, and blood pressure. If intact pituitary function, human growth hormone levels should rise after arginine administration to 10 to 30 ng/mL.

ASFOTASE ALFA (STRENSIQ)

INDICATIONS AND USE: Perinatal/infantile- and juvenile-onset hypophosphatasia.

ACTIONS: Human recombinant tissue-nonspecific alkaline phosphatase-Fc-deca-aspartate fusion protein with enzymatic activity that promotes bone mineralization in patients with hypophosphatasia.

DOSAGE: Subcutaneous.

- 6 mg/kg/wk administered as either 2 mg/kg/dose 3 times weekly or 1 mg/kg/dose 6 times weekly. Maximum total weekly dose: 9 mg/kg/wk.

ADVERSE EFFECTS: Ectopic calcification, injection site reactions, hypocalcemia.

PHARMACOLOGY: Onset of action in reducing plasma tissue-nonspecific alkaline phosphatase (TNSALP) takes 6 to 12 weeks of treatment. Elimination half-life approximately 5 days.

COMMENTS: Round patient weight to the nearest kilogram when determining dose. Do not administer the 80 mg/0.8 mL concentration to neonates.

ATROPINE SULFATE

INDICATIONS AND USE: Sinus bradycardia, in conjunction with neostigmine for the reversal of nondepolarizing neuromuscular blockade. Used preoperatively to inhibit salivation and reduce excessive secretions of the respiratory tract.

ACTIONS: A competitive antagonist of acetylcholine at parasympathetic sites in smooth muscle, cardiac muscle, and various glandular cells, leading to increased heart rate, increased cardiac output, reduced gastrointestinal (GI) motility and tone, urinary retention, cycloplegia, and decreased salivation and sweating.

DOSAGE: IM, IV, endotracheal tube (ETT), PO.

Bradycardia in infants and children:

- **IV, intraosseous (IO):** 0.02 mg/kg/dose; may repeat once in 3 to 5 minutes; reserve use for those patients unresponsive to improved oxygenation and epinephrine. **No longer part of American Heart Association neonatal resuscitation algorithm.**

Preanesthetic:

- **Infants <5 kg:** 0.02 mg/kg/dose IV, IM, subcutaneous 30 to 60 minutes preoperatively, then every 4 to 6 hours as needed.
- **Infants >5 kg:** 0.01 to 0.02 mg/kg/dose IV, IM, subcutaneous 30 to 60 minutes preoperatively, then every 4 to 6 hours as needed. Maximum single dose: 0.4 mg.

Reversal of neuromuscular blockade:

- Neostigmine 0.06 mg/kg/dose with atropine 0.02 mg/kg/dose.

Intubation, nonemergent (preferred vagolytic):

- 0.02 mg/kg/dose IM, IV.

ETT:

- 0.04 to 0.06 mg/kg/dose; may repeat once if needed. Flush with 3 to 5 mL normal saline (NS) based on patient size.

ADVERSE EFFECTS: Xerostomia, mydriasis, tachycardia, palpitations, constipation, urinary retention, ataxia, tremor, hyperthermia, and swelling. Toxic effects are especially likely in children receiving low doses.

COMMENTS: Avoid use in patients with thyrotoxicosis, tachycardia secondary to cardiac insufficiency, and obstructive GI disease. In low doses, it may cause paradoxical bradycardia secondary to its central actions. Monitor heart rate, blood pressure, and pulse.

AZITHROMYCIN

ACTION AND SPECTRUM: Treatment of upper respiratory tract infections due to *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pyogenes*, *Chlamydophila pneumoniae*, *Mycoplasma pneumoniae*, *Streptococcus pneumoniae*, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Staphylococcus aureus*, *Mycobacterium avium* complex, *Chlamydophila psittaci*, and *Mycoplasma hominis*. Has also been used for treatment of pertussis.

DOSAGE: PO, IV.

Infants <6 months:

- **Pertussis:** 10 mg/kg/dose PO, IV once daily for 5 days (based on AAP *Red Book*, 2018–2021). Azithromycin is drug of choice for age <1 month because of idiopathic hypertrophic pyloric stenosis with erythromycin.
- **Chlamydial conjunctivitis or chlamydial pneumonia:** 20 mg/kg PO once daily for 3 days.

Children ≥6 months:

- **Respiratory tract infections:** 10 mg/kg on day 1 (maximum dose 500 mg) followed by 5 mg/kg/day (maximum dose 250 mg) once daily on days 2 to 5.
- **Pertussis:** 10 mg/kg on day 1 (maximum dose 500 mg) followed by 5 mg/kg/day (maximum dose 250 mg) once daily on days 2 to 5 (based on AAP *Red Book*, 2018–2021).

ADVERSE EFFECTS: Diarrhea, vomiting, irritability, rash, fever.

PHARMACOLOGY: Macrolide antibiotic; elimination half-life of approximately 55 hours in infants and children.

COMMENTS: Limited data in neonates. Monitor liver function tests and white blood cell count, and monitor infants for diarrhea.

AZTREONAM (AZACTAM)

ACTION AND SPECTRUM: Monobactam antibiotic that is bactericidal against most Enterobacteriaceae, *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Serratia*, *Haemophilus influenzae*, and *Citrobacter* spp., but essentially no activity against gram-positive aerobic or anaerobic bacteria.

DOSAGE: IV, IM.

Body weight <1 kg:

- PNA ≤14 days: 30 mg/kg/dose every 12 hours.
- PNA 15 to 28 days: 30 mg/kg/dose every 8 hours to 12 hours.

Body weight 1 to 2 kg:

- PNA ≤7 days: 30 mg/kg/dose every 12 hours.
- PNA 8 to 28 days: 30 mg/kg/dose every 8 to 12 hours.

Body weight >2 kg:

- PNA ≤7 days: 30 mg/kg/dose every 8 hours.
- PNA 8 to 28 days: 30 mg/kg/dose every 6 hours.

Children >1 month:

- 90 to 120 mg/kg/day divided every 6 to 8 hours.

ADVERSE EFFECTS: Diarrhea, nausea, vomiting, rash, hypoglycemia, irritation at the infusion site. May cause transient eosinophilia, leukopenia, thrombocytopenia, hypoglycemia, and elevated liver enzymes.

PHARMACOLOGY: Renal elimination as unchanged drug. Half-life is 3 to 9 hours in neonates. Widely distributed into body tissues, CSF, bronchial secretions, peritoneal fluid, bile, bone.

COMMENTS: Demonstrates synergistic activity with aminoglycosides against most strains of *P aeruginosa*, many strains of Enterobacteriaceae, and other gram-negative aerobic bacilli.

BACITRACIN OPHTHALMIC

See Chapter 58.

BERACTANT (SURVANTA)

INDICATIONS AND USE: Prevention and treatment of respiratory distress syndrome in preterm infants. Also has been used for treatment of meconium aspiration syndrome in term and near-term infants.

ACTIONS: A natural bovine lung extract containing phospholipids, neutral lipids, fatty acids, and surfactant-associated proteins to which dipalmitoylphosphatidylcholine (DPPC), palmitic acid, and tripalmitin are added to mimic the surface tension-lowering properties of natural lung surfactant. Surfactant lowers surface tension on alveolar surfaces during respiration and stabilizes the alveoli against collapse.

DOSAGE: ETT.

- 4 mL/kg (100 mg of phospholipids/kg) birthweight. Divide dose into 4 aliquots, repositioning the infant with each dose. Inject each aliquot gently into the catheter over 2 to 3 seconds. Ventilate the infant after each one-quarter dose for at least 30 seconds or until stable. Four doses of 4 mL/kg can be given in the first 48 hours of life, no more frequently than every 6 hours. Wean ventilator settings rapidly after administration.

ADVERSE EFFECTS: Most adverse effects are associated while administering beractant to the infant: transient bradycardia, oxygen desaturation, ETT reflux, pallor, vasoconstriction, hypotension, endotracheal blockage, hypertension, hypocarbia, hypercarbia, and apnea. Pulmonary hemorrhage has been reported, especially in very low birthweight infants.

BUMETANIDE (BUMEX)

WARNING: Bumetanide is a potent diuretic that, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dosage schedule have to be adjusted to the individual patient's needs.

INDICATIONS AND USE: A potent loop diuretic used for the management of edema associated with congenital heart disease, congestive heart failure, and hepatic or renal disease.

ACTIONS: Inhibition of sodium and chloride in the ascending loop of Henle and proximal renal tubule. Urinary excretion of sodium, chloride, potassium, hydrogen, calcium, magnesium, ammonium, phosphate, and bicarbonate increases with bumetanide-induced diuresis. Renal blood flow increases substantially as a result of renovascular dilation and increases prostaglandin secretion.

DOSAGE: IV, IM, PO.

- **Preterm neonates:** 0.01 to 0.05 mg/kg/dose every 24 to 48 hours.
- **Term neonates:** 0.01 to 0.05 mg/kg/dose every 12 to 24 hours.
- **Infants and children:** 0.015 mg/kg/dose up to 0.1 mg/kg/dose every 6 to 24 hours (maximum dose is 10 mg/day).

Neonatal seizures, refractory (emerging therapy to be given concurrently with phenobarbital):

- 0.05 to 0.3 mg/kg/dose every 12 hours for 4 doses.

ADVERSE EFFECTS: Hypokalemia, hypochloremia, hyponatremia, metabolic alkalosis, and hypotension. Potentially ototoxic but less so than furosemide.

COMMENTS: Patients refractory to furosemide may respond to bumetanide for diuretic therapy. Although patients may respond differently, bumetanide is approximately 40 times more potent on a milligram-per-milligram basis than furosemide. Follow electrolytes and serum creatinine.

CAFFEINE CITRATE

INDICATIONS AND USE: Treatment of apnea of prematurity; postextubation and postanesthesia apnea.

ACTIONS: Similar to other methylxanthine drugs (eg, aminophylline and theophylline). Caffeine appears to be more active on and less toxic to the CNS and the respiratory system. Proposed mechanisms of action include increased production of cyclic adenosine monophosphate (cAMP) alterations of intracellular calcium concentrations. Stimulates the CNS, which increases the medullary respiratory center sensitivity to carbon dioxide, stimulates central inspiratory drive, and improves diaphragmatic contractility. Caffeine exerts a positive inotropic effect on the myocardium, increases renal blood flow and glomerular filtration rate, and stimulates glycogenolysis and lipolysis.

DOSAGE: IV, PO.

- **Loading dose:** 20 to 40 mg/kg of caffeine citrate IV or PO (equivalent to 10–20 mg of caffeine base).
- **Maintenance:** 5 to 20 mg/kg/day caffeine citrate IV or PO every 24 hours, starting 24 hours after loading dose (equivalent to 2.5–10 mg of caffeine base).

ADVERSE EFFECTS: Nausea, vomiting, gastric irritation, agitation, tachycardia (if heart rate >180 beats/min, may consider holding dose), and diuresis. Symptoms of overdosage include arrhythmias and tonic-clonic seizures.

PHARMACOLOGY: **Therapeutic serum trough levels** 8 to 20 mcg/mL; potential toxicity >20 mcg/mL; severe toxicity is with levels >50 mcg/mL. Draw trough on day 5 of treatment. The serum half-life in neonates ranges from 40 to 230 hours and decreases with increased PNA; in infants >9 months, half-life is approximately 5 hours. Half-life is prolonged with cholestasis. FDA approved in infants with gestational age of 28 to <33 weeks.

CALCIUM CHLORIDE (VARIOUS)

INDICATIONS AND USE: Acute treatment of symptomatic hypocalcemia, treatment of hypermagnesemia, cardiac disturbances of hyperkalemia, hypocalcemia, or calcium channel blocker toxicity and prevention of hypocalcemia.

ACTIONS: Calcium is essential for the functional integrity of the nervous, muscular, skeletal, and cardiac systems and for clotting function.

DOSAGE: IV. Dosage expressed in milligrams of calcium chloride.

- **Acute treatment of symptomatic hypocalcemia:** 10 to 20 mg/kg/dose, dilute in appropriate fluid and infuse IV over 10 minutes. May repeat every 4 to 6 hours as needed.
- **Cardiac arrest in the presence of hyperkalemia or hypocalcemia, magnesium toxicity, or calcium antagonist toxicity:** 20 mg/kg/dose IV, IO every 10 minutes as needed. If effective, consider IV infusion 20 to 50 mg/kg/h.
- **Tetany:** IV: 10 mg/kg over 5 to 10 minutes; may repeat after 6 hours or follow with an infusion with a maximum dose of 200 mg/kg/day.

ADVERSE EFFECTS: Arrhythmias (in particular, bradycardia) and deterioration of cardiovascular function; may potentiate digoxin-related arrhythmias; may increase risk of metabolic acidosis. Calcium chloride is contraindicated in ventricular fibrillation or hypercalcemia. Extravasation may cause severe tissue damage (sloughing and necrosis).

COMMENTS: Supplied as a 10% solution (10 mL) (equivalent to elemental calcium 27 mg [1.36 mEq]/mL). Chloride salt is preferred to the gluconate form in cardiac arrest because it may be more bioavailable. Calcium chloride precipitates when mixed with sodium bicarbonate.

Warning: Multiple salt forms of calcium exist; when ordering and administering calcium, incorrect selection or substitution of one salt for another without proper dosage adjustment may result in serious over- or underdosing. There is a 3-fold difference in the primary cation concentration between calcium chloride (1 g = 13.6 mEq [270 mg] of elemental Ca^{2+}) and calcium gluconate (1 g = 4.65 mEq [90 mg] of elemental Ca^{2+}).

CALCIUM GLUCONATE

INDICATIONS AND USE: Treatment and prevention of hypocalcemia and prevention of hypocalcemia during exchange transfusion.

ACTIONS: See Calcium Chloride. Calcium gluconate must be metabolized to release calcium ion.

DOSAGE: IV, PO (dosage expressed in milligrams of calcium gluconate).

- **Acute treatment of symptomatic hypocalcemia:** 100 to 200 mg/kg/dose IV diluted in appropriate fluid and administered over 10 to 30 minutes.
- **Maintenance IV:** 200 to 800 mg/kg/day divided every 6 hours or as infusion; maximum rate: 50 to 100 mg/min of calcium gluconate. Continuous infusion is more efficacious than intermittent infusion due to less renal calcium loss.
- **Maintenance PO:** 200 to 800 mg/kg/day divided every 6 hours, mixed in feedings. The 10% calcium gluconate injection may be administered orally in young pediatric patients.
- **Cardiac arrest in the presence of hyperkalemia or hypocalcemia, magnesium toxicity, or calcium antagonist toxicity:** 60 to 100 mg/kg/dose IV, IO every 10 minutes as needed.
- **Exchange transfusion:** 100 mg calcium gluconate/100 mL of citrated blood exchanged infused IV over 10 minutes.

ADVERSE EFFECTS: See Calcium Chloride. Oral administration may cause gastrointestinal irritation; dilute and use with caution in infants at risk for necrotizing enterocolitis.

CALFACTANT (INFASURF)

INDICATIONS AND USE: Prevention and treatment of neonatal respiratory distress syndrome (RDS). FDA approved in premature infants <29 weeks' gestational age.

ACTIONS: Natural, preservative-free calf lung extract that contains phospholipids, neutral lipids, fatty acids, and surfactant-associated proteins B and C. Each milliliter of calfactant contains 35 mg of total phospholipids and 0.65 mg of proteins (0.26 mg of protein B). Calfactant decreases the surface tension on alveolar surfaces, stabilizing the alveoli and preventing collapse. This results in improved ventilation, lung compliance, and gas exchange.

DOSAGE: ETT.

- **RDS:** As soon as possible after birth, give 3 mL/kg/dose, divided into two 1.5 mL/kg aliquots. After the instillation of each aliquot, position infant either on the right or left side. Ventilation is continued during administration over 20 to 30 seconds. The 2 aliquots should be separated by a pause to evaluate respiratory status and reposition the patient.
- The initial dose may be followed by 3 subsequent doses of 3 mL/kg/dose at 12-hour intervals, if necessary.

ADVERSE EFFECTS: Bradycardia, cyanosis, airway obstruction, pneumothorax, pulmonary hemorrhage, and apnea. Most adverse effects occur during administration of dose.

COMMENTS: Following administration, lung compliance and oxygenation often rapidly improve. Patients should be closely monitored, and appropriate changes in ventilatory support should be made as clinically indicated.

CAPTOPRIL (CAPOTEN)

INDICATIONS AND USE: Moderate to severe congestive heart failure (reduction of afterload) and hypertension.

ACTIONS: Competitive inhibitor of angiotensin-converting enzyme. Causes a decrease in angiotensin II and aldosterone levels; increases plasma and tissue renin activity; decreases systemic vascular resistance without reflex tachycardia and augmentation of cardiac output.

DOSAGE: PO.

- **Premature and term neonates, PNA ≤7 days:** Initial dose: 0.01 mg/kg/dose every 8 to 12 hours; titrate dose and interval based on response.
- **Term neonates, PNA >7 days:** Initial dose: 0.05 to 0.1 mg/kg/dose every 8 to 24 hours; titrate dose up to maximum 0.5 mg/kg/dose given every 6 to 24 hours.
- **Infants:**
 - **Hypertension:** Initial dose: 0.15 to 0.3 mg/kg/dose; titrate dose up to 6 mg/kg/day divided in 1 to 4 doses.
 - **Heart failure:** Initial dose: 0.3 to 2.5 mg/kg/day divided every 8 to 12 hours.

ADVERSE EFFECTS: Hypotension, rash, fever, eosinophilia, angioedema, neutropenia, gastrointestinal disturbances, and hyperkalemia. Significant decreases in cerebral and renal blood flow have occurred in premature infants who have chronic hypertension and received higher doses (0.15–0.3 mg/kg/dose); may result in neurologic complications including seizures, apnea and lethargy, and oliguria.

COMMENTS: Administer 1 hour before or 2 hours after feedings if possible; food decreases absorption. Contraindicated in patients with bilateral renovascular disease. Use with caution in patients with low renal perfusion pressure. Reduce the dose with renal impairment and in sodium- and water-depleted patients (use with caution if on concurrent diuretic therapy).

CARBAMAZEPINE (TEGRETOL)

WARNING: Serious dermatologic reactions associated with HLA-B1502 allele (mostly Asian ancestry). Aplastic anemia and agranulocytosis have been reported. Monitor complete blood count (CBC), platelets, and differential prior to and during therapy; discontinue if significant bone marrow suppression occurs.

INDICATIONS AND USE: Anticonvulsant. Treatment of partial (especially complex partial), primary generalized tonic-clonic seizures and mixed partial or generalized seizures.

ACTIONS: Decrease synaptic transmission, limits influx of sodium ions across cell membrane.

DOSAGE: PO.

- 10 to 20 mg/kg/day of oral suspension, initially divided 4 times a day; may increase weekly to optimal response, then to a maximum of 35 mg/kg/day. Administer daily dose in 3 to 4 divided doses with feedings.

ADVERSE EFFECTS: Nausea, vomiting, leukopenia, thrombocytopenia, aplastic anemia and agranulocytosis, congestive heart failure, heart block, dystonia, drowsiness, behavioral changes, syndrome of inappropriate antidiuretic hormone secretion, hyponatremia, hepatitis and cholestasis, rash and Stevens-Johnson syndrome, urine retention, azotemia, oliguria, and anuria. Monitor CBC, liver function, blood urea nitrogen, serum iron, and urinalysis; perform periodic eye examination. Do not discontinue abruptly because seizures may result in epileptic patients.

PHARMACOLOGY: Metabolized in liver by cytochrome P450 3A4. Induces liver enzymes and increases its own metabolism. Half-life in neonates is 8 to 28 hours. Therapeutic range is 4 to 12 mcg/mL. If used in combination with other anticonvulsants, therapeutic range is 4 to 8 mcg/mL.

COMMENTS: Avoid switching between Tegretol and generic carbamazepine; changes in serum concentration and seizure activity may result; monitor serum concentrations. Interactions are numerous. Erythromycin, isoniazid, and cimetidine may inhibit hepatic metabolism of carbamazepine, resulting in increased carbamazepine serum concentrations. Concurrent phenobarbital may lower carbamazepine serum levels. Carbamazepine may induce metabolism of warfarin, phenytoin, theophylline, benzodiazepines, and corticosteroids.

CASPOFUNGIN

ACTION AND SPECTRUM: Treatment of invasive aspergillosis that is refractory to other antifungal agents or in patients intolerant of other agents; infections caused by susceptible *Candida* species.

DOSAGE: IV.

- **Preterm neonates—infants <3 months:** 25 mg/m² (or equivalent to ~2 mg/kg)/dose IV every 24 hours; infuse over at least 1 hour via syringe pump.
- **Infants ≥3 months:** Initial dose of 70 mg/m²/dose IV followed by 50 mg/m²/dose IV every 24 hours starting on day 2. May increase to 70 mg/m²/dose IV every 24 hours if clinical response is inadequate. Maximum dose is 70 mg/day.
- **Length of therapy:** At least 14 days after last positive culture.

ADVERSE EFFECTS: Hypokalemia, hypercalcemia, elevated liver enzymes, thrombocytopenia, direct hyperbilirubinemia, thrombophlebitis, hypotension, fever, and rash.

PHARMACOLOGY: An echinocandin acts by inhibiting the synthesis of β-(1,3)-D-glucan, an important component of the fungal cell wall. Fungicidal against *Candida* species and fungistatic against *Aspergillus*. Metabolized by the liver, not cytochrome P450 enzymes; results in fewer drug–drug interactions than the azole class of antifungal agents. Serum concentrations of caspofungin may be lower if concomitant therapy with dexamethasone, phenytoin, carbamazepine, nevirapine, and rifampin. Caspofungin clearance is induced and higher doses may be required: 70 mg/m²/dose.

COMMENTS: Note: Dosing information based on very limited pharmacokinetic data of 18 neonates and infants (Saez-Lioren, 2009). Do not use diluents containing dextrose for reconstitution. Maximum concentration not to exceed 0.5 mg/mL.

CEFAZOLIN SODIUM (ANCEF, KEFZOL)

ACTION AND SPECTRUM: First-generation cephalosporin; a broad-spectrum semisynthetic β-lactam antibiotic with bactericidal activity. Activity against susceptible gram-positive cocci (except enterococci), including penicillinase-producing staphylococci; some gram-negative coverage of susceptible *Escherichia coli*, *Klebsiella*, and *Proteus*. Primarily used in neonates for urinary tract infections, perioperative prophylaxis, and soft tissue infections.

DOSAGE: IV.**Neonates:**

- **Body weight ≤2 kg:**
 - PNA ≤7 days: 25 mg/kg/dose every 12 hours.
 - PNA >7 days: 25 mg/kg/dose every 8 hours.
- **Body weight >2 kg:**
 - PNA ≤7 days: 50 mg/kg/dose every 12 hours.
 - PNA >7 days: 50 mg/kg/dose every 8 hours.

Infants and children:

- 50 to 150 mg/kg/day divided every 8 hours; maximum dose: 6 g/day.

ADVERSE EFFECTS: Infrequent; fever, rash, and urticaria. May cause eosinophilia, leukopenia, neutropenia, and thrombocytopenia. Excessive dosage (especially in renal impairment) may result in CNS irritation with seizure activity.

PHARMACOLOGY: 70% to 80% excreted unchanged in urine. Half-life is 3 to 5 hours in neonates.

COMMENTS: Dosage reduction is required in moderate to severe renal failure.

CEFEPIME

ACTION AND SPECTRUM: Fourth-generation cephalosporin used for treatment of infections caused by susceptible gram-negative bacteria: *Escherichia coli*, *Haemophilus influenzae*, *Enterobacter*, *Klebsiella*, *Providencia*, *Serratia*, *Proteus*, *Morganella*, *Neisseria*, *Pseudomonas aeruginosa*, *Acinetobacter*, and *Citrobacter*. Treatment of infections caused by susceptible gram-positive bacteria: *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *Streptococcus agalactiae*.

DOSAGE: IV.

- **Body weight <1 kg:**
 - PNA (PNA) <14 days: 50 mg/kg/dose IV every 12 hours.
 - PNA ≥14 days: 50 mg/kg/dose every 8 hours.

- **Body weight 1 to 2 kg:**
 - PNA <8 days: 50 mg/kg/dose every 12 hours.
 - PNA ≥8 days: 50 mg/kg/dose every 8 hours.
- **Body weight >2 kg:** 50 mg/kg/dose every 8 hours.
- **Red Book 2018–2021 dose:**
 - GA <36 wks: 30 mg/kg every 12 hours.
 - GA ≥36 weeks: 50 mg/kg every 12 hours (may give 30 mg/kg every 12 hours if target pathogen MIC <8 mg/L).

ADVERSE EFFECTS: Rash, elevated hepatic transaminase enzymes, prothrombin time (PT), partial thromboplastin time (PTT), thrombocytopenia, leukopenia, neutropenia, eosinophilia, and hypophosphatemia.

PHARMACOLOGY: Distributes well into body tissues and fluids. Low protein binding; primarily excreted in urine unchanged.

COMMENTS: Manufacturer does not recommend use for treatment of serious infections due to *H influenzae* type b for suspected meningitis.

CEFOTAXIME SODIUM (CLAFORAN)

ACTION AND SPECTRUM: Third-generation cephalosporin with bactericidal activity against susceptible gram-negative organisms (except *Pseudomonas*), including *Escherichia coli*, *Enterobacter*, *Klebsiella*, *Haemophilus influenzae* (including ampicillin-resistant strains), *Proteus*, *Serratia*, *Neisseria gonorrhoeae*, and *Neisseria meningitidis*. Generally poor activity against gram-positive aerobic organisms.

DOSAGE: IV, IM.

- **Body weight <1 kg:**
 - PNA ≤14 days: 50 mg/kg/dose every 12 hours.
 - PNA 15 to 28 days: 50 mg/kg/dose every 8 to 12 hours.
- **Body weight 1 to 2 kg:**
 - PNA ≤7 days: 50 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 50 mg/kg/dose every 8 to 12 hours.
- **Body weight >2 kg:**
 - PNA ≤7 days: 50 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 50 mg/kg/dose every 8 hours.

Infants and children ≥1 month:

- **Body weight <50 kg:** 100 to 225 mg/kg/day divided every 6 to 8 hours. Maximum daily dose: 12 g/day.

Meningitis:

- PNA ≤7 days and ≥2 kg: 100 to 150 mg/kg/day divided every 8 to 12 hours.
- PNA >7 days and ≥2 kg: 150 to 200 mg/kg/day divided every 6 to 8 hours.
- **Infants >1 month:** 225 to 300 mg/kg/day divided every 6 to 8 hours. Maximum dose: 2000 mg.

Disseminated gonococcal infection, disseminated/scalp abscesses:

- The Centers for Disease Control and Prevention recommends cefotaxime as an alternative to ceftriaxone in the treatment of disseminated gonococcal infection and gonococcal scalp abscesses in newborns. The dose of cefotaxime is 25 mg/kg/dose every 12 hours IM or IV for 7 days; duration is 10 to 14 days for meningitis.

Gonococcal ophthalmia prophylaxis in newborns of mothers with gonorrhea at delivery:

- 100 mg/kg IV or IM as a single dose (topical antibiotic therapy alone is inadequate).

ADVERSE EFFECTS: Arrhythmias; transient neutropenia, thrombocytopenia, eosinophilia, leukopenia; transient hepatic and renal dysfunction.

PHARMACOLOGY: Excreted principally unchanged in the urine (~60%). Half-life in neonates is 1 to 4 hours.

COMMENTS: Reserved for suspected or documented gram-negative meningitis or sepsis. When used as empiric therapy, combine with ampicillin or penicillin to provide gram-positive coverage (ie, group B streptococci, pneumococci, and *Listeria monocytogenes*). Third-generation cephalosporins induce the emergence of multidrug-resistant bacteria or fungal infection when used excessively and without proper clinical indications. Cefotaxime is currently unavailable in the United States due to manufacturing issues.

CEFOXITIN (MEFOXIN)

ACTIONS AND SPECTRUM: Second-generation cephalosporin used for infections from gram-negative enteric organisms *Escherichia coli*, *Klebsiella*, and *Proteus*; active against many strains of *Neisseria gonorrhoeae*, ampicillin-resistant *Haemophilus influenzae*, and anaerobic bacteria, including *Bacteroides* species of the gastrointestinal (GI) tract.

DOSAGE: IV.

Neonates:

- 90 to 100 mg/kg/day divided every 8 hours.

Infants ≥ 3 months and children:

- **Mild-moderate infection:** 80 mg/kg/day divided every 6 to 8 hours.
- **Severe infection:** 160 mg/kg/day divided every 6 hours. Maximum dose: 12 g/day.
- **Surgical prophylaxis:** 30 to 40 mg/kg 30 to 60 minutes prior to incision, followed by 30 to 40 mg/kg every 6 hours for up to 24 hours. Maximum dose: 2000 mg/dose.

PHARMACOLOGY: Highly protein bound and renally excreted essentially unchanged (85%).

ADVERSE EFFECTS: Usually well tolerated. May cause diarrhea, rash, thrombophlebitis; transient leukopenia, thrombocytopenia, neutropenia, anemia, and eosinophilia; and transient elevation of blood urea nitrogen, serum creatinine, and liver enzymes.

COMMENTS: Not inactivated by β -lactamase. Has poor CNS penetration. The safety and efficacy in infants < 3 months have not been established.

CEFTAZIDIME (FORTAZ, TAZIDIME)

ACTION AND SPECTRUM: Third-generation cephalosporin with bactericidal activity against gram-negative aerobic bacteria, including *Neisseria*, *Haemophilus influenzae*, some Enterobacteriaceae, and *Pseudomonas*. Pseudomonal infections in patients at risk of developing aminoglycoside-induced nephrotoxicity and/or ototoxicity. Poor gram-positive activity. Aminoglycosides act synergistically with ceftazidime.

DOSAGE: IV.

- **Body weight < 1 kg:**
 - PNA ≤ 14 days: 50 mg/kg/dose every 12 hours.
 - PNA 15 to 28 days: 50 mg/kg/dose every 8 to 12 hours.
- **Body weight 1 to 2 kg:**
 - PNA ≤ 7 days: 50 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 50 mg/kg/dose every 8 to 12 hours.
- **Body weight > 2 kg:**
 - PNA ≤ 7 days: 50 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 50 mg/kg/dose every 8 hours.

Infants and children ≥ 1 month:

- 100 to 200 mg/kg/day divided every 8 hours; maximum dose: 6 g/day.

Meningitis:

- PNA ≤ 7 days and ≥ 2 kg: 100 to 150 mg/kg/day divided every 8 to 12 hours.
- PNA > 7 days and ≥ 2 kg: 150 mg/kg/day divided every 8 hours.
- **Infants > 1 month:** 150 mg/kg/day divided every 8 hours; maximum dose: 6 g/day.

ADVERSE EFFECTS: Infrequent except for fever, rash, urticaria. May cause transient leukopenia, neutropenia, thrombocytopenia, and hemolytic anemia; transient elevation in liver enzymes, hyperbilirubinemia, and transient elevation of blood urea nitrogen and serum creatinine.

PHARMACOLOGY: Renally excreted 80% to 90% unchanged. Half-life is 2.2 to 4.7 hours; penetrates well into CSF.

CEFTRIAXONE SODIUM (ROCEPHIN)

ACTION AND SPECTRUM: Third-generation cephalosporin with activity against gram-negative aerobic bacteria, *Haemophilus influenzae*, Enterobacteriaceae, and *Neisseria*, and activity against gram-positive cocci, methicillin-susceptible *Staphylococcus*, and *Streptococcus*. No activity

against *Pseudomonas aeruginosa*, *Chlamydia trachomatis*, methicillin-resistant staphylococci, and enterococci.

DOSAGE: IV, IM.

Meningitis:

- PNA <14 days: 50 mg/kg/day every 24 hours.
- PNA ≥14 days:
 - ≤2 kg: 50 mg/kg/day every 24 hours.
 - >2 kg: 80 to 100 mg/kg/day every 24 hours.

Gonococcal prophylaxis:

- 25 to 50 mg/kg as a single dose. Maximum dose: 125 mg/dose.

Gonococcal infection:

- 25 to 50 mg/kg/dose every 24 hours for 7 days; up to 10 to 14 days if meningitis is documented. Maximum dose: 125 mg/dose. (**Note:** Use cefotaxime in place of ceftriaxone in hyperbilirubinemic neonates.)

Ophthalmia neonatorum:

- 25 to 50 mg/kg as a single dose. Maximum dose: 125 mg/dose.

Infants and children:

- 50 to 100 mg/kg/day divided every 12 to 24 hours.

Meningitis:

- 80 to 100 mg/kg/day divided every 12 to 24 hours; loading dose of 75 mg/kg may be administered at the start of therapy. Maximum dose: 4 g/day.

ADVERSE EFFECTS: Diarrhea, cholelithiasis, gallbladder sludging. May also cause neutropenia, eosinophilia, hemolytic anemia, increased prothrombin times, rash, thrombophlebitis, elevated liver enzymes, jaundice, hyperbilirubinemia; use with caution in infants with hyperbilirubinemia.

PHARMACOLOGY: Biliary and renal excretion. Half-life is 5 to 19 hours.

COMMENTS: **Warning:** Use extreme caution in neonates due to risk of hyperbilirubinemia. Ceftriaxone use is contraindicated in hyperbilirubinemic neonates and neonates <41 weeks' postmenstrual age. Ceftriaxone is incompatible with calcium-containing solutions. Calcium-containing solutions or products must not be administered within 48 hours of the ceftriaxone dose due to the fatal reaction involving calcium-ceftriaxone precipitates in the lungs and kidneys of neonates. Dosage reduction is required only in patients with both renal and hepatic dysfunction.

CEFUROXIME SODIUM (KEFUROX, ZINACEF)

ACTION AND SPECTRUM: Second-generation cephalosporin with activity against susceptible staphylococci, group B streptococci, pneumococci, *Haemophilus influenzae* (type A and B), *Escherichia coli*, *Enterobacter*, and *Klebsiella*.

DOSAGE: IM, IV.

- **Meningitis:** Not recommended due to reports of treatment failures and slower bacteriologic response time.
- **Body weight <1 kg:**
 - PNA ≤14 days: 50 mg/kg/dose every 12 hours.
 - PNA 15 to 28 days: 50 mg/kg/dose every 8 to 12 hours.
- **Body weight 1 to 2 kg:**
 - PNA ≤7 days: 50 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 50 mg/kg/dose every 8 to 12 hours.
- **Body weight >2 kg:**
 - PNA ≤7 days: 50 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 50 mg/kg/dose every 8 hours.
- **Infants and children:**
 - IV, IM: 75 to 200 mg/kg/day divided every 8 hours. Maximum dose: 1500 mg/dose.
 - PO: 20 to 30 mg/kg/day divided every 12 hours. Maximum dose: 500 mg/dose.

ADVERSE EFFECTS: Fever, seizures, rash, thrombophlebitis, diarrhea, hemolytic anemia, transient neutropenia and leukopenia, eosinophilia, increased prothrombin time. Transient elevation in liver enzymes, hepatitis, and cholestasis; elevation in blood urea nitrogen and serum creatinine.

PHARMACOLOGY: Primarily excreted unchanged in the urine. Half-life is approximately 5.8 hours in infants <3 days old and 1.4 to 3.8 hours in infants ≥ 8 days of age.

COMMENTS: Decrease the dosage in renal failure. Limited experience in neonates. Safety and efficacy in infants <3 months of age have not been established.

CHLORAL HYDRATE (NOCTEC)

INDICATIONS AND USE: Short-term sedative and hypnotic; CNS depressant.

DOSAGE: PO, PR. Use the lowest effective dose.

- **Usual dose:** 25 to 50 mg/kg/dose PO or PR every 6 to 8 hours as needed.
- **Sedation prior to electroencephalography and other procedures:** 25 to 75 mg/kg/dose once PO or PR. Typical dose: 50 mg/kg/dose once; repeat 25 mg/kg/dose once if needed. Maximum total dose: 100 mg/kg or 1 g total for infants.

ADVERSE EFFECTS: Gastrointestinal irritation resulting in nausea, vomiting, and diarrhea; paradoxical excitation; and respiratory depression, particularly if administered with opiates and barbiturates. May cause direct hyperbilirubinemia with chronic use (active metabolite 2,2,2-trichloroethanol [TCE]); competes with bilirubin for glucuronide conjugation in the liver); overdose can be lethal.

COMMENTS: Contraindicated with marked renal or hepatic impairment. Syrup may contain sodium benzoate; benzoic acid (benzoate) is a metabolite of benzyl alcohol, which can be toxic and fatal in neonates.

CHLORAMPHENICOL (CHLOROMYCETIN)

WARNING: Serious and fatal blood dyscrasias (aplastic anemia, hypoplastic anemia, thrombocytopenia, and granulocytopenia) have occurred after both short-term and prolonged therapy; do not use for minor infections or when less potentially toxic agents are effective. Monitor complete blood count (CBC) frequently in all patients.

ACTION AND SPECTRUM: Broad-spectrum bacteriostatic agent, reserved for serious infections due to organisms resistant to other less toxic agent such as *Haemophilus influenzae*, *Neisseria meningitides*, and *Escherichia coli*; *Klebsiella*, *Serratia*, *Enterobacter*, *Salmonella*, *Shigella*, *Neisseria gonorrhoeae*, staphylococci, *Streptococcus pneumoniae*, and *Bacteroides*; active against many vancomycin-resistant enterococci.

DOSAGE: IV.

Neonates:

- **Meningitis:**
 - PNA ≤ 7 days: 25 mg/kg/dose IV every 24 hours.
 - PNA 8 to 28 days: 25 mg/kg/dose every 12 hours or 50 mg/kg/dose every 24 hours.
- **Severe infection: age-based dosing**
 - PNA ≤ 7 days: 25 mg/kg/dose IV every 24 hours; or loading dose of 20 mg/kg followed 12 hours later by 12.5 mg/kg/dose IV every 12 hours.
 - PNA >7 days: 25 mg/kg/dose IV every 12 hours; or 12.5 mg/kg/dose IV every 6 hours.

Infants and children:

- **Meningitis:** 75 to 100 mg/kg/day IV divided every 6 hours.
- **Other infections:** 50 to 100 mg/kg/day IV divided every 6 hours. Maximum daily dose 4 g/day.

ADVERSE EFFECTS: Idiosyncratic reactions result in aplastic anemia (irreversible and rare), reversible bone marrow suppression (dose related), allergy (rash and fever), diarrhea, vomiting, stomatitis, glossitis, fungal overgrowth, “gray baby” syndrome (early signs are hyperammonemia and unexplained metabolic acidosis; other signs are abdominal distention, hypotonia, gray

skin color, and cardiorespiratory collapse), and cardiotoxicity due to left ventricular dysfunction. Use with extreme caution in neonates.

PHARMACOLOGY: Metabolized by hepatic glucuronyl transferase. Half-life is 10 to 24 hours in neonates.

COMMENTS: Must monitor serum levels. Desired peak is 15 to 25 mcg/mL; levels >50 mcg/mL are strongly associated with “gray baby” syndrome. Trough 5 to 15 mcg/mL. Draw peak concentrations 30 minutes to 1.5 hours after completion of IV dose; trough immediately before next dose. Monitor CBC with differential, platelet count, and reticulocyte count every 3 days.

CHLORAMPHENICOL OPHTHALMIC

See Chapter 58.

CHLOROTHIAZIDE (DIURIL)

INDICATIONS AND USE: Mild to moderate edema, hypertension, central diabetes insipidus of infancy, and hyperinsulinemia.

ACTIONS: Thiazide diuretic; inhibits sodium reabsorption in the distal renal tubules. Sodium, potassium, bicarbonate, magnesium, phosphate, and chloride excretion are increased, whereas calcium excretion is decreased.

DOSAGE: PO, IV. Note: IV dosage in infants and children has not been established. IV doses in infants and children are based on anecdotal reports. The IV dosing regimens have been extrapolated from oral dosing regimens considering only 10% to 20% of an oral dose is absorbed.

Neonates:

- **Edema, heart failure, bronchopulmonary dysplasia:**
 - **Oral:** 20 to 40 mg/kg/day PO divided every 12 hours; maximum 375 mg/day.
 - **IV:** 5 to 10 mg/kg/day IV divided every 12 hours; doses up to 20 mg/kg/day have been used.
- **Hyperinsulinemia hypoglycemia, congenital hyperinsulinemia:**
 - **Oral:** 7 to 10 mg/kg/day PO divided every 12 hours in combination with diazoxide.
- **Diabetes insipidus (central):**
 - **Oral:** 10 mg/kg/day PO divided every 12 hours; may titrate dose to target urine osmolality of 100 to 150 mOsm/L.

Infants <6 months:

- **Oral:** 10 to 30 mg/kg/day PO in divided doses once or twice daily.

Infants >6 months and children:

- **Oral:** 10 to 20 mg/kg/day PO divided once or twice daily; maximum 1 g/day in children ≥ 2 years.
- **IV:** 5 to 10 mg/kg/day IV divided once or twice daily; doses up to 20 mg/kg/day have been used. Maximum dose 500 mg.

ADVERSE EFFECTS: Hypokalemia, hypercalcemia, hypochloremic alkalosis, dehydration and pre-renal azotemia, hyperuricemia, hyperglycemia, hypermagnesemia, hyperlipidemia, Stevens-Johnson syndrome, aplastic anemia, thrombocytopenia, hypotension, respiratory distress.

PHARMACOLOGY: Duration of action for oral is 6 to 12 hours and onset of action is within 2 hours. Duration of action for IV is about 2 hours and onset of action is 15 minutes.

COMMENTS: Do not use in patients with anuria or severe hepatic dysfunction.

CHOLESTYRAMINE RESIN (QUESTRAN)

INDICATIONS AND USE: Diaper dermatitis and as a skin protectant around enterostomy fistula sites.

ACTION: Cholestyramine resin binds to bile acids in the intestine, forms a nonabsorbable complex preventing the reabsorption and enterohepatic recirculation of bile salts, and releases chloride ions in the process.

DOSAGE: Topical.

- Apply to affected area with each diaper change.

ADVERSE EFFECTS: Constipation. High doses can cause hyperchloremic acidosis and increase urinary calcium excretion. Adverse effects seen when medication taken orally.

PHARMACOLOGY: Not absorbed; excreted in the feces.

COMMENTS: Not commercially available. Extemporaneous compound ointment or paste in Aquaphor; usual concentration 5% to 10%.

CHOLIC ACID (CHOLBAM)

INDICATIONS AND USE: Bile acid synthesis disorders.

ACTIONS: Cholic acid enhances bile flow and provides the physiologic feedback inhibition of bile acid synthesis to maintain bile acid homeostasis.

DOSAGE: PO.

• **Neonates ≥ 3 weeks, infants, and children:** 10 to 15 mg/kg/day divided once or twice daily.

ADVERSE EFFECTS: Increased serum bilirubin, increased serum transaminases, cholestasis, jaundice.

PHARMACOLOGY: Hepatic metabolism, absorbed by passive diffusion along the gastrointestinal tract.

COMMENTS: Patients with concomitant familial hypertriglyceridemia may have poor absorption.

CIMETIDINE (TAGAMET)

INDICATIONS AND USE: Prevention and treatment of duodenal and gastric ulcers, gastroesophageal reflux, esophagitis, and hypersecretory conditions.

ACTIONS: A histamine (H_2)-receptor antagonist; competitively inhibits the action of histamine on the gastric parietal cells, decreasing gastric acid secretion.

DOSAGE: PO.

• **Neonates:** 5 to 10 mg/kg/day PO divided every 6 to 12 hours.

• **Infants:** 20 to 40 mg/kg/day PO divided every 6 to 8 hours. Maximum dose: 400 mg/dose.

ADVERSE EFFECTS: CNS toxicity such as agitation and alterations in consciousness, neutropenia, agranulocytosis, thrombocytopenia, antiandrogenic effects; elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), and creatinine levels.

PHARMACOLOGY: Cimetidine reduces the hepatic metabolism of drugs metabolized by the cytochrome P450 pathway, which may result in decreased elimination of diazepam, theophylline, phenytoin, propranolol, and carbamazepine. Doses of these drugs may need to be decreased.

COMMENTS: Limited use in neonates due to association of H_2 blocker use and increased incidence of necrotizing enterocolitis, mortality, and infection in very low birthweight neonates receiving ranitidine.

CIPROFLOXACIN OPHTHALMIC

See Chapter 58.

CISATRACURIUM (NIMBEX)

HIGH-ALERT MEDICATION: To be administered only by experienced clinicians or adequately trained individuals supervised by an experienced clinician familiar with the use and actions, characteristics, and complications of neuromuscular-blocking agents.

INDICATIONS AND USE: Skeletal muscle relaxation during surgery; increases pulmonary compliance during assisted mechanical ventilation and facilitates endotracheal intubation.

ACTIONS: Nondepolarizing neuromuscular-blocking agent that produces skeletal muscle paralysis by blocking acetylcholine binding at the receptor at the myoneural junction.

DOSAGE: IV.

Infants and children < 2 years:

• 0.15 mg/kg/dose; repeat every hour as needed; may be administered as a continuous infusion at 1 to 4 mcg/kg/min (0.06–0.24 mg/kg/h).

ADVERSE EFFECTS: May cause hypoxemia with inadequate mechanical ventilation; bronchospasm, apnea, arrhythmias, tachycardia, hypotension, hypertension, excessive salivation. Potentiation of neuromuscular blockade may result from aminoglycosides, electrolyte abnormalities, severe

hyponatremia, severe hypocalcemia, severe hypokalemia, hypermagnesemia, neuromuscular diseases, acidosis, renal failure, and hepatic failure. Antagonism of neuromuscular blockade may result from alkalosis, hypercalcemia, hyperkalemia, and epinephrine.

PHARMACOLOGY: Onset of action is 2 to 3 minutes with a duration that varies with dose and age.

COMMENTS: When used with narcotics, decreases in heart rate and blood pressure have been observed.

CITRATE AND CITRIC ACIDS SOLUTIONS (ORACIT, OTHERS)

INDICATIONS AND USE: Treatment of metabolic acidosis or as a urinary alkalinizing agent for conditions that require the maintenance of alkaline urine.

ACTIONS: Sodium and potassium citrate salts are capable of buffering gastric acidity (pH >2.5) and are metabolized to bicarbonate to act as systemic alkalinizers.

DOSAGE: PO.

- 2 to 3 mEq/kg/day of bicarbonate in divided doses 3 to 4 times per day with water.

ADVERSE EFFECTS: Metabolic alkalosis, hypernatremia (if sodium salt used), hypocalcemia, hyperkalemia (if potassium salt used), diarrhea, nausea, vomiting.

COMMENTS: Supplied as oral solutions: Sodium citrate–citric acid solution contains 1 mEq of sodium and 1 mEq of potassium and 2 mEq of bicarbonate equivalents per milliliter; potassium citrate–citric acid oral solution contains 2 mEq of potassium and 2 mEq of bicarbonate equivalents per milliliter. Conversion to bicarbonate may be impaired in patients with hepatic failure. Polycitra: only generic available (citric acid 334 mg, sodium citrate 500 mg, and potassium citrate 550 mg/5 mL). Oracit: available in brand and generic formulations (different concentrations).

CLINDAMYCIN (CLEOCIN)

ACTION AND SPECTRUM: Bacteriostatic agent active against most aerobic gram-positive staphylococci and streptococci (except enterococci); *Fusobacterium*, *Bacteroides* spp., *Actinomyces*, and certain anaerobic gram-positive organisms.

DOSAGE: IM, IV, PO.

Neonates:

- **Body weight <1 kg:**
 - PNA ≤14 days: 5 mg/kg/dose every 12 hours.
 - PNA 15 to 28 days: 5 mg/kg/dose every 8 hours.
- **Body weight 1 to 2 kg:**
 - PNA ≤7 days: 5 mg/kg/dose every 12 hours.
 - PNA 8 to 28 days: 5 mg/kg/dose every 8 hours.
- **Body weight >2 kg:**
 - PNA ≤7 days: 5 mg/kg/dose every 8 hours.
 - PNA 8 to 28 days: 5 mg/kg/dose every 6 hours.

Infants and children:

- **IM/IV:** 20 to 40 mg/kg/day divided every 6 to 8 hours; doses as high as 4.8 g/day have been given IV in life-threatening situations; general maximum: 2.7 g/day.
- **PO:** 10 to 30 mg/kg/day PO divided every 6 to 8 hours; maximum dose: 1.8 g/day.

ADVERSE EFFECTS: Diarrhea, colitis, pseudomembranous colitis rash, pruritus, neutropenia, granulocytopenia and thrombocytopenia, hypersensitivity reactions, and elevated liver enzymes. Sterile abscess formation at the IM injection site.

PHARMACOLOGY: Primarily hepatic metabolism, highly protein bound.

COMMENTS: Does not cross the blood–brain barrier; therefore, do not use to treat meningitis.

CLONAZEPAM (KLONOPIN)

INDICATIONS AND USE: For the treatment of petit mal, Lennox-Gastaut, infantile spasms, and akinetic and myoclonic seizures, either as a single agent or as adjunctive therapy.

ACTIONS: Depresses all levels of the CNS, including the limbic and reticular formation, by binding to the benzodiazepine site on the γ -aminobutyric acid (GABA) receptor complex; suppresses the spike-and-wave discharge in absence seizures by depressing nerve transmission in the motor cortex.

DOSAGE: PO.

Seizure disorders

- **Infants and children <10 years or 30 kg.**
- **Initial daily dose:** 0.01 to 0.03 mg/kg/day PO (maximum 0.05 mg/kg/day) given in 2 to 3 divided doses; increase by no more than 0.5 mg every third day until seizures are controlled or adverse effects occur.
- **Maintenance:** 0.1 to 0.2 mg/kg/day PO divided into 3 doses; do not exceed 0.2 mg/kg/day.

ADVERSE EFFECTS: Hypotension, drowsiness, hypotonia, thrombocytopenia, anemia, leukopenia, eosinophilia, tremor, choreiform movements, bronchial hypersecretion, respiratory depression.

PHARMACOLOGY: Cytochrome P450 isoenzyme CYP3A3/4 substrate. CNS depressants increase sedation; phenytoin, carbamazepine, rifampin, and barbiturates increase clonazepam clearance; drugs that inhibit cytochrome P450 isoenzyme CYP3A3/4 may increase levels and effects of clonazepam (monitor for altered benzodiazepine response); concurrent use with valproic acid may result in absence status.

COMMENTS: Caution in patients with chronic respiratory disease, hepatic disease, or impaired renal function. Abrupt discontinuation of clonazepam may precipitate withdrawal symptoms, status epilepticus, or seizures. (Withdraw gradually when discontinuing therapy in children. Safely reduce by ≤ 0.04 mg/kg/wk and discontinue when the daily dose is ≤ 0.04 mg/kg/day.) Worsening of seizures may occur when clonazepam is administered to patients with multiple seizure types.

CLONIDINE (CATAPRES; CATAPRES-TTS)

INDICATIONS AND USE: Adjunctive treatment of neonatal abstinence syndrome (NAS) and iatrogenic narcotic dependency.

ACTIONS: Stimulates CNS α_2 -adrenergic receptors, which results in decreased sympathetic outflow, peripheral vascular resistance, systolic and diastolic blood pressure, and heart rate. Clonidine reduces circulating plasma renin levels.

DOSAGE: PO.

Neonatal abstinence syndrome (opioid withdrawal):

- **Preterm neonate <35 weeks' gestation:** 0.5 to 1 mcg/kg/dose PO every 6 hours. Taper dose when stabilized by 0.25 mcg/kg/dose PO every 6 hours (Leikin et al, 2009).
- **Neonate ≥ 35 weeks' gestation:** 0.5 to 1 mcg/kg/dose PO every 4 to 6 hours in combination with diluted opium tincture. A randomized, controlled, comparative trial in 80 neonates (gestational age: ≥ 35 weeks) with NAS demonstrated a decreased length of therapy and opioid doses in the combination treatment (clonidine plus diluted opium tincture) as compared to diluted tincture of opium alone (Agthe et al, 2009).
- **Alternate dosing:** Initial dose of 0.5 to 1 mcg/kg/dose every 3 to 6 hours; maximum dose 1 mcg/kg/dose every 3 hours (AAP Clinical Report—Neonatal Drug Withdrawal, reaffirmed February 2016).

ADVERSE EFFECTS: Very few side effects reported when used to treat NAS. Observe for hypotension and bradycardia and avoid abrupt discontinuation.

COMMENTS: More experience is needed before clonidine is routinely used to treat opioid withdrawal in infants. Compounded oral suspensions may be available in multiple concentrations. Precautions should be taken to verify and avoid confusion between different concentrations.

COSYNTROPIN (CORTROSYN)

INDICATIONS AND USE: Aid in the diagnosis of adrenocortical insufficiency; used in the diagnosis of congenital adrenal hyperplasia.

ACTIONS: Stimulates the adrenal cortex to secrete cortisol (hydrocortisone and cortisone), androgenic substances, and a small amount of aldosterone.

DOSAGE: IM/IV. Diagnostic test doses.

Adrenocortical insufficiency:

- **Preterm neonates:** Not well defined; 0.1 mcg/kg, 0.2 mcg/kg, 1 mcg/kg, and 3.5 mcg/kg have been used.
- **Neonates:** 15 mcg/kg (1 dose only).
- **Infants and children ≤2 years:** 0.125 mg or 15 mcg/kg; maximum dose 0.125 mg.

Congenital adrenal hyperplasia evaluation:

- 125 to 250 mcg.

ADVERSE EFFECTS: Bradycardia, hypertension, skin rash, urticaria at injection site.

COMMENTS: Plasma cortisol concentrations should be measured immediately before and exactly 30 minutes after administration of cosyntropin; dose should be given in early morning; 0.25 mg of cosyntropin = 25 USP units of corticotropin.

CYCLOPENTOLATE

INDICATIONS AND USE: For diagnostic and therapeutic ophthalmologic procedures that require mydriasis and cycloplegia.

ACTIONS: Causes pupillary dilatation by inhibition of the cholinergic response of the ciliary body muscle and sphincter muscle of iris.

DOSAGE: Ocular.

- 1 to 2 drops into the eye 10 to 30 minutes prior to procedure; usually used in conjunction with phenylephrine 2.5%. The 0.5% concentration is recommended for neonates.

ADVERSE EFFECTS: Tachycardia, vasodilatation, restlessness, delayed gastric emptying, urinary retention.

PHARMACOLOGY: Maximal effect occurs 30 to 60 minutes after administration, with pharmacologic effects lasting 6 to 24 hours.

COMMENTS: Consider holding feeds for 4 hours after procedure.

DEXAMETHASONE (DECADRON)

INDICATIONS: Treatment of airway edema prior to extubation. Used in infants with bronchopulmonary dysplasia/chronic lung disease to facilitate weaning from the ventilator.

ACTIONS: Long-acting, potent glucocorticoid without mineralocorticoid properties; prevents or suppresses inflammatory and immune responses in pharmacologic doses. Inhibits leukocyte infiltration at site of inflammation, interferes in function of mediators of inflammatory response, and suppresses humoral immune responses. May reduce edema and scar tissue formation; reversal of increased capillary permeability and general suppression in immune response.

DOSAGE: IV, PO.

Neonates:

- **Airway edema or extubation:** Usual dose: 0.25 mg/kg/dose IV given approximately 4 hours prior to scheduled extubation and then every 8 hours for 3 doses total. Range: 0.25 to 0.5 mg/kg/dose for 1 to 3 doses. Maximum dose: 1.5 mg/kg/day. **Note:** A longer duration of therapy may be needed with more severe cases.
- **Bronchopulmonary dysplasia/chronic lung disease (facilitate ventilator weaning):**
 - **Numerous dosing schedules proposed:** Range: 0.5 to 0.6 mg/kg/day given in divided doses PO or IV every 12 hours for 3 to 7 days, then taper over 1 to 6 weeks.
 - **DART trial protocol (Doyle et al, 2006):** 0.075 mg/kg/dose every 12 hours for 3 days, 0.05 mg/kg/dose every 12 hours for 3 days, 0.025 mg/kg/dose every 12 hours for 2 days, 0.01 mg/kg/dose every 12 hours for 2 days. Total dose 0.89 mg/kg over 10 days.

ADVERSE EFFECTS: With long-term use, increased susceptibility to infection, osteoporosis, growth retardation, hyperglycemia, fluid and electrolyte disturbances, cataracts, myopathy, gastrointestinal perforation and hemorrhage, hypertension, and acute adrenal insufficiency.

Dexamethasone use for low birthweight infants has come under close scrutiny because of increasing numbers of reports indicating neurodevelopmental compromise (see Comments). **COMMENTS:** Please review the important statement from the American Academy of Pediatrics Committee on Fetus and Newborn (2002, reaffirmed 2014). High-dose dexamethasone (~0.5 mg/kg/day) is associated with adverse neurodevelopmental outcomes without additional clinical benefit over lower doses.

DEXTROSE (GLUCOSE [ORAL GEL])

INDICATIONS AND USE: Hypoglycemia, hyperkalemia (used in combination with regular insulin).

ACTIONS: Restores low blood glucose levels; stimulates transient uptake of potassium into the cells.

DOSAGE: IV, buccal, IO.

For hypoglycemia:

- **Intravenous:** 0.2 g/kg/dose (2 mL/kg/dose of dextrose 10% in water [D10W]) followed by continuous IV infusion rate of 5 to 8 mg/kg/min. If plasma glucose remains low, increase infusion in 2 mg/kg/min increments. If rates >12 to 14 mg/kg/min are needed, further workup may be necessary.
- **Buccal:** (Dextrose gel 40%) 0.2 g/kg/dose (0.5 mL/kg of 40% dextrose gel); dry mouth with gauze and massage into the buccal mucosa, dividing the dose between the 2 sides of the mucosa. If still hypoglycemic after 30 minutes or if it recurs later, give a repeat dose. Maximum of 6 doses over 48 hours. Should also offer a bottle at time of treatment.
- **Pediatric Advanced Life Support guidelines:** IV, IO: 0.5 to 1 g/kg/dose (5–10 mL/kg/dose of D10W).

For hyperkalemia:

- Recommended 4 g of dextrose for every 1 unit of insulin; 0.4 g/kg/dose (4 mL/kg/dose of D10W) in combination with regular insulin.

COMMENTS: Dextrose is an IV vesicant at concentrations $\geq 10\%$; avoid extravasation. Rapid administration of hypertonic solutions may cause shifts in electrolytes, particularly potassium and sodium; in very low birthweight infants, increased serum osmolarity creates risk for intracerebral hemorrhage.

DIAZEPAM (VALIUM)

INDICATIONS: Alternative choice to lorazepam for status epilepticus. Treatment of seizures refractory to other combined anticonvulsant agents. Reduces anxiety, and can use for preoperative or preprocedural sedation.

ACTIONS: Exact action is unknown; acts as a CNS depressant. Like other benzodiazepines, diazepam increases the activity of the inhibitory neurotransmitter γ -aminobutyric acid (GABA) by binding the benzodiazepine receptor sites in the CNS.

DOSAGE: IV, PO.

Status epilepticus:

- **Neonates:** 0.1 to 0.3 mg/kg/dose IV given over 3 to 5 minutes, every 15 to 30 minutes to a maximum total dose of 2 mg. (Not recommended as first line; injection contains benzoic acid, benzyl alcohol, and sodium benzoate.)
- **Infants >30 days and children <5 years:** 0.1 to 0.3 mg/kg/dose given over 3 to 5 minutes, every 5 to 10 minutes to a maximum total dose of 10 mg, or 0.2 to 0.5 mg/dose every 2 to 5 minutes to a maximum total dose of 5 mg; repeat in 2 to 4 hours as needed.

ADVERSE EFFECTS: May cause rash, vasodilation, bradycardia, respiratory arrest, and hypotension. Use with caution in patients receiving other CNS depressants; may have additive CNS and respiratory depressant effects.

COMMENTS: Observe for and be prepared to manage respiratory arrest. Rapid IV push may cause sudden respiratory depression, apnea, or hypotension. Use of the rectal gel formulation in infants <6 months is not recommended; for use in children <2 years, the safety and efficacy

have not been studied; contains benzoic acid, benzyl alcohol, ethanol 10%, propylene glycol, and sodium benzoate.

DIAZOXIDE (PROGLYCEM)

INDICATIONS AND USE: Persistent hyperinsulinemic neonatal hypoglycemia (oral).

ACTIONS: Nondiuretic thiazide with antihypertensive and hyperglycemic effects. Inhibits the release of insulin from the pancreas and reduces total peripheral vascular resistance by direct relaxation of arteriolar smooth muscle, which results in a decrease in blood pressure and reflex increase in heart rate and cardiac output.

DOSAGE: PO.

Hyperinsulinemic hypoglycemia:

- **Neonates:** Initial: 10 mg/kg/day PO in divided doses every 8 hours; usual range: 5 to 15 mg/kg/day in divided doses every 8 to 12 hours.
- **Infants:** Initial: 10 mg/kg/day in divided doses every 8 hours; usual range: 5 to 20 mg/kg/day in divided doses every 8 hours (Hussain et al, 2004; Kapoor et al, 2009).

ADVERSE EFFECTS: Tachycardia; sodium and fluid retention is common; congestive heart failure may cause bilirubin displacement from albumin, hypotension, hyperglycemia, hyperuricemia, rash, fever, leukopenia, thrombocytopenia, and ketosis.

COMMENTS: Oral solution contains propylene glycol and sodium benzoate.

DIGIBIND (DIGOXIN IMMUNE FAB)

INDICATIONS AND USE: Treatment of potentially life-threatening digoxin or digitoxin toxicity in carefully selected patients; use in life-threatening ventricular arrhythmias secondary to digoxin, acute digoxin ingestion (ie, >0.1 mg/kg or >4 mg in children), and hyperkalemia (serum potassium >6 mEq/L) in the setting of digoxin toxicity.

ACTIONS: Binds with molecules of free (unbound) digoxin or digitoxin and then is removed from the body by renal excretion.

DOSAGE: IV.

Dose determination:

- Determine the dose by determining the total body-loading dose (TBL) of digoxin using either method 1 or method 2.
 - **Method 1:** An approximation of the amount ingested:
 - TBL of digoxin (in mg) = Concentration (in ng/mL) \times 5.6 \times body weight (in kg)/1000 or TBL = mg of digoxin ingested (as tablets or elixir) \times 0.8.
 - Dose of Digibind (in mg) IV = TBL \times 76.
 - Dose of digoxin immune Fab (Digibind) (number of vials) IV = TBL/0.5.
 - **Method 2:** A postdistribution serum digoxin concentration determination (Table 155–1).
 - Digoxin immune Fab dose (mg) = [(serum digoxin concentration [ng/mL] \times weight [kg])/100] \times 40 mg/vial
 - Digoxin immune Fab dose (vials) = (serum digoxin concentration [ng/mL] \times weight [kg])/100

Acute digoxin toxicity:

- **Ingestion of known amount of digoxin:** Each vial (38 mg) IV binds approximately 0.5 mg digoxin. Bioavailability of digoxin is 0.8 for 0.25-mg tablets or 1 for 0.2-mg Lanoxicaps.
- **Use the following formula:** Dose (in vials) = digoxin ingested (mg) \times bioavailability/0.5 mg of digoxin bound/vial.

Chronic digoxin toxicity:

- **Infants and small children:** Single vial (38 mg) IV initially.
- **Or use the following formula:** Number of vials needed = (serum digoxin concentration in ng/mL) \times (weight in kg)/100, then dose (in mg) = number of vials \times 38 mg/vial.

ADVERSE EFFECTS: Caution in renal or cardiac failure; allergic reactions possible; epinephrine should be immediately available; patients may deteriorate due to withdrawal of digoxin and

Table 155–1. DOSE ESTIMATES OF DIGOXIN IMMUNE FAB BASED ON SERUM ON DIGOXIN CONCENTRATION

Patient Weight 1 kg and Serum Digoxin Concentration	Patient Weight 3 kg and Serum Digoxin Concentration	Patient Weight 5 kg and Serum Digoxin Concentration
1 ng/mL: 0.4 mg	1 ng/mL: 1 mg	1 ng/mL: 2 mg
2 ng/mL: 1 mg	2 ng/mL: 2–2.5 mg	2 ng/mL: 4 mg
4 ng/mL: 1.5 mg	4 ng/mL: 5 mg	4 ng/mL: 8 mg
8 ng/mL: 3 mg	8 ng/mL: 9–10 mg	8 ng/mL: 15–16 mg
12 ng/mL: 5 mg	12 ng/mL: 14 mg	12 ng/mL: 23–24 mg
16 ng/mL: 6–6.5 mg	16 ng/mL: 18–19 mg	16 ng/mL: 30–32 mg
20 ng/mL: 8 mg	20 ng/mL: 23–24 mg	20 ng/mL: 38–40 mg

may require IV inotropic support (eg, dobutamine) or vasodilators. Hypokalemia reported following reversal of digitalis intoxication; monitor serum potassium levels.

PHARMACOLOGY: Volume of distribution: 0.3 L/kg; half-life: 15 to 20 hours; renal impairment prolongs the half-life of both agents. Improvement in signs and symptoms occurs within 20 to 90 minutes following IV infusion.

DIGOXIN (LANOXIN)

INDICATIONS AND USE: Treatment of congestive heart failure, atrial fibrillation or flutter, and supraventricular tachycardia.

ACTIONS: Exerts a positive inotropic effect (increased myocardial contractility). Its negative chronotropic effects (antiarrhythmic actions/decrease in heart rate) are due to the slowing of conduction through the sinoatrial (SA) and atrioventricular (AV) nodes caused by vagal stimulation.

DOSAGE: IV, PO. Total digitalizing dose (TDD) to be divided one-half, one-fourth, and one-fourth every 8 hours. **Note:** Oral doses (elixir) are approximately 25% higher than IV doses listed in the following.

Preterm neonates:

- **TDD:** 15 to 25 mcg/kg IV or 20 to 30 mcg/kg PO.
- **Daily maintenance:** 4 to 6 mcg/kg/day IV divided every 12 hours or 5 to 7.5 mcg/kg/day PO divided every 12 hours.

Full-term neonates:

- **TDD:** 20 to 30 mcg/kg IV, 25 to 35 mcg/kg PO.
- **Daily maintenance:** 5 to 8 mcg/kg/day IV divided every 12 hours or 8 to 10 mcg/kg/day PO divided every 12 hours.

1 month to 2 years:

- **TDD:** 30 to 50 mcg/kg IV or 35 to 60 PO mcg/kg.
- **Daily maintenance:** 7.5 to 12 mcg/kg/day IV divided every 12 hours or 10 to 15 mcg/kg/day PO divided every 12 hours.

ADVERSE EFFECTS: Sinus bradycardia may be a sign of digoxin toxicity. Any dysrhythmias (paroxysmal ventricular contractions, bradycardia, tachycardia) in a child on digoxin should be considered as digoxin toxicity. The gastrointestinal and CNS symptoms are not frequently seen in children. To manage toxicity, see Digibind.

COMMENTS: Therapeutic levels: 0.5 to 2.0 ng/mL. Considerable overlap exists between toxic and therapeutic serum levels. Digoxin-like immunoreactive substance (DLIS) may cross-react with digoxin immunoassay and falsely increases serum concentrations; DLIS has been found

in neonates. Use with caution and reduce dosage in patients with renal impairment; use with caution in patients with sinus nodal disease (may worsen condition). Correct electrolyte disturbances, especially hypokalemia or hypomagnesemia, prior to use and throughout therapy. Hypercalcemia may increase the risk of digoxin toxicity. Contraindicated in second- and third-degree block, idiopathic hypertrophic subaortic stenosis, and atrial flutter or fibrillation with slow ventricular rates.

DOBUTAMINE HCL (DOBUTREX)

INDICATIONS AND USE: To increase cardiac output during states of depressed contractility, such as septic shock, organic heart disease, or cardiac surgical procedures. Treat hypotension and hypoperfusion related to myocardial dysfunction.

ACTIONS: A direct β_1 -agonist that increases myocardial contractility, oxygen delivery, and oxygen consumption; actions on β_2 - and α -adrenergic receptors are much less marked than those of dopamine. Unlike dopamine, dobutamine does not cause release of endogenous norepinephrine, nor does it have any effect on dopaminergic receptors.

DOSAGE: IV.

- 2 to 20 mcg/kg/min by continuous infusion; titrate gradually to desired response. Maximum: 20 mcg/kg/min.

ADVERSE EFFECTS: Tachycardia and arrhythmias at higher doses, hypotension if patient is hypovolemic, ectopic heartbeats, and elevated blood pressure.

PHARMACOLOGY: Has more prominent effect on cardiac output than dopamine and less effect on blood pressure. Onset of action 1 to 2 minutes; peak effect in 10 minutes. Serum half-life is several minutes. Metabolized in liver and renally excreted.

COMMENTS: Correct hypovolemia prior to initiation of therapy; contraindicated in idiopathic subaortic stenosis and atrial fibrillation. Correct electrolyte abnormalities and monitor throughout therapy to minimize risk of arrhythmias (especially potassium and magnesium).

DOPAMINE HCL

INDICATIONS AND USE: To increase cardiac output, blood pressure, renal perfusion, and glomerular filtration rate (low dosages), which persists despite volume resuscitation.

ACTIONS: Actions are dose dependent. Low doses act directly on dopaminergic receptors to produce renal and mesenteric vasodilation. In moderate doses, β_1 -adrenergic effects become prominent, resulting in a positive inotropic effect on the myocardium. High doses stimulate α -adrenergic receptors, producing increased peripheral resistance (vasoconstriction and increased blood pressure) and renal vasoconstriction.

DOSAGE: IV. *Note:* Dose-effect relationship is speculative in neonates.

Continuous IV infusion:

- 1 to 20 mcg/kg/min; titrate to desired response.
- **Low:** 1 to 5 mcg/kg/min may increase renal perfusion and urine output.
- **Moderate:** 5 to 15 mcg/kg/min facilitates increased cardiac output, renal blood flow, heart rate, cardiac contractility, blood pressure.
- **High:** >15 mcg/kg/min causes systemic vasoconstriction and blood pressure.

ADVERSE EFFECTS: Dopamine may cause ectopic heartbeats, tachycardia, ventricular arrhythmias, hypertension, and azotemia. Gangrene of the extremities has occurred with high doses over prolonged periods. **Extravasation may cause tissue necrosis and sloughing of surrounding tissues; if this occurs,** infiltrate area with a small amount (1 mL) of phentolamine, made by diluting 5 to 10 mg in 10 to 15 mL of preservative-free normal saline (NS); do not exceed 0.1 mg/kg or 2.5 mg total for neonates and 0.1 to 0.2 mg/kg or 5 mg total for infants (see Chapter 42).

PHARMACOLOGY: Rapidly metabolized; serum half-life 2 to 5 minutes, variable clearance. Individual developmental differences in endogenous norepinephrine stores; α -adrenergic,

β -adrenergic, and dopaminergic receptor function and the ability of the neonatal heart to increase stroke volume will affect response to different dopamine doses.

COMMENTS: Administration of phenytoin IV to patients receiving dopamine may result in severe hypotension and bradycardia; therefore, use with extreme caution. Do not infuse through umbilical arterial catheter or other arterial catheter.

DORNASE ALPHA

INDICATIONS AND USE: Reduce frequency of pulmonary infections and improve pulmonary function in cystic fibrosis patients; treatment of atelectasis as a result of mucous plugging that has failed to respond to conventional therapies.

ACTIONS: Selectively cleaves DNA, resulting in a reduction of the viscosity of mucus in pulmonary secretions.

DOSAGE:

- 2.5 mg/day administered through selected nebulizers

ADVERSE EFFECTS: Airway obstruction secondary to mobilization of secretions in airway, desaturations, fever, cough, dyspnea, wheezing.

PHARMACOLOGY: Recombinant human DNA enzyme; hydrolyzes DNA released by degenerating leukocytes from purulent pulmonary secretions resulting in decreased viscosity.

COMMENTS: Not formally approved for use in infants and children ≤ 5 years of age; however, studies with small numbers of children as young as 3 months have shown efficacy and similar side effect profile with slightly increased frequency of cough and rhinitis reported in children < 5 years old.

DOXAPRAM HCL (DOPRAM)

INDICATIONS AND USE: Apnea of prematurity unresponsive to methylxanthine therapy.

ACTIONS: Stimulates respiration through action on central respiratory centers and reflex stimulation of carotid, aortic, or other peripheral chemoreceptors; decreases PCO_2 and increases minute ventilation and tidal volume without changing respiratory rate or inspiratory and expiratory times.

DOSAGE: IV.

- **Loading dose:** 2.5 to 3 mg/kg IV over 30 minutes followed by maintenance dose.
- **Continuous IV infusion:** 0.5 to 1.5 mg/kg/h (maximum 2.5 mg/kg/h); decrease the infusion rate when control of apnea is achieved.

ADVERSE EFFECTS: Hypertension, QT prolongation with heart block, tachycardia, skeletal muscle hyperactivity, abdominal distention, increased gastric residuals, bloody stools, necrotizing enterocolitis, vomiting, jitteriness, hyperglycemia, and glycosuria.

PHARMACOLOGY: **Therapeutic range:** 1.5 to 3 mcg/mL (toxicity seen typically at $> 4\text{--}5$ mcg/mL). Onset of respiratory stimulation is 20 to 40 seconds; maximum effect is 1 to 2 minutes; duration is 5 to 12 minutes.

COMMENTS: Use cautiously in premature neonates because of its side effects. Avoid use during the first few days of life, when hypertensive episodes may be associated with increased risk of intraventricular hemorrhage; contraindicated in cardiovascular and seizure disorders. Potential adverse effects on mental development have been reported (Lando, 2005; Sreenan, 2001). Doxapram contains benzyl alcohol.

ENALAPRIL (PO)/ENALAPRILAT (IV) (VASOTEC)

INDICATIONS AND USE: Treatment of moderate to severe hypertension and heart failure by reducing left ventricular preload and afterload.

ACTIONS: An angiotensin-converting enzyme inhibitor that acts by inhibiting the conversion of angiotensin I to angiotensin II and results in lower levels of angiotensin II, which causes an increase in plasma renin activity and a reduction in aldosterone secretion and the breakdown

of bradykinin, causing vasodilation. Enalapril increases sodium loss, fluid loss, and serum potassium.

DOSAGE: IV, PO.

- **IV:** 5 to 10 mcg/kg/dose every 8 to 24 hours. Maximum dose: 1.25 mg/dose. The frequency depends on blood pressure response. Monitor patient closely.
- **PO:** Initial: 0.04 to 0.3 mg/kg/dose every 12 to 24 hours; initiate at the lower end of the range and titrate to effect as required every few days;

ADVERSE EFFECTS: Hypotension, hyperkalemia, decreased renal function, oliguria, cough, anemia, neutropenia, and angioedema.

PHARMACOLOGY: Onset of action after oral dose is 1 to 2 hours. The duration of action is variable (12–24 hours).

COMMENTS: Use with extreme caution in renal dysfunction; reduce dose. Use a low initial dose to avoid a profound drop in blood pressure, especially in patients on diuretics who are hyponatremic or hypovolemic. Monitor blood pressure hourly for the first 12 hours. Note that the IV dose is much smaller than the PO dose; use caution to adjust the dose when changing route of administration.

ENOXAPARIN (LOVENOX)

INDICATIONS AND USE: Prophylaxis and treatment of thromboembolic disorders. (See Chapter 92.)

ACTIONS: Low molecular weight heparin that potentiates the action of antithrombin III and inactivates coagulation factor Xa and factor IIa (thrombin).

DOSAGE: Subcutaneous.

Initial treatment:

- **Infants <2 months:** 1.5 mg/kg subcutaneous every 12 hours.
- **Infants >2 months and children ≤18 years:** 1 mg/kg subcutaneous every 12 hours.
- **Maintenance:** Adjust dose to maintain antifactor Xa level between 0.5 and 1.0 units/mL. It may take several days to reach target range. Preterm infants may require higher doses to maintain antifactor Xa levels in target range: mean dose of 2 mg/kg every 12 hours, range of 0.8 to 3 mg/kg every 12 hours.

Initial prophylaxis:

- **Infants <2 months:** 0.75 mg/kg subcutaneous every 12 hours.
- **Infants >2 months and children ≤18 years:** 0.5 mg/kg subcutaneous every 12 hours.
- **Maintenance:** Adjust to maintain antifactor Xa level between 0.1 and 0.3 units/mL.

ADVERSE EFFECTS: Bleeding, intracranial hemorrhage, thrombocytopenia (incidence of heparin-induced thrombocytopenia is less than that with heparin therapy). Hematoma, irritation, ecchymosis, and erythema can occur at the injection site.

PHARMACOLOGY: Measure antifactor Xa levels 4 to 6 hours after a dose. After target level is reached, dosage adjustments may be required once or twice a month. Preterm infants and infants with hepatic or renal dysfunction may require more frequent adjustments.

COMMENTS: Compared with standard heparin, enoxaparin has much less activity against thrombin. Low antithrombin plasma concentration reduces the efficacy in neonates. Enoxaparin is less likely to cause thrombocytopenia and osteoporosis.

EPINEPHRINE

INDICATIONS AND USE: Bradycardia, cardiac arrest, cardiogenic shock, anaphylactic reactions, and bronchospasm.

ACTIONS: Acts directly on both α - and β -adrenergic receptors; β_2 effects predominate at lower doses. Exerts both positive chronotropic and inotropic effects on the heart, and relaxes bronchial smooth muscle. The α -adrenergic stimulation increases systolic blood pressure and constricts renal blood vessels.

DOSAGE: IV, ETT.

- **IV bolus:** (0.1 mg/mL) 0.01 to 0.03 mg/kg (0.1–0.3 mL/kg) every 3 to 5 minutes, as needed. Follow administration with a flush of 0.5 to 1 mL of normal saline (NS).

- **IV infusion:** Initial rate: 0.05 to 0.3 mcg/kg/min; titrate to desired response to a maximum of 1 mcg/kg/min.
 - **Endotracheal:** 0.05 to 0.1 mg/kg (0.5–1 mL/kg of 0.1 mg/mL solution) every 3 to 5 minutes until IV access is established or return of spontaneous circulation; immediately followed by 1 mL of NS.
 - **Nebulization:** 0.25 to 0.5 mL of 2.25% racemic epinephrine diluted in 2 to 3 mL of NS.
- ADVERSE EFFECTS:** Hypertension, tachycardia, nausea, pallor, tremor, cardiac arrhythmias, increased myocardial oxygen consumption, and decreased renal and splanchnic blood flow.

ERYTHROMYCIN

ACTION AND SPECTRUM: Macrolide antibiotic; bactericidal or bacteriostatic depending on the tissue concentration of drug and the microorganism. Spectrum of activity is broad and includes susceptible streptococci and staphylococci; also *Mycoplasma*, *Legionella*, pertussis, *Chlamydia*, and *Campylobacter* gastroenteritis.

DOSAGE: PO, IV, ocular.

Neonates:

- **Oral ethylsuccinate form, PNA:**
- **Body weight <1 kg:**
 - PNA ≤14 days: 10 mg/kg/dose PO every 12 hours.
 - PNA 15 to 28 days: 10 mg/kg/dose PO every 8 hours.
- **Body weight ≥1 kg**
 - PNA ≤7 days: 10 mg/kg/dose PO every 12 hours.
 - PNA 8 to 28 days: 10 mg/kg/dose PO every 8 hours.
- **IV lactobionate form:** 5 to 10 mg/kg/dose every 6 hours for severe infections or when PO route is unavailable.
- **Chlamydial conjunctivitis or pneumonia:** Oral: ethylsuccinate 50 mg/kg/day divided every 6 hours for 14 days (based on AAP *Red Book*, 2018–2021).
- **Pertussis; treatment or postexposure prophylaxis:** Oral: ethylsuccinate 10 mg/kg/dose every 6 hours for 14 days (AAP *Red Book*, 2018–2021).

Infants and children:

- **Oral base and ethylsuccinate:** 30 to 50 mg/kg/day PO divided every 6 to 8 hours; do not exceed 2 g/day (as base) or 3.2 g/day (as ethylsuccinate). **Note:** 200 mg erythromycin ethylsuccinate produces the same serum levels as 125 mg erythromycin base due to absorptive differences.
- **IV lactobionate:** 15 to 20 mg/kg/day IV divided every 6 hours, not to exceed 4 g/day.
- **Stearate:** 30 to 50 mg/kg/day PO divided every 6 hours; maximum 2 g/day.
- ***Chlamydia trachomatis*:** Infants and children <45 kg: 50 mg/kg/day PO divided every 6 hours for 14 days; maximum 2 g/day.
- **Pertussis treatment or postexposure prophylaxis:** Ethylsuccinate: 40 mg/kg/day divided every 6 hours for 14 days. **Note:** Azithromycin considered first-line agent in infants <1 month of age; erythromycin is associated with infantile hypertrophic pyloric stenosis in neonates (based on AAP *Red Book*. 2018–2021).
- **Ophthalmic prophylaxis:** 0.5- to 1-cm ribbon in each eye once. (See also Chapter 58.)
- **Ophthalmic for acute infection:** 0.5- to 1-cm ribbon in each eye every 6 hours. (See also Chapter 58.)
- **Gastrointestinal motility disorders:** 1.5 to 10 mg/kg/dose PO every 6 to 8 hours, 30 minutes before feedings; in neonates up to 2 weeks old, exposure to high doses (30–50 mg/kg/day) for ≥14 days has been associated with a 10-fold increase in the risk of hypertrophic pyloric stenosis. May be given IV 1 to 3 mg/kg infused over 60 minutes, but PO is preferred route.

ADVERSE EFFECTS: Infantile hypertrophic pyloric stenosis, stomatitis, epigastric distress, transient cholestatic hepatitis, and allergic reactions occur rarely. Cardiac toxicity requiring cardiopulmonary resuscitation may occur with IV erythromycin; reduce risk of arrhythmias by slowly infusing over 1 hour.

PHARMACOLOGY: Hepatic metabolism, excreted via the bile and kidneys. Half-life is 1.5 to 3 hours (prolonged in renal failure). May cause increased serum levels of theophylline, digoxin, and carbamazepine.

COMMENTS: Parenteral forms are painful and irritating; dilute to 5 mg/mL and infuse >60 minutes. Do not use IM.

ERYTHROPOIETIN/EPOETIN ALFA (EPOGEN, PROCRIT) [EPO, REPO]

WARNING: ESAs increase the risk of death, myocardial infarction, stroke, venous thromboembolism, thrombosis of vascular access and tumor progression or recurrence.

INDICATIONS AND USE: To stimulate erythropoiesis and decrease the need for erythrocyte transfusions (rEpo) in preterm infants; treatment of anemia of prematurity.

ACTIONS: Epoetin alfa (EPO) induces erythropoiesis by stimulating division and differentiation of committed erythroid progenitor cells; induces release of reticulocytes from the bone marrow into the bloodstream where they mature to erythrocytes (dose-response relationship).

DOSAGE: Subcutaneous, IV.

- **Anemia of prematurity:** 200 to 400 units/kg/dose, 3 to 5 times per week, for 2 to 6 weeks. Total dose per week: 150 to 1500 units/kg/wk. Short course: 250 units/kg/dose 3 times weekly \times 10 doses.
- **Neuroprotective/hypoxic ischemia encephalopathy:**
 - **Low dose:** 300 or 500 units/kg/dose every other day for 2 weeks beginning within first 48 hours of life
 - **High dose:** 1000 or 2500 units/kg/dose once daily for 3 to 5 days beginning within 24 hours of life

ADVERSE EFFECTS: May cause hypertension, edema, fever, rash, possible seizures, transient early thrombocytosis and late neutropenia, polycythemia, and local skin reaction at injection site.

PHARMACOLOGY: Noticeable effects on hematocrit and reticulocyte counts occur within 2 weeks. Half-life in neonates: subcutaneous: 7.6 to 19.4 hours.

COMMENTS: Supplement with oral iron therapy 3 to 8 mg/kg/day; optimal response is achieved when iron stores are adequate. EPO should be used in conjunction with restrictive transfusion guidelines and minimizing of phlebotomy losses. EPO is not a substitute for emergency blood transfusion. Do not use in patients with uncontrolled hypertension.

ESMOLOL

INDICATIONS AND USE: Treatment of supraventricular tachycardia (SVT); acute management of postoperative tachycardia and hypertension.

ACTIONS: Competitively blocks response to β_1 -adrenergic stimulation with little or no effect on β_2 -receptors except at high doses.

DOSAGE: IV.

Neonatal (limited data available):

- **SVT:** 100 mcg/kg/min by continuous infusion; adjust dose based on individual clinical response and tolerance. Increase by 50 to 100 mcg/kg/min every 5 minutes until ventricular rate is controlled.
- **Postoperative tachycardia and hypertension:**
 - **≤ 7 days:** 50 mcg/kg/min by continuous infusion; increase by 25 to 50 mcg/kg/min every 20 minutes until target blood pressure is reached.
 - **8 to 28 days:** 75 mcg/kg/min by continuous infusion; increase by 50 mcg/kg/min every 20 minutes until target blood pressure is reached.
- **Maximum dosage:** 1000 mcg/kg/min.

Infants and children (limited data available):

- **SVT:** 100 to 500 mcg/kg over 1 minute; initial rate 25 to 100 mcg/kg/min; titrate infusion rate by 25 to 50 mcg/kg/min every 5 to 10 minutes until ventricular rate is controlled.

- **Postoperative tachycardia and hypertension:** Loading dose of 100 to 500 mcg/kg/min over 1 minute followed by continuous infusion of 100 to 500 mcg/kg/min; titrate infusion rate by 50 mcg/kg/min every 10 minutes until target blood pressure is reached.
- **Maximum dose:** 1000 mcg/kg/min.

ADVERSE EFFECTS: Hypotension and bradycardia at higher doses; peripheral ischemia, agitation, local induration, inflammation phlebitis, and skin necrosis after extravasation.

PHARMACOLOGY: Ultra-short-acting β_1 -selective blocking agent with half-life of 2.8 to 4.5 minutes and duration of action of 10 to 30 minutes. Onset of action ranges from 2 to 10 minutes; shorter if loading dose is given.

COMMENTS: Monitor IV site for infiltration, especially with the use of concentrations >10 mg/mL.

ETHACRYNIC ACID (EDECRIN)

WARNING: Ethacrynic acid is a potent diuretic that, if given in excessive amounts, may lead to profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule must be adjusted to the individual patient's needs.

INDICATIONS AND USE: Reserved for use only when other diuretics have failed to produce effective diuresis due to toxicities.

ACTIONS: Loop diuretic that inhibits reabsorption of sodium and chloride in ascending loop of Henle and distal tubules, resulting in increased excretion of water, sodium, chloride, magnesium, and calcium. The inhibition of sodium reabsorption is greater than that of other diuretics. Also, there is not a direct effect on the pulmonary vasculature, as seen with furosemide.

DOSAGE: IV, PO.

- **IV:** 0.5 to 1 mg/kg/dose. Repeat doses are not routinely recommended; however, if indicated, repeat doses every 8 to 12 hours.
- **PO:** 1 mg/kg/dose once daily; increase at intervals of 2 to 3 days to a maximum of 3 mg/kg/day.

ADVERSE EFFECTS: Inject IV dose slowly over several minutes; may cause hypotension, dehydration, electrolyte depletion, diarrhea, gastrointestinal bleeding, hearing loss, rash, local irritation and pain, hematuria, and, rarely, hypoglycemia and neutropenia.

COMMENTS: Close medical supervision and dose evaluation are required; may increase risk of gastric hemorrhage associated with corticosteroid treatment.

FAMOTIDINE (PEPCID)

Caution: Use of proton pump inhibitors and H₂ blockers have been associated with an increased risk for developing acute gastroenteritis and community-acquired pneumonia in children (Canani, 2006). A cohort analysis with over 11,000 neonates reported an increased incidence of NEC in VLBW neonates associated with H₂ blockers use (Guillet, 2006). An approximate six-fold increase in mortality, NEC, and infection (ie, sepsis, pneumonia, UTI) was reported in patients receiving ranitidine in a cohort analysis of 274 VLBW neonates (Terrin, 2012).

INDICATIONS AND USE: Prevention and short-term treatment of gastroesophageal reflux disease (GERD), stress, gastric and duodenal ulcers, and gastrointestinal (GI) hemorrhage.

ACTIONS: Inhibits gastric acid secretion by reversible, competitive antagonism of histamine on the H₂ receptor of the gastric parietal cells.

DOSAGE: IV, PO (neonatal dosing).

- **Stress ulcer prophylaxis/gastric acid suppression:** IV 0.25 to 0.5 mg/kg/dose every 24 hours via slow IV push.
- **GERD/gastric acid suppression:** PO 0.5 mg/kg/dose once daily; may increase to 1 mg/kg/dose once daily if ineffective with lower dose.

ADVERSE EFFECTS: Hypotension and cardiac arrhythmias with rapid IV administration; agitation, constipation, diarrhea, necrotizing enterocolitis (very low birthweight neonates), vomiting, tachycardia, thrombocytopenia, elevated liver enzymes, and cholestatic jaundice.

PHARMACOLOGY: Onset of GI effect is within 1 hour. Duration is 10 to 12 hours. Elimination with IV administration is 65% to 70% unchanged in urine versus 25% to 30% unchanged in urine with PO administration.

COMMENTS: Limited experience in infants and children. Famotidine does not inhibit cytochrome P450. Prolonged treatment (ie, ≥ 2 years) may result in vitamin B12 deficiency due to dietary vitamin B12 malabsorption (Lam et al, 2013). Dosing adjustment is recommended in patients with moderate to severe renal impairment.

FENTANYL (SUBLIMAZE)

INDICATIONS AND USE: Analgesia, anesthesia, and sedation.

ACTIONS: A synthetic opiate agonist that binds to the opioid μ -receptors within the CNS, increases the pain threshold, alters pain reception, and inhibits ascending pain pathway. Acts similarly to morphine and meperidine but without the cardiovascular effects of those drugs and with shorter respiratory depressant effects.

DOSAGE: IV.

Neonates:

- **Analgesia:** World Health Organization Guidelines for Pediatric Pain (2012).
- **Intermittent doses:** Slow IV push: 1 to 2 mcg/kg/dose and may repeat every 2 to 4 hours as needed.
- **Continuous infusion:** Initial 1 to 2 mcg/kg IV bolus, followed by 0.5 to 1 mcg/kg/h. May titrate up to 3 mcg/kg/h.

Continuous analgesia/sedation in mechanically ventilated patient: Initial 1 to 2 mcg/kg IV bolus, followed by 0.5 to 1 mcg/kg/h; titrate to effect.

Continuous sedation/analgesia during extracorporeal life support (ECLS): Initial IV bolus: 5 to 10 mcg/kg slow IV push over 10 minutes, then 1 to 5 mcg/kg/h; titrate to effect; tolerance may develop; higher doses (up to 20 mcg/kg/h) may be needed by day 6 of ECLS.

Endotracheal intubation: Slow IV push: 1 to 4 mcg/kg.

ADVERSE EFFECTS: CNS and respiratory depression (US boxed warning); hypotension, bradycardia; seizures; skeletal muscle and chest wall rigidity with reduced pulmonary compliance, apnea, and laryngospasm, which is reversible with naloxone. Tolerance and withdrawal symptoms reported with continuous use. Urinary retention, gastrointestinal symptoms, and biliary spasms may occur.

PHARMACOLOGY: Metabolized in liver by CYP3A4 enzyme and excreted primarily by kidneys as inactive metabolites. Clearance may be significantly correlated to birthweight and gestational age in newborn infants. Liver failure prolongs serum half-life; 79% to 87% protein bound; highly lipid soluble. The volume of distribution and half-life are highly variable.

COMMENTS: Synthetic opioid narcotic analgesic that is 50 to 100 times more potent on a weight basis than morphine. Concurrent ventilatory assistance is suggested with its use. Tachypnea occurs after several days of therapy. Adheres to ECLS filter membranes; may have to adjust the dose. Neonates who receive a total fentanyl dose > 1.6 mg/kg or continuous infusion duration > 5 days have increased risk of developing opioid withdrawal symptoms. Infants and children age 1 week to 22 months who receive a total dose of 1.5 mg/kg or duration > 5 days have a 50% chance of developing opioid withdrawal; those receiving a total dose > 2.5 mg/kg or duration of infusion > 9 days have a 100% chance of developing withdrawal.

FERROUS SULFATE (20% ELEMENTAL IRON)

INDICATIONS AND USE: Treatment and prevention of iron deficiency anemia; supplemental therapy for patients receiving epoetin alfa.

ACTIONS: Iron is required for production of heme proteins. Iron is released from the plasma to replenish the depleted stores in the bone marrow where it is incorporated into hemoglobin.

DOSAGE: PO. Recommendations of the American Academy of Pediatrics (AAP) for treatment and prevention of iron deficiency in breastfed infants; dosages are for **elemental iron**.

- **Term infants:** 1 mg/kg/day divided every 12 to 24 hours. Begin at 4 months of age.
- **Preterm infants:** 2 to 4 mg/kg/day divided every 12 to 24 hours. Begin therapy by 1 month of age after vitamin E level are restored.
- **Iron deficiency anemia:** 4 to 6 mg/kg/day in 3 divided doses.
- **Iron supplementation with erythropoietin:** 6 mg/kg/day in 1 or 2 divided doses.

ADVERSE EFFECTS: Gastrointestinal irritation (vomiting, diarrhea, constipation, and darkened stool color).

COMMENTS: The use of iron-fortified formulas during the first year of life usually prevents iron deficiency anemia in both preterm and term infants. Iron-fortified formulas can be fed safely to preterm infants. Of the ferrous salts available (sulfate, fumarate, and gluconate), sulfate is preferred. **Note:** Multiple concentrations of ferrous sulfate oral liquid exist. Caution parents to guard against iron poisoning from accidental ingestion. Antidote is chelation with deferoxamine; consult specialized references and regional poison control center for further information.

FILGRASTIM (GRANULOCYTE COLONY-STIMULATING FACTOR [G-CSF])

INDICATIONS AND USE: For the reduction of neutropenia in neonates with sepsis or congenital neutropenia.

ACTIONS: Stimulates the production, maturation, and activation of neutrophil granulocytes and activates neutrophils to enhance both their migration and cytotoxicity.

DOSAGE: IV or subcutaneous.

- **Neutropenia with sepsis:** 10 mcg/kg/day in 1 or 2 divided doses for 3 to 14 days with 3-day regimen being the most used.
- **Neutropenia, infection prophylaxis:** 5 to 10 mcg/kg/day once daily for 3 to 5 days.
- **Neutropenia, congenital:** Subcutaneous with initial dose at 5 mcg/kg/day, then 10 mcg/kg/day. May titrate up by 10 mcg/kg/day every 2 weeks to maintain goal absolute neutrophil count (ANC) with maximum dose at 120 mcg/kg/day. Reduce to the lowest effective dose if ANC >5000/mm³.

ADVERSE EFFECTS: Thrombocytopenia, anemia, leukocytosis, increase in serum alkaline phosphatase, and transient decrease in blood pressure.

PHARMACOLOGY: There is an immediate transient leukopenia with nadir occurring 5 to 15 minutes after an IV dose or 30 to 60 minutes after a subcutaneous dose followed by a sustained elevation in neutrophil levels within the first 24 hours, which plateaus in 3 to 5 days. Following discontinuation of granulocyte colony-stimulating factor, ANC decreases by 50% within 2 days and returns to pretreatment levels within 1 week; WBC counts return to normal range in 4 to 7 days.

FLECAINIDE

WARNING: Should only be used for sustained, life-threatening arrhythmias that have not responded to conventional therapies.

INDICATIONS AND USE: Prevention and treatment of sustained, life-threatening ventricular arrhythmias; prophylaxis of paroxysmal atrial flutter and fibrillation and supraventricular tachycardia. Contraindicated in patients with structural heart disease.

ACTIONS: Class 1C antiarrhythmic that slows conduction throughout the myocardium, with the greatest effect on the His-Purkinje system.

DOSAGE: PO.

- **Supraventricular tachycardia:** Initial dose 2 mg/kg/day divided into 2 doses; titrate dose based on response up to 8 mg/kg/day divided into 2 doses.
- **Arrhythmias:** Initial dose: 1 to 3 mg/kg/day divided into 2 or 3 doses; maintenance dose of 3 to 6 mg/kg/day up to 8 mg/kg/day divided into 2 or 3 doses. Titrate dose based on response. Higher doses have been associated with increased risk of proarrhythmias.

ADVERSE EFFECTS: May cause new or worsening ventricular arrhythmias, heart block, bradycardia, torsade de pointes, dizziness, blurred vision, headache, blood dyscrasias, and hepatic dysfunction.

PHARMACOLOGY: Demonstrates both local anesthetic and moderate negative inotropic effects. Reduction in conduction throughout the myocardium results in increased PR, QRS, and QT intervals. Infant formula and milk products may inhibit absorption. Elimination half-life in children <1 year of age is approximately 11 to 12 hours, and in newborns and after maternal administration, it is approximately 29 hours. Half-life is increased with congestive heart failure or renal impairment.

COMMENTS: Therapeutic trough concentration: 0.2 to 1 mcg/mL. Obtain serum concentration at steady state (at least 5 doses administered) after initiation or dose adjustment. Milk consumption can interfere with drug absorption, and monitoring of serum trough levels during major changes in dietary milk intake is recommended.

FLUCONAZOLE (DIFLUCAN)

INDICATIONS AND USE: Antifungal agent for treatment of susceptible fungal infections including oropharyngeal and esophageal candidiasis; treatment of systemic candidal infections including urinary tract infection, peritonitis, cystitis, and pneumonia. There continues to be an increased number of strains of *Candida* isolated with decreased susceptibility to fluconazole. Fluconazole is more active against *Candida albicans* than other *Candida* strains such as *Candida parapsilosis*, *Candida glabrata*, and *Candida tropicalis*; alternative to amphotericin B in patients with preexisting renal impairment or when requiring concomitant therapy with other potentially nephrotoxic drugs.

ACTIONS: Interferes with fungal cytochrome P450 and sterol C-14 α -demethylation, resulting in a fungistatic effect.

DOSAGE: IV, PO.**Treatment for systemic invasive candidiasis:**

- **PNA <8 days:** 12 to 25 mg/kg IV loading dose, then 12 mg/kg IV/PO every 48 hours.
- **PNA \geq 8 days:** 12 to 25 mg/kg IV loading dose, then 12 mg/kg IV/PO every 24 hours.

Treatment for oral thrush/esophageal disease in term neonates:

- **PNA \leq 14 days:** 6 mg/kg loading dose, then 3 mg/kg IV/PO every 24 to 72 hours for a minimum of 14 to 21 days, depending on indication and clinical response.
- **PNA >14 days:** 6 mg/kg loading dose, then 3 mg/kg IV/PO every 24 hours for a minimum of 14 to 21 days, depending on indication and clinical response.

Cryptococcal meningitis:

- **PNA >14 days:** 12 mg/kg loading dose, then 6 to 12 mg/kg IV/PO every 24 hours for a minimum of 10 weeks after the first negative CSF culture.

Candidiasis prophylaxis (IV/PO):

- **<30 weeks' gestation and PNA at the time of therapy initiation:**
 - **PNA <7 days:** 3 or 6 mg/kg/dose IV twice weekly for 6 weeks is recommended in extremely low birthweight infants at increased risk of invasive fungal infection (eg, nurseries with >10% of invasive candidiasis) per Infectious Diseases Society of America clinical practice guideline 2016 update. Dose of 6 mg/kg may be used if targeting *Candida* strains with higher minimal inhibitory concentrations >2 mcg/mL.
 - **PNA \geq 7 to 42 days:** 3 mg/kg/dose every 24 hours or 6 mg/kg/dose every 72 hours.
 - **PNA >42 days:** 6 mg/kg/dose every 48 hours.
- **30 to 40 weeks' gestation:** 6 mg/kg/dose every 48 hours.

ADVERSE EFFECTS: Usually well tolerated. Vomiting, diarrhea, rash, and elevations in liver transaminases. Eosinophilia, leukopenia, thrombocytopenia, neutropenia.

PHARMACOLOGY: Good oral bioavailability; absorption not affected by food, with peak serum concentrations achieved in 1 to 2 hours; good penetration into tissues and body fluids including CSF. Less than 12% protein bound; primarily excreted unchanged in urine.

COMMENTS: Reduce dose in renal dysfunction. Use caution in preexisting renal dysfunction. Monitor liver function tests. Cimetidine and rifampin decrease fluconazole levels. Hydrochlorothiazide increases fluconazole area under the curve. Fluconazole interferes with the metabolism of barbiturates, theophylline, midazolam, phenytoin, and zidovudine. Contraindicated in patients receiving cisapride.

FLUCYTOSINE (ANCOBON)

WARNING: Use with extreme caution in renally impaired patients and monitor closely for hematologic, renal, and hepatic toxicity.

ACTION AND SPECTRUM: Antifungal agent that penetrates fungal cells and is converted to fluoro-uracil, which competes with uracil interfering with fungal RNA and protein synthesis. Used in combination with amphotericin B in the treatment of serious *Candida* or cryptococcal pulmonary or urinary tract infections, sepsis, meningitis, or endocarditis (resistance emerges if flucytosine is used as a single agent); used in combination with another antifungal agent for treatment of chromomycosis and aspergillosis.

DOSAGE: PO. Monitoring of serum drug levels is highly recommended.

- Neonates:
 - General dosing:
 - Weight <1 kg and postnatal age ≤14 days: 75 mg/kg/day divided in 3 doses.
 - Weight <1 kg and postnatal age 15 to 28 days: 75 mg/kg/day divided in 4 doses.
 - Weight 1 to 2 kg and postnatal age ≤7 days: 75 mg/kg/day divided in 3 doses.
 - Weight 1 to 2 kg and postnatal age 8 to 28 days: 75 mg/kg/day divided in 4 doses.
 - Weight >2 kg and postnatal age ≤60 days: 75 mg/kg/day divided in 4 doses.
 - Candidal meningitis: 75 to 100 mg/kg/day divided in 3 to 4 doses in combination with amphotericin B.
 - Infants and children: 50 to 150 mg/kg/day PO divided every 6 hours.
 - Renal impairment: Use lower initial dose.
 - Creatinine clearance 30 to 50 mL/min/1.73 m²: Usual dose every 8 hours.
 - Creatinine clearance 10 to 29 mL/min/1.72 m²: Usual dose every 12 hours.
 - Creatinine clearance <10 mL/min/1.72 m²: Usual dose every 24 hours.

ADVERSE EFFECTS: Vomiting, diarrhea, rash, anemia, leukopenia, thrombocytopenia, elevated liver enzymes and bilirubin, increased blood urea nitrogen and creatinine, renal failure, CNS disturbances and cardiotoxicity.

PHARMACOLOGY: Obtain peak level 2 hours after dose and desired peak serum concentration: 50 to 100 mcg/mL or obtain trough level just prior to dose and desired trough serum concentration: 25 to 50 mcg/mL. Half-life, neonates: 4 to 34 hours. Renal elimination.

COMMENTS: Toxicities related to serum concentration >100 mcg/mL and usually reversible when drug is discontinued or dose is reduced. Amphotericin B may increase toxicity by decreasing renal excretion. Liquid formulation of flucytosine is not commercially available.

FLUDROCORTISONE

INDICATIONS AND USE: Used for partial replacement therapy for adrenocortical insufficiency and used in conjunction with hydrocortisone in patients with salt-losing forms of congenital adrenogenital syndrome.

ACTIONS: Fludrocortisone is a potent mineralocorticoid with glucocorticoid activity that acts on the renal distal tubules to enhance loss of potassium and hydrogen ion and increase reabsorption of sodium with subsequent water retention.

DOSAGE: PO.**Congenital adrenal hyperplasia (salt losers):**

- **Neonates:** Maintenance: 0.05 to 0.2 mg/day in 1 to 2 divided doses in combination with sodium supplementation.
- **Infants/children:** Maintenance: 0.05 to 0.3 mg/day in 1 to 2 divided doses with or without concurrent glucocorticoid and sodium supplementation (American Academy of Pediatrics, Section on Endocrinology and Committee on Genetics, 2000).

ADVERSE EFFECTS: Hypertension, congestive heart failure, abdominal distention, seizure, hypokalemia, growth suppression, hyperglycemia, salt and water retention, edema, hypothalamic-pituitary-adrenal suppression, osteoporosis, and muscle weakness resulting from excessive potassium loss. Monitor serum electrolytes (particularly sodium and potassium).

COMMENTS: Fludrocortisone 0.1 mg has a sodium retention activity equal to deoxycorticosterone acetate 1 mg. May administer with feeds.

FLUMAZENIL

WARNING: Flumazenil has been associated with the occurrence of seizures. These are most frequent in patients who have been on benzodiazepines for long-term sedation or in overdose cases where patients are showing signs of serious cyclic antidepressant overdose. Individualize the dosage of flumazenil injection and be prepared to manage seizures.

INDICATIONS AND USE: Reversal of benzodiazepine sedative effect; management of benzodiazepine overdose.

ACTIONS: Competitive inhibition of effects of benzodiazepines on the γ -aminobutyric acid (GABA)/benzodiazepine receptor complex and does not reverse opioids effects.

DOSAGE: IV.

- **Intermittent dosing:** 0.01 mg/kg up to a maximum of 0.2 mg IV over 15 seconds; may repeat after 45 seconds and then every minute until patient is awake. The maximum total cumulative dose is 0.05 mg/kg or 1 mg, whichever is lower.
- **Continuous IV infusion:** 0.005 to 0.01 mg/kg/h (as an alternative to repeat bolus doses).
- **Benzodiazepine-induced myoclonus:** 0.0078 mg/kg/dose for 1 dose.

ADVERSE EFFECTS: Very limited data in neonates; hypotension, arrhythmias reported in adults. Use with caution in patients with preexisting seizure disorders. May precipitate acute withdrawal in patients with long-term benzodiazepine exposure.

PHARMACOLOGY: Highly lipid soluble. In children, peak concentration is achieved in 3 minutes and half-life is 20 to 75 minutes. There are very limited data in neonates.

COMMENTS: Administer IV through a large vein to minimize pain on injection and phlebitis. Monitor injection site for extravasation.

FOLIC ACID

INDICATIONS AND USE: Treatment of anemia due to nutritional deficit, prematurity, megaloblastic anemia, or macrocytic anemia.

ACTIONS: Required for formation of a number of coenzymes in many metabolic systems, specifically for purine and pyrimidine synthesis, nucleoprotein synthesis, and maintenance of erythropoiesis. Also stimulates white blood cell and platelet production in folate deficiency anemia.

DOSAGE: PO, IM, IV, subcutaneous.**Recommended daily allowance (Vanek, 2012):**

- **Premature neonates:** 25 to 50 mcg/kg/day PO or 56 mcg/kg/day IV via parental nutrition.
- **Full-term neonates:** 65 mcg/day PO or 140 mcg/day IV via parental nutrition.
- **Neonates to 6 months:** 25 to 35 mcg/day PO.

Folic acid deficiency (PO, IM, IV, subcutaneous):

- **Infants:** 0.1 mg/day.
- **Children <4 years:** Up to 0.3 mg/day.

ADVERSE EFFECTS: Generally well tolerated.

PHARMACOLOGY: Absorbed in the proximal portion of small intestine; metabolized in the liver and renally eliminated.

FOLINIC ACID/LEUCOVORIN CALCIUM

CAUTION: May be confused with folic acid.

INDICATIONS: Adjunctive treatment with sulfadiazine and pyrimethamine to prevent hematologic toxicity; antidote for folic acid antagonist overdose; treatment of folinic acid–responsive seizures and treatment of megaloblastic anemias secondary to folic acid deficiency.

ACTIONS: Folinic acid is a derivative of tetrahydrofolic acid, a reduced form of folic acid; enables purine and thymidine synthesis; required for normal erythropoiesis.

DOSAGE: PO, IV.

Folic acid antagonist overdose (eg, pyrimethamine, trimethoprim):

- 5 to 15 mg PO/IV per day for 3 days or until blood counts are normal.

Adjunctive treatment with sulfadiazine to prevent pyrimethamine hematologic toxicity: For congenital toxoplasmosis:

- **Human immunodeficiency virus (HIV) exposed or positive:**
 - Neonates, infants, and children: 10 mg IM/PO with each pyrimethamine dose for 12 months.
 - Non-HIV exposed or positive:
- Neonates, infants, and children: 10 mg IM/PO 3 times weekly for 12 months.

Folinic acid–dependent seizures (limited data):

- 2.5 to 5 mg PO twice a day; may titrate dose up to 8 mg/kg/day (ie, 25 mg PO 3 times a day), as reported in a small case series.

ADVERSE EFFECT: Thrombocytosis, erythema, and wheezing.

PHARMACOLOGY: Onset of action following oral dose is within 30 minutes; IV administration is within 5 minutes. Metabolism: Folinic acid is rapidly converted to 5-methyl-tetrahydrofolate, an active metabolite, in the intestinal mucosa and liver.

FOSPHENYTOIN (CEREBYX)

INDICATIONS AND USE: Management of generalized convulsive status epilepticus; used for short-term parenteral administration of phenytoin, prevention and management of seizures.

ACTIONS AND SPECTRUM: Fosphenytoin is a water-soluble prodrug of phenytoin that is rapidly converted by phosphatases in blood and tissues.

DOSAGE: IM, IV (fosphenytoin 1 mg phenytoin equivalent [PE] = phenytoin 1 mg).

- **Loading dose:** 15 to 20 mg PE/kg IM or IV infusion over at least 10 minutes.
- **Maintenance dose:** 4 to 10 mg PE/kg/day divided every 12 hours IM or IV over at least 10 minutes. Start maintenance dose \geq 12 hours after loading dose.

ADVERSE EFFECTS: Hypotension (with rapid IV administration), vasodilation, tachycardia, bradycardia, drowsiness, anemia, thrombocytopenia, and fever.

PHARMACOLOGY: Conversion to phenytoin half-life is approximately 7 minutes. Fosphenytoin is highly protein bound. (Caution in neonates with hyperbilirubinemia: Both fosphenytoin and bilirubin displace phenytoin from protein-binding sites, which results in increased serum-free phenytoin concentrations.)

COMMENTS: Dilute with 5% dextrose in water (D5W) or normal saline (NS) to 1.5 to 25 mg PE/mL. Maximum rate of infusion is 2 mg PE/kg/min. Flush IV with saline before and after administration. Monitor blood pressure during infusion. Wait at least 2 hours after end of the loading dose infusion prior to drawing a serum phenytoin concentration.

FUROSEMIDE (LASIX)

INDICATIONS AND USE: Fluid overload, pulmonary edema, congestive heart failure, and hypertension.

ACTIONS: Inhibits reabsorption of sodium and chloride in the ascending limb of the loop of Henle and proximal and distal renal tubules. Furosemide-induced diuresis results in enhanced

excretion of sodium, chloride, potassium, calcium, magnesium, bicarbonate, ammonium, hydrogen, and possibly phosphate. Nondiuretic effects include decreased pulmonary transvascular fluid filtration and improved pulmonary function.

DOSAGE: PO, IM, IV.

Neonates, premature:

- **PO:** 1 to 2 mg/kg/dose 1 to 2 times a day as initial dose has been used, and increase slowly if needed; highly variable oral bioavailability.
- **IV or IM:** 1 to 2 mg/kg/dose every 12 to 24 hours.

Infants and children:

- **Oral:** 2 mg/kg PO once daily; if effective, may increase in increments of 1 to 2 mg/kg/dose every 6 to 8 hours; not to exceed 6 mg/kg/dose. In most cases, it is unnecessary to exceed individual doses of 4 mg/kg or a dosing frequency of once or twice daily.
- **IM, IV:** 1 to 2 mg/kg/dose every 6 to 12 hours.
- **Continuous infusion:** 0.05 to 0.2 mg/kg/h; titrate in 0.1 mg/kg/h increments every 12 to 24 hours to a maximum infusion rate of 0.4 mg/kg/h.

ADVERSE EFFECTS: Hypokalemia, hypocalcemia, hyponatremia, hypercalciuria; and with prolonged use, nephrocalcinosis and hypochloremic metabolic alkalosis. Ototoxicity is possible, especially in association with concurrent use of aminoglycosides.

PHARMACOLOGY: Onset of action: oral within 30 to 60 minutes; IV 5 minutes. Duration of action: oral dose is 6 to 8 hours; IV dose is 2 hours.

GANCICLOVIR (CYTOVENE IV)

INDICATIONS AND USE: Symptomatic congenital cytomegalovirus (CMV) infection for the prevention of progressive hearing loss and decreased developmental delay.

ACTIONS AND SPECTRUM: An acyclic nucleoside structurally related to acyclovir, possesses antiviral activity against herpes viruses. Ganciclovir is a prodrug that is phosphorylated to a substrate that inhibits viral DNA synthesis by competitive inhibition of viral DNA polymerases and incorporation into viral DNA, resulting in eventual termination of viral DNA elongation. Ganciclovir is preferentially metabolized in virus-infected cells.

DOSAGE: IV.

- **Neonates:** 6 mg/kg/dose every 12 hours IV, infused over 1 hour. Treat for a minimum of 6 weeks. Reduce dose by half for significant neutropenia (<500 cells/mm³).

ADVERSE EFFECTS: Edema, arrhythmias, hypertension, seizures, sedation, vomiting, diarrhea, neutropenia, thrombocytopenia, leukopenia, anemia, eosinophilia, elevated liver enzymes, phlebitis, retinal detachment in patients with CMV retinitis, hematuria, elevated blood urea nitrogen and serum creatinine, and dyspnea.

PHARMACOLOGY: Oral bioavailability is poor. Renal excretion is the major route of elimination; primarily excreted unchanged in the urine via glomerular filtration and active tubular secretion.

COMMENTS: Handle and dispose according to guidelines issued for cytotoxic drugs; avoid direct contact of skin or mucous membranes with the powder contained in capsules or the IV solution. Dosage adjustment or interruption of ganciclovir therapy may be necessary in patients with neutropenia and/or thrombocytopenia and patients with impaired renal function.

GANCICLOVIR OPHTHALMIC

See Chapter 58.

GENTAMICIN OPHTHALMIC

See Chapter 58.

GENTAMICIN SULFATE

ACTION AND SPECTRUM: Aminoglycoside with bactericidal activity by binding to 30S ribosomal subunit interfering with bacterial protein synthesis. It is active against gram-negative aerobic

bacteria, including most *Pseudomonas*, *Proteus*, and *Serratia*. Some activity against coagulase-negative staphylococci, but ineffective against anaerobes and streptococci.

DOSAGE: IV, IM, intrathecal, intraventricular. Base the initial dose on body weight, then monitor levels and adjust using pharmacokinetics. Many dosing strategies exist such as extended interval, age based, weight based, and traditional.

Age based:

- **≤30 weeks' gestational age:**
 - PNA ≤14 days: 5 mg/kg/dose IV/IM every 48 hours.
 - PNA ≥15 days: 5 mg/kg/dose IV/IM every 36 hours.
- **30 to 34 weeks' gestational age:**
 - PNA ≤10 days: 4.5 mg/kg/dose IV/IM every 36 hours.
 - PNA ≥11 days: 5 mg/kg/dose IV/IM every 36 hours.
- **≥35 weeks' gestational age:**
 - PNA ≤7 days: 4 mg/kg/dose IV/IM every 24 hours.
 - PNA ≥8 days: 5 mg/kg/dose IV/IM every 24 hours.

Intrathecal or intraventricular (use preservative-free):

- **Newborns:** 1 mg/day.
- **Infants >3 months and children:** 1 to 2 mg/day.

Ophthalmic solution: 1 drop into each eye every 4 hours.

Ophthalmic ointment: Apply 2 to 3 times a day.

ADVERSE EFFECTS: Ototoxicity (may be associated with high serum aminoglycoside concentrations persisting for prolonged periods) with tinnitus, hearing loss; early toxicity usually affects high-pitched sound; nephrotoxicity (high trough levels) with proteinuria, elevated serum creatinine, oliguria, and macular rash.

PHARMACOLOGY: Renal excretion by glomerular filtration. Half-life is 3 to 11.5 hours initially. Volume of distribution is increased in neonates and with fever, edema, ascites, and fluid overload.

COMMENTS: Desired serum peak is 4 to 12 mcg/mL (sample obtained 30 minutes after infusion has been completed), and desired serum trough is 0.5 to 2 mcg/mL (sample obtained 30 minutes prior to next dose). Obtain serum levels if treating for >48 hours or patient has declining renal function. Monitor serum creatinine. Aminoglycosides should not be used alone against gram-positive pathogens.

GLUCAGON

INDICATIONS AND USE: Management of severe hypoglycemia unresponsive to routine treatment.

ACTIONS: Glucagon, a hormone produced by the alpha cells of the pancreas, stimulates synthesis of cyclic adenosine monophosphate, hepatic glycogenolysis, and gluconeogenesis, causing an increase in blood glucose levels; it inhibits small bowel motility and gastric acid secretion and produces both positive inotropic and chronotropic effects.

DOSAGE: IV, IM, subcutaneous.

Persistent hypoglycemia:

- 0.02 to 0.2 mg/kg/dose IV, IM, subcutaneous; may repeat in 20 minutes as needed. Maximum single dose: 1 mg.
- **Continuous infusion:** Initial: 0.01 to 0.02 mg/kg/h or 0.5 to 1 mg infused over 24 hours.

Congenital hyperinsulinism; hyperinsulinemic hypoglycemia:

- **Continuous IV infusion:** 0.005 to 0.02 mg/kg/h.

ADVERSE EFFECTS: Tachycardia, hypertension, hypotension up to 2 hours after GI procedure, thrombocytopenia, nausea, and vomiting.

COMMENTS: Do not delay initiation of glucose infusion while observing for glucagon effect.

HEPARIN SODIUM

INDICATIONS AND USE: Prophylaxis and treatment of thromboembolic disorders, anticoagulant for dialysis and extracorporeal procedures and to maintain patency of arterial or venous catheters. (See Chapter 84.)

ACTIONS: Activates antithrombin III (heparin cofactor) and inactivates coagulation factors IX, X, XI, and XII and thrombin, inhibiting the conversion of fibrinogen to fibrin. Heparin also stimulates release of lipoprotein lipase (lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids).

DOSAGE: IV.

Treatment of thrombosis:

- **Loading dose:** 75 units/kg as IV bolus given over 10 minutes, followed by 28 units/kg/h as continuous infusion; adjust dose to maintain an anti-Xa activity of 0.35 to 0.7 units/mL.

Maintain catheter patency:

- **Heparinized fluid** with a usual final concentration of 0.5 to 1 unit/mL; may use concentration as low as 0.25 unit/mL.

Line flushing:

- **Daily flushes of heparin to maintain patency of central catheters:** a dose of 10 units/mL is commonly used for younger infants (eg, <10 kg); 100 units/mL is used for older infants and children with central line access or infusion port devices. May need to flush every 6 to 8 hours for some catheters.

ADVERSE REACTIONS: Heparin-induced thrombocytopenia, bleeding tendency, hemorrhage, fever, rash, and abnormal liver function tests. Follow platelet counts every 2 to 3 days.

PHARMACOLOGY: Clearance in neonates is more rapid than in children or adults; half-life is dose dependent, but the average is 1 to 2 hours.

COMMENTS: Antidote: protamine sulfate; refer to monograph for dosing.

HEPATITIS B IMMUNE GLOBULIN (HBIG; HYPERHEP B S/D, HEPAGAM B)

INDICATIONS AND USE: Provide prophylactic passive immunity to hepatitis B infection following perinatal, sexual, household or bloodborne exposure.

ACTIONS: Passive immunization agent. Immune serum provides protection against the hepatitis B virus by directly providing specific immunoglobulin G to hepatitis B surface antigen (HBsAg). The duration of immunity is short (3–6 months).

DOSAGE: IM.

Neonates born to HBsAg-positive mothers:

- 0.5 mL as soon after birth as possible (within 12 hours; efficacy decreases significantly if treatment is delayed >48 hours); hepatitis B vaccine series to begin at the same time; if this series is delayed for as long as 3 months, the HBIG dose may be repeated.

Neonates born to mothers with unknown HBsAg status at birth:

- **Birthweight <2 kg:** 0.5 mL within 12 hours of birth (along with hepatitis B vaccine) if unable to determine maternal HBsAg status within 12 hours.
- **Birthweight ≥2 kg:** 0.5 mL within 7 days of birth while awaiting maternal HBsAg result.

ADVERSE EFFECTS: Swelling, warmth, erythema, and soreness at the injection site. Rash, fever, and urticaria are rare.

COMMENTS: Administer with caution in patients with immunoglobulin A deficiency, thrombocytopenia, or coagulopathy. Do not administer IV. Do not administer hepatitis vaccine and HBIG in same syringe because vaccine will be neutralized. However, they can be given concurrently at separate sites.

HEPATITIS B VACCINE (RECOMBIVAX HB, ENGERIX-B)

INDICATIONS AND USE: Immunization against infection caused by all known subtypes of hepatitis B virus in individuals considered at high risk of potential exposure to hepatitis B virus.

ACTIONS: Promotes immunity to hepatitis B virus by inducing the production of specific antibodies to the virus.

DOSAGE: IM. Recommended schedule: 0.5 mL/dose in 3 total doses.

Infants born to hepatitis B surface antigen (HBsAg)-positive mothers:

- **First dose within the first 12 hours of life, even if premature** and regardless of birthweight (hepatitis immune globulin should also be administered at the same time/different site);

second dose at 1 to 2 months of age; and third dose at 6 months of age. Check anti-HBs and HBsAg at 9 to 15 months of age. If anti-HBs and HBsAg are negative, reimmunize with 3 doses 2 months apart and reassess. **Note:** Premature infants <2000 g should receive 4 total doses at 0, 1, 2 to 3, and 6 to 7 months of chronological age.

Infants born to HBsAg-negative mothers:

- **First dose prior to discharge;** however, the first dose may be given at 1 to 2 months of age. Another dose is given 1 to 2 months later, and a final dose at 6 months of age. A total of 4 doses of vaccine may be given if a “birth dose” is administered and a combination vaccine is used to complete the series. **Note:** Premature infants <2000 g may have the initial dose deferred to up to 30 days of chronological age.

Infants born to mothers whose HBsAg status is unknown at birth:

- **First dose within 12 hours of birth even if premature, regardless of birthweight;** second dose following 1 to 2 months later; the third dose at 6 months of age; if the mother’s blood HBsAg test is positive, the infant should receive hepatitis immune globulin as soon as possible (no later than age 1 week). Due to possible decreased immunogenicity, premature neonates <2 kg who received an initial dose within 12 hours of birth should receive 4 total doses at 0, 1, 2 to 3, and 6 to 7 months of chronological age.

ADVERSE EFFECTS: Swelling, warmth, erythema, soreness at the injection site, and, rarely, vomiting, rash, and low-grade fever.

COMMENTS: Do not give IV or intradermally.

HYALURONIDASE (HYLENEX, AMPHADASE, VITRASE)

INDICATIONS AND USE: Treatment of extravasation injuries.

ACTIONS: An enzyme that temporarily hydrolyzes hyaluronic acid (1 of the chief components of tissue cement) and thereby allows the infiltrated drug or solution to be absorbed over a larger surface area. This speeds absorption and reduces tissue contact time with the irritant substance.

DOSAGE: Subcutaneous, intradermal.

- Using a 25- or 26-gauge needle, inject 5 separate 0.2-mL injections of 150 units/mL solution around the periphery of the extravasation site. Change the needle after each injection. Elevate the extremity. Do not apply heat. Repeat as needed. Some use 5 separate 0.2-mL subcutaneous injections of 15 units/mL dilution.

ADVERSE EFFECTS: Usually well tolerated. Urticaria occurs rarely. Administer hyaluronidase within 1 hour of the extravasation, if possible. Reduction in swelling can be observed within 15 to 30 minutes after administration.

HYDRALAZINE HCL (APRESOLINE HCL)

INDICATIONS AND USE: For the management of moderate to severe hypertension and as an afterload-reducing agent to treat congestive heart failure.

ACTIONS: Causes direct relaxation of smooth muscle in the arteriolar resistance vessels; decreases systemic vascular resistance and increases cardiac output; increases renal, coronary, cerebral, and splanchnic blood flow.

DOSAGE: IM, IV, PO.

- **IM or IV:** 0.1 to 0.5 mg/kg/dose every 6 to 8 hours (maximum 2 mg/kg/dose). In case of hypertensive emergency/urgency in infants, may administer initial dose of 0.1 to 0.2 mg/kg/dose every 4 to 6 hours as needed and increase up to 0.6 mg/kg/dose or 20 mg/dose as required.
- **PO:** 0.25 to 1 mg/kg/dose every 6 to 8 hours; increase over 3 to 4 weeks to maximum of 7.5 mg/kg/day in infants.

ADVERSE EFFECTS: Most frequent are tachycardia and hypotension; most serious is a reversible lupus-like syndrome. Tachyphylaxis often occurs on chronic therapy. Gastrointestinal bleeding, diarrhea, anemia, leukopenia, agranulocytosis, and purpura have also been reported.

COMMENTS: Contraindicated in mitral valve rheumatic heart disease or coronary artery disease. Due to concern for reflex tachycardia, concurrent use of β -blocker is recommended in heart failure patients.

HYDROCHLOROTHIAZIDE (MICROZIDE)

INDICATIONS AND USE: Mild to moderate edema and hypertension, bronchopulmonary dysplasia, idiopathic hypercalciuria, congenital nephrogenic diabetes insipidus.

ACTIONS: Inhibits reabsorption of sodium in the distal tubules, resulting in increased excretion of sodium and water as well as potassium, hydrogen, magnesium, and bicarbonate ions.

DOSAGE: PO.

Neonates:

- 2 to 4 mg/kg/day divided in 2 doses.

Edema:

- **Infants <6 months:** 1 to 3 mg/kg/day in 2 divided doses; maximum dose 37.5 mg/day.
- **Infants \geq 6 months and children <2 years:** 1 to 2 mg/kg/day in 1 to 2 divided doses; maximum dose 37.5 mg/day.

Hypertension:

- **Infants and children <2 years:** Initially, administer 1 mg/kg/day once daily; increase to maximum of 3 mg/kg/day if needed; not to exceed 50 mg/day.

ADVERSE EFFECTS: Hypokalemia, hyperglycemia, hyperuricemia, hypochloremic metabolic alkalosis.

PHARMACOLOGY: Onset of action (infants) approximately 2 to 6 hours with a duration of 8 hours. Half-life is roughly 6 to 15 hours. Drug is renally eliminated.

HYDROCORTISONE, SYSTEMIC

INDICATIONS AND USE: Management of acute adrenal insufficiency, congenital adrenal hyperplasia, and vasopressor-resistant hypotension. Adjunctive treatment for persistent hypoglycemia.

ACTIONS: The short-acting adrenal corticosteroid that possesses glucocorticoid activity, anti-inflammatory activity, and minimal mineralocorticoid effects; most effects probably result from modification of enzyme activity, thus affecting almost all body systems. Promotes protein catabolism, gluconeogenesis, renal excretion of calcium, capillary wall permeability and stability, and red blood cell production; suppresses immune and inflammatory responses.

DOSAGE: IV, IM, PO.

Acute adrenal insufficiency/adrenal crisis:

- 2 to 3 mg/kg IV bolus (maximum at 100 mg/dose), then 1 to 5 mg/kg/dose IV every 6 hours.

Congenital adrenal hyperplasia (AAP recommendations):

- **Initial:** 10 to 20 mg/m²/day PO in 3 divided doses.
- **Usual requirement for infants:** 2.5 to 5 mg 3 times per day using tablet formulation.

Physiologic replacement:

- **PO:** 8 to 12 mg/m²/day divided every 8 hours.

Stress doses (treatment-resistant hypotension; shock):

- **IV:** 50 to 100 mg/m²/day IV divided into 2 to 4 doses; alternatively, 1 mg/kg/dose IV every 8 hours or 2 mg/kg IV bolus followed by 1 mg/kg/dose IV every 12 hours.

Refractory hypoglycemia (refractory to continuous glucose infusion rates >12–15 mg/kg/min):

- **IV, PO:** 5 mg/kg/day divided every 8 to 12 hours or 1 to 2 mg/kg/dose every 6 hours. Consider consultation with pediatric endocrinologist for treatment guidance.

ADVERSE EFFECTS: Hypertension, hypothalamic-pituitary-adrenal axis suppression, hypokalemia, hyperglycemia, growth suppression, sodium and water retention, decreased bone mineral density, and immunosuppression.

COMMENTS: *Note:* Morning dose should be administered as early as possible; tablets may result in more reliable serum concentrations than oral liquid formulation; individualize dose by monitoring growth, hormone levels, and bone age; mineralocorticoid (eg, fludrocortisone) and sodium supplement may be required in salt losers.

HYDROXYCHLOROQUINE (PLAQUENIL)

ACTION AND SPECTRUM: Interferes with digestive vacuole function within sensitive malarial parasites by increasing the pH and interfering with lysosomal degradation of hemoglobin. Suppression or treatment of acute attacks of malaria.

DOSAGE: All doses below are expressed as hydroxychloroquine sulfate; hydroxychloroquine sulfate 200 mg is equivalent to 155 mg of hydroxychloroquine base and 250 mg of chloroquine phosphate.

Malaria:

- **Treatment:** 13 mg/kg/dose PO (maximum initial dose 800 mg) followed by 6.5 mg/kg/dose at 6, 24, and 48 hours after initial dose (maximum per dose 400 mg).
- **Prophylaxis:** 6.5 mg/kg/dose once weekly on the same day each week (maximum per dose 400 mg); begin 1 to 2 weeks before exposure and continue for at least 4 weeks after leaving endemic area. If initiation of prophylaxis is delayed (ie, 2 weeks of therapy not competed prior to the exposure), the manufacturer recommends doubling the initial dose to 13 mg/kg/dose and administering in 2 divided doses 6 hours apart (maximum per dose 400 mg); continue for 8 weeks after leaving endemic area.

ADVERSE EFFECTS: Cardiomyopathy, QT interval prolongation, dermatitis, erythema, bone marrow suppression (anemia, leukopenia, thrombocytopenia), hypoglycemia, proximal myopathy or neuromyopathy, visual disturbances, acute hepatic insufficiency, renal toxicity. Use with caution in patients with glucose-6-phosphate dehydrogenase deficiency due to a potential for hemolytic anemia.

COMMENTS: A 25 mg/mL hydroxychloroquine sulfate oral suspension may be made with tablets. With a towel moistened with alcohol, remove the coating from 15 200-mg hydroxychloroquine sulfate tablets. Crush tablets in a mortar and reduce to a fine powder. Add 15 mL of Ora-Plus and mix to a uniform paste; add an additional 45 mL of vehicle and mix until uniform. Mix while adding sterile water for irrigation in incremental proportions to almost 120 mL; transfer to a calibrated bottle, rinse mortar with sterile water, and add sufficient quantity of sterile water to make 120 mL. Label "shake well." A 30-day expiration date is recommended, although stability testing has not been performed.

IBUPROFEN (MOTRIN, OTHERS)

INDICATIONS AND USE: Treatment of mild to moderate pain, fever, and inflammatory diseases. Oral ibuprofen may be a safe alternative for patent ductus arteriosus (PDA) closure as shown in recent studies, but larger studies are needed.

ACTIONS: Decreases prostaglandin synthesis by reversibly inhibiting the activities of cyclooxygenase-1 and -2 enzymes.

DOSAGE: PO.

Infants and children:

- **Analgesic:** 4 to 10 mg/kg/dose PO every 6 to 8 hours; maximum daily dose is 40 mg/kg/day.
- **Antipyretic:** (>6 months) 5 to 10 mg/kg/dose PO every 6 to 8 hours; maximum daily dose is 40 mg/kg/day or 2400 mg/day.
- **PDA closure:** 10 mg/kg for the first dose, followed by 2 doses of 5 mg/kg at 24 and 48 hours after the first dose. Use birthweight to calculate all doses.

ADVERSE EFFECTS: Edema, hypertension, fluid retention, hyperkalemia, gastrointestinal (GI) bleed, GI perforation, neutropenia, anemia, inhibition of platelet aggregation, elevated liver enzymes, acute renal failure/acute kidney injury.

PHARMACOLOGY: Highly protein bound (>95%). Hepatic metabolism via oxidation. Primarily renally excreted.

COMMENTS: To reduce the risk of adverse cardiovascular and GI effects, use the lowest effective dose for the shortest time period. May increase risk of GI irritation, ulceration, bleeding, and perforation; may compromise existing renal function; use with caution in patients with decreased liver function.

IBUPROFEN LYSINE (NEOPROFEN)

INDICATIONS AND USE: Pharmacologic closure of patent ductus arteriosus. Not indicated for intraventricular hemorrhage prophylaxis.

ACTIONS: Nonsteroidal anti-inflammatory drug with analgesic and antipyretic properties. Action is principally by inhibition of prostaglandin synthesis, thus inhibiting cyclooxygenase, an enzyme that catalyzes the formation of prostaglandin precursors (endoperoxides) from arachidonic acid.

DOSAGE: IV (use birthweight for all dosing calculation).

- **Standard-dose regimen (manufacturer's labeling):** 10 mg/kg for the initial dose, followed by 2 doses of 5 mg/kg at 24- and 48-hour intervals after the first dose.
- **High-dose regimen (limited data):** 20 mg/kg for the initial dose, followed by 2 doses of 10 mg/kg at 24- and 48-hour intervals after the first dose. Of note, high-dose regimen was found to have a higher rate of PDA closure without additional side effects (Dani, 2012; Meißner, 2012).

ADVERSE EFFECTS: Anemia, fluid retention, edema, tachycardia, hepatic dysfunction, decrease in urine output, elevated blood urea nitrogen and serum creatinine (renal effects are less severe and less frequent than those with indomethacin); may inhibit platelet aggregation; monitor for signs of bleeding. Use with caution in infants when total bilirubin is elevated (ibuprofen may displace bilirubin from albumin-binding sites). Feeding intolerance, gastrointestinal irritation, ileus.

COMMENTS: Contraindicated in preterm neonates with infection, active bleeding, thrombocytopenia or coagulation defects, necrotizing enterocolitis, significant renal dysfunction, and congenital heart disease with ductal-dependent systemic blood flow. Withhold subsequent dose(s) in patients who became anuric or with urinary output <0.6 mL/kg/h until renal function is normalized.

IMIPENEM/CILASTATIN (PRIMAXIN IV)

ACTION AND SPECTRUM: Treatment of non-CNS infections caused by documented multidrug-resistant gram-negative organisms in children.

DOSAGE: IV. (Dosing based on imipenem component.)

Neonates (AAP Red Book, 2018–2021):

- PNA ≤7 days: 25 mg/kg every 12 hours.
- PNA >7 to 28 days: 25 mg/kg every 8 hours.

Infants >28 days and children:

- 60 to 100 mg/kg/day divided every 6 hours; maximum dose 4 g/day.

ADVERSE EFFECTS: Irritation, pain, phlebitis at injection site, elevated liver transaminases; urine discoloration, decreased in hematocrit, elevated serum creatinine, diarrhea, and seizures in patients with meningitis.

PHARMACOLOGY: Broad-spectrum carbapenem combines with cilastatin (renal dipeptidase inhibitor that prevents renal metabolism of imipenem). Inhibits cell wall biosynthesis. Half-life is prolonged with renal insufficiency.

COMMENTS: Dosing adjustment is recommended in patients with renal impairment. Caution use in preterm infants due to risk of cilastatin accumulation and possible seizures.

IMMUNE GLOBULIN, INTRAVENOUS (IVIG; VARIOUS)

INDICATIONS AND USE: Neonatal alloimmune thrombocytopenia, isoimmune hemolytic disease, adjuvant treatment of fulminant neonatal sepsis (*controversial*) and immunodeficiency syndromes.

ACTIONS: The pooled, heterogeneous immunoglobulin G (IgG) present in IVIG provides a plethora of antibodies capable of opsonization and neutralization of many toxins and microbes, as well as complement activation. Although the amount of each IgG subclass in the parenteral products is similar to that of human plasma, the titers against specific antigens vary from manufacturer to manufacturer. The passive immunity imparted by IVIG is capable of attenuating or preventing infectious diseases or deleterious reactions from toxins,

Mycoplasma, parasites, bacteria, and viruses. IVIG is thought to promote blockade of Fc receptors in macrophages (preventing phagocytosis of circulating opsonized platelets or cells tagged with autoantibodies).

DOSAGE: IV.

- **Usual dosage:** 400 to 1000 mg/kg/dose infused over 2 to 6 hours daily for 2 to 5 days (total dose of 2000 mg/kg). Many different products available; consult specific product insert for dosing details.

ADVERSE EFFECTS: Hypotension, transient tachycardia, and anaphylaxis. If either occurs, the rate of infusion should be decreased or stopped until resolved, then resumed at a slower rate as tolerated. Contraindicated in IgA deficiency (except with the use of Gammagard S/D or Polygam S/D).

PHARMACOLOGY: Initial response seen in 1 to 3 days with peak response between 2 and 7 days in the treatment of immune thrombocytopenia. Immune effect is expected to last for 3 to 4 weeks.

INDOMETHACIN, IV

INDICATIONS AND USE: Pharmacologic closure of patent ductus arteriosus (PDA). May provide prophylaxis for intraventricular hemorrhage (IVH) in low birthweight infants.

ACTIONS: Nonsteroidal anti-inflammatory drug with analgesic and antipyretic properties. Inhibits prostaglandin synthesis by decreasing cyclooxygenase activity, an enzyme that catalyzes the formation of prostaglandin precursors (endoperoxides) from arachidonic acid. Decreases cerebral blood flow.

DOSAGE: IV.

PDA:

- **Initially,** 0.2 mg/kg IV, followed by 2 doses depending on PNA:
 - **PNA at first dose <48 hours:** 0.1 mg/kg at 12- to 24-hour intervals.
 - **PNA at first dose 2 to 7 days:** 0.2 mg/kg at 12- to 24-hour intervals.
 - **PNA at first dose >7 days:** 0.25 mg/kg at 12- to 24-hour intervals.
- **Dosing interval:**
 - **12-hour dosing interval** if urine output is >1 mL/kg/h after prior dose.
 - **24-hour dosing interval** if urine output is <1 mL/kg/h but >0.6 mL/kg/h.
 - **Hold dose if patient has oliguria** (urine output <0.6 mL/kg/h) or anuria.

IVH prophylaxis: 0.1 mg/kg/dose IV every 24 hours for 3 doses; give first dose at 6 to 12 hours of age.

ADVERSE EFFECTS: May cause decreased platelet aggregation, transient oliguria (decreased glomerular filtration rate), increased serum creatinine, and increased serum concentration of renally excreted drugs such as gentamicin. May also cause hyponatremia, hyperkalemia, and hypoglycemia. Gastrointestinal perforations are known to occur if used concurrently with corticosteroids.

COMMENTS: Contraindicated in premature neonates with necrotizing enterocolitis, severe renal impairment (urine output <0.6 mL/kg/h or creatinine \geq 1.8 mg/dL), thrombocytopenia, or active bleeding or if there has been intraventricular bleeding within the preceding 7 days (*controversial*). Do not administer via umbilical catheter or intra-arterially.

INSULIN, REGULAR

INDICATIONS AND USE: Hyperglycemia, acute management of hyperkalemia, and increasing caloric intake in infants with glucose intolerance on parenteral nutrition.

ACTIONS: Hormone derived from the β cells of the pancreas and the principal hormone required for glucose utilization. In skeletal and cardiac muscle and adipose tissue, insulin facilitates transport of glucose into these cells. Insulin stimulates lipogenesis and protein synthesis and inhibits lipolysis and release of free fatty acids from adipose cells. Promotes intracellular shift of potassium and magnesium.

DOSAGE: IV.**Hyperglycemia (Cloherty et al, 2012):**

- **Continuous IV infusion:** 0.01 to 0.2 units/kg/h (titrate in 0.01 unit/kg/h increments with blood glucose monitoring every 30 minutes until stable, then every 4–6 hours).
- **Intermittent:** 0.05 to 0.1 unit/kg/dose infused over 15 minutes every 4 to 6 hours as needed; monitor blood glucose 30 minutes to 1 hour after doses.

Hyperkalemia:

- **Continuous IV infusion:** 0.05 to 0.1 unit/kg/h in combination with a continuous infusion of 0.2 to 0.4 g/kg/h of dextrose. Adjust infusion rates based on serum glucose and potassium concentrations.
- **Intermittent:** 0.1 unit/kg given IV in combination with 400 mg/kg glucose.

ADVERSE EFFECTS: Hypoglycemia (may cause coma and severe CNS injury), hyperglycemic rebound (Somogyi effect), hypokalemia, urticaria, and anaphylaxis.

COMMENTS: To minimize adsorption of insulin to plastic IV solution bag or tubing: If new tubing is not needed, wait a minimum of 30 minutes between the preparation of the solution and the initiation of the infusion. If new tubing is needed, after receiving the insulin continuous infusion solution, the administration set should be attached to the IV container and the line should be flushed with the insulin solution; wait 30 minutes, then flush the line again with the insulin solution prior to initiating the infusion. Because of adsorption, the actual amount of insulin being administered could be substantially less than the apparent amount. Therefore, adjustment of the insulin drip rate should be based on the effect and not solely on the apparent insulin dose.

IODODEOXYURIDINE OPHTHALMIC

See Chapter 58.

IPRATROPIUM BROMIDE (ATROVENT)

INDICATIONS AND USE: Bronchodilator for adjunctive treatment of acute bronchospasm.

ACTIONS: Anticholinergic drug that acts by antagonizing the action of acetylcholine at the parasympathetic receptor sites, thereby producing bronchodilation.

DOSAGE: Inhalation.

- **Neonates:** 25 mcg/kg/dose nebulized every 8 hours.
- **Infants:** 125 to 250 mcg/dose nebulized every 8 hours. Dilute to 3 mL with normal saline or concurrent albuterol.
- **Metered inhaler:** 2 to 4 puffs as needed every 6 to 8 hours.

ADVERSE EFFECTS: Rebound airway hyperresponsiveness after discontinuation. Nervousness, dizziness, nausea, blurred vision, dry mouth, exacerbation of symptoms, airway irritation, cough, palpitations, rash, and urinary retention. Use with caution in narrow-angle glaucoma or bladder neck obstruction.

COMMENTS: Compatible when admixed with albuterol if given within 1 hour. Bronchodilator effect may be potentiated when given with β_2 -agonist (ie, albuterol).

IRON DEXTRAN

INDICATIONS AND USE: Used to treat iron deficiency anemia, as an iron supplement for infants on epoetin, and for infants on long-term parenteral nutrition (PN). Oral iron is much safer than the parenteral form; the parenteral form is usually reserved for patients who cannot take oral iron.

ACTIONS: Iron is a component in the formation of hemoglobin, and adequate amounts are necessary for erythropoiesis and oxygen transport capacity of blood.

DOSAGE: IV. Note: Multiple parenteral iron forms exist.

Total replacement dosage of iron dextran for iron deficiency anemia:

- Dose (mL) = $0.0442 \times \text{LBW (kg)} \times (\text{Hbn} - \text{Hbo}) + [0.26 \times \text{LBW (kg)}]$
 - LBW = lean body weight
 - Hbn = desired hemoglobin (g/dL) = 12 if <15 kg or 14.8 if >15 kg
 - Hbo = measured hemoglobin (g/dL)

Total iron replacement dosage for acute blood loss (assumes 1 mL of normocytic, normochromic red cells = 1 mg elemental iron):

- Iron dextran (mL) = $0.02 \times \text{blood loss (mL)} \times \text{hematocrit (expressed as a decimal fraction)}$

Anemia of prematurity:

- 0.2 to 1 mg/kg/day IV or 20 mg/kg/wk with epoetin alfa therapy.

PN addition:

- Admixed in the PN solution (solution must contain at least 2% amino acids): 0.4 to 1 mg/kg/day (or 3–5 mg/kg as a single weekly dose).

ADVERSE EFFECTS: Iron accumulation in patients with serious liver dysfunction; anaphylaxis, fever, and arthralgia. IV use: Pain and redness at IV site, rash, shivering; hypotension and flushing with rapid infusion.

ISONIAZID (INH)

INDICATIONS AND USE: Treatment of susceptible *Mycobacterium* spp. (eg, *Mycobacterium tuberculosis*, *Mycobacterium kansasii*, and *Mycobacterium avium*) and for prophylaxis for individuals exposed to tuberculosis.

ACTION AND SPECTRUM: Antimycobacterial agent that is bactericidal for both extracellular and intracellular organisms. Inhibits mycolic acid synthesis resulting in disruption of the bacterial cell wall.

DOSAGE: PO.

- **Perinatal tuberculosis:** 10 to 15 mg/kg/day PO divided every 12 hours with rifampin (see Rifampin for dosage) for 3 to 12 months. If skin test conversion is positive, treat with 10 to 15 mg/kg/day PO every 24 hours for 9 to 12 months.

ADVERSE EFFECTS: Peripheral neuropathy, seizures, encephalopathy, blood dyscrasias, nausea, vomiting, and diarrhea (associated with administration of syrup formulation) and hypersensitivity reactions. May be hepatotoxic; follow liver function tests at regular intervals during treatment.

ISOPROTERENOL (ISUPREL, OTHERS)

INDICATIONS AND USE: Low cardiac output or vasoconstrictive shock states, cardiac arrest, ventricular arrhythmias resulting from atrioventricular block.

ACTIONS: Stimulates both β_1 - and β_2 -adrenergic receptors with minimal or no effect on α -receptors in therapeutic doses. Relaxes bronchial smooth muscle, cardiac stimulation (inotropic and chronotropic), and peripheral vasodilation (reduces cardiac afterload).

DOSAGE: IV.

- 0.05 to 0.5 mcg/kg/minute IV continuous infusion; maximum dose is 2 mcg/kg/minute. Correct acidosis before initiating therapy.

ADVERSE EFFECTS: Tremor, vomiting, hypertension, tachycardia, cardiac arrhythmias, hypotension, and hypoglycemia.

COMMENTS: Contraindicated in hypertension, hyperthyroidism, tachycardia caused by digoxin toxicity, and preexisting cardiac arrhythmias. Increases cardiac oxygen consumption disproportional to the increase in cardiac oxygen output. Not considered an inotropic agent of choice.

KETAMINE HYDROCHLORIDE (KETALAR)

INDICATIONS AND USE: Ketamine is a rapid-acting general anesthetic agent for short diagnostic and minor surgical procedures that do not require skeletal muscle relaxation.

ACTIONS: Produces dissociative anesthesia by direct action on the cortex and limbic system; does not usually impair pharyngeal or laryngeal reflexes. Induces coma, analgesia, and amnesia. Increases cerebral blood flow and cerebral oxygen consumption; improves pulmonary compliance and relieves bronchospasm.

DOSAGE: IV, IM, PO.

- **IV: 0.5 to 2 mg/kg/dose;** use smaller doses (0.5–1 mg/kg) for sedation for minor procedures.
- **Usual induction dose: 1 to 2 mg/kg IV.** Reduce dose in hepatic dysfunction.

ADVERSE EFFECTS: Avoid use of ketamine in patients with increased intracranial pressure, increased cerebral blood flow, increased CSF pressure, increased cerebral metabolism, or if

a significant elevation in blood pressure may present a risk to the patient. Elevated blood pressure (frequent), tachycardia, arrhythmia, hypotension, bradycardia, increased cerebral blood flow, and decreased cardiac output may occur. Respiratory depression and apnea after rapid IV administration of high doses; laryngospasm; and hypersalivation. Increased airway resistance, cough reflex may be depressed, decreased bronchospasm. Nystagmus and increased intraocular pressure. Emergence reactions (psychic disturbances such as hallucinations and delirium lasting up to 24 hours). Minimize by reducing verbal, tactile, and visual stimulation in the recovery period. These occur less commonly in pediatric patients than in adults. Severe reactions can be treated with a benzodiazepine. Increased muscle tone that may resemble seizures and extensor spasm with opisthotonos may occur in infants receiving high, repeated doses. Rash as well as pain and redness at the IM injection site.

PHARMACOLOGY: IV acts in 30 seconds and lasts 5 to 10 minutes. Amnesia lasts for 1 to 2 hours. Concurrent narcotics or barbiturates prolong recovery time.

COMMENTS: Pretreatment with a benzodiazepine 15 minutes before ketamine may reduce side effects such as psychic disturbances, increased intracranial pressure and cerebral blood flow, tachycardia, and jerking movements. Monitor heart rate, respiratory rate, blood pressure, and pulse oximetry. Observe for CNS side effects during the recovery period. Have equipment for resuscitation available.

KETOCONAZOLE (NIZORAL)

WARNING: Ketoconazole has been associated with hepatic toxicity. Coadministration of cisapride or astemizole with ketoconazole is contraindicated. Serious cardiovascular adverse events have occurred.

INDICATIONS AND USE: Synthetic broad spectrum antifungal.

ACTION AND SPECTRUM: An antifungal agent that acts by disrupting cell membranes. Fungicidal against susceptible candidiasis, blastomycosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, chronic mucocutaneous candidiasis, as well as certain recalcitrant cutaneous dermatophytoses (FDA approved in those ≥ 2 years of age).

DOSAGE: PO.

- 3.3 to 6.6 mg/kg/day PO once daily with food to decrease nausea and vomiting; administer 2 hours prior to antacids, proton pump inhibitors, or H_2 -receptor antagonists to prevent decreased ketoconazole absorption; shake suspension well before use.

ADVERSE EFFECTS: Gastric distress is the most common side effect. Check periodic liver function tests; caution in patients with impaired hepatic function; high doses of ketoconazole may depress adrenocortical function and decrease serum testosterone concentrations.

PHARMACOLOGY: Hepatic metabolism. Penetration into CSF is poor.

COMMENTS: Not indicated for treatment of fungal meningitis. Minimum period of treatment for candidiasis is 1 to 2 weeks, but duration should be based on clinical response. Limited experience in neonates.

LABETALOL

INDICATIONS AND USE: Treatment of mild to severe hypertension. IV form for hypertensive emergencies.

ACTIONS: Dose-related decrease in blood pressure through α -, β_1 -, and β_2 -adrenergic receptor blockade without causing significant reflex tachycardia or a decrease in heart rate. Reduces elevated renin levels.

DOSAGE: PO, IV. Limited experience in neonates; labetalol should be initiated cautiously; carefully monitor blood pressure, heart rate, and electrocardiogram, and adjust the dose accordingly. Use the lowest effective dose.

IV intermittent bolus:

- 0.2 to 0.5 mg/kg/dose over 2 to 3 minutes every 4 to 6 hours with a range of 0.2 to 1 mg/kg/dose has been suggested; maximum dose 20 mg/dose.

Treatment of pediatric hypertensive emergencies:

- **Continuous IV infusion:** 0.4 to 1 mg/kg/h, with a maximum of 3 mg/kg/h.
- **Alternate dosing:** Bolus 0.2 to 1 mg/kg followed by a continuous infusion of 0.25 to 1.5 mg/kg/h.

Oral:

- **Initial:** 1 to 2 mg/kg/day in 2 divided doses. Maximum dose 10 to 20 mg/kg/day.

ADVERSE EFFECTS: Orthostatic hypotension, bronchospasm, nasal congestion, edema, congestive heart failure, bradycardia, myopathy, and rash. Intensifies atrioventricular block. Reversible hepatic dysfunction (rare).

PHARMACOLOGY: Peak effect with PO is 1 to 4 hours after the dose, while peak effect with IV is 5 to 15 minutes. Metabolized in the liver by glucuronidation. Oral labetalol has a bioavailability of only 25% because of extensive first-pass effect. Oral absorption is improved by taking with food. Concomitant oral cimetidine may increase the bioavailability of oral labetalol.

COMMENTS: Do not discontinue chronic labetalol abruptly; taper over 1 to 2 weeks. Contraindicated in patients with asthma, overt cardiac failure, heart block, cardiogenic shock, or severe bradycardia. May cause a paradoxical increase in blood pressure in patients with pheochromocytoma. Use with caution in hepatic dysfunction. Incompatible with sodium bicarbonate.

LAMIVUDINE (EPIVIR, EPIVIR HBV)

WARNING: Risk of lactic acidosis, exacerbations of hepatitis B upon discontinuation of epivir-HBV[®], and risk of HIV-1 resistance if epivir-HBV is used in patients with unrecognized or untreated HIV-1.

ACTION AND SPECTRUM: Antiretroviral agent that inhibits reverse transcription by viral DNA chain termination. Used for the prevention of mother-to-child transmission of human immunodeficiency virus (HIV); treatment of HIV infection.

DOSAGE: PO. Use in combination with other antiretroviral agents—regimen containing 3 antiretroviral agents is strongly recommended.

Prevention of maternal-to-child HIV transmission:

- 2 mg/kg/dose every 12 hours for 7 days; given from birth to 1 week of age. Given to neonate in combination with nevirapine and 6 weeks of zidovudine in certain maternal situations, such as no treatment prior to labor or during labor, only intrapartum therapy; inadequate viral suppression at time of delivery or known drug-resistant virus.

Treatment of HIV infection:

- **Neonates <30 days:** 2 mg/kg/dose every 12 hours.
- **Infants 1 to 3 months:** 4 mg/kg/dose every 12 hours.
- **Infants >3 months and children <16 years:** 4 mg/kg/dose every 12 hours; maximum dose 150 mg every 12 hours.

ADVERSE EFFECTS: Very limited data in neonates; Black Box warning of lactic acidosis and severe hepatomegaly in adults; some fatal cases.

PHARMACOLOGY: Synthetic nucleoside analog that is converted to active metabolite; oral solution is well absorbed with 66% bioavailability. Resistance develops rapidly with monotherapy.

COMMENTS: Blood levels/effects may be increased by ganciclovir, valganciclovir, ribavirin, and trimethoprim.

LANSOPRAZOLE (PREVACID)

INDICATIONS AND USE: Short-term treatment of gastroesophageal reflux disease (GERD); erosive esophagitis.

ACTIONS: Suppression of gastric acid secretion by selective inhibition of parietal cell membrane enzyme hydrogen-potassium adenosine triphosphatase (ATPase) or proton pump.

DOSAGE: PO.**Neonatal:**

- **0.2 to 0.3 mg/kg/dose once daily** (Zhang et al, 2008) based on pharmacokinetic data; patients <10 weeks of age have decreased clearance.

- **Alternate dosing has been used:** 0.5 to 1 mg/kg/dose once daily (Springer, 2008).

Infants >4 weeks:

- 1 to 1.5 mg/kg/dose once daily (Springer, 2008).

Infants ≥10 weeks:

- 1 to 2 mg/kg/dose once daily (Orenstein et al, 2009; Springer, 2008; Zhang et al, 2008).

ADVERSE EFFECTS: Limited data; proteinuria, abdominal pain, mild elevation of serum transaminases.

PHARMACOLOGY: Degrades in acid pH of stomach; extensively metabolized in liver by CYP2C19 and CYP3A4; the absorption of weakly acidic drugs such as digoxin and furosemide is increased, and absorption of weakly basic drugs is inhibited.

COMMENTS: Recent clinical trial (Orenstein et al, 2009) did not demonstrate efficacy in the treatment of GERD in patients <12 months of age, and the use in this patient population is *controversial*.

LEVETIRACETAM (KEPPRA)

INDICATIONS AND USE: Adjunctive therapy in the treatment of partial-onset seizures in patients 1 month of age and older. It is only approved for use in combination with other seizure medications.

ACTIONS: Mechanism of action unknown; studies suggest that ≥1 of the following central pharmacologic effects may be involved: inhibition of voltage-dependent N-type calcium channels; blockade of γ -aminobutyric acid (GABA)-ergic inhibitory transmission through displacement of negative modulators; reversal of the inhibition of glycine currents; reduction of delayed rectifier potassium current; and/or binding to synaptic proteins that modulate neurotransmitter release.

DOSAGE: IV, PO. (*Note:* When switching from PO to IV formulation, the total daily dose should be the same.)

Neonatal dosing:

- **Initial dose:** 10 mg/kg/day IV given in 2 divided doses; may increase over 3 days to 30 mg/kg/day, if tolerated, to maximum of 45 to 60 mg/kg/day. Loading doses of 20 to 30 mg/kg have been used. (Dosing information is from studies with very small sample size.)
- **Oral:** 10 mg/kg/day PO in 1 to 2 divided doses; increase daily by 10 mg/kg to 30 mg/kg/day (maximum dose used: 60 mg/kg/day).

Infant (FDA approved):

- **1 month to <6 months:** 7 mg/kg twice daily; increase in increments of 7 mg/kg twice daily every 2 weeks to recommended dose of 21 mg/kg twice daily.

ADVERSE EFFECTS: Somnolence, nervousness. Use with caution in patients with renal dysfunction; decrease dose.

PHARMACOLOGY: Oral absorption is rapid and complete; oral bioavailability 100%.

COMMENTS: Do not abruptly discontinue therapy; gradually decrease dose to reduce risk of increased seizure activity.

LEVOTHYROXINE SODIUM (T₄) (SYNTHROID, LEVOXYL, OTHERS)

INDICATIONS AND USE: Replacement or supplemental therapy in congenital or acquired hypothyroidism.

ACTIONS: The exact mechanism of action is unknown; however, it is believed the thyroid hormone exerts its many metabolic effects through control of DNA transcription and protein synthesis. Thyroid hormones increase the metabolic rate of body tissues, noted by increases in oxygen consumption; respiratory rate; body temperature; cardiac output; heart rate; blood volume; rates of fat, protein, and carbohydrate metabolism; and enzyme system activity, growth, and maturation. Thyroid hormones are very important in CNS development. Deficiency in infants results in growth retardation and failure of brain growth and development.

DOSAGE: PO, IV, IM (use 50%–75% of the oral dose).

- **0 to 3 months:** 10 to 15 mcg/kg PO; if the infant is at risk for development of cardiac failure, use a lower starting dose, approximately 25 mcg/day; if the initial serum thyroxine is very low (<5 mcg/dL), begin treatment at a higher dosage, approximately 50 mcg/day.

- **>3 to 6 months:** 8 to 10 mcg/kg or 25 to 50 mcg PO.
- **>6 to 12 months:** 6 to 8 mcg/kg or 50 to 75 mcg PO.
- **Alternate dosing:** 8 to 10 mcg/kg/day PO for infants from birth to 1 year.

ADVERSE EFFECTS: Adverse effects are usually due to excessive dose. If the following occur, discontinue and reinstitute at a lower dose: tachycardia, cardiac arrhythmias, tremors, diarrhea, weight loss, and fever.

PHARMACOLOGY: Onset of action—PO: 3 to 5 days; IV: 6 to 8 hours. Maximum effect occurs in 4 to 6 weeks. Protein binding >99%.

LIDOCAINE (XYLOCAINE, OTHERS)

INDICATIONS AND USE: IV lidocaine is used almost exclusively for the short-term control of ventricular arrhythmias (premature beats, tachycardia, and fibrillation) or for prophylactic treatment of such arrhythmias. Also used as a local anesthetic or for the treatment of severe recurrent or prolonged seizures that fail to respond to first-line therapies.

ACTIONS: Class IB antiarrhythmic agent; suppresses spontaneous depolarization of the ventricles during diastole by a direct action on the tissues; blocks both the initiation and conduction of nerve impulses by decreasing the neuronal membrane's permeability to sodium ions; inhibits depolarization and results in blockade of conduction.

DOSAGE: IV, ETT.

Antiarrhythmic:

- **Initial:** 0.5 to 1 mg/kg/dose as IV bolus over 5 minutes. May repeat dose every 10 minutes as necessary to control arrhythmia; maximum total bolus dose is 5 mg/kg.
- **Maintenance IV infusion:** 10 to 50 mcg/kg/min. Use lowest possible dose for preterm infants.
- **Endotracheal:** 2 to 3 mg/kg; flush with 5 mL of normal saline and follow with 5 assisted manual ventilations.

Anticonvulsant in term, normothermic neonates:

- **Loading dose** of 2 mg/kg IV over 10 minutes, immediately followed by
- **Maintenance infusion** of 6 mg/kg/h for 6 hours, then 4 mg/kg/h for 12 hours, then 2 mg/kg/h for 12 hours.

ADVERSE EFFECTS: Drowsiness, dizziness, tremulousness, paresthesias, muscle twitching, seizures, and coma; respiratory depression and/or arrest. Hypotension and heart block can occur.

PHARMACOLOGY: Onset of action 1 to 2 minutes after IV bolus; half-life in neonates is 3 hours; primarily metabolized by the liver.

COMMENTS: Therapeutic levels: 1.5 to 5 mcg/mL; toxic levels >6 mcg/mL. Adjust dosage in liver failure. Contraindicated in sinoatrial or atrioventricular nodal block and Wolff-Parkinson-White syndrome. Avoid using with epinephrine.

LIDOCAINE/PRILOCAINE CREAM (EMLA)

INDICATIONS AND USE: Topical anesthetic for use on intact skin for minor procedures such as insertion of intravenous catheters, venipuncture, and lumbar puncture in infants ≥ 37 weeks' gestational age.

ACTIONS: EMLA (eutectic mixture of local anesthetics) contains 2 local anesthetics: lidocaine and prilocaine. Local anesthetics inhibit conduction of nerve impulses from sensory nerves by changing the cell membrane's permeability to ions.

DOSAGE: Topical.

Maximum EMLA dose, application area, and application time:

- **0 to 3 months or <5 kg:** Maximum 1 g over 10 cm² for 1 hour.
- **3 to 12 months and >5 kg:** Maximum 2 g over 20 cm² for 4 hours.
- **1 to 6 years and >10 kg:** Maximum 10 g over 100 cm² for 4 hours.

ADVERSE EFFECTS: Not for use on mucous membranes or for ophthalmic use. May cause methemoglobinemia. Not for use in infants <37 weeks' gestational age or infants <12 months old receiving concurrent methemoglobin-inducing agents (sulfonamides, acetaminophen, nitroprusside, nitric oxide, phenobarbital, phenytoin). Reduce amounts if infant has hepatic and/or renal dysfunction.

COMMENT: Do not rub into skin; cover with occlusive dressing.

LINEZOLID (ZYVOX)

ACTIONS AND SPECTRUM: Oxazolidinone agent for treatment of pneumonia; complicated and uncomplicated skin and soft tissue infections; bacteremia caused by susceptible vancomycin-resistant *Enterococcus faecium* (VREF), *Enterococcus faecalis*, *Streptococcus pneumoniae* including multidrug-resistant strains, *Staphylococcus aureus* including methicillin-resistant *S aureus* (MRSA), *Streptococcus pyogenes*, or *Streptococcus agalactiae*. **Note:** There have been reports of VREF and MRSA developing resistance to linezolid during its clinical use.

DOSAGE: PO, IV.

Neonates 0 to 4 weeks and <1.2 kg:

- **PO, IV:** 10 mg/kg/dose every 8 to 12 hours. (**Note:** Use every 12 hours in patients <34 weeks' gestation and <1 week of age.)

Neonates <7 days and ≥1.2 kg:

- **PO, IV:** 10 mg/kg/dose every 8 to 12 hours. (**Note:** Use every 12 hours in patients <34 weeks' gestation and <1 week of age.)

Neonates ≥7 days and ≥1.2 kg (infants and children):

- **PO, IV:** 10 mg/kg/dose every 8 hours.

Complicated skin and skin structure infections and nosocomial or community-acquired pneumonia including concurrent bacteremia: Treat for 10 to 14 days.

VREF: Treat for 14 to 28 days.

ADVERSE EFFECTS: Thrombocytopenia, anemia, leukopenia, and pancytopenia have been reported in patients receiving linezolid—may be dependent on duration of therapy (generally >2 weeks of treatment); monitor patient's complete blood cell count weekly during linezolid therapy; discontinuation of therapy may be required in patients who develop or have worsening myelosuppression. *Clostridium difficile*-associated colitis has been reported; fluid and electrolyte management, protein supplementation, antibiotic treatment, and surgical evaluation may be indicated. Peripheral and optic neuropathy with vision loss has been reported primarily in patients treated for >28 days with linezolid. Cases of lactic acidosis in which patients experienced repeated episodes of nausea and vomiting, acidosis, and low bicarbonate levels have been reported. Elevated transaminases, rash, and diarrhea.

PHARMACOLOGY: Orally well absorbed; low protein binding; metabolized in the liver.

COMMENTS: Therapeutic linezolid concentrations inconsistently achieved in the CSF of pediatric patients with ventriculoperitoneal shunts; not recommended for the empiric treatment of pediatric CNS infections. Not approved for the treatment of catheter-related bloodstream, catheter-site, or gram-negative infections. Linezolid is a reversible, nonselective inhibitor of monoamine oxidase: enhanced vasopressor effects if used with sympathomimetic agents such as dopamine, epinephrine; myelosuppressive drugs (may increase risk of myelosuppression with linezolid).

LORAZEPAM (ATIVAN)

INDICATIONS AND USE: Treatment of status epilepticus resistant to conventional anticonvulsant therapy; sedation.

ACTIONS: A benzodiazepine that binds to the γ -aminobutyric acid (GABA) receptor complex and facilitates the inhibitory effect of GABA on the CNS.

DOSAGE: IV.

Status epilepticus:

- **Neonates:** 0.05 mg/kg/dose IV over 2 to 5 minutes. If no response after 10 to 15 minutes, repeat the dose; dilute with an equal volume of sterile water, normal saline (NS), or 5% dextrose in water (D5W).
- **Infants and children:** 0.05 to 0.1 mg/kg slow IV over 2 to 5 minutes; do not exceed 4 mg per single dose; may repeat second dose of 0.05 mg/kg slow IV in 10 to 15 minutes if needed; dilute with an equal volume of sterile water, NS, or D5W.

Sedation, anxiety:

- 0.02 to 0.1 mg/kg/dose IV or PO every 4 to 8 hours as needed; not to exceed 2 mg/dose.

ADVERSE EFFECTS: May cause respiratory depression, apnea, hypotension, bradycardia, cardiac arrest, and seizure-like activity. Paradoxical CNS stimulation may occur, usually early in

therapy. Some preterm infants may exhibit myoclonic activity; discontinue if any CNS effect occurs. Overdose may be reversed using flumazenil (Romazicon), 5 to 10 mcg/kg/dose IV. Reversal agent may trigger seizures.

COMMENTS: *Note:* IV preparations contain benzyl alcohol, propylene glycol, and polyethylene glycol. Contraindicated for infants with preexisting CNS, hepatic, or renal disease.

MAGNESIUM SULFATE

INDICATIONS AND USE: Treatment and prevention of hypomagnesemia and refractory hypocalcemia.

ACTIONS: Magnesium is an important cofactor in many enzymatic reactions. In the CNS, magnesium prevents or controls seizures by blocking neuromuscular transmission and decreasing the amount of acetylcholine liberated. It also has a depressant effect on the CNS. In the heart, magnesium acts as a calcium channel blocker and acts on cardiac muscle to slow sinoatrial nodal impulse formation and prolong conduction time. Magnesium is necessary for the maintenance of serum potassium and calcium levels through its effect on the renal tubule.

DOSAGE: IV, IM (1 g of magnesium sulfate = 98.6 mg elemental magnesium = 8.12 mEq magnesium).

Hypomagnesemia:

- **Neonates:** 25 to 50 mg/kg/dose (0.2–0.4 mEq/kg/dose) IV every 8 to 12 hours for 2 to 3 doses until magnesium level is normal or symptoms resolve.
- **Maintenance:** 0.25 to 0.5 mEq/kg every 24 hours IV (add to infusion or give IV).
- **Children:** 25 to 50 mg/kg/dose (0.2–0.4 mEq/kg/dose) IM/IV every 4 to 6 hours for 3 to 4 doses; maximum single dose 2000 mg (16 mEq).

ADVERSE EFFECTS: Primarily related to magnesium serum level; hypotension, bradycardia, flushing, depression of reflexes, depressed cardiac function, and CNS and respiratory depression.

COMMENTS: Contraindicated in renal failure. Monitor serum magnesium, calcium, and phosphate levels. For intermittent infusion: dilute to a concentration of 0.5 mEq/mL (60 mg/mL) of magnesium sulfate; maximum concentration 1.6 mEq/mL (200 mg/mL) of magnesium sulfate; infuse magnesium sulfate over 2 to 4 hours and do not exceed 1 mEq/kg/h.

MEROPENEM (MERREM IV)

ACTIONS AND SPECTRUM: Broad-spectrum carbapenem that penetrates well into CSF and most body tissues; specifically active against pneumococcal and *Pseudomonas* meningitis, extended-spectrum β -lactamase-producing *Klebsiella pneumoniae*. Treatment of serious infections caused by multidrug-resistant gram-negative organisms and gram-positive aerobic and anaerobic pathogens susceptible to meropenem.

DOSAGE: IV.

Neonatal sepsis:

- **Gestational age <32 weeks and \leq 14 days postnatal:** 20 mg/kg/dose IV every 12 hours; >14 days postnatal, dosing interval is every 8 hours.
- **Gestational age \geq 32 weeks and \leq 7 days postnatal:** 20 mg/kg/dose IV every 12 hours; >7 days postnatal, dosing interval is every 8 hours.

Neonatal meningitis caused by *Pseudomonas* species:

- **All ages:** 40 mg/kg/dose IV every 8 hours.

Children \geq 3 months:

- **Complicated skin and skin structure infection:** 10 mg/kg/dose IV every 8 hours; maximum dose 500 mg.
- **Intra-abdominal infection:** 20 mg/kg/dose IV every 8 hours; maximum dose 1 g.
- **Meningitis:** 40 mg/kg/dose IV every 8 hours; maximum dose 2 g.

ADVERSE EFFECTS: Gastrointestinal effects such as diarrhea, vomiting, and rarely pseudomembranous colitis; fungal infections are a risk. Thrombocytosis and eosinophilia have been noted. Monitoring liver enzymes is recommended. Some cautionary reports have noted seizure-like episodes in a few preterm infants.

COMMENT: Serum half-life of meropenem is relatively short in infants (≤ 3 hours).

METHADONE HCL (DOLOPHINE)

WARNING: Deaths have been reported during initiation of methadone treatment for opioid dependence. Respiratory depression is the chief hazard associated with methadone hydrochloride administration. Cases of QT interval prolongation and serious arrhythmia (torsade de pointes) have been observed.

INDICATIONS AND USE: Long-acting narcotic analgesic used for the treatment of neonatal abstinence syndrome and opioid dependence.

ACTIONS: CNS opiate receptor agonist resulting in analgesia and sedation; produces generalized CNS depression.

DOSAGE: PO, IV.

Neonatal abstinence syndrome:

- 0.05 to 0.2 mg/kg/dose PO/IV every 12 to 24 hours or 0.5 mg/kg/day divided every 8 hours. Individualize dose and tapering schedule to control symptoms of withdrawal; usually taper dose by 10% to 20% per week over 1 to 1.5 months. **Note:** Due to long elimination half-life, tapering is difficult; consider alternate agent like morphine.

ADVERSE EFFECTS: Respiratory depression, gastric residuals, abdominal distension, constipation, hypotension, bradycardia, prolongation of QT interval, torsade de pointes, CNS depression, sedation, increased intracranial pressure, urinary tract spasm, urine retention, biliary tract spasm, and dependence with prolonged use.

COMMENTS: **Caution:** Methadone may accumulate; reassess for the need to adjust the dose downward after 3 to 5 days to avoid overdose. Smaller doses or less frequent administration may be required in renal and hepatic dysfunction. Rifampin and phenytoin increase metabolism of methadone and may precipitate withdrawal symptoms. Methadone 10 mg IM = morphine 10 mg IM.

METOCLOPRAMIDE HCL (REGLAN)

WARNING: Tardive dyskinesia may occur with metoclopramide use, and the risk increases with duration of treatment and total cumulative dose. Discontinue therapy immediately in patients who develop signs and symptoms of tardive dyskinesia. Symptoms may improve or resolve after drug is discontinued. Avoid treatment with metoclopramide for longer than 12 weeks due to increased risk of developing tardive dyskinesia.

INDICATIONS AND USE: In neonates and infants, the drug is used to facilitate gastric emptying and gastrointestinal (GI) motility. May improve feeding intolerance and gastroesophageal reflux.

ACTIONS: Dopamine receptor antagonist acting on the CNS. Metoclopramide improves GI motility by releasing acetylcholine from the myenteric plexus, resulting in contraction of the smooth muscle. Metoclopramide's effects on the GI tract include the following: increased resting esophageal sphincter tone, improved gastric tone and peristalsis, relaxed pyloric sphincter, and augmented duodenal peristalsis, which leads to increased gastric emptying and a decrease in the transit time through the duodenum, jejunum, and ileum.

DOSAGE: PO, IM, IV.

Gastroesophageal reflux:

- **Neonates:** 0.1 to 0.15 mg/kg/dose PO/IM/IV every 6 hours, 30 minutes before feedings.
- **Infants and children:** 0.4 to 0.8 mg/kg/day PO/IM/IV divided into 4 doses.

ADVERSE EFFECTS: CNS effects include restlessness, drowsiness, and fatigue. Extrapyramidal reactions may occur, generally manifested as acute dystonic reactions within the initial 24 to 48 hours of use (increased with higher doses). May cause tardive dyskinesia, which is often irreversible; duration of treatment and total cumulative dose are associated with an increased risk.

COMMENTS: Therapy durations >12 weeks should be avoided (except in rare cases where benefit exceeds risk). Contraindicated with bowel obstruction and seizure disorders.

METRONIDAZOLE (FLAGYL)

ACTION AND SPECTRUM: Treatment of meningitis, ventriculitis, and endocarditis due to *Bacteroides fragilis* and other anaerobes that are resistant to penicillin; serious intra-abdominal infections; treatment of *Clostridium difficile* colitis.

DOSAGE: PO, IV.

Neonates, susceptible infections:

- **Loading dose:** 15 mg/kg
- **Maintenance dose:**
 - ≤ 2 kg:
 - PNA ≤ 28 days: 7.5 mg/kg/dose every 12 hours.
 - PNA 29 to 60 days: 10 mg/kg/dose every 8 hours.
 - > 2 kg:
 - PNA ≤ 7 days: 7.5 mg/kg/dose every 8 hours.
 - PNA ≥ 8 days: 10 mg/kg/dose every 8 hours.

Infants and children:

- **Anaerobic infections:** 30 mg/kg/day PO/IV in divided doses every 6 hours; maximum dose 4 g/day.
- **C difficile diarrhea:** 30 mg/kg/day PO divided every 6 hours for at least 10 days; do not exceed 2 g/day.

ADVERSE EFFECTS: Occasional vomiting, diarrhea, insomnia, irritability, seizures, rash, discoloration of urine (dark or reddish brown), phlebitis at the injection site, and (rarely) leukopenia.

PHARMACOLOGY: Hepatic metabolism with final excretion via the urine and feces. Large volume of distribution (penetrates into all body tissues and fluids).

COMMENTS: Effectively penetrates the CSF (indicated for meningitis). **Note:** Some centers use metronidazole for empiric coverage with ampicillin and gentamicin for necrotizing enterocolitis (NEC). Use of metronidazole in NEC remains *controversial*.

MICAFUNGIN (MYCAMINE)

ACTION AND SPECTRUM: Treatment of fungal septicemia, peritonitis, and disseminated infections due to *Candida* species, including *Candida albicans* and non-albicans species—*Candida krusei*, *Candida glabrata*, *Candida tropicalis*, and *Candida parapsilosis*.

DOSAGE: IV.

Neonates:

- < 1 kg: 10 mg/kg/dose every 24 hours; doses as high as 15 mg/kg/dose have been used in extremely low birthweight neonates.
- ≥ 1 kg: 7 mg/kg/dose every 24 hours.

Infants and children:

- 2 to 4 mg/kg/dose every 24 hours.

ADVERSE EFFECTS: Limited data in neonates; in adults—vomiting, diarrhea, hypokalemia, thrombocytopenia.

PHARMACOLOGY: Echinocandin agent with broad-spectrum fungicidal activity. The volume of distribution in extremely premature infants is very high; therefore, higher doses are required. Highly protein bound to albumin but does not displace bilirubin. Metabolized in the liver.

COMMENTS: Infuse over at least 1 hour. Not FDA approved for use in children, and data are limited.

MIDAZOLAM HCL (VERSED)

WARNING: Intravenous midazolam has been associated with respiratory depression and respiratory arrest, especially when used for sedation in noncritical care settings. In some cases where this was not recognized promptly and treated effectively, death or hypoxic encephalopathy has resulted.

INDICATIONS AND USE: Anxiolytic and antiepileptic agent. Used as a sedative before procedures and given IV continuously to sedate intubated patients.

ACTIONS: Short-acting benzodiazepine; depresses CNS by binding to the benzodiazepine site on the γ -aminobutyric acid (GABA) receptor complex and increasing GABA, which is a major inhibitory neurotransmitter in the brain.

DOSAGE: IM, IV, PO, intranasal, sublingual.

Intermittent:

- 0.05 to 0.15 mg/kg/dose IV/IM over at least 5 minutes every 2 to 4 hours as needed.

Continuous infusion:

- <32 weeks: Initial 0.03 mg/kg/h (0.5 mcg/kg/min).
- >32 weeks: Initial 0.06 mg/kg/h (1 mcg/kg/min).
- **Dosage ranges from 0.01 to 0.06 mg/kg/h.** May need to increase dose after several days due to tolerance or increased clearance. **Note:** Do not use IV loading doses in neonates; for faster sedation effect, infuse the continuous infusion at a faster rate for the first several hours; use the smallest dose possible.

Antiepileptic:

- **Loading dose:** 0.06 to 0.15 mg/kg/dose IV followed by a continuous infusion of 0.06 to 0.4 mg/kg/h (1–7 mcg/kg/min). Start with lower end of dosing range.

Oral sedation:

- 0.25 to 0.5 mg/kg/dose using oral syrup.

Intranasal:

- 0.2 to 0.3 mg/kg/dose using 5-mg/mL injectable form; may repeat in 5 to 15 minutes.

Sublingual:

- 0.2 mg/kg/dose using 5-mg/mL injectable form mixed with small amount of flavored syrup.

ADVERSE EFFECTS: Respiratory depression and cardiac arrest with excessive doses or rapid IV infusions. May cause hypotension and bradycardia. Myoclonic activity and other seizure-like activity have been reported in preterm infants.

COMMENT: Infuse IV slowly. Benzodiazepine withdrawal may occur if abruptly discontinued in patients receiving prolonged IV continuous infusions; doses should be tapered slowly with prolonged use. Contraindicated if preexisting CNS depression.

MILRINONE (PRIMACOR)

INDICATIONS AND USE: Short-term (<72 hours) treatment of acute low cardiac output due to septic shock or following cardiac surgery.

ACTIONS AND SPECTRUM: Inhibits phosphodiesterase III (PDE III), which increases cyclic adenosine monophosphate and potentiates the delivery of calcium to myocardial contractile systems; results in a positive inotropic effect. Inhibition of PDE III in vascular tissue results in relaxation of vascular muscle and vasodilatation. Unlike catecholamines, milrinone does not increase myocardial oxygen consumption.

DOSAGE: IV, intraosseous.

Neonates, infants, and children: A limited number of studies have used different dosing schemes. Further pharmacodynamic studies are needed to define pediatric milrinone guidelines. Several centers use the following guidelines:

- **Loading dose:** 50 mcg/kg over 15 minutes followed by a continuous infusion of 0.5 mcg/kg/min; range: 0.25 to 0.75 mcg/kg/min; titrate to effect.
- **IV, IO (Pediatric Advanced Life Support Guidelines, 2019):** Loading dose 50 mcg/kg over 10 to 60 minutes followed by a continuous infusion of 0.25 to 0.75 mcg/kg/min; titrate dose to effect.

ADVERSE EFFECTS: Hypokalemia, thrombocytopenia, abnormal liver function tests, ventricular arrhythmias, and hypotension.

PHARMACOLOGY: Excreted in urine as unchanged drug (83%) and glucuronide metabolite (12%). With renal impairment, half-life is prolonged and clearance is decreased.

COMMENTS: Use with caution and modify dosage in patients with impaired renal function; adequate intravascular volume is necessary prior to initiating therapy. Omit bolus dose to reduce risk of hypotension.

MORPHINE SULFATE (VARIOUS)

INDICATIONS AND USE: Analgesia, preoperative sedation, supplement to anesthesia, treatment of opioid withdrawal, and relief of dyspnea associated with pulmonary edema.

ACTIONS: A pure opioid agonist, selective to the μ -receptor in the CNS. The interaction with these opioid receptors results in effects that mimic the actions of enkephalins, β -endorphin, and other exogenous ligands.

DOSAGE: IM, IV, PO, subcutaneous.

Neonates (use preservative-free form):

- **Initial:** 0.05 mg/kg IM, IV, subcutaneous every 4 to 8 hours; titrate carefully to effect; maximum dose 0.1 mg/kg/dose.
- **Continuous infusion:** Initial: 0.01 mg/kg/h (10 mcg/kg/h); do not exceed infusion rates of 0.015 to 0.02 mg/kg/h due to decreased elimination, increased CNS sensitivity, and adverse effects; may need to use slightly higher doses, especially in neonates who develop tolerance.
- **International evidence-based group for neonatal pain recommendations (Anand et al, 2001):**
 - **Intermittent dose:** 0.05 to 0.1 mg/kg/dose.
 - **Continuous infusion:** Range: 0.01 to 0.03 mg/kg/h.
 - **Neonatal narcotic abstinence:** 0.03 to 0.1 mg/kg/dose PO every 3 to 4 hours. Taper dose by 10% to 20% every 2 to 3 days based on abstinence scoring.

Infants and children:

- **Oral:** 0.2 to 0.5 mg/kg/dose every 4 to 6 hours as needed.

ADVERSE EFFECTS: Dose-dependent side effects include miosis, respiratory depression, drowsiness, bradycardia, and hypotension. Constipation, sedation, gastrointestinal upset, urinary retention, histamine release, and sweating may occur. Causes physiologic dependence; taper the dose gradually after long-term use to avoid withdrawal.

PHARMACOLOGY: Metabolized in the liver via glucuronide conjugation to morphine-6-glucuronide (active) and morphine-3-glucuronide (inactive). Morphine is 20% to 40% bioavailable when administered orally. Metabolites are renally excreted.

COMMENTS: When changing routes of administration in chronically treated patients, oral doses are approximately 3 to 5 times the parenteral dose.

MOXIFLOXACIN OPHTHALMIC

See Chapter 58.

MUPIROCIN (BACTROBAN)

INDICATIONS AND USE: Topical treatment of impetigo resulting from *Staphylococcus aureus* (including methicillin-resistant strains), β -hemolytic *Streptococcus*, and *Streptococcus pyogenes*. Used for minor bacterial skin infections resulting from susceptible organisms and eradication of *S aureus* from nasal and perineal carriage sites.

ACTIONS: Inhibits protein and RNA synthesis by binding to bacterial isoleucyl-tRNA synthetase.

DOSAGE: Intranasal, topical.

Intranasal:

- Apply sparingly 2 to 3 times a day for 5 to 14 days. Reevaluate in 5 days if no response.

Topical:

- **Cream:** Apply small amount 3 times a day for 10 days.
- **Ointment:** Apply a small amount 3 to 5 times a day for 5 to 14 days.

ADVERSE EFFECTS: Burning, rash, erythema, and pruritus.

COMMENTS: Use with caution in burn patients and patients with impaired renal function. Avoid contact with eyes; not for ophthalmic use. When applied to extensive open wounds or burns, the possibility of absorption of the polyethylene glycol vehicle, resulting in serious renal toxicity, should be considered.

NAFCILLIN SODIUM

ACTION AND SPECTRUM: Semisynthetic penicillinase-resistant penicillin with bactericidal activity against susceptible bacteria; treatment of bacterial infections such as osteomyelitis, septicemia, endocarditis, and CNS infections due to susceptible penicillinase-producing strains of *Staphylococcus*.

DOSAGE: IM, IV. Consider higher doses when treating CNS infections.

Neonates:

- **0 to 14 days and <1 kg:** 50 mg/kg/day IM/IV in divided doses every 12 hours.
- **≤7 days:**
 - **1 to 2 kg:** 50 mg/kg/day IM/IV in divided doses every 12 hours.
 - **>2 kg:** 75 mg/kg/day IM/IV in divided doses every 8 hours.
- **>7 days:**
 - **1 to 2 kg:** 75 mg/kg/day IM/IV in divided doses every 8 hours.
 - **>2 kg:** 100 mg/kg/day IM/IV in divided doses every 6 hours.

Meningitis:

- **0 to 7 days:** 75 mg/kg/day IM/IV in divided doses every 8 to 12 hours.
- **>7 days:** 100 to 150 mg/kg/day in divided doses every 6 to 8 hours.

Infants and children:

- **Mild to moderate infections:** 100 to 150 mg/kg/day IM/IV in divided doses every 6 hours; maximum dose 4 g/day.
- **Severe infections:** 150 to 200 mg/kg/day IM/IV in divided doses every 4 to 6 hours; maximum dose 12 g/day.

ADVERSE EFFECTS: Thrombophlebitis, hypersensitivity, granulocytopenia, and agranulocytosis. Severe tissue injury after IV extravasation.

PHARMACOLOGY: Hepatic metabolism, undergoes enterohepatic recirculation; concentrated in bile. Has better CNS penetration than methicillin.

COMMENTS: Avoid IM use if possible.

NALOXONE HCL (EVIZIO, NARCAN)

INDICATIONS AND USE: Narcotic antagonist that reverses CNS and respiratory depression in suspected narcotic overdose; neonatal opiate depression.

ACTIONS: An opiate antagonist that competes with and displaces narcotics at narcotic receptor sites. It has little to no agonistic activity.

DOSAGE: IV. May be given IM if perfusion is adequate. Also ETT, intranasal.

Opioid intoxication:

- **Usual dose:** 0.1 mg/kg IV/IO and may repeat every 2 to 3 minutes as needed; repeat doses may be required every 20 to 60 minutes if duration of action of narcotic is longer than naloxone.
- **ETT:** Optimal dose unknown; current recommendation is 2 to 3 times the IV dose.
- **IM:** 0.4 mg as a single dose, may repeat every 2 to 3 minutes as needed; absorption may be delayed or erratic.
- **Intranasal:** 4 mg nasal spray as a single dose, may repeat every 2 to 3 minutes in alternating nostrils as needed; absorption may be delayed or erratic.

Alternative dosing to reverse opioid-induced depression: 0.01 mg/kg and repeat every 2 to 3 minutes as needed.

ADVERSE EFFECTS: Hypertension, hypotension, tachycardia, ventricular arrhythmias, hyperreflexia, withdrawal syndrome, seizure, and excessive crying.

PHARMACOLOGY: Onset of action is within 1 to 2 minutes after IV injection, 2 to 5 minutes after IM injection, and 8 to 15 minutes after intranasal inhalation. Duration of action is generally 30 to 60 minutes. Bioavailability of intranasal naloxone is only 43 to 54% when compared to IM route.

COMMENTS: Avoid use in infants of narcotic-addicted mothers and infants with physical dependence to opiates (may precipitate acute withdrawal syndrome). IV/IO administration preferred to allow dosing according to weight and titration to effect. Infants must be monitored for reappearance of respiratory depression and the need for repeated doses. Naloxone is not recommended as part of initial resuscitation in the delivery room for newborns with respiratory depression.

NEOMYCIN OPHTHALMIC

See Chapter 58.

NEOMYCIN SULFATE

ACTION AND SPECTRUM: Aminoglycoside indicated in the treatment of diarrhea resulting from enteropathogenic *Escherichia coli* and as preoperative prophylaxis before intestinal surgery; an adjunct therapy in hepatic encephalopathy. Neomycin is inactive against anaerobic organisms.

DOSAGE: PO.

- 50 to 100 mg/kg/day PO divided every 6 to 8 hours.

ADVERSE EFFECTS: Diarrhea, colitis, and malabsorption; nephrotoxicity and ototoxicity.

PHARMACOLOGY: Renal excretion if systemic absorption occurs. Poorly absorbed from the gastrointestinal tract if administered orally; 97% of unchanged drug in the feces.

NEOSTIGMINE METHYLSULFATE (BLOXIVERZ)

INDICATIONS AND USE: Improvement of muscle strength in the treatment of myasthenia gravis; may be used to reverse nondepolarizing neuromuscular-blocking agents.

ACTIONS: Neostigmine competitively inhibits hydrolysis of acetylcholine by acetylcholinesterase, facilitating transmission of impulses across the myoneural junction and producing cholinergic activity.

DOSAGE: IV, IM, subcutaneous.

Myasthenia gravis:

- **Diagnostic testing:** 0.025 to 0.04 mg/kg/dose IM once. (Discontinue all cholinesterase medications at least 8 hours before; atropine should be administered IV immediately prior to or IM 30 minutes before neostigmine.)
- **Treatment:** 0.01 to 0.04 mg/kg/dose IM, IV, or subcutaneous every 2 to 6 hours as needed or 1 mg PO given 2 hours prior to feeding.

Reversal of nondepolarizing neuromuscular blockade:

- 0.03 to 0.07 mg/kg/dose; recommend lower dose for agents with shorter half-lives and higher dose for agents with lower half-lives. (Use with atropine: 0.01 to 0.04 mg/kg, or 0.4 mg of atropine for each 1 mg of neostigmine.)

ADVERSE EFFECTS: Cholinergic crisis, which may include bronchospasm, increased bronchial secretions and salivation, vomiting, diarrhea, bradycardia, respiratory depression, and seizures.

COMMENTS: Does not antagonize and may prolong the phase I block of depolarizing muscle.

NEVIRAPINE (VIRAMUNE)

WARNING: Reports of fatal hepatotoxicity even after short-term use; severe life-threatening skin reactions (Stevens-Johnson, toxic epidermal necrolysis, and allergic reactions); monitor closely during first 8 weeks of treatment.

ACTION AND SPECTRUM: Nonnucleoside antiretroviral agent that inhibits human immunodeficiency virus (HIV) type 1 replication by selectively interfering with viral reverse transcriptase. Acts synergistically with zidovudine. Used for the prevention of maternal-fetal HIV transmission and HIV treatment. FDA approved in ages ≥ 15 days, although recommended as preferred agent in infants from birth to 14 days of age per guidelines.

DOSAGE: PO (based on aidsinfo.nih.gov/guidelines, 2019).

Prevention of maternal-fetal HIV transmission:

- **Three doses given in the first week of life as follows:** First dose within 48 hours of birth, second dose 48 hours after first dose, and third dose 96 hours after second dose. Give in combination with **zidovudine**. Used in select situations such as infants born to HIV-infected mothers with no antiretroviral therapy prior to labor or during labor; infants born to mothers with only intrapartum therapy; infants born to mothers with suboptimal viral suppression at delivery; or infants born to mothers with known antiretroviral drug-resistant virus.

- **Birthweight 1.5 to 2 kg:** 8 mg/dose PO.
- **Birthweight >2 kg:** 12 mg/dose PO.

Treatment of HIV infection (in combination with other antiretroviral agents): Consultation with infectious disease expert is recommended.

ADVERSE EFFECTS: Limited data in neonates; rash, elevated liver enzymes, hepatotoxicity, liver failure, cholestatic hepatitis, hepatic necrosis, jaundice.

PHARMACOLOGY: Metabolized by cytochrome P450 isoenzymes 3A4 and 2B6 and has potential for drug interactions; more rapidly metabolized in pediatric patients. It does not require intracellular phosphorylation for antiviral activity.

COMMENTS: Please note manufacturers' Black Box warning regarding severe life-threatening and fatal skin reactions and hepatotoxicity. If administering with a dosing cup, rinse cup with water and also administer rinse.

NICARDIPINE (CARDENE IV)

INDICATIONS AND USE: Short-term treatment of severe hypertension.

ACTIONS: Inhibits calcium ions from entering select voltage-sensitive channels in vascular smooth muscle and myocardium during depolarization; produces relaxation of coronary vascular smooth muscle and coronary vasodilatation.

DOSAGE: IV.

Neonates:

- **Initial dose:** 0.5 mcg/kg/min by continuous infusion. Titrate to desired response; blood pressure will decrease within minutes of starting infusion. Maintenance doses of 0.5 to 2 mcg/kg/min.

Infants and children:

- **Initial dose:** 0.5 to 1 mcg/kg/min by continuous infusion. Titrate increasing rate of infusion every 15 to 30 minutes to a maximum dose of 4 to 5 mcg/kg/min.

ADVERSE EFFECTS: Hypotension, tachycardia, peripheral edema, hypokalemia.

PHARMACOLOGY: Extensively metabolized by the liver and is highly protein bound. Experience in neonates is very limited, and there are no pharmacokinetic data.

COMMENTS: Use with caution in the presence of cardiac, renal, and hepatic disease.

NITRIC OXIDE (INOMAX FOR INHALATION; INHALED NITRIC OXIDE [iNO])

INDICATIONS AND USE: iNO is indicated for the treatment of term and near-term (≥ 34 weeks) neonates with hypoxic respiratory failure associated with clinical or echocardiographic evidence of persistent pulmonary hypertension of the newborn.

ACTIONS: iNO is a selective pulmonary vasodilator without significant effects on the systemic circulation that decreases extrapulmonary right-to-left shunting. Nitric oxide relaxes vascular smooth muscle by binding to the heme moiety of cytosolic guanylate cyclase, activating guanylate cyclase, and increasing intracellular levels of cyclic guanosine 3'5'-monophosphate, which leads to vasodilation and an increase in the partial pressure of arterial oxygen.

DOSAGE: Inhalation.

Term infants or >34 weeks' gestation:

- **Begin at 20 ppm.** Reduce dose to lowest possible level. Doses >20 ppm are usually not used due to increased risk of methemoglobinemia and elevated nitric dioxide (NO_2). Maintain treatment up to 14 days or until the underlying oxygen desaturation has resolved and the infant is ready to be weaned from iNO. Abrupt discontinuation may lead to worsening hypotension, oxygenation, and increasing pulmonary artery pressure; clinical trials suggest weaning by 5 to 10 ppm every 4 hours until the patient is stable at 5 ppm, then decreasing by 1 ppm every 4 hours until discontinued. Further diagnostic testing should be sought for infants who are unable to be weaned off iNO after 4 days of therapy.

ADVERSE EFFECTS: Do not use in neonates dependent on right-to-left shunting of blood. Direct pulmonary injury from excess levels of NO_2 and ambient air contamination may occur. May cause methemoglobinemia and elevated NO_2 . Risk of adverse effects increases when iNO is given

at doses >20 ppm. Conflicting data have been published on whether or not iNO inhibits platelet aggregation and prolongs bleeding time. Monitor methemoglobin levels, iNO, NO₂, and oxygen levels. iNO therapy should be directed by physicians qualified by education and experience in its use and offered only at centers that are qualified to provide multisystem support, generally including on-site ECLS capability or with a collaborating ECLS center. Consult the manufacturer's product literature and specialized references for complete information on the use of iNO.

NITROPRUSSIDE SODIUM (NIPRIDE RTU, NITROPRESS)

WARNING: Nitroprusside is not suitable for direct injection and must be further diluted in sterile 5% dextrose in water (D5W) before infusion. Nitroprusside can cause precipitous decreases in blood pressure. In patients not properly monitored, these decreases can lead to irreversible ischemic injuries or death. Nitroprusside can give rise to cyanide ion, which can reach toxic, potentially lethal levels. If blood pressure has not been adequately controlled after 10 minutes of infusion at the maximum rate, stop the infusion. Review package insert before administration.

INDICATIONS AND USE: Severe hypertension and hypertension crisis; acute reduction of afterload in patients with refractory congestive heart failure.

ACTIONS: Direct-acting vasodilator (arterial and venous) that reduces peripheral vascular resistance (afterload). Venous return is reduced (preload); increases cardiac output by decreasing afterload.

DOSAGE: IV. Infuse through a large vein.

- **Initial:** 0.25 to 0.5 mcg/kg/min; titrate dose every 20 minutes to the desired response.
- **Usual dose:** 3 mcg/kg/min; rarely need >4 mcg/kg/min; maximum dose 8 to 10 mcg/kg/min.

ADVERSE EFFECTS: Generally related to a very rapid reduction in blood pressure. Thiocyanate may accumulate, especially in patients receiving high doses or those who have impaired renal function. Cyanide toxicity can develop abruptly if large doses are administered rapidly. Cyanide causes early persistent acidosis. Thiocyanate toxicity appears at plasma levels of approximately 35 to 100 mcg/mL; levels >200 mcg/mL are associated with death. Thiocyanate levels should be monitored in any patient receiving ≥ 3 mcg/kg/min of nitroprusside or prolonged infusion (>3 days), especially those with renal impairment. Toxicity is treated with IV sodium thiosulfate.

PHARMACOLOGY: Acts within seconds to lower blood pressure; when discontinued, the effect dissipates within minutes. Rapidly metabolized to thiocyanate, which is eliminated by the kidneys.

COMMENTS: Contraindicated with decreased cerebral perfusion, hypertension secondary to arteriovenous shunts, or coarctation of the aorta. May add sodium thiosulfate to infusion solution at a 10:1 ratio to minimize thiocyanate toxicity; however, this has not been studied. Protect from light.

NOREPINEPHRINE BITARTRATE (LEVARTERENOL BITARTRATE) (LEVOPHED)

WARNING: Antidote for extravasation ischemia. To prevent sloughing and necrosis, the area should be infiltrated as soon as possible with saline solution containing phentolamine, an adrenergic blocking agent (see Comments).

INDICATIONS AND USE: Treatment of shock, which persists after adequate fluid volume replacement; severe hypotension; cardiogenic shock.

ACTIONS: Stimulates β_1 -adrenergic receptors and α -adrenergic receptors, causing increased contractility and heart rate as well as vasoconstriction, resulting in an increase in systemic blood pressure and coronary blood flow; clinically, α -adrenergic effects (vasoconstriction) are greater than β_1 -adrenergic effects (inotropic and chronotropic effects).

DOSAGE: IV.

- 0.02 to 0.1 mcg/kg/min initially, titrated to desired perfusion; maximum dose 2 mcg/kg/min.

ADVERSE EFFECTS: Respiratory distress, arrhythmias, bradycardia or tachycardia, hypertension, chest pain, headache, and vomiting. Organ ischemia (due to vasoconstriction of renal and mesenteric arteries).

COMMENTS: Ischemic necrosis may occur after extravasation. Administer phentolamine, 0.1 to 0.2 mg/kg subcutaneous, infiltrated into the area of extravasation within 12 hours to minimize damage. (See Chapter 42.)

NUSINERSEN (SPINRAZA)

INDICATIONS AND USE: Treatment of spinal muscular atrophy (SMA).

ACTIONS: Treats SMA caused by mutations in chromosome 5q that lead to survival motor neuron (SMN) protein deficiency by binding to a specific sequence in the mRNA transcript and increasing production of SMN protein.

DOSAGE: Intrathecal

- **Loading dose:** 12 mg once every 14 days for 3 doses; then 12 mg once 30 days after the third dose.
- **Maintenance dose:** 12 mg once every 4 months.

ADVERSE EFFECTS: Feeding difficulties, dysphagia, headache, back pain, constipation, otic infection, aspiration, severe dyspnea.

COMMENTS: Allow to warm to room temperature before use. Prior to administration, remove 5 mL of CSF. Administer as an intrathecal bolus injection over 1 to 3 minutes using spinal anesthesia needle; do not administer in areas with signs of infection or inflammation.

NYSTATIN

ACTION AND SPECTRUM: May be fungistatic or fungicidal, which acts by binding to sterols and disrupting fungal cell membranes. Treatment of susceptible cutaneous, mucocutaneous, and oral cavity fungal infections normally caused by the *Candida* species.

DOSAGE: PO, topical.

ORAL THRUSH:

- **Therapeutic:** Continue for 3 days after symptoms have resolved.
 - **Neonates:** 1 to 4 mL (100,000–400,000 units) divided to each side of the mouth 4 times a day after feedings.
 - **Infants:** 2 to 4 mL (100,000–400,000 units) divided to each side of mouth 4 times a day after feedings.
- **Prophylaxis:** 1 mL (100,000 units) divided to each side of mouth or 1 mL orally or via oral gavage tube 3 to 4 times a day.

Diaper rash:

- Topical cream/ointment/powder applied 3 to 4 times a day for 7 to 10 days.

ADVERSE EFFECTS: Side effects are uncommon but may cause diarrhea, local irritation, contact dermatitis, rash, pruritus, and Stevens-Johnson syndrome.

PHARMACOLOGY: Poorly absorbed orally. Most is passed unchanged in the stool.

OCTREOTIDE (SANDOSTATIN)

INDICATIONS AND USE: Short-term management of persistent hyperinsulinemic hypoglycemia of the newborn. Useful in the management of chylothorax. Chyle accumulation usually decreases after 24 hours of continuous infusion. Has also been used to treat hypersecretory diarrhea and fistulas in infants. Significant reductions in stool or ileal output were achieved with this drug.

ACTIONS: A synthetic polypeptide that mimics natural somatostatin by inhibiting serotonin release and the secretion of gastrin, vasoactive intestinal peptide, insulin, glucagon, secretin, motilin, thyrotropin, and cholecystokinin; reduces splanchnic blood flow, decreases gastrointestinal motility, and inhibits intestinal secretion of water and electrolytes.

DOSAGE: IV, subcutaneous.

Persistent hyperinsulinemic hypoglycemia of infancy:

- **Initial dose:** 2 to 10 mcg/kg/day subcutaneous divided every 6 to 8 hours; titrate based on response up to 40 mcg/kg/day divided every 6 to 8 hours. Adjust to maintain symptomatic control.

Diarrhea:

- 1 to 10 mcg/kg/dose IV/subcutaneous given every 12 hours. Adjust the dose to maintain symptomatic control.

Chylothorax:

- 0.5 to 4 mcg/kg/h IV continuous infusion; titrate dose to response; case reports of effective dosage ranging between 0.3 and 10 mcg/kg/h; treatment duration is usually 1 to 3 weeks but may vary with clinical response.

ADVERSE EFFECTS: Possible growth retardation during long-term treatment, flushing, hypertension, insomnia, fever, chills, seizures, Bell palsy, hair loss, bruising, rash, hypoglycemia, hyperglycemia, galactorrhea, hypothyroidism, diarrhea, abdominal distention, vomiting, constipation, hepatitis, jaundice, local injection site pain, thrombophlebitis, muscle weakness, increased creatine kinase, muscle spasm, tremor, oliguria, shortness of breath, and rhinorrhea.

PHARMACOLOGY: Duration of action (subcutaneous) is 6 to 12 hours with immediate-release formulation; excreted unchanged in the urine.

COMMENTS: Tachyphylaxis may occur.

OMEPRAZOLE (PRILOSEC)

INDICATIONS AND USE: Short-term (<8 weeks) treatment of reflux esophagitis, duodenal ulcer refractory to conventional therapy.

ACTIONS: Inhibits gastric acid secretion by inactivating the parietal cell membrane enzyme (H⁺/K⁺)-adenosine triphosphatase (ATPase) or proton pump.

DOSAGE: PO.

- **Neonates:** 0.5 to 1.5 mg/kg once daily in the morning.
- **1 month to 2 years:** 0.7 mg/kg once daily; increase to 3 mg/kg once daily if necessary (maximum dose 20 mg).

ADVERSE EFFECTS: Mild elevation of liver enzymes, diarrhea (*Clostridium difficile*-associated diarrhea), and increased risk of bone fractures (decreased bone mineral density).

PHARMACOLOGY: Cytochrome P450 isoenzyme CYP1A2 inducer; isoenzyme CYP2C8, CYP2C18, CYP2C19, and CYP3A3/4 substrate; isoenzyme CYP2C9, CYP3A3/4, CYP2C8, and CYP2C19 inhibitor. Maximum secretory inhibition is 4 days. Extensive first-pass metabolism in the liver. Bioavailability: 30% to 40%; improves slightly with repeated administration.

ADVERSE EFFECTS: Mild elevation of liver enzymes, diarrhea.

COMMENTS: Lack of data regarding the safety of long-term use in children. Oral delayed-release suspension available.

OPIUM TINCTURE

HIGH-ALERT MEDICATION: May also be confused with camphorated tincture of opium (Paregoric). Opium tincture is 25 times as potent as paregoric. Avoid the use of the abbreviation "DTO."

INDICATIONS AND USE: A 25-fold dilution with water (final concentration 0.4 mg/mL) can be used to treat neonatal abstinence syndrome (opiate withdrawal).

ACTIONS: Contains many narcotic alkaloids including morphine; inhibition of gastrointestinal (GI) motility due to morphine content; decreases digestive secretions; increases GI muscle tone.

DOSAGE: PO.

Neonates (full-term):

- **Neonatal abstinence syndrome (opiate withdrawal):** Use a 25-fold dilution with water of opium tincture (final concentration 0.4 mg/mL morphine).
- **Initial dose:** Give 0.04 mg/kg/dose of a 0.4 mg/mL solution with feedings every 3 to 4 hours; increase as needed by 0.04 mg/kg/dose of a 0.4 mg/mL solution every 3 to 4 hours until withdrawal symptoms are controlled.

- **Usual dose:** 0.08 to 0.2 mg/dose of a 0.4 mg/mL solution given every 3 to 4 hours; it is rare to exceed 0.28 mg/dose of a 0.4 mg/mL solution; stabilize withdrawal symptoms for 3 to 5 days, then gradually decrease the dosage (keeping the same dosage interval) over a 2- to 4-week period.

ADVERSE EFFECTS: Hypotension, bradycardia, peripheral vasodilation, CNS depression, drowsiness, sedation, urinary retention, constipation, respiratory depression, and histamine release.

PHARMACOLOGY: Metabolized in liver and eliminated in urine and bile.

COMMENTS: Observe for excessive sedation and respiratory depression. Do not abruptly discontinue. Monitor for the resolution of withdrawal symptoms (eg, irritability, high-pitched cry, stuffy nose, rhinorrhea, vomiting, poor feeding, diarrhea, sneezing, yawning) and signs of overtreatment (eg, bradycardia, lethargy, hypotonia, irregular respirations, respiratory depression). An abstinence scoring system (eg, Finnegan abstinence scoring system) should be used to more objectively assess neonatal opiate withdrawal symptoms and the need for dosage adjustment (see Chapter 102). Use 25-fold dilution with water for the treatment of neonatal abstinence syndrome.

OXACILLIN SODIUM

ACTION AND SPECTRUM: Semisynthetic penicillinase-resistant penicillin; bactericidal activity used for the treatment of bacterial infections such as osteomyelitis, septicemia, endocarditis, and CNS infections due to susceptible penicillinase-producing strains of *Staphylococcus*.

DOSAGE: IM, IV.

Neonates:

- **0 to 14 days and <1 kg:** 50 mg/kg/day IM/IV in divided doses every 12 hours.
- **>14 days and <1 kg:** 75 mg/kg/day IM/IV in divided doses every 8 hours.
- **≤7 days and 1 to 2 kg:** 50 mg/kg/day IM/IV in divided doses every 12 hours.
- **≤7 days and >2 kg:** 75 mg/kg/day IM/IV in divided doses every 8 hours.
- **>7 days and 1 to 2 kg:** 75 mg/kg/day IM/IV in divided doses every 8 hours.
- **>7 days and >2 kg:** 100 mg/kg/day IM/IV in divided doses every 6 hours.

Meningitis:

- **0 to 7 days:** 75 mg/kg/day IM/IV in divided doses every 8 to 12 hours.
- **>7 days:** 150 to 200 mg/kg/day in divided doses every 6 to 8 hours.

Infants and children:

- **Mild to moderate infections:** 100 to 150 mg/kg/day IM/IV in divided doses every 6 hours; maximum 4 g/day.
- **Severe infections:** 150 to 200 mg/kg/day IM/IV in divided doses every 4 to 6 hours; maximum 12 g/day.

ADVERSE EFFECTS: Hypersensitivity reactions (rash), thrombophlebitis, mild leukopenia, acute interstitial nephritis, hematuria, azotemia, and elevation in aspartate aminotransferase. *Clostridium difficile* colitis has been reported.

PHARMACOLOGY: Metabolized chiefly in the liver and excreted in bile; dosage modification required in patients with renal impairment.

COMMENTS: Avoid IM injection.

PALIVIZUMAB (SYNAGIS)

INDICATIONS AND USE: Immunoprophylaxis against severe respiratory syncytial virus (RSV) lower respiratory tract infections in high-risk infants and children. The American Academy of Pediatrics recommends RSV prophylaxis with palivizumab during RSV season for:

- **Infants ≤12 months of age** who were born at gestational age ≤28 weeks and 6 days.
- **Infants ≤12 months of age** with congenital airway abnormality or neuromuscular disorder that decreases the ability to manage airway secretions.
- **Infants and children ≤24 months of age** with chronic lung disease (CLD) necessitating medical therapy within 6 months of age prior to the beginning of RSV season.

- **Infants and children ≤ 24 months** with congenital heart disease and 1 of the following:
 - Receiving medication to treat congestive heart failure
 - Moderate to severe pulmonary hypertension
 - Cyanotic heart disease
 - Cardiac transplantation during RSV season
- **Infants and children ≤ 24 months of age** who are immunocompromised due to chemotherapy or other conditions during RSV season.
- **Infants and children ≤ 12 months of age** who have cystic fibrosis (CF) and evidence of CLD or nutritional compromise with weight for length < 10 th percentile.
- **Infants and children ≤ 24 months of age** who have CF and have previous manifestations of severe lung disease.
 - Previous hospitalization for pulmonary exacerbation in the first year of life
 - Abnormalities on chest radiography or chest computed tomography that persist when stable

ACTION: Humanized monoclonal antibody directed to an epitope in the A-antigenic site of the respiratory syncytial virus F protein, resulting in neutralizing and fusion-inhibitory activity against RSV.

DOSAGE: IM.

- **15 mg/kg/dose IM once a month during the RSV season.** The first dose should be administered before the start of the RSV season; clinicians may administer up to a maximum of 5 monthly doses during the RSV season to infants who qualify for prophylaxis. Qualifying infants born during the RSV season will require fewer doses.

ADVERSE EFFECTS: Upper respiratory tract infection, otitis media, fever, and rhinitis. Rash, injection site reaction, erythema, induration. Rare cases of anaphylaxis (< 1 case/100,000 patients) and severe hypersensitivity reactions (< 1 case/1000 patients) have been reported.

PHARMACOLOGY: The mean half-life of palivizumab is approximately 20 days and adequate antibody titers are maintained for 30 days. Time to achieve adequate serum antibody titers is 48 hours.

COMMENTS: Palivizumab is not indicated for the treatment of RSV infections. Palivizumab does not interfere with the response to routine childhood vaccines and therefore may be administered concurrently. Qualifying infants who have had a cardiopulmonary bypass procedure or ECLS should receive a dose as soon as possible after conclusion, even if < 1 month from previous dose. Hospitalized neonates should receive their first dose 48 to 72 hours before discharge or promptly after discharge. If hospitalization occurs for breakthrough RSV infection, monthly prophylaxis should be discontinued for the remainder of that season.

PANCURONIUM BROMIDE

HIGH-ALERT MEDICATION: To be administered only by experienced clinicians or adequately trained individuals supervised by an experienced clinician familiar with the use and actions, characteristics, and complications of neuromuscular-blocking agents.

INDICATIONS AND USE: Skeletal muscle relaxation during surgery; increases pulmonary compliance during assisted mechanical ventilation and facilitates endotracheal intubation.

ACTIONS: Nondepolarizing neuromuscular-blocking agent that produces skeletal muscle paralysis by blocking acetylcholine binding at the receptor at the myoneural junction. Pancuronium may cause an increase in heart rate and changes in blood pressure.

DOSAGE: IV.

Neonates and infants:

- **Note:** Neonates are especially sensitive to nondepolarizing neuromuscular-blocking agents, such as pancuronium, during the first month of life. It is recommended that a test dose of 0.02 mg/kg be given first to measure responsiveness.
- 0.05 to 0.1 mg/kg IV as needed, maximum of 0.15 mg/kg/dose; or as continuous IV infusion 0.02 to 0.04 mg/kg/h or 0.4 to 0.6 mcg/kg/min.

ADVERSE EFFECTS: May cause hypoxemia with inadequate mechanical ventilation. Apnea, arrhythmias, tachycardia, hypertension, hypotension, excessive salivation, and bronchospasm

may occur. Potentiation of neuromuscular blockade may result from aminoglycosides, electrolyte abnormalities, severe hyponatremia, severe hypocalcemia, severe hypokalemia, hypermagnesemia, neuromuscular diseases, acidosis, renal failure, and hepatic failure. Antagonism of neuromuscular blockade may result from alkalosis, hypercalcemia, hyperkalemia, and epinephrine.

PHARMACOLOGY: The onset of action is generally 2 to 5 minutes, with duration of action of approximately 24 to 60 minutes, but is variable and may be prolonged in neonates.

COMMENTS: Neonates are particularly sensitive to its actions; prolonged paralysis may be noted. Ventilation must be supported during neuromuscular blockade. Neostigmine and atropine are used for reversal. Sensation remains intact; analgesia should be used with painful procedures.

PAPAVERINE HCL

INDICATIONS AND USE: Reduce peripheral arterial spasms in efforts to prolong arterial catheter patency.

ACTIONS: Directly relaxes vascular smooth muscle and results in vasodilation.

DOSAGE: IV.

Peripheral arterial catheter patency in full-term neonates:

- Add 30 mg of preservative-free papaverine to 250 mL of arterial catheter solution (normal saline [NS] or ½ NS) that contains heparin 1 unit/mL; infuse at a rate of ≤ 1 mL/h. Not recommended for use in preterm neonates < 3 weeks of age due to potential risk of developing or extending an intracranial hemorrhage.

COMMENTS: IV infusion should be performed under a physician's supervision because arrhythmias and fatal apnea may result from rapid injection. **Note:** Not FDA approved for use in children. Limited experience in neonates.

PENICILLIN G (AQUEOUS), PARENTERAL

ACTION AND SPECTRUM: Treatment of infection due to gram-positive cocci (except *Staphylococcus aureus*), including all susceptible strains of streptococci (nonenterococcal). However, penicillin G-resistant *Streptococcus pneumoniae* strains have been isolated. Gram-positive bacilli are usually sensitive to penicillin G (*Clostridium tetani*, *Corynebacterium diphtheriae*). Penicillin G is effective for some gram-negative organisms including *Neisseria meningitides*, *Haemophilus influenzae*, and *Neisseria gonorrhoeae*. The Enterobacteriaceae are resistant to penicillin G therapy, and resistance of many gram-negative organisms such as *Escherichia coli* is a result of the ability to produce β -lactamase. Used for the treatment of congenital syphilis.

DOSAGE: IM, IV.

Neonates PNA ≤ 7 days and ≥ 1 kg or ≤ 14 days and < 1 kg:

- 50,000 to 100,000 units/kg/day IM/IV in divided doses every 12 hours.

Neonates PNA > 7 days and ≥ 1 kg or > 14 days and < 1 kg:

- 75,000 to 150,000 units/kg/day IM/IV in divided doses every 8 hours.

Group B streptococcal meningitis:

- **Neonates PNA ≤ 7 days:** 250,000 to 450,000 units/kg/day IM/IV in divided doses every 8 hours.
- **Neonates PNA > 7 days:** 450,000 to 500,000 units/kg/day IM/IV in divided doses every 6 hours.

Other susceptible organism meningitis:

- **Neonates PNA ≤ 7 days:** 150,000 units/kg/day IM/IV in divided doses every 8 to 12 hours.
- **Neonates PNA > 7 days:** 200,000 units/kg/day IM/IV in divided doses every 6 to 8 hours.

Congenital syphilis:

- **Neonates PNA ≤ 7 days:** 100,000 units/kg/day IM/IV in divided doses every 12 hours for a total of 10 days.
- **Neonates PNA > 7 days:** 150,000 units/kg/day IM/IV in divided doses every 8 hours for a total of 10 days.

Infants and children:

- **Usual dose:** 100,000 to 250,000 units/kg/day IM/IV in divided doses every 4 to 6 hours.
- **Severe infections:** 250,000 to 400,000 units/kg/day IM/IV in divided doses every 4 to 6 hours; maximum dose 24 million units/day.

ADVERSE EFFECTS: Allergic reactions, rash, fever, alterations in bowel flora, *Candida* superinfection, diarrhea, and hemolytic anemia. Acute interstitial nephritis. Bone marrow suppression with granulocytopenia. Very large doses may cause seizures. Rapid IV push of potassium penicillin G may cause cardiac arrhythmias and arrest because of the potassium component. Infuse slowly over 30 minutes.

PHARMACOLOGY: Penetration across the blood–brain barrier is poor with normal meninges; excreted in urine mainly by tubular secretion.

COMMENTS: Good activity against anaerobes. Drug of choice for tetanus neonatorum.

PENICILLIN G BENZATHINE (BICILLIN L-A)

ACTION AND SPECTRUM: See Penicillin G (Aqueous), Parenteral. Treatment of asymptomatic congenital syphilis.

DOSAGE: IM.

- **Asymptomatic congenital syphilis:** Single dose of 50,000 units/kg IM.

ADVERSE EFFECTS: See Penicillin G (Aqueous).

PHARMACOLOGY: Renally excreted over a prolonged interval owing to slow absorption from the injection site.

COMMENTS: See Penicillin G (Aqueous). Not often used. For IM injection only.

PENICILLIN G PROCAINE

ACTION AND SPECTRUM: See Penicillin G (Aqueous), Parenteral. Treatment of symptomatic or asymptomatic congenital syphilis.

DOSAGE: IM.

- 50,000 units/kg/dose IM every 24 hours for 10 days; if >1 day of therapy is missed, the entire course should be restarted.

ADVERSE EFFECTS: See Penicillin G (Aqueous), Parenteral. May also cause sterile abscess formation at the injection site. Contains 120 mg of procaine per 300,000 units, which may cause allergic reactions, myocardial depression, or systemic vasodilation. There is cause for much greater concern about these effects in the neonate than in older patients, and therefore, it is not recommended for use in neonates.

COMMENTS: Not often used.

PENTOBARBITAL SODIUM (NEMBUTAL)

INDICATIONS AND USE: Sedative/hypnotic. Used for agitation, for preprocedure sedation, or as an anticonvulsant.

ACTIONS: Short-acting barbiturate.

DOSAGE: IV.

Procedural sedation:

- 1 to 3 mg/kg/dose IV slow push <50 mg/min; additional doses of 1 to 2 mg/kg may be given every 3 to 5 minutes to desired effect. Total dose: 1 to 6 mg/kg, maximum of 100 mg to desired effect.

Hypnotic:

- 2 to 6 mg/kg/dose IM. Maximum 100 mg/dose.

Status epilepticus refractory to standard therapy:

- Loading dose 5 mg/kg IV; maintenance infusion 1 mg/kg/h, may increase up to 3 mg/kg/h. Intubation is required. Adjust dose based on hemodynamics, seizure activity, and electroencephalogram.

ADVERSE EFFECTS: Observe the IV site closely during administration for extravasation injury. Tolerance and physical dependence may occur with continued use. May cause somnolence, bradycardia, rash, pain on IM injection (solutions are highly alkaline), thrombophlebitis, osteomalacia from prolonged use (rare), and excitability.

COMMENTS: Rapid IV administration may cause respiratory depression, apnea, laryngospasm, bronchospasm, and hypotension; administer over 10 to 30 minutes.

PHENOBARBITAL

INDICATIONS AND USE: Treatment of neonatal seizures; used to treat neonatal abstinence symptoms; may also be used for prevention and treatment of neonatal hyperbilirubinemia and lowering of bilirubin in chronic cholestasis.

ACTIONS: Anticonvulsant activity by increasing the threshold for electrical stimulation of the motor cortex and depresses CNS activity by binding to barbiturate site at γ -aminobutyric acid (GABA) receptor complex, enhancing GABA activity.

DOSAGE: PO, IV.

Anticonvulsant, status epilepticus, neonates and infants:

- **Loading dose:** 15 to 20 mg/kg IV in a single dose. **Note:** In select patients, may repeat additional 5 to 10 mg/kg dose every 15 to 20 minutes until seizure controlled or a total dose of 40 mg/kg; be prepared to provide respiratory support.
- **Maintenance:** Begin 12 to 24 hours after loading dose:
 - **Neonates:** 3 to 4 mg/kg/day PO/IV given in 1 to 2 divided doses; assess serum concentrations; increase to 5 mg/kg/day if needed.
 - **Infants:** 5 to 6 mg/kg/day PO/IV in 1 to 2 divided doses.

Hyperbilirubinemia: Doses of 3 to 8 mg/kg/day PO in 2 to 3 divided doses up to 12 mg/kg/day have been used; dose not clearly established and not recommended due to sedation and other adverse effects.

Neonatal abstinence syndrome: 2 to 8 mg/kg/day PO in 2 to 4 divided doses. Monitor serum concentrations coincident to abstinence scores. Loading dose is optional: 16 mg/kg IV as a single dose or PO in divided into 2 doses.

ADVERSE EFFECTS: Sedation, lethargy, paradoxical excitement, hypotension, gastrointestinal distress, ataxia, rash, and phlebitis (pH of IV solution is 10). Drug accumulation may occur if treating concurrently with phenytoin. Monitor drug levels. Respiratory depression can occur at levels exceeding 60 mcg/mL or with rapid IV administration.

PHARMACOLOGY: Initial half-life in neonates is 40 to 200 hours or longer, gradually declining to about 20 to 100 hours at 3 to 4 weeks of age. Reduction in serum bilirubin levels is attributed to increased levels of glucuronyl transferase; stimulates bile flow and increases the concentration of the Y-binding protein involved in the uptake of bilirubin by hepatocytes. Observed reductions usually require 2 to 3 days of treatment.

COMMENTS: Contraindicated if porphyria suspected. Maintenance serum levels usually fall between 15 and 40 mcg/mL. Abrupt withdrawal may precipitate status epilepticus. Do not inject IV faster than 1 mg/kg/min, with a maximum of 30 mg/min for infants and children.

PHENTOLAMINE MESYLATE INJECTION

INDICATIONS AND USE: Treatment of extravasation from IV α -adrenergic drugs (dobutamine, dopamine, epinephrine, norepinephrine, or phenylephrine). Helps prevent dermal necrosis and sloughing. (See also Chapter 42.)

ACTIONS: Phentolamine blocks α -adrenergic receptors and reverses the severe vasoconstriction from the extravasation of α -adrenergic drugs.

DOSAGE: Subcutaneous.

Neonate:

- Infiltrate area with small amount of solution (~1 mL given in 0.1- to 0.2-mL aliquots) made by diluting 2.5 to 5 mg in 10 mL of preservative-free normal saline (NS); treat within

12 hours of extravasation. Total dose required depends on size of extravasation; should not exceed 0.1 mg/kg or 2.5 mg maximum.

Infants and children:

- Infiltrate area with small amount of solution (~1 mL) made by diluting 5 to 10 mg in 10 mL of preservative-free NS; treat within 12 hours of extravasation. Total dose required depends on size of extravasation; should not exceed 0.1 to 0.2 mg/kg or 5 mg maximum.

ADVERSE EFFECTS: Hypotension, tachycardia, cardiac arrhythmias, and flushing.

PHENYLEPHRINE OPHTHALMIC

INDICATIONS AND USE: A mydriatic for ophthalmic procedures. (See also Chapter 58.)

ACTIONS: α -Adrenergic stimulation and weak β -adrenergic activity. Causes pupils to contract by activation of dilator muscle of the pupil. Causes vasoconstriction of the arterioles of the nasal mucosa and conjunctiva; produces systemic arterial vasoconstriction.

DOSAGE: Ophthalmologic.

- **Neonates:** Use combination products containing 1% phenylephrine to minimize increase in blood pressure.
- **Infants <1 year:** Instill 1 drop of 2.5% solution 15 to 30 minutes before ophthalmic procedure.
- **Children:** Instill 1 drop of 2.5% or 10% solution 15 to 30 minutes before ophthalmic procedure; may repeat in 10 to 60 minutes as needed.

ADVERSE EFFECTS: Arrhythmias, hypertension, lacrimation, respiratory distress.

PHARMACOLOGY: Mydriasis within 15 to 30 minutes of instillation; duration of mydriasis is 1 to 2 hours. Complete time to recovery is 3 to 8 hours.

COMMENTS: Apply pressure to the lacrimal sac during and for 2 minutes after instillation to minimize systemic absorption.

PHENYTOIN (DILANTIN)

INDICATIONS AND USE: Management of generalized convulsive status epilepticus; prevention and management of seizures.

ACTIONS: Stabilizes neuronal membranes and decreases seizure activity by increasing efflux or decreasing influx of sodium ions across cell membranes in the motor cortex during generation of nerve impulses.

DOSAGE: PO, IV. Phenytoin should be administered IV directly into a large vein through a large-gauge needle or IV catheter. IV injections should be followed by normal saline (NS) flushes through the same needle or IV catheter to avoid local irritation of the vein. Highly unstable in any IV solution; an in-line 0.22-micron filter is recommended due to potential for precipitation. Avoid infusion through central line due to risk of precipitation. Avoid IM use due to erratic absorption, pain on injection, and precipitation of drug at injection site. pH: 10.0 to 12.3.

- **Loading dose:** 15 to 20 mg/kg IV at a rate not to exceed 0.5 to 1 mg/kg/min or 50 mg/min, whichever is slower.
- **Maintenance:** 12 hours after loading dose, 4 to 8 mg/kg/day PO/IV divided every 12 hours; some patients may require dosing every 8 hours.

ADVERSE EFFECTS: Local tissue damage if extravasation occurs. High serum levels can precipitate seizures. Other CNS complications include drowsiness, lethargy, ataxia, and nystagmus. Cardiovascular effects include arrhythmias, hypotension, and cardiovascular collapse with too rapid an infusion. Reactions also include hypersensitivity rash or Stevens-Johnson syndrome. Other complications include hepatic dysfunction, pancreatic dysfunction with hyperglycemia and hypoinsulinemia, and blood dyscrasias.

PHARMACOLOGY: Bilirubin displaces phenytoin from albumin-binding sites, thereby increasing unbound drug levels and complicating dosage to serum level interpretations. Half-life from 7 to 42 hours in newborns postnatal age <7 days. Neonates absorb phenytoin poorly from gastrointestinal tract; separate tube feedings and oral phenytoin by 2 hours.

COMMENTS: Therapeutic levels 8 to 20 mcg/mL for total phenytoin, 1 to 2.5 mcg/mL for free phenytoin; lower end of therapeutic range preferred for preterm infants. Multiple drug interactions

include corticosteroids, carbamazepine, cimetidine, digoxin, furosemide, phenobarbital, and heparin (especially in central lines causing precipitation). Available as an oral suspension.

PHOSPHATE (POTASSIUM AND SODIUM PHOSPHATE, NEUTRA-PHOS)

INDICATIONS AND USE: Treatment of hypophosphatemia, provision of maintenance phosphorus in parenteral nutrition solutions, and treatment of nutritional rickets of prematurity.

ACTIONS: Phosphorus is an intracellular ion required for formation of energy-transfer enzymes such as adenosine diphosphate and adenosine triphosphate. Phosphorus is also needed for bone metabolism and mineralization.

DOSAGE: IV, PO.

Treatment of hypophosphatemia:

- 0.15 to 0.33 mmol/kg/dose IV over 6 hours, with repeat doses to maintain serum phosphorus >2 mg/dL. Potassium or sodium phosphate should be diluted in IV fluids and infused at a rate not faster than 0.2 mmol/kg/h.

Maintenance in hyperalimentation:

- 0.5 to 2 mmol/kg/day. May use parenteral solution for oral dose; give in divided doses and dilute in feedings.

ADVERSE EFFECTS: Hyperphosphatemia, hypocalcemia, and hypotension. Gastrointestinal discomfort may occur with oral administration. Rapid IV bolus of potassium phosphates can cause cardiac arrhythmias.

COMMENTS: Injection, sodium phosphates: 3 mmol of elemental phosphorus/mL and 4 mEq of sodium/mL; and potassium phosphates: 3 mmol of elemental phosphorus/mL and 4.4 mEq of potassium/mL. The amount of sodium and potassium must be considered when ordering phosphate. The most reliable method of ordering IV phosphate is by millimoles; then specify the potassium or sodium salt.

PIPERACILLIN-TAZOBACTAM (ZOSYN)

ACTION AND SPECTRUM: Treatment of sepsis, intra-abdominal infections, infections involving the skin and skin structure, lower respiratory tract, and urinary tract infections caused by β -lactamase-producing strains that are susceptible, including *Staphylococcus aureus*, *Haemophilus influenzae*, *Bacteroides fragilis*, *Klebsiella*, *Pseudomonas*, *Proteus mirabilis*, *Escherichia coli*, and *Acinetobacter*.

DOSAGE: IV. Each 3.375-g vial of piperacillin-tazobactam contains 3 g of piperacillin and 0.375 g of tazobactam sodium in an 8:1 ratio. Dosing recommendations are based on the piperacillin component.

Neonates PNA ≤ 7 days and ≥ 1 kg or ≤ 14 days and < 1 kg:

- 200 mg piperacillin/kg/day divided every 12 hours.

Neonates PNA > 7 days and ≥ 1 kg or > 14 days and < 1 kg:

- 300 mg piperacillin/kg/day divided every 8 hours.

Alternative dosing for neonates PNA > 7 days and ≥ 2 kg:

- 320 mg piperacillin/kg/day divided every 6 hours.

Infants < 2 months of age: IV: 320 mg of piperacillin/kg/day in divided doses every 6 hours.

Infants 2 to 9 months: IV: 240 mg of piperacillin/kg/day in divided doses every 8 hours.

Infants and children > 9 months: IV: 300 mg of piperacillin component/kg/day in divided doses every 8 hours.

Higher doses have been used for serious pseudomonal infections: 300 to 400 mg of piperacillin/kg/day in divided doses every 6 hours; maximum dose 16 g of piperacillin/day.

ADVERSE EFFECTS: Elevations in blood urea nitrogen, serum creatinine; interstitial nephritis, renal failure; leukopenia, thrombocytopenia, neutropenia, decrease in hemoglobin/hematocrit, eosinophilia, elevations in aspartate aminotransferase and alanine aminotransferase, hyperbilirubinemia, cholestatic jaundice, hypokalemia.

PHARMACOLOGY: Widely distributed into tissues and body fluids including lungs, intestinal mucosa, interstitial fluid, gallbladder, and bile; penetration into CSF is poor when meninges are not inflamed.

COMMENTS: When used to treat hospital-acquired pneumonia caused by *Pseudomonas aeruginosa*, consider the addition of an aminoglycoside.

PNEUMOCOCCAL 13-VALENT CONJUGATE VACCINE (PREVNAR 13)

INDICATIONS AND USE: For active immunization of infants and toddlers against *Streptococcus pneumoniae* invasive disease caused by the 13 capsular serotypes in the vaccine for all children 2 to 23 months of age. It is also recommended for certain children 24 to 59 months of age. *S pneumoniae* causes invasive infections such as bacteremia and meningitis, pneumonia, otitis media, and sinusitis (see Advisory Committee on Immunization Practices [ACIP] guidelines for the most current recommendations).

ACTIONS: A vaccine of saccharides of the capsular antigens of *S pneumoniae* serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F conjugated to diphtheria CRM197 protein. CRM197 protein is a nontoxic variant of diphtheria toxin.

DOSAGE: IM. According to ACIP, doses administered ≤ 4 days before minimal interval or age are considered valid.

- 0.5 mL/dose as a single dose IM at 2, 4, 6, and 12 to 15 months of age. Shake well before administration. Refer to the current American Academy of Pediatrics (AAP)/ACIP immunization recommendations. The schedule usually begins at 2 months of age, but starting at 6 weeks of age is acceptable. Three doses of 0.5 mL each are ideally given at approximately 2-month intervals, but a dosing interval of 4 to 8 weeks is acceptable, followed by a fourth dose of 0.5 mL at 12 to 15 months of age. Give the fourth dose at least 8 weeks after the third dose.

ADVERSE EFFECTS: Decreased appetite, drowsiness, irritability, fever, and injection site local tenderness, redness, and edema. Not a treatment of active infection. Do not give if patient is hypersensitive to any component of the vaccine. Use of this vaccine does not replace the use of the 23-valent pneumococcal polysaccharide vaccine in children ≥ 24 months old with sickle cell disease, chronic illness, asplenia, or human immunodeficiency virus, or those who are immunocompromised. May be administered simultaneously with other vaccines as part of the routine immunization schedule.

POLYMYXIN B OPHTHALMIC

See Chapter 58.

PORACTANT ALFA (CUROSURF)

INDICATIONS AND USE: Treatment of neonatal respiratory distress syndrome (RDS).

ACTIONS: An extract of natural porcine lung surfactant, contains phospholipids, neutral lipids, fatty acids, and surfactant-associated proteins B and C. It replaces deficient or ineffective endogenous lung surfactant in neonates with RDS; surfactant prevents the alveoli from collapsing during expiration by lowering surface tension between air and alveolar surfaces.

DOSAGE: ETT.

- **Initial 2.5 mL/kg (200 mg/kg/dose) intratracheally**, divided into 2 aliquots, followed by up to 2 doses of 1.25 mL/kg (100 mg/kg/dose) administered at 12-hour intervals as needed to infants who continue to require mechanical ventilation and oxygen supplementation. Administer intratracheally through a side port adapter or through a 5-F feeding catheter inserted into the endotracheal tube. Allow to warm to room temperature prior to administration. Do not shake or swirl vial to resuspend particles. Inspect for discoloration; normal color is creamy white. Discard unused drug.

ADVERSE EFFECTS: Transient bradycardia, hypotension, endotracheal tube blockage, and oxygen desaturation. Pulmonary hemorrhage has been reported.

COMMENTS: Following administration, lung compliance and oxygenation often improve rapidly. Patients should be closely monitored and appropriate changes in ventilation support should be made as clinically indicated.

POTASSIUM ACETATE

INDICATIONS AND USE: Treatment and prevention of hypokalemia in clinical situations where the use of chloride is not desirable, or correction of metabolic acidosis through the conversion of acetate to bicarbonate.

ACTIONS: Potassium acetate is metabolized to bicarbonate on an equimolar basis, which neutralizes hydrogen ion concentration and raises the blood and urine pH. Potassium is the major intracellular cation. Potassium is essential for maintaining intracellular tonicity; transmission of nerve impulses; contraction of cardiac, skeletal, and smooth muscle; and maintenance of normal renal function.

DOSAGE: IV.

- **Normal daily requirement (based on mEq of potassium):** 2 to 6 mEq/kg/day. Dose should be added to maintenance IV fluids.
- **Intermittent IV administration for severe hypokalemia (based on mEq of potassium):** 0.5 to 1 mEq/kg/dose, infused at a rate of ≤ 0.5 mEq/kg/h, not to exceed 1 mEq/kg/h or 40 mEq/h.

ADVERSE EFFECTS: Hyperkalemia, metabolic acidosis. Avoid rapid IV injection. Excessive dose or rate of infusion may cause cardiac arrhythmias (peaked T waves, widened QRS, flattened P waves, bradycardia, and heart block), respiratory paralysis, and hypotension. Monitor renal function, urine output, and serum potassium levels; hyperkalemia may result with renal dysfunction.

PHARMACOLOGY: 1 mEq of acetate is equivalent to the alkalinizing effect of 1 mEq of bicarbonate.

COMMENTS: Continuous monitoring should be used for the infusion of intermittent doses >0.5 mEq/kg/h. Do *not* administer undiluted or IV push. Potassium must be diluted prior to IV administration. Maximum recommended concentration is 80 mEq/L for peripheral line and 150 mEq/L for a central line.

POTASSIUM CHLORIDE (KCL)

INDICATIONS AND USE: Treatment of hypokalemia and as a supplement to maintain adequate serum potassium levels. Also corrects hypochloremia.

ACTIONS: Potassium is the major intracellular cation. Potassium is essential for maintaining intracellular tonicity; transmission of nerve impulses; contraction of cardiac, skeletal, and smooth muscle; and maintenance of normal renal function.

DOSAGE: IV, PO. Monitor serum potassium levels and adjust dose as needed.

Acute treatment of hypokalemia:

- 0.5 to 1 mEq/kg/dose IV over 1 hour. Maximum dose/rate: 1 mEq/kg/h or 40 mEq/h. Same equation from sodium bicarbonate is used for potassium acetate.

Maintenance:

- 2 to 6 mEq/kg/day (usually 2–3 mEq/kg/day) diluted in 24-hour maintenance IV solution. Higher doses are often required in infants receiving diuretics.

Oral supplementation:

- 2 to 6 mEq/kg/day (usually 2–3 mEq/kg/day) in divided doses and diluted with feedings. The injectable form of the drug may be given in divided doses PO and diluted in the infant's formula.

ADVERSE EFFECTS: Avoid rapid IV injection. Excessive dose or rate of infusion may cause cardiac arrhythmias (peaked T waves, widened QRS, flattened P waves, bradycardia, and heart block), respiratory paralysis, and hypotension. Monitor renal function, urine output, and serum potassium levels; hyperkalemia may result with renal dysfunction.

COMMENTS: Hyperkalemia, metabolic acidosis. Continuous monitoring should be used for the infusion of intermittent doses >0.5 mEq/kg/h. Do *not* administer undiluted or IV push. Potassium must be diluted prior to IV administration. It is best for the concentration of infusion to depend on the patient's condition and specific institution policy. Commonly used infusion dose in neonatal intensive care units has been 20 mEq/L (range 20–60 mEq/L) for

peripheral line and 80 mEq/L (range 80–150 mEq/L) for central line. These higher concentrations should be reserved for specific clinical situations and only with electrocardiographic monitoring.

POVIDONE-IODINE OPHTHALMIC

See Chapter 58.

PREDNISONE

INDICATIONS AND USE: Used chiefly as an anti-inflammatory or immunosuppressive agent. Prednisone is an intermediate-acting glucocorticoid that has 4 times the anti-inflammatory potency of hydrocortisone and half the mineralocorticoid potency.

DOSAGE: PO.

- 0.25 to 2 mg/kg/day as a single daily dose or divided every 6 to 12 hours. Many different dosing regimens have been used.

ADVERSE EFFECTS: Hypertension, leukocytosis, psychiatric disturbance, seizure, skin atrophy, hypokalemia, diabetes mellitus, fluid retention, growth suppression, hypothyroidism, sodium retention, peptic ulcer, osteoporosis, myopathy, glaucoma, cataracts, impaired wound healing, increased aspartate aminotransferase and alanine aminotransferase, increased susceptibility to infection. Withdraw the dose gradually after prolonged therapy to prevent acute adrenal insufficiency.

PROCAINAMIDE HCL

WARNING: The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test, with or without symptoms of a lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit versus risks of continued procainamide therapy should be assessed. Potentially fatal blood dyscrasias (agranulocytosis) have occurred with therapeutic doses; weekly monitoring is recommended during the first 3 months of therapy and periodically thereafter.

INDICATIONS AND USE: Treatment of ventricular tachycardia, premature ventricular contractions, paroxysmal atrial tachycardia, and atrial fibrillation; to prevent recurrence of ventricular tachycardia, paroxysmal supraventricular tachycardia, and atrial fibrillation or flutter.

Note: Due to proarrhythmic effects, use should be reserved for life-threatening arrhythmias.

ACTIONS: Class I antiarrhythmic agent that increases the effective refractory period of the atria and ventricles of the heart. Partially metabolized by the liver to the active metabolite *N*-acetylprocainamide (NAPA).

DOSAGE: IV. Consider consult with pediatric cardiologist prior to use.

- **Initial bolus dose (monitor electrocardiogram, heart rate, and blood pressure):** 7 to 10 mg/kg (dilute to 20 mg/mL) IV over 10 to 60 minutes, then infusion of 20 to 80 mcg/kg/min (dilute to 2–4 mg/dL in dextrose 5% in water [D5W]); maximum dose is 2 g/day. Use lowest dose in preterm neonates.

ADVERSE EFFECTS: Toxic effects if given rapidly IV, including asystole, myocardial depression, ventricular fibrillation, hypotension, and reversible lupus-like syndrome. May cause nausea, vomiting, diarrhea, anorexia, skin rash, tachycardia, agranulocytosis, and hepatic toxicity. Potentially fatal blood dyscrasias have occurred with therapeutic doses.

PHARMACOLOGY: Therapeutic levels—Procainamide: 4 to 10 mcg/mL, toxicity with levels >10 mcg/mL; NAPA: 6 to 20 mcg/mL, toxicity with levels >30 mcg/mL. Draw 6 to 12 hours after start of IV infusion.

COMMENTS: Contraindicated in second- or third-degree heart block, bundle branch block, digitalis intoxication, and allergy to procaine. Do not use in atrial fibrillation or flutter until the ventricular rate is adequately controlled to avoid a possible paradoxical increase in ventricular rate. Do not administer with amiodarone; may cause severe hypotension and prolongation of QT interval.

PROPARACAINE OPHTHALMIC

See Chapter 58.

PROPRANOLOL (HEMANGEOL, INDERAL)

INDICATIONS AND USE: Hypertension; supraventricular tachycardia, especially if associated with Wolff-Parkinson-White syndrome; tachyarrhythmias; and tetralogy of Fallot spells. Adjunctive therapy for neonatal thyrotoxicosis. Treatment of infantile hemangiomas.

ACTIONS: Nonselective β -adrenergic blocking agent that inhibits adrenergic stimuli by competitively blocking β -adrenergic receptors within the myocardium and bronchial and vascular smooth muscle. Propranolol decreases heart rate, myocardial contractility, blood pressure, and myocardial oxygen demand.

DOSAGE: IV, PO.

Arrhythmias:

- **IV:** 0.01 to 0.15 mg/kg/dose IV as slow push over 10 minutes; may repeat every 6 to 8 hours as needed; maximum dose 1 mg (infants) and 3 mg (children).
- **PO:** 0.25 to 1 mg/kg/dose PO every 6 to 8 hours.

Hypertension:

- **PO:** 0.25 to 0.5 mg/kg/dose PO every 8 hours. Increase slowly as needed to 5 mg/kg/day.

Tetralogy spells:

- **IV:** 0.015 to 0.02 mg/kg/dose IV over 10 minutes; titrate to effect, up to 0.1 to 0.2 mg/kg/dose. Some centers use 0.15 to 0.25 mg/kg/dose slow IV; may repeat in 15 minutes; maximum initial dose is 1 mg.
- **Oral palliation:** Initial: 0.25 mg/kg/dose every 6 hours; if ineffective within first week, may increase by 1 mg/kg/day every 24 hours to maximum of 5 mg/kg/day; if patient is refractory, may increase slowly to a maximum of 10 to 15 mg/kg/day but must carefully monitor heart rate, heart size, and cardiac contractility.

Thyrotoxicosis:

- 0.5 to 2 mg/kg/day PO in divided doses every 6 to 12 hours; occasionally higher doses may be required.

ADVERSE EFFECTS: Generally dose-related hypotension and related to β -adrenergic blockage; nausea, vomiting, bronchospasm, increased airway resistance, heart block, depressed myocardial contractility, hypoglycemia.

COMMENTS: Contraindicated in obstructive pulmonary disease, asthma, heart failure, shock, second- or third-degree heart block, and hypoglycemia. Use with caution in renal or hepatic failure. Do not use in neonates with chronic lung disease because bronchoconstriction may occur.

PROTAMINE SULFATE

WARNING: Severe hypersensitivity reaction with hypotension, cardiovascular collapse, pulmonary edema, and pulmonary vasoconstriction/hypertension possible. Risk factors: high dose/overdose, repeat doses, rapid administration, prior protamine use, current or prior protamine-containing products (neutral protamine Hagedorn [NPH; isophane] or protamine zinc insulin, some β -blockers), severe left ventricular dysfunction, abnormal pulmonary hemodynamics. Vasopressors and resuscitation equipment must be available in case of reaction.

INDICATIONS AND USE: Treatment of heparin overdose; neutralize heparin during surgery.

ACTIONS: Combines with heparin, forming a stable salt complex and neutralizing the anticoagulation activity of both drugs. Effect on heparin is rapid (~5 minutes) and persists for approximately 2 hours.

DOSAGE: IV.**Heparin overdosage:**

- Blood heparin concentrations decrease rapidly after heparin administration is stopped; adjust the protamine dosage depending on the duration of time since heparin administration as follows:
 - **Time since last heparin <30 minutes:** 1 mg neutralizes 100 units heparin.
 - **Time since last heparin 30 to 60 minutes:** 0.5 to 0.75 mg neutralizes 100 units heparin.
 - **Time since last heparin >60 to 120 minutes:** 0.375 to 0.5 mg neutralizes 100 units heparin.
 - **Time since last heparin >120 minutes:** 0.25 to 0.375 mg protamine neutralizes 100 units heparin.

Low molecular weight heparin (LMWH) overdosage:

- If most recent LMWH dose has been administered within the past 8 hours, use 1 mg protamine/1 mg LMWH; a second dose of 0.5 mg protamine/1 mg LMWH may be given if activated partial thromboplastin time remains prolonged 2 to 4 hours after the first dose.

ADVERSE EFFECTS: May cause hypotension, bradycardia, dyspnea, and anaphylaxis. Excessive administration beyond that needed to reverse a heparin effect may cause bleeding as a paradoxical coagulopathy.

PYRIDOXINE (VITAMIN B6)

INDICATIONS AND USE: Treatment of pyridoxine-dependent seizures; to prevent or treat vitamin B6 deficiency; treatment of drug-induced deficiency or acute intoxication of isoniazid or hydralazine.

ACTIONS: Vitamin B6 is essential in the synthesis of γ -aminobutyric acid (GABA), an inhibitory neurotransmitter in the CNS; GABA increases the seizure threshold. Pyridoxine is also required for heme synthesis and protein, carbohydrate, and fat metabolism.

DOSAGE: PO, IV.

Pyridoxine-dependent seizures:

- 50 to 100 mg IV single test dose, followed by a 30-minute observation period. If a response is seen, begin maintenance of 50 to 100 mg PO daily; range: 10 to 200 mg.

Adequate intake: 0.1 mg/day PO (0.01 mg/kg/day).

ADVERSE REACTIONS: Sensory neuropathy (after chronic administration of large doses), seizures (following IV administration of very large doses), acidosis, nausea, decreased serum folic acid concentration, respiratory distress.

PYRIMETHAMINE (DARAPRIM)

ACTION AND SPECTRUM: Inhibits parasitic dihydrofolate reductase resulting in inhibition of tetrahydrofolic acid synthesis. Used in combination with sulfadiazine for treatment of toxoplasmosis.

DOSAGE: PO.

Newborns and infants:

- **Toxoplasmosis:** 2 mg/kg/day once daily for 2 days, then 1 mg/kg/day once daily together with sulfadiazine for 2 to 6 months, followed by 1 mg/kg/day 3 times weekly with sulfadiazine. Total treatment duration of 12 months. Oral leucovorin (folic acid) 5 to 10 mg 3 times per week should be administered throughout course to prevent hematologic toxicity.

Infants and children ≥ 1 month of age:

- **Prophylaxis for first episode of *Toxoplasma gondii*:** 1 mg/kg/day (maximum 25 mg/day) once daily with dapsone plus oral folic acid (5 mg every 3 days).
- **Prophylaxis for recurrence of *T gondii*:** 1 mg/kg/day (maximum 25 mg/day) once daily given with sulfadiazine or clindamycin plus oral folic acid (5 mg every 3 days).

ADVERSE EFFECTS: Anorexia, vomiting, hematuria, megaloblastic anemia, leukopenia, thrombocytopenia, pancytopenia, atrophic glossitis, rash, seizures, and cardiac arrhythmia.

COMMENTS: Administer with feedings if vomiting persists. Upon discontinuation of pyrimethamine, leucovorin should be continued for another week (due to long half-life of pyrimethamine). Dose reduction is necessary in hepatic dysfunction. Although an FDA-labeled indication, use of pyrimethamine for prophylaxis or treatment of malaria is not routinely recommended due to reports of resistance.

RANITIDINE (ZANTAC)

INDICATIONS AND USE: Short-term treatment of duodenal and gastric ulcers, gastroesophageal reflux disease (GERD), upper gastrointestinal bleed, and hypersecretory conditions.

ACTIONS: Histamine (H₂)-receptor antagonist; competitively inhibits the action of histamine on the gastric parietal cells; inhibits gastric acid secretion.

DOSAGE: PO, IV.

IV dosing:

- **Loading dose:** 1.5 mg/kg/dose IV, then maintenance 12 hours later. Maintenance 1 to 2 mg/kg/day divided every 12 hours IV.
- **Continuous infusion:** 1.5 mg/kg/dose loading dose, then 0.04 to 0.08 mg/kg/h infusion (or 1 to 2 mg/kg/day).

Oral dosing:

- **Neonatal:** 2 to 6 mg/kg/day PO divided every 8 to 12 hours.
- **Infants >1 month:** GERD: 4 to 10 mg/kg/day PO divided twice daily.

Gastric/duodenal ulcer:

- **Treatment:** 4 to 8 mg/kg/day PO divided twice daily.
- **Maintenance:** 2 to 4 mg/kg/day PO once daily.

ADVERSE EFFECTS: Constipation, abdominal discomfort, sedation, malaise, leukopenia, thrombocytopenia, elevated serum creatinine, bradycardia, and tachycardia.

COMMENTS: Use of H₂ blockers in preterm infants is associated with increased risk for necrotizing enterocolitis, late-onset sepsis, and fungal sepsis. Routine use of gastric acid suppression in neonates should be avoided. Dose adjustment needed in renal dysfunction. May add the daily dose to the total parenteral nutrition regimen and infuse over 24 hours to avoid the need for intermittent dosing.

RIFAMPIN

ACTION AND SPECTRUM: Broad-spectrum antibiotic with bacteriostatic activity against mycobacteria, *Neisseria meningitidis*, and gram-positive cocci; used to eliminate meningococci from asymptomatic carriers; for prophylaxis in contacts of patients with *Haemophilus influenzae* type B infection; management of active tuberculosis (TB) in combination with other agents; and used in combination with other antibiotics for the treatment of staphylococcal infections.

DOSAGE: PO, IV.

Synergy for staphylococcal infections:

- **Neonates:** 5 to 20 mg/kg/day PO/IV in divided doses every 12 hours with other antibiotics.

***H influenzae* prophylaxis:**

- **Neonates <1 month:** 10 mg/kg/day PO/IV every 24 hours for 4 days.
- **Infants and children:** 20 mg/kg/day PO every 24 hours for 4 days, not to exceed 600 mg/dose.

Nasal carriers of *Staphylococcus aureus*:

- **Children:** 15 mg/kg/day PO/IV divided every 12 hours for 5 to 10 days, not to exceed 600 mg/dose in combination with at least 1 other systemic antistaphylococcal antibiotic. Not recommended for first-line therapy.

Meningococcal prophylaxis:

- **Neonates <1 month:** 10 mg/kg/day PO/IV in divided doses every 12 hours for 2 days.
- **Infants and children:** 20 mg/kg/day PO in divided doses every 12 hours for 2 days, not to exceed 600 mg/dose.

TB:

- **Active infection:** A 4-drug regimen (isoniazid, rifampin, pyrazinamide, and ethambutol) is preferred for the initial, empiric treatment of TB. Alter therapy regimen when drug susceptibility results are available.

- **Infants and children:** 10 to 20 mg/kg/day PO/IV every 24 hours, not to exceed 600 mg/dose.

ADVERSE EFFECTS: Anorexia, vomiting, and diarrhea; rash, pruritus, and eosinophilia; drowsiness, ataxia, blood dyscrasias (leukopenia, thrombocytopenia, and hemolytic anemia), hepatitis (rare), and elevation of serum urea nitrogen and uric acid levels. Causes red-orange discoloration of body fluids.

PHARMACOLOGY: Highly lipophilic; crosses the blood–brain barrier and is widely distributed into body tissues and fluids; hepatic metabolism; undergoes enterohepatic recycling. Half-life is approximately 1 to 3 hours.

COMMENTS: Rifampin should always be used in combination with other agents; if used as monotherapy, resistance develops rapidly. Administer by slow IV infusion over 30 minutes to 3 hours at 6 mg/mL concentration. Extravasation may cause local irritation and inflammation. Administer oral doses on an empty stomach and avoid acid suppressive medications. Shake oral suspension well or may mix content of capsule with applesauce. **Note:** A potent enzyme inducer of hepatic metabolism. Patients receiving digoxin, phenytoin, phenobarbital, or theophylline may have a substantial decrease in the serum concentration of these drugs after starting rifampin. Careful monitoring of serum drug concentrations is necessary.

ROCURONIUM

HIGH-ALERT MEDICATION: To be administered only by experienced clinicians or adequately trained individuals supervised by an experienced clinician familiar with the use and actions, characteristics, and complications of neuromuscular-blocking agents.

INDICATIONS AND USE: Skeletal muscle relaxation during surgery; increases pulmonary compliance during assisted mechanical ventilation and facilitates endotracheal intubation.

ACTIONS: Nondepolarizing neuromuscular-blocking agent that produces skeletal muscle paralysis by blocking acetylcholine binding at the receptor at the myoneural junction.

DOSAGE: IV.

- 0.6 to 1.2 mg/kg/dose IV push over 5 to 10 seconds for tracheal intubation (not recommended for rapid sequence intubation in pediatrics).

ADVERSE EFFECTS: May cause hypoxemia with inadequate mechanical ventilation. Apnea, arrhythmias, tachycardia, hypertension, hypotension, excessive salivation, and bronchospasm may occur. Potentiation of neuromuscular blockade may result from aminoglycosides, electrolyte abnormalities, severe hyponatremia, severe hypocalcemia, severe hypokalemia, hypermagnesemia, neuromuscular diseases, acidosis, renal failure, and hepatic failure. Antagonism of neuromuscular blockade may result from alkalosis, hypercalcemia, hyperkalemia, and epinephrine.

PHARMACOLOGY: Onset of clinical effect is within 30 second to 2 minutes, and the duration of effect ranges from 20 minutes to 2 hours.

COMMENTS: Adequate sedation/analgesia should be provided with the use of rocuronium.

SILDENAFIL (VIAGRA, REVATIO)

INDICATIONS AND USE: (Revatio) Treatment of persistent pulmonary hypertension of the newborn refractory to treatment with inhaled nitric oxide; to facilitate weaning from nitric oxide (by attenuating rebound effects after discontinuing inhaled nitric oxide); secondary pulmonary hypertension following cardiac surgery.

ACTIONS: Selective phosphodiesterase type 5 (PDE-5) inhibitor found in the pulmonary vascular smooth muscle, vascular and visceral smooth muscle, corpus cavernosum, and platelets, and is responsible for the degradation of cyclic guanosine monophosphate (cGMP). Normally,

nitric oxide activates the enzyme guanylate cyclase, which increases the levels of cGMP; cGMP produces smooth muscle relaxation. Inhibition of PDE-5 by sildenafil increases the cellular levels of cGMP that potentiate vascular smooth muscle relaxation, particularly in the lung where there are high PDE-5 concentrations. Sildenafil causes vasodilation in the pulmonary vasculature and, to a lesser extent, in the systemic circulation.

DOUSAGE: PO, IV. Limited pediatric information exists; most pediatric literature consists of case reports or small studies, and a wide range of doses have been used; further studies are needed.

PO dosing (suspension available):

- **Full-term neonates:** 0.3 to 2 mg/kg/dose PO every 6 to 24 hours. Usual range: 0.5 to 3 mg/kg/dose every 6 to 12 hours.
- **Infants and children:** Initial: 0.25 to 0.5 mg/kg/dose PO every 6 to 8 hours; increase if needed and tolerated to 1 mg/kg/dose every 6 to 8 hours; doses as high as 2 mg/kg/dose every 6 to 8 hours have been used in several case reports.

IV dosing:

- **Neonates >34 weeks' gestation and <72 hours:** Loading dose of 0.4 mg/kg over 3 hours followed by continuous infusion of 1.6 mg/kg/day or 0.067 mg/kg/h for up to 7 days.

ADVERSE EFFECTS: Use in neonatal and pediatric patients should be limited and considered experimental; chronic use is not recommended due to a dose-dependent increased mortality risk observed in trials. The safety and efficacy in pediatric patients have not been established. There is short-term concern for worsening oxygenation and systemic hypotension, and concern for increased risk of retinopathy of prematurity and platelet dysfunction.

PHARMACOLOGY: Metabolism is via the liver via cytochrome P450 isoenzyme CYP3A4 (major) and CYP2C9 (minor). Major metabolite is formed via the *N*-demethylation pathway and has 50% of the activity of sildenafil.

COMMENTS: Significant increases in sildenafil concentrations may occur when used concurrently with CYP3A4 inhibitors such as azole antifungal agents, cimetidine, and erythromycin. Concurrent use with heparin may have an additive effect on bleeding time.

SODIUM ACETATE

INDICATIONS AND USE: Correction of metabolic acidosis through the conversion of acetate to bicarbonate; sodium replacement.

ACTIONS: Sodium acetate is metabolized to bicarbonate on an equimolar basis, which neutralizes hydrogen ion concentration and raises the blood and urine pH. Sodium is the primary extracellular cation.

DOUSAGE: IV. If sodium acetate is desired over sodium bicarbonate (dosing and same equation used for sodium acetate as sodium bicarbonate; see Sodium Bicarbonate).

- **Neonates, infants, and children:** IV 2 to 5 mEq/kg/day, maintenance sodium requirements.

ADVERSE EFFECTS: Hyponatremia, hypokalemic metabolic alkalosis, hypocalcemia, edema.

COMMENTS: Use with caution with hepatic failure, congestive heart failure.

SODIUM BICARBONATE

INDICATIONS AND USE: Management of metabolic acidosis; alkalinization of urine; stabilization of acid-base status in cardiac arrest; and treatment of life-threatening hyperkalemia or management of overdose of certain drugs.

ACTIONS: Alkalinizing agent that dissociates to provide bicarbonate ion, which neutralizes hydrogen ions and raises the pH of the blood and urine.

DOUSAGE: IV.

Initial dose: 1 to 2 mEq/kg; can be given in either of the following 2 ways:

- Slow IV over 30 minutes using 4.2% (0.5 mEq/mL) sodium bicarbonate solution.
- Further dilute in dextrose solution to a maximum concentration of 0.5 mEq/mL and infuse over 2 hours at a maximum rate of 1 mEq/kg/h.

Blood gas–directed dosing (the following equations provide an estimated replacement dose):

$$\text{HCO}_3^- \text{ (mEq)} = 0.3 \times \text{weight (kg)} \times \text{base deficit (mEq/L)}$$

or

$$\text{HCO}_3^- \text{ (mEq)} = 0.5 \times \text{weight (kg)} \times [24 \text{ a serum HCO}_3^- \text{ (mEq/L)}]$$

- Administer half of the calculated dose initially, and then reassess clinical status, serum bicarbonate, and pH. Give remaining half dose as infusion over the next 24 hours if needed.

ADVERSE EFFECTS: Rapid correction of metabolic acidosis with sodium bicarbonate can lead to intraventricular hemorrhage, hyperosmolality, metabolic alkalosis, hyponatremia, hypokalemia, and hypocalcemia.

COMMENTS: Use with close monitoring of arterial blood pH. Use only when adequate ventilation is confirmed. Routine use in cardiac arrest is not recommended. Avoid extravasation; tissue necrosis can occur due to the hypertonicity of sodium bicarbonate. For direct IV administration: in neonates and infants, use the 0.5 mEq/mL solution or dilute the 1 mEq/mL solution 1:1 with sterile water for injection; administer slowly, maximum rate in neonates and infants: 10 mEq/min; for infusion, dilute to a maximum concentration of 0.5 mEq/mL in dextrose solution and infuse over 2 hours at a maximum rate of 1 mEq/kg/h.

SODIUM CHLORIDE

INDICATIONS AND USE: Hyponatremia.

DOSAGE: IV. Dosage is dependent on clinical condition and fluid, electrolyte, and acid-base balance of neonate.

- **Sodium chloride 0.9% isotonic solution** or **3% hypertonic solution** depending on clinical severity and etiology.

$$\text{Dose (mEq sodium)} = [\text{desired serum sodium (mEq/L)} \\ - \text{actual serum sodium (mEq/L)}] \times 0.6 \times \text{weight (kg)}$$

- Use 125 mEq/L as the desired serum sodium for acute correction with a serum correction rate of <0.5 mEq/L/h; goal serum correction rate ≤8 to 10 mEq/L/day. [To determine dose in “mL” using 3% NaCl: Calculated dose in mEq of Na using equation above divided by 0.513; infuse NO faster than 1 mEq/kg/h via CENTRAL LINE ONLY.]

ADVERSE EFFECTS: Extravasation of hypertonic saline (>0.9%) is a vesicant; sodium toxicity with osmotic demyelination syndrome for rapid or overcorrection of serum sodium levels, transient hypotension, cardiac failure, electrolyte disturbances.

PHARMACOLOGY: Normal saline (0.9%) = 154 mEq/L; hypertonic saline (3%) = 513 mEq/L, 1027 mOsm/L.

COMMENTS: Hypertonic saline should be used with caution and only for severe cases of hyponatremia with a serum sodium <120 mEq/L and patient experiencing symptoms. Central line administration is preferred for hypertonic saline (>0.9%).

SODIUM POLYSTYRENE SULFONATE

INDICATIONS AND USE: Treatment of hyperkalemia.

ACTIONS: Cation exchange resin that removes potassium by exchanging sodium ions for potassium ions in the intestine before the resin is passed from the body.

DOSAGE: PO, PR (1 g of resin will exchange 1 mEq of sodium for 1 mEq of potassium).

- **Infants and children:** 1 g/kg/dose every 6 hours PO or every 2 to 6 hours PR.

ADVERSE EFFECTS: Large doses may cause fecal impaction, ischemic colitis, or intestinal perforation. Hypokalemia, hypocalcemia, hypomagnesemia, and sodium retention may occur.

COMMENTS: Due to complications of hypernatremia and necrotizing enterocolitis, **use in neonates is not usually recommended. Contraindicated in neonates via oral route or those with reduced gut motility or obstructive bowel disease.** Small amounts of magnesium and calcium may also be lost in binding. When using the powder for oral administration, dilute in 3 to 4 mL of fluid per gram of resin; 10% sorbitol, water, or syrup may be used as diluent. When using powder for rectal administration, dilute in water or 25% sorbitol at a concentration of 0.3 to 0.5 g/mL; retain enema in colon for at least 30 to 60 minutes or several hours, and follow with a cleansing enema of non-sodium-containing solution.

SOTALOL (BETAPACE, SORINE, SOTYLIZE)

INDICATIONS AND USE: Treatment of supraventricular tachycardia and maintenance of normal sinus rhythm in patients with symptomatic atrial fibrillation or flutter.

ACTIONS: Dose-related decrease in blood pressure through β_1 - and β_2 -adrenergic receptor blockade without causing significant reflex tachycardia or a decrease in heart rate.

DOSAGE: PO.

- **PNA ≥ 3 days:** 30 mg/m²/dose PO every 8 hours; dose should be reduced by an age-related factor obtained from a graph available within the package insert. Dose should be adjusted based on individual response and tolerance with continuous electrocardiogram monitoring.
- **Alternative dosing (limited data available):** 2 mg/kg/day PO divided every 8 hours; increase dose gradually by increments of 1 to 2 mg/kg/day a minimum of 3 days between titrations. Proposed target dose: 4 mg/kg/day PO divided every 8 hours; it is not necessary to achieve target dose if desired clinical effect has been achieved at a lower dosage.

ADVERSE EFFECTS: Hypotension and bradycardia at higher doses, congestive heart failure; edema, diaphoresis, dyspnea, increased liver enzymes, thrombocytopenia, inflammation phlebitis. Prolonged QT_c interval ≥ 500 ms, reduce dose or discontinue sotalol.

PHARMACOLOGY: Larger drug exposure (area under the curve) and greater pharmacologic effects were observed in studies in smaller subjects (body surface area <0.33 m²). Time to reach steady state in a neonate may be ≥ 1 week. Half-life elimination in neonates and infants is 7.5 to 8.5 hours.

COMMENTS: Baseline QT_c interval must be determined prior to initiation. Contraindicated in patients with asthma, overt cardiac failure, heart block, cardiogenic shock, or severe bradycardia. May cause a paradoxical increase in blood pressure in patients with pheochromocytoma. Use with caution in renal dysfunction.

SPIRONOLACTONE (ALDACTONE, CAROSPIR)

WARNING: Aldactone has been shown to be tumorigenic in chronic animal studies. Unnecessary use of this drug should be avoided.

INDICATIONS AND USE: Primarily used in conjunction with other diuretics for the treatment of hypertension, congestive heart failure, and edema with prolonged diuretic therapy.

ACTIONS: Competes with aldosterone for receptor sites in the distal renal tubules; increases sodium chloride and water excretion while conserving potassium and hydrogen ions; it also may block the effect of aldosterone on arteriolar smooth muscle.

DOSAGE: PO. Commercially available suspension (25 mg/5 mL) is not therapeutically equivalent to the tablets; pediatric dosing is based on experience with tablets and extemporaneously compounded suspension.

- 1 to 3 mg/kg/day PO divided every 12 to 24 hours.

ADVERSE EFFECTS: Hyperkalemia, dehydration, hyponatremia, hyperchloremic metabolic acidosis, rash, vomiting, diarrhea, hepatotoxicity, and gynecomastia in males.

COMMENTS: Contraindicated in hyperkalemia, anuria, and rapidly deteriorating renal function. Monitor potassium closely when giving potassium supplements.

SUCROSE (SWEET-EASE, TOOTSWEET)

INDICATIONS AND USE: Mild analgesia in neonates during minor procedures, such as heel stick, eye examination for retinopathy of prematurity, circumcision, immunization, venipuncture, endotracheal tube intubation and suctioning, nasogastric tube insertion, or IM or subcutaneous injection. (See also Chapters 15 and 81.)

ACTIONS: Exact mechanism of action is unknown; sucrose may induce endogenous opioid release.

DOSAGE: PO. May be administered directly into baby's mouth or via a pacifier dipped into solution.

- **Neonates:** 0.1 to 0.5 mL of 24% solution placed on the tongue or buccal surface 2 minutes prior to procedure.
- **Infants:** 2 mL of 24% solution.

ADVERSE EFFECTS: Avoid in patients with gastrointestinal tract abnormalities—use only in patients with functioning gastrointestinal tract; necrotizing enterocolitis has not been reported with sucrose administration. Avoid use in patients at risk for aspiration. Do not use in patients requiring ongoing analgesia.

PHARMACOLOGY: Time to maximum effect is 2 minutes; duration of effect is 3 to 10 minutes.

COMMENTS: Sucrose 24% solution has an osmolarity of 1000 mOsmol/L.

SULFACETAMIDE OPHTHALMIC

See Chapter 58.

SULFACETAMIDE SODIUM

ACTION AND SPECTRUM: Interferes with bacterial growth by inhibiting bacterial folic acid synthesis. Used for the treatment and prophylaxis of conjunctivitis caused by susceptible strains of gram-positive and gram-negative bacteria such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella*.

DOSAGE: Ocular.

- Instill 1 to 2 drops into each eye every 2 to 3 hours initially, then increase the time interval as the condition responds; apply ointment to each eye every 3 to 4 hours and at bedtime; treatment duration is usually 7 to 10 days.

ADVERSE EFFECTS: May cause burning and stinging sensation of eyes, increased sensitivity to light, blurred vision, and pruritus.

COMMENTS: Contraindicated in infants <2 months of age or with hypersensitivity to sulfonamides.

SULFADIAZINE

ACTION AND SPECTRUM: Interferes with bacterial growth by inhibiting bacterial folic acid synthesis. Used for adjunctive treatment of *Toxoplasma gondii* in combination with pyrimethamine.

DOSAGE: PO. See also Pyrimethamine (page 1302) for dosing information.

Congenital toxoplasmosis:

- **Newborns and infants:** 100 mg/kg/day PO divided every 12 hours for 12 months in conjunction with pyrimethamine and supplemental leucovorin.

Acquired toxoplasmosis:

- **Infants ≥2 months and children:** 100 to 200 mg/kg/day PO divided every 4 to 6 hours in conjunction with pyrimethamine (maximum dose 6000 mg/day) and supplemental leucovorin.

ADVERSE EFFECTS: Hypersensitivity (fever, rash, hepatitis, vasculitis, and lupus-like syndrome), neutropenia, agranulocytosis, thrombocytopenia, aplastic anemia, Stevens-Johnson syndrome, and crystalluria (keep urine alkaline, maintain adequate hydration and high urine output). Kernicterus may occur.

COMMENTS: Avoid use in neonates, except for treatment of congenital toxoplasmosis. Concurrent leucovorin (oral folic acid) supplementation is necessary to prevent folic acid deficiency.

Caution in patients with glucose-6-phosphate dehydrogenase deficiency. Contraindicated with hypersensitivity to sulfonamides.

TETRACYCLINE OPHTHALMIC

See Chapter 58.

TOBRAMYCIN OPHTHALMIC

See Chapter 58.

TOBRAMYCIN SULFATE

ACTION AND SPECTRUM: Aminoglycoside antibiotic used for documented or suspected infections caused by susceptible gram-negative bacilli including *Pseudomonas aeruginosa* and nonpseudomonal enteric bacillus infection, which is more sensitive to tobramycin than gentamicin based on susceptibility tests; usually used in combination with a β -lactam antibiotic.

DOSAGE: IV, IM, ocular, inhalation. Base the initial dose on body weight, then monitor levels and adjust using pharmacokinetics. Many dosing strategies exist such as extended interval, age based, weight based, and traditional. Monitor serum levels after 2 days of therapy.

Age based:

- **≤29 weeks' gestational age (GA):**
 - **0 to 7 days:** 5 mg/kg/dose IV/IM every 48 hours.
 - **8 to 28 days:** 4 mg/kg/dose IV/IM every 36 hours.
 - **≥29 days:** 4 mg/kg/dose IV/IM every 24 hours.
- **30 to 34 weeks' GA:**
 - **0 to 7 days:** 4.5 mg/kg/dose IV/IM every 36 hours.
 - **>7 days:** 4 mg/kg/dose IV/IM every 24 hours.
- **>35 weeks GA:** 4 mg/kg/dose IV/IM every 36 hours.

Infants and children: 2.5 mg/kg/dose IM/IV every 8 hours.

Ophthalmic:

- Instill 1 to 2 drops into each eye every 4 hours or more often if infection is severe, or apply a small amount of ointment into each eye 2 to 3 times per day or, for severe infections, every 3 to 4 hours.

Inhalation:

- 150 mg twice daily nebulized has been used for difficult-to-manage neonatal intensive care unit patients.

ADVERSE EFFECTS: Ototoxicity (may be associated with high serum aminoglycoside concentrations persisting for prolonged periods) with tinnitus, hearing loss; early toxicity usually affects high-pitched sound; nephrotoxicity (high trough levels) with proteinuria, elevated serum creatinine, oliguria, and macular rash.

COMMENTS: Reserve for cases resistant to gentamicin. Obtain serum peak and trough concentrations at about the third maintenance dose. Desired peak is 4 to 12 mcg/mL (sample 30 minutes after the infusion is complete); desired trough is 0.5 to 2 mcg/mL (sample 30 minutes to just before the next dose).

TOPIRAMATE (TOPAMAX)

INDICATIONS AND USE: Treatment of refractory neonatal seizures; infantile spasms; neuroprotectant following anoxic injury (with cooling).

ACTIONS: Combination of potential mechanisms: blocks neuronal voltage-dependent sodium channels, enhances γ -aminobutyric acid activity, antagonizes glutamate receptors, and weakly inhibits carbonic anhydrase.

DOSAGE: PO. Very limited data.

Infantile spasms: Initial: 1 to 3 mg/kg/day in 1 to 2 divided doses, titrate every 3 to 7 days in increments of 1 to 3 mg/kg/day as tolerated until seizures are controlled; reported range 4 to 27 mg/kg/day.

Neonatal seizures, refractory: 5 to 10 mg/kg/day PO in 1 to 2 divided doses.

Neuroprotectant following anoxic injury: 5 mg/kg/dose PO on day 1, followed by 3 mg/kg/dose PO on days 2 and 3.

ADVERSE EFFECTS: Cognitive dysfunction, somnolence, fatigue, hyperammonemia, encephalopathy, metabolic acidosis (increased with diarrhea, hepatic impairment, renal dysfunction, ketogenic diet, or surgery), oligohydrosis, hyperthermia, increased intraocular pressure, renal calculus, reduction in growth.

PHARMACOLOGY: Percentage of dose metabolized in liver and clearance are increased in patients receiving enzyme inducers; hypothermia significantly decreases elimination rate. Dosing adjustment may be required in renal and hepatic impairment. Immediate-release preparations are bioequivalent.

COMMENTS: Pediatric patients <24 months of age may be at increased risk for topiramate-associated hyperammonemia, especially when used concurrently with valproic acid. Sprinkle capsules may be opened and mixed in a small amount of soft food (applesauce, pudding, yogurt) to be swallowed immediately; do not chew or store for later use. Abrupt discontinuation may increase seizure frequency.

TRIFLURIDINE OPHTHALMIC

See Chapter 58.

TROPICAMIDE OPHTHALMIC

INDICATIONS AND USE: Mydriasis and cycloplegia for diagnostic and therapeutic ophthalmic procedures. (See also Chapter 58.)

ACTIONS: Anticholinergic activity produces pupillary dilation.

DOSAGE: Ocular.

- One drop of 0.5% ophthalmic solution instilled into eye at least 15 minutes prior to procedure. Apply pressure to lacrimal sac during and for 2 minutes after instillation to reduce systemic absorption.

ADVERSE EFFECTS: Blurred vision, photophobia, stinging of the eyes, tachycardia, vasodilatation, restlessness, decreased gastrointestinal motility, xerostomia, urinary retention.

PHARMACOLOGY: Onset of mydriasis is 5 to 20 minutes; cycloplegia 20 to 40 minutes.

COMMENTS: Consider holding feeds for 4 hours after procedure.

URSODIOL (ACTIGALL)

INDICATIONS AND USE: Facilitate bile excretion in infants with biliary atresia; treatment of cholestasis secondary to parenteral nutrition; improve the hepatic metabolism of essential fatty acids in patients with cystic fibrosis.

ACTIONS: A hydrophobic bile acid that decreases the cholesterol content of bile and bile stones by reducing the secretion of cholesterol from the liver and decreases the fractional reabsorption of cholesterol by the intestines.

DOSAGE: PO.

Biliary atresia:

- **Neonates and infants:** 10 to 20 mg/kg/day PO in 2 to 3 divided doses.

Total parenteral nutrition–induced cholestasis:

- **Infants and children:** 30 mg/kg/day PO in 3 divided doses.

Improvement in the hepatic metabolism of essential fatty acids in cystic fibrosis:

- **Infants and children:** 20 mg/kg/day PO in 2 divided doses.

ADVERSE EFFECTS: Rash, diarrhea, biliary pain, constipation, stomatitis, flatulence, nausea, vomiting, abdominal pain, elevated liver enzymes.

PHARMACOLOGY: Absorbed well orally. During metabolism, the drug undergoes extensive enterohepatic recycling; following hepatic conjugation and biliary secretion, the drug is hydrolyzed to the unconjugated form and is recycled or transformed to lithocholic acid by colonic microbial flora.

COMMENTS: Use with caution in patients with nonvisualizing gallbladder and patients with chronic liver disease.

VALGANCICLOVIR (VALCYTE)

WARNING: Valganciclovir may cause severe neutropenia, anemia, thrombocytopenia, pancytopenia, and bone marrow failure.

ACTION AND SPECTRUM: Prodrug of ganciclovir that is converted to ganciclovir by the liver and intestinal esterases. Used to treat symptomatic congenital cytomegalovirus infection.

DOSAGE: PO.

- 16 mg/kg/dose PO every 12 hours for 6 months. Use commercially available product only.

ADVERSE EFFECTS: Neutropenia is frequent; if absolute neutrophil count (ANC) is <500 cells/mm³, hold dose until ANC is >750 cells/mm³. If ANC falls below 750 cells/mm³, reduce dose by 50%; if ANC falls again to below 500 cells/mm³, discontinue drug. Also, granulocytopenia, anemia, thrombocytopenia; acute renal failure/acute kidney injury, dysuria, increased serum creatinine; hyperglycemia, hyper-/hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, and edema.

PHARMACOLOGY: Excreted primarily as ganciclovir by the kidney; elimination half-life is 3 hours; dosing adjustment necessary with renal impairment.

VANCOMYCIN HCL

ACTION AND SPECTRUM: Bactericidal action through inhibition of cell wall synthesis by blocking glycopeptide polymerization with activity against most gram-positive cocci and bacilli, including streptococci, staphylococci (including methicillin-resistant staphylococci), clostridia (including *Clostridium difficile*), *Corynebacterium*, and *Listeria monocytogenes*. Bacteriostatic against enterococci.

DOSAGE: PO, IV, intrathecal, intraventricular.

Neonates:

- PNA <7 days:
 - <1.2 kg: 15 mg/kg/day IV every 24 hours.
 - 1.2 to 2 kg: 10 to 15 mg/kg/dose IV every 12 to 18 hours.
 - >2 kg: 10 to 15 mg/kg/dose IV every 8 to 12 hours.
- PNA ≥ 7 days:
 - <1.2 kg: 15 mg/kg/day IV every 24 hours.
 - 1.2 to 2 kg: 10 to 15 mg/kg/dose IV every 8 to 12 hours.
 - >2 kg: 10 to 15 mg/kg/dose IV every 6 to 8 hours.

Infants >1 month and children:

- 40 to 45 mg/kg/day IV in divided doses every 6 to 8 hours.
- Intrathecal/intraventricular:** Use a preservative-free preparation.

- Neonates: 5 to 10 mg/day.

Serious infection or organisms with a minimum inhibitory concentration (MIC) = 1 mcg/mL:

- **Initial:** 15 to 20 mg/kg/dose IV every 6 to 8 hours.
- **Methicillin-resistant *Staphylococcus aureus* (MRSA) infections/bacteremia:** 15 mg/kg/dose IV every 6 hours for 2 to 6 weeks depending on severity.
- **Complicated skin and skin structure infections:** Treat for 7 to 14 days.
- **Meningitis:** Treat for 2 weeks (\pm rifampin).
- **Osteomyelitis:** Treat for minimum of 4 to 6 weeks.
- **Pneumonia:** Treat for 7 to 21 days.

Antibiotic-associated pseudomembranous colitis:

- (**Note:** Metronidazole is the drug of initial choice based on 2018–2021 AAP *Red Book* recommendations.) Children: 30 mg/kg/day PO in divided doses every 6 hours for 10 days, not to exceed 2 g/day.

ADVERSE EFFECTS: Allergy (rash and fever), ototoxicity (with prolonged peak >40 mcg/mL), nephrotoxicity (higher incidence with trough >10 mcg/mL), and thrombophlebitis at the site of injection. Rapid infusion may cause rash, chills, and fever ("red man" syndrome), mimicking anaphylactic reaction. Apnea and bradycardia without other signs of red man syndrome have also been associated with rapid infusion. Infuse dose over at least 60 minutes.

PHARMACOLOGY: Renally excreted. Half-life is 6 to 10 hours.

COMMENTS: Peak drawn 60 minutes after completion of infusion, goal range 25 to 40 mcg/mL; 30 to 40 mcg/mL recommended when treating meningitis. Trough level drawn 30 minutes prior to scheduled dose, goal range 10 to 15 mcg/mL; experts recommend 15 to 20 mcg/mL for organisms with an MIC ≥ 1 mcg/mL when treating MRSA pneumonia, endocarditis, or bone/joint infections. Draw serum peak and trough levels around the fourth maintenance dose. Monitor serum creatinine, blood urea nitrogen, and urine output. If staphylococci exhibit tolerance to the drug, combine with an aminoglycoside, with or without rifampin. Oral doses are poorly absorbed.

VANCOMYCIN OPHTHALMIC

See Chapter 58.

VARICELLA-ZOSTER IMMUNE GLOBULIN (VARIZIG)

INDICATIONS AND USE: For protection of infants of mothers with onset of varicella-zoster infections (chickenpox) within 5 days before or 48 hours after delivery of postnatally exposed preterm infants ≤ 1 kg or <28 weeks' gestation regardless of maternal history, and of postnatally exposed premature infants ≥ 28 weeks' gestation whose mothers have no evidence of immunity.

ACTIONS: Passive immunity through infusion of immunoglobulin G antibodies. Protection lasts 1 month or longer and does not reduce the incidence, but acts to decrease the risk of complications.

DOSAGE: IM.

- ≤ 2 kg: 62.5 units.
- 2.1 to <10 kg: 125 units

ADVERSE EFFECTS: Pain, erythema, swelling, rash at the site of injection, and, rarely, anaphylaxis.

COMMENTS: Best results are achieved if given within 96 hours after exposure. VZIG was discontinued in the United States in 2006. It is currently available as VariZIG under an Investigational New Drug Application Expanded Access protocol. Inventory for anticipated patients may be obtained by contacting FFF Enterprises at 800-843-7477. Additional information may be found at: <http://www.fffenterprises.com/products/varizig.html>.

VASOPRESSIN

INDICATIONS AND USE: Treatment of diabetes insipidus, vasoconstriction to increase blood pressure in patients with vasodilatory shock who remain hypotensive despite fluids and catecholamines, systemic hypotension, and persistent pulmonary hypertension in neonates.

ACTIONS: Stimulates a family of arginine vasopressin receptors, oxytocin receptors, and purinergic receptors; increases systemic vascular resistance and mean arterial blood pressure; in response to these effects, a decrease in heart rate and cardiac output may be seen; increases water permeability at the renal tubule, resulting in decreased urine volume and increased osmolality.

DOSAGE: IV. Units of measure vary by indication and age (eg, milliunits/kg/h, units/kg/h, milliunits/kg/min, units/kg/min, units/h, units/min); extra precautions should be taken.

Cardiac surgery: Continuous IV infusion 0.3 to 0.5 milliunits/kg/min, titrated to hemodynamic goals.

Diabetes insipidus: Variable dosage; titrate based on serum and urine osmolality in addition to fluid balance and urine output. *Central diabetes insipidus:* Continuous IV infusion 0.5 milliunits/kg/h; titrate in increments of 0.5 milliunits/kg/h every 10 minutes to target urine output (approximately <2 mL/kg/h).

Hypotension: Very limited data; continuous IV infusion 0.17 to 0.67 milliunits/kg/min (0.01–0.04 units/kg/h); dosing initiated at low end of range and titrated at 20-minute intervals.

Persistent pulmonary hypertension of the newborn: Very limited data; continuous IV infusion 0.1 milliunits/kg/min; increase by 0.1 milliunits/kg/min every hour as needed for clinical response to maximum dose of 1.2 milliunits/kg/min.

Shock, refractory hypotension unresponsive to fluid resuscitation and catecholamines: Continuous IV infusion 0.17 to 10 milliunits/kg/min (0.01–0.6 units/kg/h); dosing initiated at the lower end of the range and titrated to effect.

ADVERSE EFFECTS: Hyponatremia, atrial fibrillation, bradycardia, low cardiac output, right heart failure, peripheral vasoconstriction and limb ischemia, water intoxication, mesenteric ischemia, increased serum bilirubin, renal insufficiency, bronchoconstriction.

PHARMACOLOGY: Rapid vasopressor effect when administered IV; peak effect occurs within 15 minutes of initiation of continuous infusion.

COMMENTS: Vesicant; infusion through central line is highly recommended. Monitor blood pressure, heart rate, fluid intake and output, urine specific gravity, and urine and serum osmolality.

VECURONIUM BROMIDE

WARNING: This drug should be administered by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USE: Skeletal muscle relaxation during surgery; increases pulmonary compliance during assisted mechanical ventilation and facilitates endotracheal intubation.

ACTIONS: Nondepolarizing neuromuscular-blocking agent that produces skeletal muscle paralysis by blocking acetylcholine binding at the receptor at the myoneural junction.

DOSAGE: IV.

Neonates:

- 0.1 mg/kg/dose, then maintenance 0.03 to 0.15 mg/kg IV push every 1 to 2 hours as needed.

Infants >7 weeks:

- 0.1 mg/kg/dose, repeat every hour as needed; may be administered as a continuous infusion at 0.8 to 1.7 mcg/kg/min (0.05–0.1 mg/kg/h).

ADVERSE EFFECTS: May cause hypoxemia with inadequate mechanical ventilation; bronchospasm, apnea, arrhythmias, tachycardia, hypotension, hypertension, and excessive salivation may occur. Potentiation of neuromuscular blockade may result from aminoglycosides, electrolyte abnormalities, severe hyponatremia, severe hypocalcemia, severe hypokalemia, hypermagnesemia, neuromuscular diseases, acidosis, renal failure, and hepatic failure. Antagonism of neuromuscular blockade may result from alkalosis, hypercalcemia, hyperkalemia, and epinephrine.

PHARMACOLOGY: Onset of action is 2.5 to 3 minutes, with a duration that varies with dose and age. Elimination is reduced with hepatic dysfunction.

COMMENTS: Causes less tachycardia than pancuronium bromide. When used with narcotics, decreases in heart rate and blood pressure have been observed. Adequate sedation/analgesia should be provided with the use of vecuronium. Must be reconstituted prior to administration; for neonates, reconstitute with sterile water for injection instead of provided diluent.

VIDARABINE OPHTHALMIC

See Chapter 58.

VITAMIN A

INDICATIONS AND USE: Treatment and prevention of vitamin A deficiency; to reduce the risk of chronic lung disease in high-risk premature neonates with vitamin A deficiency.

ACTIONS: Vitamin A is required for growth and bone development, vision, reproduction, and differentiation and maintenance of epithelial tissue. The pulmonary histopathologic changes

seen in patients with bronchopulmonary dysplasia/chronic lung disease are similar to those seen with vitamin A deficiency. Retinol metabolites exhibit potent and site-specific effects on gene expression as well as lung growth and development.

DOSAGE: PO, IM.

Prevention of bronchopulmonary dysplasia/chronic lung disease in premature infants:

- 5000 units IM 3 times a week for 4 weeks; start within first 4 days of life.

Prophylactic therapy for children at risk for developing deficiency:

- Infants age 6 months to 1 year: 100,000 units PO every 4 to 6 months.

Adequate intake:

- 1 to <6 months: 400 mcg/day (1330 units).
- 6 to <12 months: 500 mcg/day (1670 units).

ADVERSE EFFECTS: Concomitant use with glucocorticoids should be avoided, as it significantly raises plasma vitamin A concentrations; seen only with doses that exceed physiologic replacement. Monitor for signs of toxicity: full fontanel, lethargy, irritability, hepatosplenomegaly, edema, and mucocutaneous lesions. Avoid products containing benzyl alcohol in neonates.

VITAMIN D3 (CHOLECALCIFEROL)

INDICATIONS AND USE: Prevention and treatment of vitamin D deficiency and/or rickets; dietary supplement.

ACTIONS: Stimulates calcium and phosphate absorption from the small intestine; promotes secretion of calcium from bone to blood; promotes renal tubule phosphate resorption; acts on osteoblasts to stimulate skeletal growth and on the parathyroid glands to suppress parathyroid hormone synthesis and secretion.

DOSAGE: PO.

Prevention of vitamin D deficiency:

- **Premature infants:** ≤ 1.5 kg 200 international units per day; > 1.5 kg 200 international units per day; increase to 400 international units per day when tolerating full enteral nutrition.
- **Breast-fed neonates (fully or partially):** 400 international units per day beginning in first few days of life. Continue supplementation until infant is weaned to ≥ 1000 mL/day or 1 quart per day of vitamin D–fortified formula or whole milk (after 12 months of age).
- **Formula-fed neonates ingesting <1000 mL of vitamin D–fortified formula:** 400 international units per day.

Treatment of vitamin D deficiency and/or rickets:

- 2000 international units per day for 2 to 3 months together with calcium and phosphorus supplementation; once radiologic evidence of healing is observed, decrease to 400 to 1000 international units per day.

ADVERSE EFFECTS: Hypercalcemia, azotemia, vomiting, and nephrocalcinosis.

PHARMACOLOGY: 25(OH)-D concentration > 250 nmol/L may be associated with risk of vitamin D intoxication.

COMMENTS: For detailed information, see the 2008 American Academy of Pediatrics (AAP) statement, *Prevention of Rickets and Vitamin D Deficiency in Infants, Children and Adolescents* (Wagner et al, 2008) and the 2013 AAP statement, *Calcium and Vitamin D Requirements of Enterally Fed Preterm Infants* (Abrams et al, 2013). Excessive doses may lead to hypervitaminosis D, manifested by hypercalcemia and its associated complications. (See also Chapter 91.)

VITAMIN E (DL- α -TOCOPHEROL ACETATE)

INDICATIONS AND USE: Treatment or prevention of vitamin E deficiency.

ACTIONS: Antioxidant that prevents oxidation of vitamins A and C; protects polyunsaturated fatty acids in membranes from attack by free radicals and protects red blood cells against hemolysis by oxidizing agents.

DOSAGE: PO.**Prevention of vitamin E deficiency:**

- **Premature or low birthweight neonates:** 5 units PO per day diluted with feedings. Do not give simultaneously with iron; will decrease iron absorption.

Vitamin E deficiency:

- 25 to 50 units PO per day.

COMMENTS: Physiologic serum vitamin E levels are 0.8 to 3.5 mg/dL. Serum levels should be monitored when pharmacologic doses of vitamin E are administered. Liquid preparation is very hyperosmolar (3620 mOsmol/kg H₂O) and should be diluted (1 mg of DL- α -tocopherol acetate = 1 unit), large dosage has been associated with necrotizing enterocolitis.

VITAMIN K1 (PHYTONADIONE)

INDICATIONS AND USE: Prevention and treatment of hemorrhagic disease of the newborn and vitamin K deficiency.

ACTIONS: Required for the synthesis of blood coagulation factors II, VII, IX, and X. Because vitamin K1 may require 3 hours or more to stop active bleeding, fresh-frozen plasma, 10 mL/kg, may be necessary when bleeding is severe. The drug has no antagonistic effects against heparin.

DOSAGE: PO, IM, IV.

Neonatal hemorrhagic disease: For prophylaxis, administer within 1 hour of birth.

- **Term neonate prevention:** 1 mg IM at birth.
- **Preterm infant <32 weeks' gestation, prevention:**
 - **Birthweight <1000 g:** 0.3 to 0.5 mg/kg IM at birth.
 - **Birthweight \geq 1000 g:** 0.5 to 1 mg IM at birth.
- **Treatment:** 1 to 2 mg IM per day.

Vitamin K deficiency (drugs, malabsorption, or decreased synthesis of vitamin K):

- **Infants and children:** 2.5 to 5 mg PO per day or 1 to 2 mg subcutaneous, IM, IV, as a single dose.

Oral anticoagulant overdose:

- 0.5 to 2 mg/dose subcutaneous, IV every 12 hours as needed. (Monitor the serial prothrombin time and partial thromboplastin time for response.)

ADVERSE EFFECTS: Relatively nontoxic. Hemolytic anemia and kernicterus have been reported in neonates given greater than recommended dose. Severe hypersensitivity or anaphylactic reactions have been associated with IV administration of vitamin K1. Efficacy of treatment with vitamin K1 is decreased in patients with liver disease.

ZIDOVUDINE (AZT, ZDV; RETROVIR)

WARNING: Zidovudine may cause hematologic toxicity including severe neutropenia and anemia. Lactic acidosis and severe hepatomegaly with steatosis have been reported with nucleoside analogs. Prolonged use has been associated with symptomatic myopathy and myositis.

INDICATIONS AND USE: Chemoprophylaxis to reduce perinatal human immunodeficiency virus (HIV) transmission; prophylactic treatment of neonates born to HIV-infected mothers; treatment of HIV infection in combination with other antiretroviral agents.

ACTIONS: Nucleoside reverse transcriptase inhibitor that inhibits HIV viral polymerases and DNA replication.

DOSAGE: IV, PO (aidsinfo.nih.gov/guidelines, 2017).

Prevention of maternal–fetal HIV transmission and treatment of HIV infection:

- Dosing should begin as soon as possible after birth (by 6–12 hours after delivery) and continue for the first 4 to 6 weeks of life. Use IV route only until oral therapy can be

administered. For infants unable to tolerate oral agents, the IV dose should be 75% of the oral dose while maintaining the same dosing interval. Syrup available 50 mg/5 mL

- **<30 weeks' gestation:** 2 mg/kg/dose PO every 12 hours; or if unable to tolerate oral medications, 1.5 mg/kg/dose IV every 12 hours. Advance to every 3 mg/kg PO every 12 hours at 4 weeks' PNA. Advance to 12 mg/kg PO every 12 hours at 8 weeks' PNA.
- **≥30 to <35 weeks' gestation:** 2 mg/kg/dose PO every 12 hours; or if unable to tolerate oral medications, 1.5 mg/kg/dose IV every 12 hours. Advance to 3 mg/kg PO every 12 hours at 2 weeks' PNA. Advance to 12 mg/kg PO every 12 hours at 6 weeks' PNA.
- **≥35 weeks' gestation:** 4 mg/kg/dose PO twice daily; or if unable to tolerate oral medications, 3 mg/kg/dose IV every 12 hours. Advance to 12 mg/kg PO every 12 hours at 4 weeks' PNA.

ADVERSE EFFECTS: The most frequent are granulocytopenia and severe anemia. Others include thrombocytopenia, leukopenia, diarrhea, fever, seizures, insomnia, cholestatic hepatitis, and lactic acidosis.

COMMENTS: Use with caution in patients with impaired hepatic function, bone marrow compromise, or folic acid or vitamin B12 deficiency.

INTERACTIONS: Concurrent acetaminophen, probenecid, cimetidine, indomethacin, morphine, and benzodiazepines may increase toxicity as a result of decreased glucuronidation or reduced renal excretion of zidovudine. Concomitant acyclovir may cause neurotoxicity; ganciclovir and flucytosine may cause severe hematologic toxicity as a result of synergistic myelosuppression. Ribavirin and zidovudine are antagonistic and should not be used concurrently.

156 Effects of Drugs and Substances on Lactation and Infants

The chapter provides some summary data on some of the medications and substances that may be taken by the mother during pregnancy and/or breast feeding. **Regardless of the designated risk category or presumed safety, no drug or substance should be used during pregnancy and/or breast feeding unless it is clearly needed and the potential benefits clearly outweigh the risks.** The table lists the generic medication name and, in parentheses, the US Food and Drug Administration (FDA) fetal risk category followed by the breast-feeding compatibility. At the present time, there is no formally FDA-sanctioned breast-feeding category, and the system used here is discussed later. Lastly, any reported effects on lactation or on infant effects based on breast milk consumption are noted. The editorial board has made an attempt to summarize the data based on the best information available for an individual agent where sources disagree. These data are subject to change as new information becomes available. The reader is advised to consult the FDA (www.fda.gov) and manufacturer's website for the latest information concerning risks of these medications. The FDA developed a revised labeling that replaces the old 5-letter (A, B, C, D, X) system with more helpful information about a medication's risks to the expectant mother, the developing fetus, and the breast-fed infant. The labeling changes went into effect on June 30, 2015, for all new drugs, which will use the new format immediately, whereas labeling for prescription drugs approved on or after June 30, 2001, will be phased in gradually. Lactation will include (1) risk summary; (2) clinical considerations; and (3) data. This project will take several years to complete. Labeling for over-the-counter (OTC) medicines will not change.

US FDA FETAL RISK CATEGORIES

CATEGORY A

Adequate studies in pregnant women have not demonstrated a risk to the fetus in the first trimester of pregnancy; there is no evidence of risk in the last 2 trimesters.

CATEGORY B

Animal studies have not demonstrated a risk to the fetus, but there are no adequate studies in pregnant women.

or

Animal studies have shown an adverse effect, but adequate studies in pregnant women have not demonstrated a risk to the fetus during the first trimester of pregnancy, and there is no evidence of risk in the last 2 trimesters.

CATEGORY C

Animal studies have shown an adverse effect on the fetus, but there are no adequate studies in humans. The benefits from the use of the drug in pregnant women may be acceptable despite its potential risks.

or

There are no animal reproduction studies and no adequate studies in humans.

CATEGORY D

There is evidence of human fetal risk, but the potential benefits from the use of the drug in pregnant women may be acceptable despite its potential risks.

CATEGORY X

Studies in animals or humans or adverse reaction reports, or both, have demonstrated fetal abnormalities. The risk of use in pregnant women clearly outweighs any possible benefit.

BREAST-FEEDING COMPATIBILITY

As noted, no formal system exists for categorizing drugs or substances and their effect on breast feeding, lactation, and effects on the infant. The following system is used in this book:

CATEGORY (+): Generally compatible with breast feeding.

CATEGORY (-): Avoid with breast feeding. Toxicity can be seen.

CATEGORY (CI): Contraindicated.

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Abacavir (C/-)	CDC recommends HIV-infected mothers in developed countries to not breast feed.
Acarbose (B/-)	No human lactation data available. Avoid breast feeding until safety data available.
Acebutolol (B/-)	AAP recommends to use cautiously due to adverse effects of hypotension, cyanosis, and bradycardia related to β -blockade.
Acetaminophen (B/+)	AAP classifies acetaminophen as compatible with breast feeding.
Acetylcysteine (B/+)	No human lactation data available. Probably compatible.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Acitretin (X/C)	Because of the teratogenicity of acitretin, a program called PPET (Pregnancy Prevention Is Essential with Treatment) has been developed to educate women of childbearing potential and their healthcare providers about the serious risks associated with acitretin and to help prevent pregnancies from occurring with the use of this drug and for 3 years after its discontinuation.
Acyclovir (B/+)	AAP classifies acyclovir as compatible with breast feeding; breast-feeding mothers with herpetic lesions near or on the breast should avoid breast feeding.
Adalimumab (C/+)	Excreted into breast milk in low concentrations. Effects on nursing infant unknown.
Adenosine (C/+)	IV drug, used in acute care situations, short half-life.
Ado-trastuzumab emtansine (X/C)	No human lactation data available. Due to potential for serious adverse effects, breast feeding not recommended during treatment and for 7 months following the last dose.
Albendazole (C/+)	Probably compatible with a single oral dose. Low oral bio-availability suggests excretion into breast milk not clinically significant. Avoid ingestion with high-fat meal.
Albiglutide (C/-)	No human lactation data available. Manufacturer recommends a decision be made to continue nursing or discontinue the drug, taking into account the importance of treatment to the mother.
Albuterol (C/+)	Monitor nursing infant for agitation and spitting up. Use inhaled form to decrease maternal absorption. Generally considered acceptable in breast-feeding women when used in usual doses.
Alendronate (C/+)	Probably compatible. Low plasma concentrations and rapid plasma clearance suggest minimal amounts excreted into breast milk. Consider monitoring the infant's serum calcium during the first 2 months postpartum.
Alfentanil (C/-)	Used epidurally or intravenously during labor or for a short time immediately postpartum would not be expected to cause adverse effects. Opioid therapy should be avoided in breast-feeding mothers due to potential for apnea and sedation in the infant.
Allopurinol (C/+)	Allopurinol and its metabolite are excreted into human milk. AAP classifies allopurinol as compatible with breast feeding.
Almotriptan (C/+)	No human lactation data available. Low molecular weight of drug suggests excretion into breast milk but effect on nursing infant is unknown.
Alogliptin (C/-)	No human lactation data available. Low molecular weight of drug suggests excretion into breast milk, but effect on nursing infant is unknown. Alternative agents are preferred.
Alprazolam (D/-)	Excreted into breast milk. Because of the potent effects on neurodevelopment, probable withdrawal, lethargy, and weight loss in infant, use should be avoided during breast feeding.
Amantadine (C/C)	Excreted into breast milk in low concentrations. Not recommended due to potential for urinary retention, vomiting, and skin rash.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Amikacin (D/–)	Low concentrations in breast milk because of poor oral absorption. Risk for modification of bowel flora.
Amiloride (B/+)	Excreted into breast milk of lactating rats at higher concentrations than in blood. No human lactation data available. Probably compatible.
Amiodarone (C/–)	Long half-life, iodine-containing molecule, neonates should be monitored for thyroid disorders and cardiac arrhythmias with in utero exposure.
Amitriptyline (C/–)	Milk/plasma ratio of 1.0. AAP classifies amitriptyline effect on breast feeding as unknown but may be of concern.
Amlodipine (C/+)	No human lactation data available. Low molecular weight suggests excretion into breast milk. Effects on nursing infant are unknown. Probably compatible.
Amoxapine (C/–)	Active metabolites in milk. AAP classifies amoxapine effect on breast feeding as unknown but may be of concern.
Amoxicillin (B/+)	Monitor nursing infant for diarrhea, rash, and somnolence. Potential for allergic sensitization and modification of bowel flora. AAP classifies amoxicillin as compatible with breast feeding.
Amphetamine (C/Cl)	AAP classifies amphetamine as contraindicated during breast feeding. Monitor nursing infant for irritability and poor sleeping pattern.
Amphotericin B (B/+)	No human lactation data available. Probably compatible.
Amphotericin B lipid complex (B/+)	No human lactation data available. Probably compatible.
Ampicillin (B/+)	Monitor nursing infant for diarrhea. Potential for allergic sensitization and modification of bowel flora. AAP classifies ampicillin as compatible with breast feeding.
Anakinra (B/–)	No human lactation data available. Recommended to avoid in breast feeding.
Aripiprazole (C/–)	Mixed data concerning concentrations in breast milk. Potential for toxicity. The low molecular weight of the drug combined with the prolonged half-life and the active metabolite suggest that 1 or both will be excreted into breast milk. However, the extensive protein binding should limit the excretion. If mother breast feeds while taking drug, observe nursing infant for potent CNS effects, orthostatic hypotension, seizures, dysphasia, nausea, and vomiting. Long-term evaluation is warranted.
Aspirin (C, D/–)	May affect platelet function; monitor nursing infant for hemolysis or bleeding. Increased risk with high doses used for rheumatoid arthritis (3–5 g/day). Metabolic acidosis may occur. Theoretical risk of Reye syndrome. AAP recommends to use cautiously due to potential adverse effects.
Atazanavir (B/Cl)	CDC recommends HIV-infected mothers in developed countries to not breast feed.
Atenolol (D/–)	AAP recommends to use cautiously due to adverse effects of hypotension, cyanosis, and bradycardia; suggested to avoid water-soluble, low-protein-bound, renally excreted β -blockers during lactation.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Atorvastatin (X/CI)	Some excretion into breast milk is expected; therefore, the potential for adverse effects in nursing infants exists and breast feeding should be avoided.
Atropine (C/+)	Mixed data concerning passage into breast milk. AAP classifies atropine as compatible with breast feeding.
Azathioprine (D/–)	Theoretical concerns of potential for toxicity with the active metabolites of the drug. May be considered acceptable; monitor complete blood count with differential and liver function tests.
Azithromycin (B/+)	Accumulates in breast milk. Macrolide antibiotics may be associated with risk of infantile hypertrophic pyloric stenosis; potential for modification of bowel flora. Recommended agent for various infections.
Aztreonam (B/+)	Excreted into breast milk in low amounts, due to acidic nature of the drug and low lipid solubility. Oral absorption is poor, and systemic effects in nursing infants are unlikely. AAP classifies aztreonam as compatible with breast feeding.
Bacitracin (C/+)	No human lactation data available. Topical use compatible.
Baclofen (C/+)	Limited human lactation data available. AAP classifies baclofen as compatible with breast feeding.
Beclomethasone (C/+)	Limited human lactation data available. May be excreted into breast milk. Use of inhaled corticosteroids is considered acceptable during breast feeding.
Belladonna (C/–)	No human lactation data available. Due to narrow therapeutic index and viable potency, use should be avoided during lactation.
Benazepril (C 1st tri; D 2nd, 3rd tri/+)	Limited human lactation data available. Some excretion into breast milk is expected; not expected to cause adverse effects on nursing infants.
Benztropine (C/–)	No human lactation data available. Probably compatible.
Betamethasone (C, D/+)	No human lactation data available. Molecular weight suggests excretion into breast milk. Best avoided in favor of a shorter acting and better studied alternative due to potency and low protein binding.
Bethanechol (C/–)	Limited human lactation data available. Low molecular weight suggests excretion into breast milk. Abdominal pain and diarrhea reported in nursing infant exposed to bethanechol.
Bisacodyl (C/+)	Not absorbed from the gastrointestinal tract; active metabolite is not detectable in breast milk. Probably compatible.
Bismuth subsalicylate (C/–)	AAP recommends to use cautiously due to adverse effects because of potential for adverse effects from salicylates. Should be avoided because of systemic absorption.
Bisoprolol (C/–)	No human lactation data available. AAP recommends to use cautiously due to adverse effects of hypotension, cyanosis, and bradycardia related to β -blockade.
Botulinum toxin type A (C/+)	No human lactation data available. Probably compatible. Toxin not expected to appear in circulation and therefore will not appear in breast milk.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Brompheniramine (C/+)	Monitor nursing infant for agitation, poor sleeping pattern, and feeding problems. AAP classifies brompheniramine as usually compatible with breast feeding.
Budesonide (oral/inhaler/nasal) (B, inhaler; C, oral/+)	Systemic bioavailability of inhaled budesonide is low, so the actual amount in breast milk may also be low. Use of inhaled corticosteroids is considered acceptable during breast feeding.
Bumetanide (C/+)	No human lactation data available. Probably compatible. Diuretics may suppress lactation.
Buprenorphine (C/-)	Excreted into breast milk. When used to treat opioid addiction, most guidelines allow breast feeding as long as the infant is tolerant to the dose and other contraindications do not exist. Monitor for drowsiness, adequate weight gain, and developmental milestones; observe infants for withdrawal signs if breast feeding is stopped abruptly.
Bupropion (B/-)	Excreted into breast milk. Seizures and sleep disturbances have been reported; monitor for changes in sleep, feeding patterns, and behavior. AAP classifies the effect of bupropion on breast feeding as unknown but may be of concern.
Buspirone (B/-)	Limited human lactation data available. Buspirone and its metabolites are excreted into the milk of lactating rats. Potential exists for CNS impairment in nursing infant. AAP classifies the effect of buspirone on breast feeding as unknown but may be of concern because of effects on the developing brain that may not be known until later in life.
Butorphanol (C/+)	Limited human lactation data available. Excreted into breast milk at levels that are probably not clinically significant. AAP classifies butorphanol as usually compatible with breast feeding. Opioid therapy should be avoided in breast-feeding mothers due to potential for apnea and sedation in the infant.
Caffeine (C/+)	Monitor nursing infant for irritability and poor sleeping pattern. AAP classifies caffeine as usually compatible with breast-feeding with moderate intake (2–3 cups/day).
Calcifediol (C/+)	Low molecular weight of drug suggests excretion into breast milk but effect on nursing infant is unknown.
Calcitonin—salmon (C/+)	Calcitonin is a normal component of human milk; exogenous administration may inhibit lactation.
Calcitriol (C/+)	High-dose supplementation in mothers can lead to elevated levels of vitamin D2 in breast milk and subsequently lead to hypercalcemia in breast-fed infants. Caution is advised.
Canagliflozin (D, -)	No human lactation data available. Alternative agents are preferred.
Candesartan (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Low molecular weight suggests that the drug would be excreted into breast milk. Effects on the nursing infant are unknown.
Captopril (C 1st tri; D 2nd, 3rd tri/+)	Excreted into breast milk in low concentrations. Available data showed no effects on nursing infants. AAP classifies captopril as compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Carbamazepine (D/+)	Monitor for sedation, poor sucking, and potential for withdrawal. Risk of bone marrow suppression if taken chronically; recommend monitoring complete blood count and liver enzymes. AAP classifies carbamazepine as compatible with breast feeding.
Carbidopa/levodopa (C/+)	Excreted into breast milk in low concentrations. Effects on nursing infant unknown.
Carisoprodol (C/+)	Limited human lactation data available. Probably compatible. Observe nursing infant for sedation and other behavioral changes.
Carvedilol (C/-)	AAP recommends to use cautiously due to adverse effects of hypotension, cyanosis, and bradycardia related to β -blockade.
Cascara sagrada (C/+)	Limited human lactation data available. Probably compatible. Observe nursing infant for diarrhea.
Cefaclor (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Cefadroxil (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding.
Cefazolin (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding.
Cefdinir (B/+)	Probably excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Cefepime (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Cefixime (B/+)	Probably excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Cefotaxime (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding.
Cefotetan (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Cefoxitin (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Ceftazidime (B/+)	Excreted into breast milk in low concentrations; not absorbed when given orally. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding.
Ceftolozane/tazobactam (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora.
Ceftriaxone (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding.
Cefuroxime (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Celecoxib (C 1st, 2nd tri; D 3rd tri/–)	Excreted into breast milk. Safest course of action is to avoid use during breast feeding.
Cephalexin (B/+)	Excreted into breast milk in low concentrations. Potential for allergic sensitization and modification of bowel flora. AAP classifies other cephalosporins as compatible with breast feeding.
Cetirizine (B/+)	Manufacturer states drug excreted into breast milk. Effects on nursing infant unknown but observe for sedation, irritability, or jitteriness.
Chloral hydrate (C/+)	Monitor nursing infant for sedation and rash. AAP classifies chloral hydrate as compatible with breast feeding.
Chlordiazepoxide (D/–)	No human lactation data available. Low molecular weight suggests excretion into breast milk should be expected. Other benzodiazepines have produced adverse effects in nursing infants. Use should be avoided during breast feeding.
Chlorhexidine (B/+)	No reports of excretion into breast milk available. Oral rinse is not intended to be swallowed. Rinse nipples if chlorhexidine is used to cleanse them. Probably compatible.
Chloroquine (C/+)	Insufficient amounts excreted in breast milk to provide adequate protection against malaria. AAP classifies chloroquine as compatible with breast feeding.
Chlorothiazide (C/+)	Diuretics may suppress lactation, especially in the first month. Adverse effects have not been reported, but infant's electrolytes and platelets should be monitored. AAP classifies chlorothiazide as compatible with breast feeding.
Chlorpheniramine (B/+)	Effects on nursing infant unknown, but observe for sedation, irritability, or jitteriness. Second-generation antihistamines are preferred.
Chlorpromazine (C/–)	Excreted into breast milk in low amounts. Observe nursing infant for sedation. AAP classifies the effect of chlorpromazine on breast feeding as unknown but may be of concern due to potential drowsiness and lethargy in addition to galactorrhea in adults.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Cholecalciferol (C, D/+)	Excreted into breast milk in limited amounts. The Committee on Nutrition of the AAP recommends vitamin D supplementation in breast-fed infants if maternal intake is low or exposure to ultraviolet light is insufficient. AAP classifies cholecalciferol as compatible with breast feeding. Monitor serum calcium levels of nursing infant if mother is taking pharmacologic doses of vitamin D.
Cholestyramine (C/+)	Nonabsorbable resin. No human lactation data available. Drug binds fat-soluble vitamins, and prolonged use may result in deficiencies of these vitamins in mother and nursing infant.
Cimetidine (B/+)	Use with caution. May suppress gastric acidity in infant, inhibit drug metabolism, and cause CNS stimulation. AAP classifies cimetidine as compatible with breast feeding.
Ciprofloxacin (C/+)	Data are limited and the amount of drug in breast milk does not appear to represent significant risk to nursing infant. Potential for modification of bowel flora. AAP classifies ciprofloxacin as compatible with breast feeding. However, the manufacturer recommends that mother should wait 48 hours after last dose before breast feeding.
Citalopram (C/-)	Doses >20 mg/day or concurrent use of other sedative agents may increase risk of adverse effects to nursing infants. Observe for excessive somnolence, changes in sleep, decreased feeding, and weight loss. Long-term effects on neurobehavioral development are unknown. AAP classifies effect of SSRIs on breast feeding as unknown but may be of concern. However, if required by the mother, it is not a reason to discontinue breast feeding.
Clarithromycin (C/+)	Excreted into breast milk. Macrolide antibiotics may be associated with risk of infantile hypertrophic pyloric stenosis; potential for modification of bowel flora, rash, diarrhea, and loss of appetite.
Clavulanate (B/+)	No human lactation data available. Molecular weight suggests excretion into breast milk. Effects of lactamase inhibitors on nursing infants are unknown.
Clindamycin (B/+)	Excreted into breast milk. Potential for allergic sensitization and modification of bowel flora. Monitor for bloody stools associated with colitis. AAP classifies clindamycin as compatible with breast feeding.
Clonazepam (D/-)	Long half-life may cause accumulation in a breast-feeding infant. If chronic use of a benzodiazepine is needed, other shorter acting agents preferred. Monitor nursing infant for decreased feeding and respiratory and CNS depression.
Clonidine (C/+)	Excreted in breast milk. Hypotension was not observed in nursing infants, although clonidine was found in the serum of these nursing infants. Long-term significance of this exposure is unknown; other agents may be preferred.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Clopidogrel (B/+)	No human lactation data available. Low molecular weight suggests excretion into breast milk. Effects on nursing infants are unknown. Manufacturer recommends a decision be made to continue nursing or discontinue the drug, taking into account the importance of treatment to the mother.
Clotrimazole (B/+)	Absorption from skin and vagina is minimal. Unlikely that the levels of this antifungal agent appear in breast milk.
Clozapine (B/-)	Concentrated in breast milk. Avoid breast feeding. AAP classifies clozapine as a drug for which the effect on the nursing infant is unknown but may be of concern.
Cobicistat (C/C)	CDC recommends HIV-infected mothers in developed countries to not breast feed.
Cocaine (C/C)	Causes cocaine intoxication in infant from maternal intranasal use (hypertension, tachycardia, mydriasis, and apnea) and from topical use on mother's nipples (apnea and seizures). AAP classifies cocaine as contraindicated during breast feeding.
Codeine (C, D/-)	Codeine and active metabolite, morphine, are present in breast milk; concentrations are dependent on CYD2D6 metabolism. Short term therapy (1–2 days) with close monitoring is compatible, however long term therapy is not compatible with breast feeding. May suppress lactation. Opioid therapy should be avoided in breast-feeding mothers due to potential for apnea and sedation in the infant.
Colchicine (C/+)	Excreted into breast milk. No adverse effects on nursing infants have been observed. Waiting 8 hours after dose to breast feed or taking the dose after breast feeding minimizes exposure of nursing infant. AAP classifies colchicine as compatible with breast feeding.
Cortisone (C, D/+)	Corticosteroids are excreted in breast milk. Monitor for growth suppression, interference with endogenous production. Unlikely that it poses risk to nursing infant.
Cromolyn sodium (B/+)	No human lactation data available. Maternal levels are likely to be low; considered to be compatible with breast feeding.
Cyclobenzaprine (B/-)	No reports of excretion into breast milk available. Low molecular weight suggests excretion into breast milk.
Dactinomycin (D 1st tri; C 2nd, 3rd tri/-)	No human lactation data available. Despite the high molecular weight, women receiving the drug should avoid breast feeding because of the potential risk of severe adverse effects.
Dalbavancin (C/-)	No human lactation data available. Drug has a long half-life and caution should be exercised when used among nursing women.
Dalteparin (B/+)	No human lactation data available. Based on the molecular weight and because the drug would be inactivated in the GI tract, the risk to the nursing infant would be negligible.
Dapagliflozin (C/-)	No human lactation data available. Avoid breast feeding until safety data available.
Darbepoetin alfa (C/+)	No human lactation data available. Passage into breast milk is not expected. Risk to nursing infant appears to be negligible.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Deferasirox (C/-)	No human lactation data available. Molecular weight and long elimination half-life suggest excretion into breast milk. Amount of oral absorption in infants unknown; in adults, oral bioavailability is 70%. With the potential to deplete infant's iron stores, breast feeding should be avoided during therapy.
Deferoxamine (C/+)	No human lactation data available. Molecular weight is low enough for some excretion into breast milk to be expected. Effects, if any, on nursing infant are unknown.
Delafloxacin (C/-)	No human lactation data available. Avoid breast feeding until safety data available.
Delavirdine (C/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Desloratadine (C/+)	No human lactation data available. Desloratadine and loratadine are excreted into breast milk. Probably compatible.
Dexamethasone (C, D/+)	No human lactation data available. Excretion into breast milk should be expected. Probably compatible.
Dextroamphetamine (C/-)	May cause infant stimulation. Nonmedical use is considered contraindicated in breast feeding.
Dextromethorphan (C/+)	No human lactation data available. Low molecular weight suggests excretion into breast milk. Probably compatible. Use alcohol-free preparation.
Diatrizoate (C/+)	In 1 study, not detected in breast milk. Probably compatible.
Diazepam (D/-)	May cause infant sedation. May accumulate in breast-fed infants.
Diclofenac (C/D ≥30 weeks' gestation/+)	No human lactation data available. Manufacturer states that the drug is excreted into breast milk. Short half-life in adults. Probably compatible.
Dicloxacillin (B/+)	No human lactation data. However, other penicillins are excreted into breast milk in low concentrations. Adverse effects rare. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction.
Didanosine (B/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Digoxin (C/+)	Excreted into breast milk in small amounts. Monitor nursing infant for spitting up, diarrhea, and heart rate changes. Compatible with breast feeding.
Dihydroergotamine (X/C)	No human lactation data available. Molecular weight and long half-life suggest excretion into breast milk, but high protein binding will limit this. Concern for symptoms of ergotism: vomiting, diarrhea, and convulsions in nursing infants. Breast feeding is contraindicated.
Diltiazem (C/+)	Excreted into breast milk. Two nursing infants were not affected. Probably compatible.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Dimenhydrinate (B/+)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Probably compatible. Caution: newborns and premature infants have increased sensitivity to antihistamines.
Diphenhydramine (B/+)	Excreted into breast milk, but levels are thought not to be in sufficiently high amounts to affect the nursing infant. Monitor the nursing infant for agitation, poor sleeping pattern, and feeding problems. Probably compatible.
Diphenoxylate (C/–)	Active metabolite probably excreted into breast milk. Potential toxicity.
Diphtheria and tetanus vaccine (C/+)	No human lactation data. Probably compatible.
Dipyridamole (B/+)	Excreted into breast milk. Effect unknown on nursing infant. Probably compatible.
Docusate (calcium, potassium, sodium) (C/+)	Probably compatible. Monitor nursing infant for diarrhea.
Dolasetron (B/+)	No human lactation data available. Low molecular weight of drug suggests excretion into breast milk should be expected. Effects on nursing infant are unknown.
Dolutegravir (B/C)	No human lactation data available. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Dornase alfa (B/+)	No human lactation data available. Inhaled drug does not increase endogenous serum concentration of DNase. Not expected to be excreted into breast milk. Negligible risk to nursing infant.
Doxycycline (D/+)	Excreted into breast milk in low concentrations. Theoretical dental staining and inhibition of bone growth are remote. The bowel flora of nursing infants may be altered and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. AAP classifies doxycycline as compatible with breast feeding.
Doxylamine (C/–)	No human lactation data available. Low molecular weight suggests excretion into breast milk should be expected. Effects on nursing infant unknown. Potential effects include sedation, excitement, and irritability. Avoid breast feeding.
Dulaglutide (C/–)	No human lactation data available. Avoid breast feeding until safety data available.
Echinacea (C/–)	Avoid use during breast feeding.
Edoxaban (C/–)	No human lactation data available. Avoid breast feeding until safety data available.
Efavirenz (C/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Eletriptan (C/+)	Excreted into breast milk. Effects of exposure to nursing infants are unknown, but low concentration not thought to be significant. Compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Empagliflozin (C/-)	No human lactation data available. Avoid breast feeding until safety data available.
Emtricitabine (B/C)	No human lactation data available. Molecular weight, low plasma protein binding, and long half-life suggest excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Enalapril (C 1st tri; D 2nd, 3rd tri/+)	Enalapril and enalaprilat are excreted into breast milk in small amounts such that risk to nursing infant appears negligible/clinically insignificant. AAP classifies enalapril as compatible with breast feeding.
Enfuvirtide (B/C)	No human lactation data available. Molecular weight and high plasma protein binding should inhibit but not prevent excretion into breast milk. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Enoxaparin (B/+)	No human lactation data available. Based on high molecular weight and probable inactivation by GI tract, the passage of drug into breast milk and its risk to nursing infant is considered negligible.
Entecavir (C/Ci HIV; C/hepatitis B)	No human lactation data available. Molecular weight and half-life suggest the drug should be excreted into breast milk. Effects on nursing infants are unknown. Infants of HBsAg-positive or HBeAg-positive mothers should receive HBIG at birth and hepatitis B vaccine soon after birth. Then breast feeding is permitted. Breast feeding is contraindicated in HIV-1 positive mothers in the United States.
Ephedrine (C/-)	Limited human lactation data available. Observe nursing infant for irritability, excessive crying, and disturbed sleeping patterns. Avoiding breast feeding is recommended.
Epoetin alfa (C/+)	No human lactation data available. Excretion into breast milk is not expected and drug would be digested in GI tract. No risk to nursing infant expected.
Epoprostenol (B/+)	No human lactation data available. Based on its rapid degradation, a physiologic pH, and the GI tract, the amount of drug the nursing infant would be exposed to would not be clinically significant.
Eprosartan (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Expect excretion into breast milk. Effects on nursing infant are unknown. AAP classifies ACE inhibitors, a similar class of agents, as compatible with breast feeding.
Ergotamine (X/Ci)	Causes vomiting, diarrhea, and convulsions in the nursing infant. May hinder lactation. Breast feeding is contraindicated.
Ertapenem (B/+)	Excreted into breast milk in low concentrations. Effects on nursing infant unknown but probably are not clinically significant. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. Probably compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Erythromycin (B/+)	Excreted into breast milk in low concentrations. No reports of adverse effects in nursing infants. The bowel flora of nursing infants may be altered, and there is potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. AAP classifies erythromycin as compatible with breast feeding.
Escitalopram (C/-)	No human lactation data available. Expect excretion into breast milk. Effects on nursing infant unknown. Adverse effects have been seen with similar agent (citalopram), expect similar effects. Closely monitor nursing infants. AAP classifies other SSRIs as drugs for which effect on nursing infants is unknown but may be of concern.
Esllicarbazepine (C/+)	No human lactation data available. Expect excretion into breast milk. Closely monitor nursing infants for common side effects reported in adults.
Esomeprazole (B/-)	No human lactation data available. Expect excretion into breast milk. Effects on nursing infant unknown. Potential for toxic effects: headache, diarrhea and abdominal pain, and suppression of gastric acid secretion. Half-life is short, 1–1.5 hours. Waiting 5–7.5 hours after dose should eliminate 97% of drug from plasma.
Estrogens, conjugated (X/+)	No adverse effects in nursing infants reported. May decrease milk volume and nitrogen and protein content.
Etelcalcetide (C/-)	No human lactation data available. Avoid breast feeding until safety data available.
Ethambutol (C/+)	Excreted into breast milk. AAP classifies ethambutol as compatible with breast feeding.
Ethanol (X/-)	Passes freely into breast milk in levels similar to those in maternal serum. Because of risk of toxicity in nursing infant, safest course is to hold breast-feeding for 1–2 hours for each ounce of alcohol consumed.
Ethinyl estradiol (X/+)	No adverse effects in nursing infants reported. Expect trace amount in breast milk. May decrease milk volume and nitrogen and protein content. Monitor weight gain of infant, and use lowest dose.
Evolocumab (B/-)	No human lactation data available. Avoid breast feeding until safety data available.
Famciclovir (B/-)	No human lactation data available. Expect excretion into breast milk. Avoid breast feeding.
Famotidine (B/+)	Excreted into breast milk but to lesser extent than cimetidine and ranitidine. Effects on nursing infant are unknown. Potential risk for adverse effects; however, AAP classifies cimetidine as compatible with breast feeding. Famotidine may be preferred over other H ₂ blockers because of lesser amount in breast milk.
Ferric citrate (B/-)	No human lactation data available. Avoid breast feeding until safety data available.
Flecainide (C/+)	Excreted into breast milk but effects on nursing infant are unknown. Probably not toxic. AAP classifies flecainide as compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Fluconazole (C for single dose, D/+)	Excreted into breast milk. No drug-associated toxicity has been reported. AAP classifies fluconazole as compatible with breast feeding.
Flucytosine (C/-)	No human lactation data available. Because of potential serious adverse effects in nursing infant, breast feeding should be avoided.
Fluoxetine (C 1st, 2nd tri; D 3rd tri/-)	Excreted into breast milk. Long-term effects on neurobehavioral development from exposure to potent serotonin reuptake blocker during period of rapid CNS development have not been adequately studied. Manufacturer recommends breast feeding should be avoided during fluoxetine therapy. AAP indicates that effects on nursing infant are unknown but may be of concern. Maternal benefits may outweigh risks to nursing infant if treating postpartum depression. Colic, irritability, sleep disorders, and poor weight gain may occur.
Fondaparinux (B/+)	No human lactation data available. Excretion into breast milk should be expected. Effects on nursing infants unknown but not thought to be clinically significant.
Fosamprenavir (C/CI)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Furosemide (C/+)	Excreted into breast milk. No reports of adverse effects in a nursing infant. Probably compatible.
Gabapentin (C/+)	No human lactation data available. Probably compatible. Low molecular weight of drug suggests excretion into breast milk but effect on nursing infant is unknown.
Gadopentetate dimeglumine (MRI contrast) (C/+)	Excreted into breast milk in small amounts. Very little is absorbed systemically. AAP classifies gadopentetate dimeglumine as compatible with breast feeding.
Ganciclovir (D 1st tri; C 2nd, 3rd tri/-)	No human lactation data available. Potential for serious toxicity in nursing infant. Avoid breast feeding.
Gentamicin (C/+)	Small amounts excreted into breast milk and absorbed by nursing infants. Observe infant for bloody stools and diarrhea. AAP classifies as compatible with breast feeding.
Ginkgo biloba (C/-)	No human lactation data available. Herbal product that is not standardized and may contain other compounds. Safest course is to avoid breast feeding.
Ginseng (B/-)	No human lactation data available. Herbal product that is not standardized and may contain other compounds. Safest course is to avoid breast feeding.
Glimepiride (C/+)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Risk of neonatal hypoglycemia. Breast-feeding women should consider insulin instead.
Glipizide (C/+)	Minimal to nondetectable levels in breast milk. Normal glucose levels in nursing infants.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Glucosamine (C/+)	No human lactation data available. Molecular weight and prolonged plasma protein elimination half-life suggest excretion into breast milk should be expected. Unbound drug is undetectable in plasma; therefore, little if any drug will be excreted into milk. Probably compatible.
Glutamine (C/-)	No human lactation data available. Avoid breast feeding until safety data available.
Glyburide (C/+)	Nondetectable levels in breast milk. Normal glucose levels in nursing infants. Probably compatible.
Guaifenesin (C/+) <i>Haemophilus b</i> conjugate vaccine (C/+)	No human lactation data available. Probably compatible. Compatible with breast feeding.
Haloperidol (C/-)	Excreted into breast milk. Use may be of concern. Effects on nursing infant unknown. Possible decline in developmental score.
Heparin (C/+)	Not excreted into breast milk.
Hepatitis A vaccine (C/+)	No human lactation data available. Probably compatible.
Hepatitis B vaccine (C/+)	No human lactation data available. Probably compatible.
Heroin (D/Cl)	Crosses into breast milk in sufficient amounts to cause addiction in nursing infant. Breast feeding is contraindicated.
Human papillomavirus vaccine (B/+)	Compatible with breast feeding.
Hydralazine (C/+)	Excreted into breast milk. No adverse effects noted in nursing infants. AAP hydralazine classifies as compatible with breast feeding.
Hydrochlorothiazide (B/+)	May suppress lactation, especially in the first month of lactation. Adverse effects have not been reported, but infant's electrolytes and platelets should be monitored.
Hydrocodone (C, D/+)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Observe nursing infant for GI effects, sedation, and changes in feeding patterns.
Hydrocortisone (C, D/+)	No human lactation data available. Unlikely that it poses risk to nursing infant. Compatible with breast feeding.
Hydromorphone (B, D/+)	Excreted into breast milk. Monitor nursing infant for sedation. Milk ejection reflex (letdown) may be inhibited.
Hydroxychloroquine (C/+)	Excreted into breast milk. Slow elimination rate. Breast feeding during daily therapy should be done with caution. Once-weekly doses significantly reduce amount of drug exposure to nursing infant. AAP classifies hydroxychloroquine as compatible with breast feeding. Amount in breast milk is not adequate to provide malaria protection for infant.
Hydroxyzine (C/+)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effects on nursing infant unknown.
Ibuprofen (B 2nd tri; D 1st, 3rd tri/+)	Excreted into breast milk. Amount of drug available to nursing infant is minimal. AAP classifies ibuprofen as compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Imipenem-cilastatin (C/+)	Small amounts excreted into breast milk in amounts comparable to other lactam antibiotics. Effects on nursing infant are unknown.
Indinavir (C/Ci)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Indomethacin (C <30 weeks' gestation, D ≥30 weeks' gestation/+)	Excreted into breast milk. One case report of seizure in nursing infant. AAP classifies indomethacin as compatible with breast feeding.
Infliximab (B/+)	Excreted into breast milk in trace amount. Compatible with breast feeding.
Influenza vaccine (B/+)	Live attenuated influenza vaccine is not recommended during pregnancy. Maternal vaccination is compatible with breast feeding.
Iodine (D/+)	May cause fetal goiter or hyperthyroidism. APP classifies iodine as compatible with breast feeding.
Isavuconazonium (C/-)	No human lactation data available. Avoid breast feeding until safety data available.
Isoniazid (C/+)	Isoniazid and its metabolite are excreted into breast milk. Monitor nursing infant for signs and symptoms of peripheral neuritis or hepatitis. Pyridoxine supplementation should be considered in both mother and infants. AAP classifies isoniazid as compatible with breast feeding.
Ivacaftor (B/-)	No human lactation data available. Molecular weight and long half-life suggest excretion into breast milk should be expected. Effects on nursing infant are unknown. Avoid breast feeding until safety data available.
Ivermectin (C/+)	Excreted into breast milk but no human lactation data available. Low drug levels in milk probably not a risk to nursing infant. AAP classifies ivermectin as compatible with breast feeding.
Kaolin/pectin (C/+)	No effect on nursing infant.
Ketamine (B/+)	Should be undetectable in maternal plasma ~11 hours after dose. Breast feeding after this time should not expose the nursing infant to drug.
Ketoconazole (C/+)	Excreted into breast milk. Effects of exposure to nursing infants are unknown but not thought to be significant. AAP classifies ketoconazole as compatible with breast feeding.
Ketorolac (C; D if used in 3rd tri or near delivery/+)	Excreted into breast milk in amounts that are considered clinically insignificant. AAP classifies ketorolac as compatible with breast feeding.
Labetalol (C/+)	Monitor nursing infant for hypotension and bradycardia. AAP classifies labetalol as compatible with breast feeding.
Lactulose (B/+)	No human lactation data. Probably compatible.
Lamivudine (C/Ci)	Excreted into breast milk. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Lamotrigine (C/–)	May be of concern. Consider monitoring infant's serum lamotrigine concentration.
Lansoprazole (B/–)	No human lactation data available. Excretion into breast milk is expected. Potential effects on nursing infant include carcinogenicity (animal data) and suppression of gastric acid secretion. Avoid breast feeding.
Levetiracetam (C/+)	No human lactation data available. Low molecular weight and protein binding suggest excretion into breast milk should be expected. Effects on nursing infant are unknown. AAP classifies levetiracetam as compatible with breast feeding.
Levofloxacin (C/+)	Excreted into breast milk. Effects on nursing infants are unknown. AAP classifies levofloxacin as compatible with breast-feeding.
Levomilnacipran (C/–)	No human lactation data available. Avoid breast feeding until safety data available.
Levothyroxine (A/+)	Probably does not interfere with neonatal thyroid screening.
Lindane (C/+)	No human lactation data available. Excreted into breast milk. Small amounts ingested by nursing infant are probably clinically insignificant. Waiting 4 days after discontinuing lotion should prevent exposure to nursing infant.
Linezolid (C/–)	No human lactation data available. Excretion into breast milk is expected. Effects on nursing infant unknown. Potential effects: myelosuppression and reversible thrombocytopenia. Avoid breast feeding.
Liraglutide (C/–)	No human lactation data available. Avoid breast feeding until safety data available.
Lisinopril (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Excretion into breast milk should be expected. AAP classifies lisinopril as compatible with breast feeding.
Lithium (D/–)	Milk levels average 40% of maternal serum concentration. Monitor nursing infant for cyanosis, hypotonia, bradycardia, and other lithium toxicities.
Loperamide (B/+)	No human lactation data available. AAP classifies loperamide as compatible with breast feeding.
Lopinavir (C/CI)	No human lactation data available. Molecular weight and lipid solubility suggest excretion into breast milk should be expected; however, extensive plasma protein binding should limit this. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Loratadine (B/+)	Loratadine and its metabolite are excreted into breast milk. Probably little clinical risk to nursing infant. AAP classifies loratadine as compatible with breast feeding.
Lorazepam (D/–)	Excretion into breast milk in small amount. Monitor nursing infant for sedation, especially if exposure is prolonged.
Losartan (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Excretion into breast milk is expected. Effects of exposure to nursing infant are unknown. AAP considers losartan compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Macitentan (X/C)	No human lactation data available. Molecular weight and half-life suggest excretion into breast milk, but high protein binding affinity may limit the amount. Monitor nursing infants for anemia, influenza, and urinary tract infections.
Measles vaccine (X, C/+)	Compatible with breast feeding.
Meclizine (B/+)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Probably compatible. Caution: newborns and premature infants have increased sensitivity to antihistamines. Prolonged use may decrease milk supply.
Medroxyprogesterone (D/+)	AAP classifies medroxyprogesterone as compatible with breast feeding.
Meloxicam (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Molecular weight would suggest excretion into breast milk. Probably compatible.
Meningococcal vaccine (B/+)	No human lactation data available. Probably compatible. ACIP recommends deferring meningococcal B vaccine in breast-feeding women unless the woman is at increased risk for meningococcal disease.
Meperidine (C, D/+)	Monitor nursing infant for sedation. Milk ejection reflex (letdown) may be inhibited. AAP classifies meperidine as compatible with breast feeding.
Meropenem (B/+)	No human lactation data available. Probably compatible. Expect excretion into breast milk. Potential effects on nursing infant are unknown.
Mesalamine (B/-)	Small amount excreted into breast milk. Risk of adverse effect (diarrhea) in nursing infant. AAP classifies mesalamine as a drug that should be used with caution during breast feeding because there is potential for toxicity.
Metformin (B/+)	Excreted into breast milk. Nursing infants had normal blood glucose levels.
Methadone (C, D/+)	Generally compatible with breast feeding. Monitor nursing infant for sedation, depression, and withdrawal on cessation of methadone treatment. AAP classifies methadone as compatible with breast feeding.
Methamphetamine (C/C)	AAP classifies amphetamines as contraindicated during breast feeding. Monitor nursing infant for irritability and poor sleeping pattern.
Methimazole (D/+)	Potential for interfering with thyroid function. AAP classifies methimazole as compatible with breast feeding.
Methocarbamol (C/+)	Probably compatible. Any amount of drug excreted into breast milk probably not clinically significant.
Methyldopa (B/C/+)	Risk of hemolysis and increased liver enzymes. AAP classifies methyldopa as compatible with breast feeding.
Methylphenidate (C/-)	Excreted into breast milk. Potential toxicity will probably occur in 1st month of life. Observe nursing infant for signs and symptoms of CNS stimulation: decreased appetite, insomnia, and irritability.
Metoclopramide (B/-)	Increases milk production. Effects on nursing infant unknown but may be of concern because it is a dopaminergic-blocking agent.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Metolazone (B/+)	May suppress lactation, especially in the first month of lactation. Probably compatible. Adverse effects have not been reported, but infant's electrolytes and platelets should be monitored.
Metoprolol (C/-)	Monitor nursing infant for bradycardia and hypotension.
Metronidazole (D 1st tri; B 2nd, 3rd tri/-)	Discontinue during breast feeding. Do not nurse until 12–24 hours after discontinuing to allow excretion of drug.
Miltefosine (D/C)	No human lactation data available. Molecular weight suggests excretion into breast milk, but high protein binding may limit amount in milk.
Minocycline (D/+)	Excreted into breast milk in low concentrations. Theoretical dental staining and inhibition of bone growth are remote. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. Compatible with breast feeding.
Mipomersen (B/-)	No human lactation data available. Molecular weight and protein binding suggest excretion into breast milk will be limited. Potential for disruption of infant lipid metabolism. Monitor nursing infant for flulike symptoms and elevated liver transaminases.
Mirtazapine (C/-)	Excreted into breast milk. Monitor infant for potential sedation and weight gain. Long-term effects on neurobehavioral development unknown. AAP classifies other antidepressants as drugs for which effect on nursing infant is unknown but may be of concern.
Montelukast (B/+)	Monitor nursing infant for sedation. Milk ejection reflex (letdown) may be inhibited.
Morphine (C/-)	Excreted into breast milk. Monitor infant for sedation, apnea and bradycardia, and cyanosis. AAP classifies morphine as compatible with breast feeding. Long-term effects on neurobehavioral development are unknown.
Mumps vaccine (C/+)	No human lactation data. Probably compatible.
Nafcillin (B/+)	No human lactation data. Refer to Penicillin.
Nalbuphine (B/+)	Monitor newborn for respiratory depression and bradycardia if used during labor. No human lactation data available. Probably compatible. Expect small amount of drug to be excreted into breast milk. Amounts are clinically insignificant.
Naloxegol (C/+)	No human lactation data available. Molecular weight and protein binding suggest excretion into breast milk is likely. Probably compatible.
Naloxone (B, C/+)	No human lactation data available. Probably compatible.
Naltrexone (C/+)	No human lactation data available. Expect excretion into breast milk. Probably compatible. Effects on nursing infant are unknown. Potential adverse effects of drug: alteration of opioid receptors in the brain; altered levels of some hormones of hypothalamic, pituitary, adrenal, and gonadal origin.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Naproxen (C/+)	Passes into breast milk in very small quantities. Effects on nursing infant are unknown. AAP classifies naproxen as compatible with breast feeding.
Naratriptan (C/+)	No human lactation data available. Excretion into breast milk should be expected. Probably compatible. Effects on nursing infant are unknown.
Nelfinavir (B/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Netupitant and palonosetron (C/+)	No human lactation data available. Molecular weight and protein binding suggest excretion into breast milk is likely. Probably compatible.
Nevirapine (C/C)	Excreted into breast milk. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Nicotine (transdermal, others) (D/-)	May be of concern. Excessive amounts may cause diarrhea, vomiting, tachycardia, irritability, decreased milk production, and decreased weight gain.
Nifedipine (C/+)	Manufacturer states significant amounts of drug excreted into breast milk. No human lactation data available. AAP classifies nifedipine as compatible with breast feeding.
Nimodipine (C/+)	Excreted in breast milk. Limited data suggest that milk is excreted in likely clinically insignificant amounts. Probably compatible.
Nitrofurantoin (B/+)	Excreted in breast milk in small amounts. Monitor nursing infants with G6PD deficiency for hemolytic anemia. AAP classifies nitrofurantoin as compatible with breast feeding.
Nortriptyline (C/-)	Excreted into breast milk in low concentrations. No adverse effects noted in breast-feeding infants. Long-term effects of chronic exposure to antidepressants in nursing infants are unknown with concern for effects on the infant's neurobehavioral development. AAP classifies nortriptyline as a drug for which effect on nursing infant is unknown but may be of concern.
Nystatin (C/+)	Poorly absorbed if at all. Excretion into breast milk would not occur.
Olanzapine (C/-)	Sedation has occurred in nursing infants. Decreasing dose may eliminate this problem but may affect control of mother's disease. Avoid use during breast feeding.
Olodaterol (C/+)	No human lactation data available. Molecular weight suggests excretion into breast milk is likely, but low systemic absorption. Probably compatible.
Olsalazine (C/-)	Active metabolite, 5-aminosalicylic acid (mesalamine), is excreted into human milk. Diarrhea reported in nursing infant of mother receiving mesalamine.
Omeprazole (C/-)	Limited human lactation data available. Excretion into breast milk is expected. Effects on nursing infant are unknown. Use during breast feeding should be avoided. Concern for suppression of gastric acid secretion and carcinogenicity observed in animals.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Ondansetron (B/+)	No human lactation data available. Expect excretion into breast milk. Probably compatible. Effects on nursing infant are unknown.
Oral contraceptives (all classes) (X/+)	Causes dose-dependent suppression of lactation. Decreased weight gain, milk production, and nitrogen and protein content of human milk have been associated with this drug. Changes probably only significant in malnourished mothers. Use lowest dose possible. AAP classifies oral contraceptives as compatible with breast feeding.
Oritavancin (C/+)	No human lactation data available. Limited oral bioavailability would suggest low risk of toxicity to nursing infant. Probably compatible.
Orlistat (X/+)	No human lactation data available. Limited systemic bioavailability would suggest that it would not appear in breast milk.
Oseltamivir (C/+)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown.
Oxacillin (B/+)	Excreted into breast milk in low concentrations. Adverse effects rare. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction.
Oxcarbazepine (C/+)	One report of use during human lactation. No adverse effects reported. Monitor infant for poor suckling, vomiting, and sedation. AAP classifies carbamazepine as compatible with breast feeding; oxcarbazepine can be also considered compatible.
Oxycodone (B/-)	Monitor nursing infant for drowsiness, sedation, feeding difficulties, or limpness. Withdrawal symptoms may occur when maternal use or breast feeding is discontinued.
Pamidronate (D/+)	No human lactation data available. Molecular weight, prolonged half-life, and lack of metabolism suggest drug will be excreted into breast milk. Considering the bioavailability, the amount absorbed by the nursing infant will be clinically insignificant. Probably compatible.
Pantoprazole (C/+)	Excreted into breast milk in small amounts. Has potential for suppression of gastric acid secretion in nursing infant, but overall risk of toxicities is low.
Paregoric (C/+)	Probably excreted into breast milk. Limited human lactation data available. Probably compatible. Refer to morphine.
Paroxetine (D, X/-)	Effect on nursing infant is unknown but may be of concern. Monitor infant for insomnia, lethargy, poor weight gain, and changes in feeding pattern.
Pasireotide (C/-)	No human lactation data available. Molecular weight and protein binding suggest excretion in breast milk. Potential adverse reactions include diarrhea, nausea, hyperglycemia, and cholelithiasis. Recommended to avoid breast feeding due to potential toxicity.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Penicillin G (all forms) (B/+)	All antibiotics are excreted in breast milk in limited amounts. Monitor nursing infant for rash, diarrhea, and spitting up. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup.
Pentamidine (C/CI)	No human lactation data available. Systemic concentrations reached with aerosolized drug are very low. Breast milk levels would be nil.
Pentobarbital (D/–)	Excreted into breast milk. Effects on nursing infant are unknown.
Permethrin (B/+)	No human lactation data available. Little if any drug expected to be excreted into breast milk. CDC considers permethrin or pyrethrins with piperonyl butoxide treatment of choice for pubic lice during lactation.
Phenobarbital (D/–)	Monitor nursing infant for sucking problems, sedation, rashes, and withdrawal. AAP classifies phenobarbital as a drug that has caused major adverse effects in some nursing infants. Use caution if breast feeding.
Phenytoin (D/+)	Monitor nursing infant for methemoglobinuria (rare), drowsiness, and decreased suckling. Keep maternal phenytoin in therapeutic range. AAP classifies phenytoin as compatible with breast feeding.
Pirfenidone (C/+)	No human lactation data available. Molecular weight and protein binding suggest excretion into breast milk is likely. Probably compatible.
Piroxicam (C/+)	Excreted into breast milk in amounts that probably do not present a risk to nursing infant. AAP classifies piroxicam as compatible with breast feeding.
Pneumococcal vaccine (C/+)	No human lactation data available. Probably compatible.
Poliovirus inactivated vaccine (C/+)	No human lactation data available. Probably compatible.
Pravastatin (X/CI)	No human lactation data available. Excreted into breast milk. Because of the potential for adverse effects in the nursing infant, avoid use during lactation.
Prednisolone (C, D/+)	Trace amounts have been measured in breast milk. Concentration did not pose clinically significant risk to nursing infant. AAP classifies prednisolone as compatible with breast feeding.
Prednisone (C, D/+)	Trace amounts have been measured in breast milk. Concentration did not pose clinically significant risk to nursing infant. AAP classifies prednisone as compatible with breast feeding.
Pregabalin (C/–)	No human lactation data available. Expect excretion into breast milk. Effects on nursing infants are unknown. Monitor nursing infant for dizziness, somnolence, blurred vision, peripheral edema, myopathy, and decreased platelet count. Avoid use during breast feeding.
Probenecid (C/+)	Excreted into breast milk. Toxicity observed probably related to concurrent antibiotic administered. Probably compatible. Observe nursing infant for diarrhea.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Procainamide (C/+)	Excreted in and accumulates in milk. AAP classifies procainamide as compatible with breast feeding. Long-term effects of exposure in nursing infants are unknown.
Prochlorperazine (C/-)	Other phenothiazines excreted into breast milk, so prochlorperazine excretion expected. Sedation in nursing infant a possible side effect.
Propranolol (C/-)	Excreted into breast milk. Monitor nursing infant for hypotension and bradycardia. AAP classifies propranolol as compatible with breast feeding.
Propylthiouracil (D/+)	Excreted into breast milk. Monitor thyroid function of infant periodically. AAP classifies propylthiouracil as compatible with breast feeding.
Prothrombin complex concentrate (C/-)	No human lactation data available. Manufacturer recommends to only use if clearly needed.
Pseudoephedrine (C/+)	Excreted into breast milk. Monitor nursing infant for agitation. AAP classifies pseudoephedrine as compatible with breast feeding.
Pyrazinamide (C/+)	Excreted into breast milk in small amounts. Probably compatible. Monitor infant for signs of toxicity such as jaundice, fever, decreased appetite, nausea, vomiting, thrombocytopenia, or rash.
Pyrimethamine (C/+)	Excreted into breast milk. AAP classifies pyrimethamine as compatible with breast feeding.
Quetiapine (C/-)	Excreted into breast milk. No reports of adverse effects in nursing infants. Long-term effects of this exposure are unknown. Manufacturer recommends avoiding breast feeding.
Quinidine (C/+)	Excreted into breast milk. Monitor nursing infant for rash, anemia, and arrhythmias. Risk of optic neuritis with chronic use. AAP classifies quinidine as compatible with breast feeding.
Quinine (C/+)	Excreted into breast milk. No adverse effects reported in nursing infants. G6PD should be ruled out in infants at risk for the disease. AAP classifies quinine as compatible with breast feeding.
Quinupristin/dalfopristin (B/-)	No human lactation data available. Large molecular size and weakly acidic nature make it unlikely to be excreted into breast milk. Caution: may alter the bowel flora of nursing infants. There is the potential for the development of resistant strains of VRE. Breast feeding is not recommended.
Rabies immune globulin (C/+)	No human lactation data available. Probably compatible.
Ranitidine (B/+)	Excreted into breast milk. Effects on nursing infant are unknown. Decreases gastric acidity but effect on nursing infant has not been studied. AAP classifies similar agent (cimetidine) as compatible with breast feeding.
Remifentanyl (C/+)	No human lactation data available. Expect excretion into breast milk. Very short half-life. Other narcotic agents are classified as compatible with breast feeding by AAP.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Rifabutin (B/C)	No human lactation data available. Excretion into breast milk expected. Milk may be stained brown-orange color. Effects on nursing infants are unknown, but serious toxicities (leukopenia, neutropenia, rash) are potential adverse effects. Contraindicated if nursing mother is HIV-1 positive.
Rifampin (C/+)	Excreted into breast milk in amounts that pose very little risk to nursing infants. No adverse effects reported. AAP classifies rifampin as compatible with breast feeding.
Rifapentine (C/+)	No human lactation data available. Expect excretion into breast milk. May cause red-orange discoloration of breast milk. Effects on nursing infants are unknown. AAP classifies rifampin, a similar agent, as compatible with breast feeding.
Rifaximin (C/+)	No human lactation data available. Expect excretion into breast milk but in very small amounts due to limited systemic absorption. Effects on nursing infants are unknown but probably not clinically significant.
Riociguat (X/-)	No human lactation data available. Expect excretion into breast milk. Effects on nursing infant unknown, but nursing infant should be monitored for diarrhea, vomiting, hypotension, GERD, and constipation.
Risperidone (C/-)	Excreted into breast milk. AAP classifies other antipsychotic drugs for which the effects on nursing infants are unknown but may be of concern, especially with long-term use. Could possibly alter short- and long-term CNS function.
Ritonavir (B/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Rizatriptan (C/+)	No human lactation data available. Expect excretion into breast milk. Effects on nursing infants are unknown. Probably compatible.
Rubella vaccine (C/+)	Compatible with breast feeding. ACOG and CDC recommend vaccination of susceptible women in immediate postpartum period.
Salmeterol (C/+)	No human lactation data available. Expect excretion into breast milk, but maternal plasma levels after inhaled dose are very low to undetectable. It is unlikely that clinically significant amounts would appear in breast milk. Probably compatible.
Saquinavir (B/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Scopolamine (C/+)	No human lactation data available. Excreted into breast milk. AAP classifies scopolamine as compatible with breast feeding.
Secobarbital (D/+)	Excreted into breast milk. Amount and effects on nursing infants are unknown. AAP classifies secobarbital as compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Senna (C/+)	Observe nursing infant for diarrhea. AAP classifies senna as compatible with breast feeding.
Sertraline (C/-)	AAP classifies sertraline as a drug for which the effect on nursing infant is unknown but may be of concern. Concentrated in human milk.
Simeprevir (C/-)	No human lactation data available. Molecular weight and elimination half-life suggest excretion into milk is likely, but high protein binding may limit amount excreted. Monitor nursing infants for rash, myalgia, and dyspnea.
Simvastatin (X/CI)	No human lactation data available. Expect excretion into breast milk. Because of the potential for adverse effects in the nursing infant, avoid use during lactation.
Smallpox vaccine (D, X/CI)	CDC recommends breast-feeding women should not routinely be vaccinated; however, if nursing woman is exposed to smallpox or monkeypox, she should be vaccinated and stop breast feeding.
Sofosbuvir (B, X/+)	No human lactation data available. Molecular weight and protein binding suggest it is likely excreted into milk. Potentially toxic if used in combination with ribavirin. Probably compatible otherwise.
Sotalol (B/-)	Milk levels 3–5 times maternal serum levels. Could cause bradycardia and hypotension. Long-term effects unknown.
Spironolactone (C/+)	Unknown if spironolactone is excreted into breast milk, but metabolite is found in breast milk—probably insignificant amount. Effects on nursing infants unknown. AAP classifies spironolactone as compatible with breast feeding.
SSKI (potassium iodide) (D/+)	The significance to nursing infant of chronic ingestion of higher levels of iodine unknown. AAP recognizes maternal use of iodides during lactation may affect infant's thyroid activity by producing elevated iodine levels in breast milk; it classifies as compatible with breast feeding. Consider monitoring infant's thyroid function.
St. John's wort (C/-)	Unknown if any of the constituents and possible contaminants are excreted into breast milk or if exposure represents risk to nursing infant.
Stavudine (C/CI)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Sucralfate (B/+)	Minimal, if any, drug expected to be excreted into breast milk because only small amounts systemically absorbed.
Sulbactam (B/+)	Excretion into breast milk expected. Effects on nursing infants are unknown. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. AAP classifies sulbactam as compatible with breast feeding.
Sulfamethoxazole (C/-)	Excreted into breast milk in low concentrations. Avoid in ill, stressed, or preterm infants and those with hyperbilirubinemia or G6PD deficiency.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Sulfasalazine (B, D/–)	Excreted into breast milk. May cause diarrhea in nursing infants. AAP classifies sulfasalazine as a drug that has been associated with significant effects on some nursing infants and should be given to nursing mother with caution.
Sulindac (C/–)	No human lactation data available. Because of prolonged half-life, use safer alternatives such as diclofenac, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, ketorolac, or tolmetin during breast feeding.
Sumatriptan (C/+)	Excreted into breast milk. Absorption from GI tract is inhibited, so amount reaching nursing infant is probably negligible. AAP classifies sumatriptan as compatible with breast feeding.
Suvorexant (C/+)	No human lactation data available. Molecular weight suggests excretion into breast milk, but high protein binding likely limits the amount in milk. Probably compatible.
Tavorole (C/+)	No human lactation data available. Probably compatible.
Tedizolid (C/+)	No human lactation data available. Molecular weight suggests that excretion into breast milk should be expected, but high protein binding may limit the amount in milk. Probably compatible.
Telavancin (C/–)	No human lactation data available. High fat solubility suggests some excretion into milk. Monitor nursing infant for diarrhea, vomiting, and foamy urine.
Telmisartan (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Molecular weight suggests that excretion into breast milk should be expected. Effects on nursing infant are unknown. AAP classifies the closely related ACE inhibitors as compatible with breast feeding.
Temazepam (X/–)	Excreted into breast milk. Observe nursing infant for sedation and poor feeding. AAP classifies temazepam as a drug for which the effect on nursing infants is unknown but may be of concern.
Tenofovir (B/C)	No human lactation data available. Molecular weight suggests excretion into breast milk should be expected. Effect on nursing infant is unknown. CDC recommends HIV-infected mothers in developed countries to not breast feed.
Terbutaline (C/+)	Excreted into breast milk. Monitor nursing infant for agitation and spitting up. Use inhaled form to decrease maternal absorption if available. AAP classifies terbutaline as compatible with breast feeding.
Tetanus/diphtheria toxoids and acellular pertussis vaccine (B, C/+)	No human lactation data available. Compatible with breast feeding.
Tetracycline (D 1st tri; CI 2nd, 3rd tri/+)	Excreted into breast milk in low concentrations. Theoretical dental staining and inhibition of bone growth are remote. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. AAP classifies tetracycline as compatible with breast feeding.
THC (marijuana) (X/CI)	Excreted into breast milk. AAP classifies marijuana as a drug that should not be used during breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Theophylline (C/+)	Excreted into breast milk. AAP classifies theophylline as compatible with breast feeding. Monitor nursing infant for irritability.
Tobramycin (C, D/+)	Excreted into breast milk. No adverse effects reported, and because of poor oral absorption, ototoxicity risk is low. The bowel flora of nursing infants may be altered, and there is the potential for interference with the interpretation of an infectious workup. Observe nursing infants for possible allergic reaction. Compatible with breast feeding.
Topiramate (D/-)	Excreted into breast milk. No adverse effects noted in limited number of exposed nursing infants. However, potential for adverse effects: fatigue, somnolence, ataxia, purpura, epistaxis, infections (viral and pneumonia), anorexia, and weight loss. Observe nursing infants for signs of toxicity.
Tramadol (C/CI)	Tramadol and active metabolite, M1 (<i>O</i> -desmethyl tramadol), are present in breast milk; concentrations are dependent on CYP2D6 metabolism. Effects on nursing infants unknown. Opioid therapy should be avoided in breast-feeding mothers due to potential for apnea and sedation in the infant.
Trazodone (C/-)	Excreted in breast milk. AAP classifies trazodone as a drug for which the effects on the nursing infant are unknown but may be of concern.
Tretinoin (systemic) (CI 1st tri; D 2nd, 3rd tri/+)	Vitamin A and probably tretinoin are natural constituents of breast milk. No human lactation data available on amounts excreted into breast milk after doses for treatment of promyelocytic leukemia or risk to nursing infant. Probably compatible.
Trimethoprim/sulfamethoxazole (D/-)	Excreted into breast milk in low concentrations. Considered negligible risk to nursing infant. Monitor for jaundice, hemolysis, and GI disturbance. The bowel flora may be altered. Avoid in ill, stressed, or preterm infants and those with hyperbilirubinemia or G6PD deficiency.
Valacyclovir (B/+)	Lack of adverse effects seen with acyclovir, the primary metabolite of valacyclovir. Considered compatible with breast feeding; breast-feeding mothers with herpetic lesions near or on the breast should avoid breast feeding.
Valganciclovir (C/CI)	Active metabolite, ganciclovir, has the potential to cause serious toxicity. CDC recommends HIV-infected mothers in developed countries to not breast feed. Breast feeding contraindicated.
Valproic acid (D, X for migraine prophylaxis/+)	Generally compatible with breast feeding per AAP but carries risk of fatal hepatotoxicity.
Valsartan (C 1st tri; D 2nd, 3rd tri/+)	No human lactation data available. Low molecular weight suggests that the drug would be excreted into breast milk. Effects on nursing infant are unknown.
Vancomycin (B/+)	Excreted into breast milk. Effects on nursing infant are unknown, but vancomycin is poorly absorbed from GI tract. Potential for allergic sensitization and modification of bowel flora. AAP classifies cephalosporins as compatible with breast feeding. Compatible with breast feeding.

(Continued)

Drug (FDA Fetal Risk Category/ Breast-Feeding Compatibility)	Effect on Lactation and Adverse Effects on Infant
Varicella vaccine (D/+)	CDC and AAP classify as compatible with breast feeding.
Vedolizumab (B/-)	No human lactation data available. Effect on nursing infant is unknown.
Velpatasvir (C/-)	No human lactation data available. Potentially toxic if used in combination with ribavirin. Effects on nursing infants are unknown.
Venlafaxine (C/-)	Excreted into breast milk. Observe for excessive somnolence, changes in sleep, decreased feeding, and weight loss.
	Long-term effects on neurobehavioral development are unknown. AAP classifies effect of SNRIs on breast feeding as unknown but may be of concern. However, if required by the mother, it is not a reason to discontinue breast feeding.
Verapamil (C/+)	Excreted into breast milk. Limited human lactation data available. AAP classifies verapamil as compatible with breast feeding.
Voriconazole (D/-)	No human lactation data available. Low molecular weight suggests excretion into breast milk. Potential for toxicity in neonatal period. Manufacturer recommends a decision be made to continue nursing or discontinue the drug, taking into account the importance of treatment to the mother.
Voxilaprevir (C/-)	No human lactation data available. Potentially toxic if used in combination with ribavirin. Effects on nursing infants are unknown.
Warfarin (X/+)	Maternal warfarin therapy does not appear to pose a significant risk to normal full-term infants; monitor for bleeding or bruising. American College of Chest Physicians (ACCP) classifies as compatible with breast feeding; other oral anticoagulants are contraindicated in lactating women.
Zanamivir (C/+)	No human lactation data available. Low molecular weight and pharmacokinetics of drug suggest it will be excreted into breast milk. Effects on nursing infants are unknown, but risk of harm is low.
Zidovudine (C/CI)	CDC recommends HIV-infected mothers in developed countries to not breast feed.
Zolmitriptan (C/+)	No human lactation data available. Molecular weight and low protein binding suggest drug and its active metabolite will be excreted into breast milk. Effects on nursing infant are unknown.
Zolpidem (C/+)	Excreted into breast milk in small amounts, which would indicate few adverse effects, if any, would occur in nursing infant. Observe for increased sedation, lethargy, and changes in feeding habits. AAP classifies zolpidem as compatible with breast feeding.

AAP, American Academy of Pediatrics; ACE, angiotensin-converting enzyme; ACIP, Advisory Committee on Immunization Practices; ACOG, American Congress of Obstetricians and Gynecologists; CDC, Centers for Disease Control and Prevention; CI, contraindicated; CNS, central nervous system; FDA, US Food and Drug Administration; G6PD, glucose-6-phosphate dehydrogenase; GERD, gastroesophageal reflux disease; GI, gastrointestinal; HBeAg, hepatitis B e antigen; HBIg, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; IV, intravenous; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRIs, selective serotonin reuptake inhibitors; tri, trimester; VRE, vancomycin-resistant enterococci.

Appendix A. Abbreviations

2,4-DNPH	2,4-Dinitrophenylhydrazine	aEEG	Amplitude-integrated electroencephalography
3-MCC	3-Methylcrotonyl-CoA carboxylase	AEP	Auditory evoked potential
17-OHP	17-Hydroxyprogesterone	AFB	Acid-fast <i>Bacillus</i>
A1AT or AAT	α_1 -Antitrypsin	AFI	Amniotic fluid index
AaDO₂	Alveolar-to-arterial oxygen gradient	AFP	α -Fetoprotein
A/a gradient	Alveolar/arterial gradient	AF PCR	Amniotic fluid polymerase chain reaction
AAOS	American Academy of Orthopedic Surgeons	AGA	Appropriate for gestational age
AAP	American Academy of Pediatrics	AGS	Adrenogenital syndrome
AAP-CON	The American Academy of Pediatrics Committee on Nutrition	AHA	American Heart Association; α -hydroxy acids
a/A ratio	Arterial/alveolar oxygen ratio	AHT	Abusive head trauma
AATD	α_1 -Antitrypsin deficiency	AI	Aortic insufficiency
A's and B's	Apnea and bradycardia	AIDS	Acquired immunodeficiency syndrome
ABC	Airway, breathing, circulation	AIS	Amniotic infection syndrome; arterial ischemic stroke
ABR	Auditory brainstem response	AIT	Alloimmune thrombocytopenia
ABS	Amniotic band syndrome	ALARA	As low as reasonably achievable
A/C	Assist/control	ALGS	Alagille syndrome
ACAAI	American College of Allergy, Asthma, and Immunology	ALP	Alkaline phosphatase
ACE	Angiotensin-converting enzyme	ALRI	Acute lower respiratory tract infection
ACF	Asymmetric crying face	ALT	Alanine aminotransferase
aCGH	Array comparative genomic hybridization	ALTE	Apparent life-threatening event
AChR	Acetylcholine receptor	AM	Morning
ACIP	Advisory Committee on Immunization Practices	AMC	Arthrogyrosis multiplex congenita
ACLS	Advanced Cardiac Life Support	ANC	Absolute neutrophil count
ACMG	American College of Medical Genetics and Genomics	Ao	Aortic
ACOG	American College of Obstetricians and Gynecologists	Aol	Aortic isthmus
ACT	Activated clotting time; activated coagulation time	AOI	Apnea of infancy
ACTH	Adrenocorticotrophic hormone	AOP	Apnea of prematurity
ADH	Antidiuretic hormone	AP	Anteroposterior
ADHD	Attention deficit hyperactivity disorder	Appar	Appearance, pulse, grimace, activity, respirations
ADMA	Asymmetric dimethylarginine	API	Anal position index
AE	Adverse effects	ApoA-1	Apolipoprotein A1
AED	Automatic external defibrillator; antiepileptic drug	APR	Acute-phase reactants
AEDV	Absent end-diastolic velocity	aPTT	Activated partial thromboplastin time
		AR	Autosomal recessive
		ARA/AA	Arachidonic acid
		ARC	AIDS-related complex
		ARC syndrome	Arthrogyrosis–renal dysfunction–cholestasis

ARD	Antibiotic removal device; antiretroviral drug	BIND	Bilirubin-induced neurologic dysfunction
ARDS	Acute respiratory distress syndrome	BIO	Binocular indirect ophthalmoscopy
AREDFV	Absent or reversed end-diastolic flow velocity	BIOT	Biotinidase deficiency
ARF/AKI	Acute renal failure/acute kidney injury	BKT	β -Ketothiolase deficiency
ARHB	Age-related/height-based	BLP	Babylance preemie
ARM	Anorectal manometry	BLS	Basic Life Support
ART	Assisted reproductive technology; antiretroviral therapy	BM	Breast milk
ARV	Antiretroviral	BMC	Bone mineral content
AS	Aortic stenosis	BMI	Body mass index
ASA	Argininosuccinic aciduria; American Society of Anesthesiologists	BNP	B-type (or brain) natriuretic peptide
ASAP	As soon as possible	BNSM	Benign neonatal sleep myoclonus
ASD	Atrial septal defect	BOHB	β -Hydroxybutyrate
ASH	Asymmetric septal hypertrophy	BOLD	Blood oxygen level dependent
ASPEN	American Society for Parenteral and Enteral Nutrition	BP	Blood pressure
AST	Aspartate aminotransferase	BPD	Biparietal diameter
ATN	Acute tubular necrosis	BPD/CLD	Bronchopulmonary dysplasia/ chronic lung disease
ATP	Adenosine triphosphate	bpm	Breaths per minute
ATTEND	Attunement, trust, touch, egalitarianism, nuance, and death education	BPP	Biophysical profile
AV	Atrioventricular; arteriovenous	BPPT	Benign pneumoperitoneum
A-VO₂	Arteriovenous oxygen difference	BPSN	Bernese Pain Scale for Neonates
B19V	Parvovirus B19	BRUE	Brief resolved unexplained event
B/A	Bilirubin-to-albumin ratio	BSEP	Bile salt export pump
BA	Biliary atresia	BUN	Blood urea nitrogen
BAEP	Brainstem auditory evoked potential	BW	Birthweight; body weight
BAER	Brainstem audiometric evoked response	BWS	Beckwith-Wiedemann syndrome
BAS	Balloon atrial septostomy	c̄	With (from the Latin word cum)
BASDs	Bile acid synthesis disorders	C	Cervical; centigrade
BBS	Bronze baby syndrome	CA	Community acquired
BCAA	Branched-chain amino acids	CAGE	Cerebral arterial gas embolism
BCG	Bacille Calmette-Guérin	CAH	Congenital adrenal hyperplasia
BD	Base deficit	CAKUT	Congenital anomalies of the kidney and urinary tract
BE	Base excess	CAM	Complementary and alternative medicine; chorioamnionitis
BEAT-ROP	Bevacizumab Eliminates the Angiogenic Threat of Retinopathy of Prematurity	CA-MRSA	Community-acquired methicillin-resistant <i>Staphylococcus aureus</i>
BF	Breast feeding	CANMWG	Chicago Area Neonatal MRSA Working Group
BG	Babygram (radiograph that includes the chest and abdomen)	CAP	Caffeine for Apnea of Prematurity
β-hCG	β -Human chorionic gonadotropin	cART	Combination antiretroviral therapy
BIA	Bacterial inhibition assay	CAVSD	Complete atrioventricular septal defect
bid	Twice daily	CBC	Complete blood count
BIIP	Behavioral Indicators of Infant Pain	CBF	Cerebral blood flow
		CBG	Capillary blood gases
		CBS	Capillary blood sampling
		CC	Congenital chylothorax
		CCAM	Congenital cystic adenomatoid malformation
		CCHB	Congenital complete heart block

CCHD	Critical congenital heart disease	CNS	Central nervous system; Crigler-Najjar syndrome
CCHS	Congenital central hypoventilation syndrome	CO	Cardiac output; carbon monoxide
CDC	Centers for Disease Control and Prevention	CO₂	Carbon dioxide
CDH	Congenital diaphragmatic hernia	COA	Coarctation of aorta
CDG	Congenital disorders of glycosylation	CoA	Coenzyme A
CDT	Catheter-directed thrombolysis	COFN	Committee on Fetus and Newborn
cEEG	Continuous conventional electroencephalogram	COHb	Carboxyhemoglobin
CF	Cystic fibrosis; clubfoot	CONS	Coagulase-negative staphylococci
CFM	Cerebral function monitor	cP	Centipoesis
CFRD	Cystic fibrosis–related diabetes	CPAM	Cystic pulmonary airway malformation
CFU	Colony-forming units	CPAP	Continuous positive airway pressure
CGH	Comparative genomic hybridization	CPD	Citrate phosphate dextrose
cGMP	Cyclic guanosine monophosphate	CPDA-1	Citrate phosphate dextrose-adenine
CGMS	Continuous glucose monitoring system	CPE	Carbapenemase-producing Enterobacteriaceae
CH	Congenital hydrocephalus; congenital hypothyroidism	CPIP	Chronic pulmonary insufficiency of prematurity
CHARGE	Coloboma of the eye, cranial nerve defects, heart defects, atresia of the choanae, restricted growth and/or development, genital abnormalities, and ear anomalies and sensorineural hearing loss.	CPM	Confined placental mosaicism
CHD	Congenital hip dislocation; congenital heart disease	CPQCC	California Perinatal Quality Care Collaborative
CHF	Congestive heart failure	CPR	Cardiopulmonary resuscitation; cerebroplacental ratio
CHG	Chlorhexidine gluconate	CPS	Carbamoyl phosphate synthetase
CHI	Congenital hyperinsulinism	CRI	Catheter-related infection
CHIME	Collaborative Home Infant Monitoring Evaluation	CRIES	Crying, requires increased oxygen administration, increased vital signs, expression, sleeplessness
CHYLD	Children with Hypoglycemia and Their Later Development	CRL	Crown-rump length
CI	Cardiac index; confidence interval	CRMS	Cystic fibrosis transmembrane conductance regulator (CFTR)–related metabolic syndrome
CICU	Cardiac intensive care unit	CRP	C-reactive protein
CID	Cytomegalic inclusion disease	CRS	Congenital rubella syndrome
CIE	Counter immunoelectrophoresis	CRT	Capillary refill time; catheter-related thrombosis
CIS	Cold injury syndrome	CRYO-ROP	Cryotherapy for Retinopathy of Prematurity
CITI/	Citrullinemia type 1	C-section	Cesarean section
CTLN1		CS	Congenital syphilis; cesarean section
CLABSI	Central line–associated bloodstream infections	CSE	Combined spinal epidural
cm	Centimeter	CSF	Cerebrospinal fluid
CMA	Chromosomal microarray analysis	CSII	Continuous subcutaneous insulin infusion
CMTC	Cutis marmorata telangiectatica congenita	CST	Contraction stress test
CMV	Cytomegalovirus	CSTS	Car seat tolerance screening
CNLDO	Congenital nasolacrimal duct obstruction	CSVT	Cerebral sinovenous thrombosis
		CT	Congenital toxoplasmosis; computed tomography

CTA	Computed tomography angiography	DICOM	Digital Imaging and Communications in Medicine
CTD	Carnitine transport defect	DISIDA	Diisopropyl iminodiacetic acid
CTG	Cardiotocography	dL	Deciliter
CUD	Carnitine uptake defect/carnitine transport defect	DLIM	Depressor labii inferioris muscle
CULLP	Congenital unilateral lower lip palsy	DLIS	Digoxin-like immunoreactive substance
cUS/CUS	Cranial ultrasound	DM	Diabetes mellitus
CVA	Coxsackievirus A, cerebrovascular accident	DMSA	Dimercaptosuccinic acid
CVAD	Central venous access device	DNR	Do not resuscitate
CVB	Coxsackievirus B	DOA	Dead on arrival
CVB3	Coxsackievirus B3	DOAC	Direct oral anticoagulants
CVC	Central venous catheters	DOCA	Deoxycorticosterone acetate
CVH	Combined ventricular hypertrophy	DORA	Directory of rare analyses
CVI	Cortical visual impairment	DP	Dorsalis pedis
CVL	Central venous line	DPT	Diphtheria-pertussis-tetanus
CVP	Central venous pressure	DRIFT	Drainage, irrigation, and fibrinolytic therapy
CVS	Chorionic villus sampling; congenital varicella syndrome	DS	Double strength
CXR	Chest x-ray	DSD	Disorder of sex development
CysC	Cystatin C	DSS	Dengue shock syndrome
CZS	Congenital Zika syndrome	DTaP	Diphtheria and tetanus toxoids with acellular pertussis
d	Day	DTI	Diffusion tensor imaging
D25	25% dextrose solution	DTO	Deodorized tincture of opium/diluted tincture of opium (do not use this abbreviation, write out drug name)
D5W	5% dextrose in water	DTPA	Diethylenetriamine penta-acetic acid
D10W	10% dextrose in water	DTR	Deep tendon reflexes
DAOM	Depressor anguli oris muscle	DtwP	Diphtheria and tetanus toxoids with the whole-cell pertussis vaccine
DAT	Direct antibody test (Coombs test)	DV	Ductus venosus
DBP	Diastolic blood pressure	DVET	Double-volume exchange transfusion
DC	Direct current; differential cyanosis	DVSNi	Distress Scale for Ventilated Newborn Infants
D/C	Discharge or discontinue	DVT	Deep venous thrombosis
DCC	Delayed cord clamping	DWI	Diffusion-weighted imaging
DDAVP	Desmopressin acetate	DW-MRI	Diffusion-weighted magnetic resonance imaging
DDH	Developmental dysplasia of hip	Dx	Diagnosis
DDST	Denver Developmental Screening Test	DXA	Dual energy x-ray absorptiometry
DDx/DD	Differential diagnosis	DXM	Dexamethasone
DEET	<i>N,N</i> -Diethyl-meta-toluamide	DZ	Disease
DEND	Developmental delay, epilepsy, neonatal diabetes	EA	Esophageal atresia
DENV	Dengue virus	EBL	Estimated blood loss
DES	Diethylstilbestrol	EBV	Epstein-Barr virus
DEX/DEXA	Dual-energy x-ray absorptiometry	ECF	Extracellular fluid
DF	Dengue fever	ECG	Electrocardiogram
DFA	Direct fluorescent antibody	ECHO	Echocardiography
DHA	Docosahexaenoic acid	ECLS	Extracorporeal life support
DHF	Dengue hemorrhagic fever	ECM	External cardiac massage
DHM	Donor human milk		
DHT	Dihydrotestosterone		
DI	Drug interactions; diabetes insipidus		
DIC	Disseminated intravascular coagulation		

ECMO	Extracorporeal membrane oxygenation	ETCO₂	End-tidal carbon dioxide (concentration)
ECP	Eosinophil cationic protein	ETROP	Early Treatment for Retinopathy of Prematurity
ECPR	Extracorporeal cardiopulmonary resuscitation	ETT	Endotracheal tube
ECS	Elective cesarean section	EUGR	Extrauterine growth restriction
ECW	Extracellular water	EV	Enterovirus
EDC	Estimated date of confinement	F	French scale (1 F = 1/3 mm)
EDTA	Ethylenediaminetetraacetic acid	FAH	Fumarylacetoacetate hydrolase
EDV	End-diastolic velocity	FANS	Faceless Acute Neonatal Pain Scale
EEG	Electroencephalogram	FAO	Fatty acid oxidation
EFA	Essential fatty acid	FAOD	Fatty acid oxidation disorders
EFM	Electronic fetal monitoring	FAS	Fetal alcohol syndrome
EFW	Estimated fetal weight	FBDS	Fetal brain disruption sequence
EHDI	Early Hearing Detection and Intervention	FBG	Fetal blood gas
EHEC	Enterohemorrhagic Escherichia coli	FBS	Fasting blood sugar; fetal blood sampling
EHMF	Enfamil human milk fortifier	FD	Forceps delivery
EHR	Electronic health records	FDA	Food and Drug Administration
EIA	Enzyme immunoassay	FDP	Fibrin degradation products
ELBW	Extremely low birthweight	Fe	Iron
ELISA	Enzyme-linked immunosorbent assay	FE	Fractional excretion
ELSO	Extracorporeal Life Support Organization	FE_{Na}	Fractional excretion of sodium
EMA	Ethylmalonic encephalopathy; European Medicines Agency	FE_{urea}	Fractional excretion of urea
EME	Early myoclonic encephalopathy	FF	Forefoot
EMG	Electromyogram	FFA	Free fatty acid
EMLA	Eutectic mixture of lidocaine and prilocaine	FFP	Fresh-frozen plasma
EMR	Electronic medical records	FFTS	Feto-fetal (twin) transfusion syndrome
EMS	Emergency medical services	FGR	Fetal growth restriction
EN	Enteral nutrition	FH	Fibular hemimelia
ENNS	Early Neonatal Neurobehavioral Scale	FHR	Fetal heart rate
ENT	Ear, nose, throat	FHT	Fetal heart tone
EOS	Early-onset sepsis	FI_{O₂}	Fraction of inspired oxygen
EPO	Erythropoietin	FIRS	Fetal inflammatory response syndrome
ERCP	Endoscopic retrograde cholangiopancreatography	FISH	Fluorescence in situ hybridization
e-ROP	Telemedicine Approaches for the Evaluation of Acute-Phase Retinopathy of Prematurity	FLM	Fetal lung maturity
ESBL	Extended-spectrum β-lactamase	FMH	Fetomaternal hemorrhage
ESPGHAN	European Society for Paediatric Gastroenterology, Hepatology, and Nutrition	fMRI	Functional magnetic resonance imaging
ESR	Erythrocyte sedimentation rate	FMVS	Federal Motor Vehicle Safety Standards
ESRD	End-stage renal disease	FOBT	Fecal occult blood testing
ET	Ejection time; exchange transfusion; endothelin	FOCUS	Focused cardiac ultrasound
ETCO_c	End-tidal carbon monoxide (concentration)	FPIES	Food protein-induced enterocolitis syndrome
		FRC	Functional residual capacity
		FSH	Follicle-stimulating hormone
		FSP	Fibrin split products
		FTA-ABS	Fluorescent treponemal antibody absorption
		FTCT	Father-to-child transmission

FTT	Failure to thrive	GxPx0000	First zero, full term; second zero, premature; third zero, abortion; fourth zero, living children
F/U	Follow-up		
FUO	Fever of unknown origin		
F-V	Flow-volume	G6PD	Glucose-6-phosphate dehydrogenase
FVC	Forced vital capacity	GROW	Gestation-related optimal growth
FVS	Fetal varicella syndrome	GSD	Glycogen synthase deficiency
FXZS	Fetal varicella-zoster syndrome	Gt/gtt	Drop, drops (from the Latin)
Fx	Fracture	GT	Gastrostomy tubes
Fxn	Function	GTT	Glucose tolerance test
g	Gram	GU	Genitourinary
G	Gravida	GVHD	Graft-versus-host disease
G6PD	Glucose-6-phosphate dehydrogenase	HAA	Hepatitis-associated antigen
GA	Gestational age; general anesthesia	HAART	Highly active antiretroviral therapy
GA I	Glutaric acidemia type I	HADH	3-Hydroxyacyl-CoA dehydrogenase
GABA	γ -Aminobutyric acid	HAND	Helping After Neonatal Death
GALD	Gestational alloimmune liver disease	HAV	Hepatitis A virus
		HB	Hepatitis B
GALE	Galactose epimerase	HBcAg	Hepatitis B core antigen
GALK	Galactokinase	HBeAg	Hepatitis B e antigen
GALT	Galactose-1-phosphate uridylyltransferase	HBIG	Hepatitis B immune globulin
		HBOT	Hyperbaric oxygen therapy
GBCA	Gadolinium-based contrast agent	HBP	High blood pressure
GBS	Group B <i>Streptococcus</i>	HBsAg	Hepatitis B surface antigen
GBV-C	Hepatitis G virus (GB virus type C)	Hb SS	Sickle cell disease/sickle cell anemia
GC	Gas chromatography	HBV	Hepatitis B virus
GCK	Glucokinase	HBW	High birthweight
GCN	Giant congenital nevi	HC	Head circumference
G-CSF	Granulocyte colony-stimulating factor	hCG	Human chorionic gonadotropin
		HCl	Hydrochloride
GDM	Gestational diabetes mellitus	HCM	Hypertrophic cardiomyopathy
GE	Gastroesophageal	HCO₃	Bicarbonate
GER	Gastroesophageal reflux	Hct	Hematocrit
GERD	Gastroesophageal reflux disease	HCTZ	Hydrochlorothiazide
GFR	Glomerular filtration rate	HCV	Hepatitis C virus
GGT	γ -Glutamyl transferase	HCW	Health care worker
GGTP	γ -Glutamyl transpeptidase	HCY	Homocystinuria
GH	Growth hormone	HD	Hirschsprung disease
GI	Gastrointestinal	HDFN/HDN	Hemolytic disease of the fetus and newborn
GINA	Genetic Information Nondiscrimination Act	HDV	Hepatitis D virus
GIR	Glucose infusion rate	HE	Hereditary elliptocytosis
GLUT	Glucose transporter	HEENT	Head, eyes, ears, nose, and throat
GM-CSF	Granulocyte-macrophage colony-stimulating factor	HELLP	Hemolysis, elevated liver enzymes, and low platelet count
GM/IVH	Germinal matrix/intraventricular hemorrhage	HETP	Head elevated tilt position
GxPxAbxLCx	Shorthand for gravida (number of pregnancies)/para (number of deliveries)/number of abortions/number of living children (subscript variables represent numbers of each)	HEV	Hepatitis E virus, human enterovirus
		HF	Hind foot
		HFJV	High-frequency jet ventilation
		HFNC	High-flow nasal cannula
		HFO	High-frequency oscillation

HFOV	High-frequency oscillatory ventilation	IAT	Indirect antiglobulin technique
HFPPV	High-frequency positive-pressure ventilation	iCa	Ionized calcium
HFV	High-frequency ventilation	ICH	Intracranial hemorrhage
Hgb	Hemoglobin	ICN	Intensive care nursery
HGV	Hepatitis G virus	ICP	Intracranial pressure
HHH	Hyperornithinemia/ hyperammonemia/ homocitrullinemia	ICPH	Intracerebellar parenchymal hemorrhage
HHS	Department of Health and Human Services	ICS	Intercostal space
HHV	Human herpes virus	ICU	Intensive care unit
HI	Hypoxia-ischemia	ICW	Intracellular water
HI/HA	Hyperinsulinism/hyperammonemia syndrome	I&D	Incision and drainage
Hib	<i>Haemophilus influenzae</i> type b vaccine	ID	Internal diameter
HIDA	Hepatobiliary iminodiacetic acid	IDAM	Infant of drug-abusing mother
HIE	Hypoxic ischemic encephalopathy	IDDM	Insulin-dependent diabetes mellitus
HIG	Hyperimmune globulin	IDM	Infant of diabetic mother
HIV	Human immunodeficiency virus	I:E	Inspiratory-to-expiratory ratio
HLA	Human leukocyte antigen	IEM	Inborn error of metabolism
HLHS	Hypoplastic left heart syndrome	IFA	Immunofluorescent antibody assay
HM	Human milk	Ig	Immunoglobulin
HMBANA	Human Milk Banking Association of North America	IG	Immune globulin
HMD	Hyaline membrane disease	I/G	Insulin-to-glucose ratio
HMG	3-Hydroxy-3-methylglutaryl CoA lyase	IgA	Immunoglobulin A
HMO	Human milk oligosaccharides	IgE	Immunoglobulin E
H/O	History of	IGF	Insulin-like growth factor
H&P	History and physical examination	IGRA	Interferon- γ release assays
HPA	Human platelet antigen	IHPS	Idiopathic/infantile hypertrophic pyloric stenosis
HPeV	Human <i>Parechovirus</i>	IL	Interleukin
HPF	High-power field	ILAE	International League Against Epilepsy
HPI	History of present illness	ILCOR	International Consensus on Cardio- pulmonary Resuscitation
HPLC	High-performance liquid chromatography	IM	Intramuscular
HPS	Hypertrophic pyloric stenosis	IMV	Intermittent mandatory ventilation
HR	Heart rate	IND	Investigational new drug
HRC	Heart rate characteristics	INF	Intravenous nutritional feedings
HS	Hereditary spherocytosis	INO	Inhaled nitric oxide
HSM	Hepatosplenomegaly	INR	International normalized ratio
HSV	Herpes simplex virus	INRGSS	International Neuroblastoma Risk Group Staging System
H/t	Head-to-trunk ratio	INSS	International Neuroblastoma Staging System
HT	Healing touch	INSURE	Intubation-surfactant-extubation
HTLV	Human T-cell lymphotropic virus	I&O	Intake and output
HTN	Hypertension	IO	Intraosseous
Hx	History	IOI	Intraosseous infusion
Hz	Hertz	IOR	Intraosseous route
IAA	Interrupted aortic arch	IPPB	Intermittent positive-pressure breathing
IAP	Intrapartum antibiotic prophylaxis	IPPV	Intermediate positive-pressure ventilation
		IPV	Inactivated poliovirus vaccine
		IQ	Intelligence quotient

IRT	Immunoreactive trypsinogen	LC	Living children
ISAGA	Immunosorbent agglutination assay	LCAD	Long-chain acyl-CoA dehydrogenase
ISAM	Infant of substance-abusing mother	LCHAD	Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
ISG	Immune serum globulin	LCMN	Large congenital melanocytic nevus
ISSD	Infantile free sialic acid storage disorder	LCPUFAs	Long-chain polyunsaturated fatty acids
IT	Intrathecal; inspiratory time	LDH	Lactate dehydrogenase
I:T	Ratio of immature to total neutrophils	LEDs	Light-emitting diodes
ITP	Idiopathic thrombocytopenic purpura	LFT	Liver function tests
IU	International unit (on do not use list; use "units")	LGA	Large for gestational age
IUGR	Intrauterine growth restriction	LH	Luteinizing hormone
IUT	Intrauterine transfusion	LISA	Less invasive surfactant administration
IV	Intravenous	LLD	Limb length discrepancy
IVA	Isovaleric acidemia	LLL	Left lower lobe
IVC	Inferior vena cava; intravenous cholangiogram	LLQ	Left lower quadrant
IVH	Intraventricular hemorrhage	LMA	Laryngeal mask airway
IVIG	Intravenous immunoglobulin	LMP	Last menstrual period
IVP	Intravenous pyelogram; intravenous push	LMPT	Late and moderately preterm
IWL	Insensible water loss	LMWH	Low molecular weight heparin
JEB	Junctional epidermolysis bullosa	L.M.X.4	Lidocaine 4%
JODM	Juvenile-onset diabetes mellitus	LOH	Loss of heterozygosity
K/K⁺	Potassium	LOS	Late-onset sepsis
KC	Kangaroo care	LOWS	Low-osmolality water soluble
kcal	Kilocalorie	LP	Lumbar puncture
KDIGO	Kidney Disease: Improving Global Outcomes	LPS	Lipopolysaccharide
kg	Kilogram	LR	Lactated Ringer's solution
KHPE	Kasai hepatic portoenterostomy	L-S ratio	Lecithin-to-sphingomyelin ratio
KIM-1	Kidney injury molecule-1	L-T₄	Levothyroxine
KMC	Kangaroo mother care	LV	Left ventricle
KOH	Potassium hydroxide	LVH	Left ventricular hypertrophy
KSD	Kernicterus spectrum disorder	LVO	Left ventricular output
KSHV	Kaposi sarcoma-associated herpes virus	LVOTO	Left ventricular outflow tract obstruction
KU	Klobusitzky unit	M/m	Molar; meter
KUB	Kidneys, ureter, bladder	MA	Metatarsus adductus
L	Liter	MAC	Minimum alveolar concentration; <i>Mycobacterium avium</i> complex
L3–L4	Third lumbar to fourth lumbar vertebra space	MAP	Mean arterial pressure; mean airway pressure
LA	Left atrium; lactic acidosis	MAS	Meconium aspiration syndrome
LAD	Left axis deviation; left atrial diameter; left anterior descending	Max	Maximum
LAE	Left atrial enlargement	MBC	Minimum bactericidal concentration
LAH	Left atrial hypertrophy	MBD	Metabolic bone disease
LANE	Mnemonic for medications acceptable through an endotracheal tube (lidocaine, atropine, naloxone, epinephrine)	MC	Most common
LBBB	Left bundle branch block	MCA	Multiple congenital anomaly; middle cerebral artery
LBC	Lamellar body count	MCAD	Medium-chain acyl-CoA dehydrogenase
LBW	Low birthweight	MCA-PSV	Middle cerebral artery peak systolic velocity

MCD	Multiple carboxylase deficiency	MS/MS	Tandem mass spectrometry
MCH	Mean cell hemoglobin	MSAF	Meconium-stained amniotic fluid
MCHC	Mean cell hemoglobin concentration	MSAFP	Maternal serum α -fetoprotein
MCPs	Medical Command Physicians	MSSA	Methicillin-susceptible <i>Staphylococcus aureus</i>
MCT	Medium-chain triglyceride	MSUD	Maple syrup urine disease
MCV	Mean cell volume; mean corpuscular volume	MTCT	Mother-to-child transmission
MDCT	Multidetector computed tomography	MV	Minute volume; multiple vitamin; mechanical ventilation
MDI	Metered dose inhaler	MVI	Multiple vitamin infusion
MDR3	Multidrug resistance protein 3	MVP	Maximum vertical pocket; mitral valve prolapse
M.E.N.D.	Mommies Enduring Neonatal Death	MZ	Monozygotic
mEq	Milliequivalent	N/A	Not applicable
Mg/Mg²⁺	Magnesium	Na/Na²⁺	Sodium
MG	Myasthenia gravis	NAA	Nucleic acid amplification; <i>N</i> -acetyl aspartate
MgSO₄	Magnesium sulfate	NAAT	Nucleic acid amplification testing
MH-TPA	Micro hemagglutination assay for <i>Treponema pallidum</i>	NACS	Neurologic and adaptive capacity score
MI	Myocardial infarction; mitral insufficiency; meconium ileus	NAIT	Neonatal alloimmune thrombocytopenia
MIC	Minimum inhibitory concentration	NANN	National Association of Neonatal Nurses
min	Minute	NAPA	<i>N</i> -Acetylprocainamide
MIST	Minimally invasive surfactant treatment	NAS	Neonatal abstinence syndrome
mL	Milliliter	NASPGHAN	North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition
mm	Millimeter	NAVEL	Mnemonic for groin anatomy (nerve, artery, vein, empty space, lymphatic)
MMA	Methylmalonic acidemia	NBAS	Neonatal behavior assessment scale
MMI	Methimazole	NBS	New Ballard score; newborn screening
MMR	Measles-mumps-rubella (vaccine)	NBW	Normal birthweight
MN	Micronucleus	NCBI	National Center for Biotechnology and Information
MOMS	Management of Myelomeningocele Study	nCPAP	Nasal continuous positive airway pressure
mOsm	Milliosmole	NCV	Nerve conduction velocity
MPH	Massive pulmonary hemorrhage	NDM	Neonatal diabetes mellitus
MPS-I	Mucopolysaccharidosis type I	NE	Norepinephrine; neonatal encephalopathy
MPS-II	Mucopolysaccharidosis type II	NEAL	Mnemonic for endotracheal tube-administered medications (naloxone, epinephrine, atropine, and lidocaine)
MR	Mitral regurgitation (insufficiency)	NEC	Necrotizing enterocolitis
MRA	Magnetic resonance arteriography	NEMU	Nose/ear/mid-umbilicus
MRCP	Magnetic resonance cholangiopancreatography	NEOCLOT	NEONatal Central Venous Line Observational Study on Thrombosis
mrem	Millirem		
MRI	Magnetic resonance imaging		
MRS	Magnetic resonance spectroscopy		
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>		
MRV	Magnetic resonance venography		
MS	Mitral stenosis; mass spectrometry (MS for morphine sulfate, magnesium sulfate: on do not use list ; better to write these out as they can be confused for one another)		

NESS	National Enterovirus Surveillance System	NPV	Negative predictive value
NETS	Neonatal emergency transport services	NRL	Nonreference laboratories
NEX	Nose to the ear to the xiphoid	NRN	Neonatal Research Network
NFCB	Neonatal Facial Coding System	NRP	Neonatal Resuscitation Program
NFKB	Nuclear factor-kappa B	NS	Normal saline
NG	Nasogastric	NS1	Nonstructural protein 1
NGAL	Neutrophil gelatinase-associated lipocalin	NSAID	Nonsteroidal anti-inflammatory drug
NGO	Nitroglycerine ointment	NSR	Normal sinus rhythm
NGS	Next-generation sequencing	NST	Nonstress test
NHLBI	National Heart, Lung, and Blood Institute	NSVD	Normal spontaneous vaginal delivery
NICHD	National Institute of Child Health and Human Development	NT	Nasotracheal; (fetal) nuchal translucency
NICHD- NRN	National Institute of Child Health and Human Development Neonatal Research Network	NTA	Nontreponemal antibody (test)
NICU	Neonatal intensive care unit	NTB	Necrotizing tracheobronchitis
NIDCAP	Newborn Individualized Developmental Care and Assessment Program	NTBC	2-(2-Nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione
NIPPV	Nasal intermittent positive-pressure ventilation	NTDs	Neural tube defects
NIPS	Neonatal Infant Pain Scale	NTE	Neutral thermal environment
NIPT	Noninvasive prenatal testing	NTEC	Neonatal transient eosinophilic colitis
NIRS	Near-infrared spectroscopy	NTG	Nitroglycerin
NISCH	Neonatal ichthyosis and sclerosing cholangitis	NTL	Nasal tragus length
NIV	Noninvasive ventilation	NTT	Nontreponemal test
NKA	No known allergies	NVP	Nevirapine
NKDA	No known drug allergy	O₂	Oxygen
NKH	Nonketotic hyperglycinemia	OA	Organic aciduria/acidemia
NI	Normal	OAE	Otoacoustic emission
NLDO	Nasolacrimal duct obstruction	OB	Obstetrics
NMR	Nuclear magnetic resonance	OCP	Oral contraceptive pill
NNP	Neonatal nurse practitioner	OCT	Oxytocin challenge test
NNS	Nonnutritive sucking	OD	Outer diameter
NNTs	Neonatal teams	OFC	Occipital frontal circumference
NO	Nitric oxide	OG	Orogastric
NO₂	Nitric dioxide	OI	Oxygenation index
NOHK	Nonliguric hyperkalemia	OM	Otitis media
NORD	National Organization for Rare Disorders	OMIM	Online Mendelian Inheritance in Man
NP	Nasopharyngeal; neonatal pneumothorax; nurse practitioner	ON	Ophthalmia neonatorum
N-PASS	Neonatal Pain, Agitation, and Sedation Scale	OPHTH	Ophthalmic
NPCPAP	Nasopharyngeal continuous positive airway pressure	OPV	Oral poliovirus vaccine
NPO	Nothing by mouth	OR	Operating room
		OSA	Obstructive sleep apnea
		Osm	Osmolality
		OTC	Over the counter (nonprescription drug); ornithine transcarbamylase
		OU	Both eyes (from the Latin <i>oculus unitas</i>)
		OWB	Oscillating waterbed
		oz	Ounce

P	Para (the number of viable [>20 weeks] births); phosphorus	PEEP	Positive end-expiratory pressure
PA	Pulmonary artery; posteroanterior; pulmonary atresia; propionic acidemia	PEP	Postexposure prophylaxis
PAC	Premature atrial contraction	PES	Pediatric Endocrine Society
PaCO₂	Partial pressure of carbon dioxide, arterial	PET	Partial exchange transfusion
PAF	Platelet-activating factor	PetCO₂	Partial pressure of end-tidal carbon dioxide
PAHO	Pan American Health Organization	PETS	Pediatric emergency transport service
PAIN	Pain Assessment in Neonates	PF	Purpura fulminans
PAL	Pacifier-Activated Lullaby	PF24	Plasma frozen 24
PALS	Pediatric Advanced Life Support	PFC	Persistent fetal circulation
PAMF-TSL	Palo Alto Medical Foundation Toxoplasma Serology Laboratory	PFFD	Proximal focal femoral deficiency
PaO₂	Partial pressure of oxygen	pfHb	Plasma free hemoglobin
PAP	Pulmonary artery pressure	PFIC	Progressive familial intrahepatic cholestasis
PAPP-A	Pregnancy-associated plasma protein A	PFO	Patent foramen ovale
PAPVR	Partial anomalies pulmonary venous return	PFT	Pulmonary function test
PAT	Paroxysmal atrial tachycardia; Pain Assessment Tool	PG	Phosphatidylglycerol
PB	Periodic breathing; preterm baby	PGDM	Pregestational diabetes mellitus
PBF	Pulmonary blood flow	PGE	Prostaglandin E
PBLC	Premature birth living child	PGE₁	Prostaglandin E ₁
PBP	Perinatal bereavement program	PGE₂	Prostaglandin E ₂
PCA	Postconceptional age; primary cutaneous aspergillosis	PGL₂	Prostaglandin I ₂ or prostacyclin
PCC	Prothrombin complex concentrate	PH	Pulmonary hemorrhage; pulmonary hypertension
PCE	Pericardial effusion	Phe	Phenylalanine
PCEP	Perinatal Continuing Education Program	PHH	Posthemorrhagic hydrocephalus
PCG	Pneumocardiogram	PHN	Pulmonary hypertension
PCN	Penicillin	PHS	Polycythemia hyperviscosity syndrome
PCP	<i>Pneumocystis jiroveci</i> pneumonia; phenacyclidine	PI	Pulsatility index
PCR	Polymerase chain reaction	PICC	Peripherally inserted central catheter
PCT	Procalcitonin	PICU	Pediatric intensive care unit
PCVC	Percutaneous central venous catheter	PID	Pelvic inflammatory disease
PCWP	Pulmonary capillary wedge pressure	PIE	Pulmonary interstitial emphysema
PD	Peritoneal drainage; peritoneal drain	PIH	Postinfectious hydrocephalus
PDA	Patent ductus arteriosus	PIP	Peak inspiratory pressure
PDE	Phosphodiesterase; pyridoxine-dependent epilepsy	PIPP-R	Premature Infant Pain Profile—Revised
PDH	Pyruvate dehydrogenase	PIV	Peripheral intravenous
PDHM	Pasteurized donor human milk	PIVKA-II	Protein induced by vitamin K absence-II
PE	Pleural effusion; physical examination; pulmonary embolus	PKU	Phenylketonuria
PEA	Pulseless electrical activity	PLAST	Percussion, lavage, suction, turn
		PLV	Partial liquid ventilation; pressure-limited ventilation
		PM	At night; pneumomediastinum
		PMA	Postmenstrual age
		PMH	Past medical history
		PMN	Polymorphonuclear neutrophil
		PN	Parenteral nutrition
		PNA	Postnatal age

PNAC	Parenteral nutrition–associated conjugated hyperbilirubinemia	PUV	Posterior urethral valves
PNALD	Parenteral nutrition–associated liver disease	P-V	Pressure volume
PNCV	Peripheral nerve conduction velocity	PV	Processus vaginalis
PNDM	Permanent neonatal diabetes mellitus	PVC	Premature ventricular contraction; polyvinyl chloride
PO	By mouth	PVD	Posthemorrhagic ventricular dilation
POCUS	Point-of-care ultrasound	PVET	Peripheral vessel exchange transfusion
POSNA	Pediatric Orthopedic Society of North America	PVG	Portal venous gas
P&PD	Percussion and postural drainage	PVH	Periventricular hemorrhage
PP	Pneumoperitoneum	PVHI	Periventricular hemorrhagic infarction
PPC	Pediatric palliative care	PV-IVH/	Periventricular (hemorrhage)–
PPD	Purified protein derivative; primary peritoneal drainage	PIVH/	intraventricular hemorrhage
PPH/PPHN	Persistent pulmonary hypertension/persistent pulmonary hypertension of the newborn	PVH-IVH	
PPI	Proton pump inhibitor	PVL	Periventricular leukomalacia; Panton-Valentine leukocidin
ppm	Parts per million	PVR	Pulmonary vascular resistance
PPN	Peripheral parenteral nutrition	PVS	Percussion, vibration, and suctioning; pulmonary vein stenosis; pulmonary valve stenosis
pProm,	Preterm premature rupture of membranes	PVT	Portal vein thrombosis
PPROM		q	Every (from the Latin <i>quaque</i>)
PPS	Peripheral pulmonic stenosis	qd	Everyday (on do not use list; better to write daily)
PPV	Positive-pressure ventilation	qXh	Every X hours
PR	Per rectum	qid	Four times daily
PRAE	Perioperative respiratory adverse events	qod	Every other day (from Latin <i>quaque</i> <i>otram diem</i> ; on do not use list; better to write out every other day)
PRBC	Packed red blood cells	Quad	Quadruple screen test (maternal serum α -fetoprotein, human chorionic gonadotropin, estriol, inhibin A)
PRN	As needed (from the Latin <i>pro re nata</i>)	screen	
PRNT	Plaque reduction neutralization test	RA	Right atrium
PRO	Prolinemia	RAD	Right axis deviation
PROM	Premature rupture of membranes	RAE	Right atrial enlargement
PROP	Propionic acidemia	RAH	Right atrial hypertrophy
PS	Pulmonary stenosis; pressure support	RAST	Radioallergosorbent test
PSV	Peak systolic velocity	RAT	Renal artery thrombosis; right atrial thrombosis
PT	Prothrombin time	RBBB	Right bundle branch block
PTB	Preterm birth	RBC	Red blood cell
PTH	Parathyroid hormone	RBL	Rhythm, Breath, and Lullaby international training
PTL	Preterm labor	RCT	Randomized controlled trial
PTNB	Preterm newborn	RDA	Recommended dietary allowance
PTT	Partial thromboplastin time	RDC	Reversed differential cyanosis
PTTN	Prolonged transient tachypnea of the newborn	RDS	Respiratory distress syndrome
PTU	Propylthiouracil	REDV	Reversed end-diastolic velocity
PTX	Pneumothorax	RFI	Renal failure index
PUBS	Percutaneous umbilical blood sampling		
PUFA	Polyunsaturated fatty acids		

RFM	Respiratory function monitor	SAE	Serious adverse event
rFVIIa	Recombinant factor VIIa	SAH	Subarachnoid hemorrhage
Rh	Rhesus factor	SaO₂	Measurement of arterial oxygen saturation
rhAPC	Recombinant human activated protein C	SBA	Suprapubic bladder aspiration
rhEPO	Recombinant human erythropoietin	sBPD	Severe bronchopulmonary dysplasia
RI	Resistance index; reflux index	SBL	Soy bean lipid
RIA	Radioimmunoassay	SBP	Systolic blood pressure
RIVUR	Randomized intervention for children with vesicoureteral reflux	SC	Subcutaneous
RL	Ringer's lactate	SCAD	Short-chain acyl-CoA dehydrogenase deficiency
RLF	Retrolental fibroplasia; retained lung fluid	SCC	Staphylococcal cassette chromosome
RLL	Right lower lobe	SCFN	Subcutaneous fat necrosis
RLQ	Right lower quadrant	SCID	Severe combined immune deficiency
RML	Right middle lobe	SCM	Sternocleidomastoid muscle
RN	Registered nurse	Scr	Serum creatinine
R/O	Rule out	SD	Standard deviation
ROM	Range of motion; rupture of membranes	SDA	Strand displacement amplification
ROP	Retinopathy of prematurity	SDH	Subdural hemorrhage
ROS	Review of systems	SEH	Subependymal hemorrhage
RP%	Reticulated platelet percentages	SEM	Systolic ejection murmur; skin, eyes, and mouth
RPR	Rapid plasma reagin	SEP	Somatosensory evoked potential
RR	Relative risk	SFH	Symphysis–fundal height
rRT-PCR	Real-time reverse transcriptase polymerase chain reaction	SGA	Small for gestational age
RSI	Rapid sequence intubation; rectosigmoid index	SGOT	Serum glutamic oxaloacetic transaminase
rSo₂	Regional hemoglobin oxygen saturation	SGPT	Serum glutamic pyruvic transaminase
RSS	Respiratory severity score	SHC	Selective head cooling
RSV	Respiratory syncytial virus	SHMF	Similac human milk fortifier
RT	Rubella titer; respiratory therapy; radiation therapy	SIADH	Syndrome of inappropriate antidiuretic hormone
RTA	Renal tubular acidosis	SIDS	Sudden infant death syndrome
rTPA	Recombinant tissue plasminogen activator	SIMV	Synchronized intermittent mandatory ventilation
RT-PCR	Reverse transcriptase–polymerase chain reaction	SIP	Spontaneous intestinal perforation
RTU	Ready to use	SIPI	Idiopathic spontaneous intestinal perforation
RUL	Right upper lobe	SIRS	Systemic inflammatory response syndrome
RUQ	Right upper quadrant	SK	Streptokinase
RUSP	Recommended Uniform Screening Panel	SLE	Systemic lupus erythematosus
RV	Right ventricle; residual volume	SMX	Sulfamethoxazole
RVH	Right ventricular hypertrophy	Sn	Tin
RVT	Renal vein thrombosis	SNAP II	Score for Neonatal Acute Physiology II
Rx	Treatment	SNC	Selective neonatal chemoprophylaxis
Rxn	Reaction	SNHL	Sensorineural hearing loss
SA	Sinoatrial		
SAAG	Serum-to-ascites albumin gradient		

SNIPPV	Synchronized nasal intermittent positive-pressure ventilation	TAPVC	Total anomalous pulmonary venous connection
SnMP	Tin mesoporphyrin	TAR	Thrombocytopenia and absent radius (syndrome)
SNP	Single nucleotide polymorphism	TB	Tuberculosis
SOAP	Mnemonic for subjective (S), objective (O), assessment (A), plan (P)	TBG	Thyroid-binding globulin
SOB	Shortness of breath	TBL	Total body-loading dose
SOS	Speed of sound	TBLC	Term birth, living child
S/P	Status post	TBW	Total body water
SpO₂	Oxygen saturation measured by pulse oximetry	tCa	Total serum calcium
SQ	Subcutaneous	TcB	Transcutaneous bilirubinometry
SS	Sensorial stimulation	TcPCO₂	Transcutaneous carbon dioxide tension
SSC	Skin-to-skin contact	TcPO₂	Transcutaneous oxygen tension
SSEP	Somatosensory evoked potential	TD	Transdermal
SSKI	Saturated solution of potassium iodide	Tdap	Tetanus, diphtheria, and pertussis
SSRI	Selective serotonin reuptake inhibitors	TDxFLM II	TDx fetal lung maturity assay
SSSS	Staphylococcal scalded skin syndrome	TE	Tracheoesophageal; thromboembolism
STA	Specific treponemal antibody	TEF	Tracheoesophageal fistula
S.T.A.B.L.E.	Sugar, temperature, airway, blood pressure, lab work, and emotional support	TEG	Thromboelastography
STAT	Immediately	TENS	Transcutaneous electric nerve stimulation
STD/STI	Sexually transmitted disease/sexually transmitted infection	TEWL	Transepidermal water loss
STL/SL	Sternal length	TFP	Trifunctional protein deficiency
STOP-ROP	Supplemental Therapeutic Oxygen for Prethreshold Retinopathy of Prematurity	TFT	Thyroid function test
S-U	Shoulder to umbilicus	TGA	Transposition of the great arteries
SUN	Scale for Use in Newborns	TGV	Transposition of the great vessels
Supp	Supplement; suppository	T&H	Type and hold
Susp	Suspension	TH	Therapeutic hypothermia
SVC	Superior vena cava	THAM	Tris-hydroxymethyl aminomethane (trometamol)
SVD	Spontaneous vaginal delivery	THAN	Transient hyperammonemia of the newborn
SvO₂	Venous oxygen saturation	Ti	Inspiratory time
SVR	Systemic vascular resistance	TI	Tricuspid incompetence (regurgitation)
SVT	Supraventricular tachycardia	tid	Three times daily (from the Latin <i>ter in die</i>)
SWC	Sleep-wake cycle	TIPP	Trial of indomethacin prophylaxis in preterm infants
SWI	Sterile water for injection	TIV	Trivalent inactivated influenza vaccine
Sx	Symptom	TJP	Tight-junction protein
Sz	Seizure	TLC	Total lung capacity
T	Testosterone	TLV	Total liquid ventilation
T₄	Thyroxine	TLR-4	Toll-like receptor-4
T1DM	Type 1 diabetes mellitus	TM	Tympanic membrane
T2DM	Type 2 diabetes mellitus	TMA	Transcription-mediated amplification
TA	Tricuspid atresia; truncus arteriosus	TNDM	Transient neonatal diabetes mellitus
TAC	Truncus arteriosus communis	TNF	Tumor necrosis factor
TA-GVHD	Transfusion-associated graft-versus-host disease		

TNMG	Transient neonatal myasthenia gravis	UCM	Umbilical cord milking
TNPM	Transient neonatal pustular melanosis	UDCA	Ursodeoxycholic acid
TOF	Tetralogy of Fallot	UDPGT	Uridine diphosphate glucuronyl transferase
TORCH	Toxoplasmosis, other, rubella, cytomegalovirus, and herpes simplex virus	UDT	Undescended testis
TORCHZ	Toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus, and Zika virus	UFH	Unfractionated heparin
TOW	Term optimal weight	UGI	Upper gastrointestinal
TOXO	Toxoplasmosis	UK	Urokinase
tPA	Tissue plasminogen activator	ULN	Upper limits of normal
TP-CIA	<i>Treponema pallidum</i> chemiluminescent assay	UNFH	Unfractionated heparin
TP-EIA	<i>Treponema pallidum</i> enzyme immunoassay	UPD	Uniparental disomy
TP-PA	<i>Treponema pallidum</i> particle agglutination	UPEP	Urine protein electrophoresis
TPN	Total parenteral nutrition	UPI	Uteroplacental insufficiency
TPR	Total peripheral resistance	UPJ	Ureteropelvic junction
TPO	Thrombopoietin	URI	Upper respiratory infection
TR	Tricuspid regurgitation	US	Ultrasound
TRAGI	Transfusion-related acute gut injury	USP	U.S. Pharmacopeia
TRALI	Transfusion-related acute lung injury	USPSTF	US Preventive Services Task Force
TREC	T-cell receptor excision circles	UtA	Uterine artery
TRH	Thyrotropin-releasing hormone	UTD	Urinary tract dilation
TS	Tricuspid stenosis	UTI	Urinary tract infection
TSB	Total serum bilirubin	UV	Umbilical vein
TSH	Thyroid-stimulating hormone	UVC	Umbilical vein catheter
TSHR	Thyroid-stimulating hormone receptor	VA	Venoarterial
TSOACs	Target-specific oral anticoagulants	VA-ECLS	Venoarterial extracorporeal life support
TSP	<i>Toxoplasma</i> serologic profile; 3-stair position	VariZIG	Varicella-zoster immune globulin
TST	Tuberculin skin testing	VATER/	Vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia/vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and radial abnormalities, and limb abnormalities
TT	Thrombin time; therapeutic touch	VACTERL	
TTM/TTNB	Transient tachypnea of the newborn		
TTTS	Twin-twin (feto-fetal) transfusion syndrome	VBG	Venous blood gas
TTV	Transfusion-transmitted virus	VC	Vital capacity
TV	Tidal volume	VCUG	Voiding cystourethrogram
TYR1	Tyrosinemia type 1	VDRL	Venereal Disease Research Laboratory
U	Unit(s) (on do not use list; dangerous abbreviation; write out "unit")	VE	Vacuum extraction
UA	Umbilical artery	VEEG	Video electroencephalogram
U/A	Urinalysis	VEGF	Vascular endothelial growth factor
UBTS	Unit-based teams	VEP	Visual evoked potential
UAC	Umbilical artery catheter	VER	Visual evoked response

VTV	Volume-targeted ventilation	WNV	West Nile virus
VUE	Villitis of unknown etiology	WPW	Wolff-Parkinson-White syndrome
VUR	Vesicoureteral reflux	X-ALD	X-Linked adrenoleukodystrophy
VUS	Variant of uncertain significance	XR	Extended release
VV	Venovenous	ZDV	Zidovudine
VV-ECLS	Venovenous extracorporeal life support	ZIKV	Zika virus
		ZnMP	Zinc mesoporphyrin

Appendix B. Apgar Score/Expanded Apgar Score

APGAR SCORE

The original Apgar score was devised by Virginia Apgar, MD, an anesthesiologist, in 1952 who invented a scoring system to assess the clinical status of the newborn infant and the need for medical intervention to establish breathing at 1 minute of age. It was presented at a national anesthesiology meeting in 1952. She published the results in 1953 in a paper titled, "A Proposal for a New Method of Evaluation of the Newborn Infant," the purpose of which was to establish a grading system of newborns to be used as a basis to discuss and compare results of obstetric practices, different types of maternal pain relief, and the effects of resuscitation techniques. It was "a simple clear classification or grading of newborns consisting of five signs" that did not require special equipment, were determined easily, did not interfere with the care of the newborn, and could be taught without difficulty. She chose heart rate, respiratory effort, reflex irritability, muscle tone, and color. The most important sign was the heart rate, followed by respiratory rate, and the least important sign was the color of the newborn. A rating of 0, 1, or 2 was given for each sign at 60 seconds after delivery (after the complete birth of the baby and the time of maximal clinical depression after birth). Two subsequent studies were done (1952–1956 and 1959–1966), and the 5-minute Apgar score was added because neonatal mortality strongly correlated with it. In 1962, a "back acronym" (APGAR) was created from Dr. Apgar's last name by 2 pediatricians to help teach the 5 signs of the Apgar score: **A**: appearance (color); **P**: pulse; **G**: grimace (response to stimulation); **A**: activity (tone); **R**: respiration.

EXPANDED APGAR SCORE

In 2015, the American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecologists (ACOG) published a statement that included the second edition of the Neonatal Encephalopathy and Neurologic Outcome about the purpose of the Apgar score because many were using the score inappropriately. They recommended the new expanded Apgar score (Figure B-1). It has the same 5 signs as the original Apgar score but includes reporting a score also at 10, 15, and 20 minutes (10-, 15-, and 20-minute assessment is recommended by the American Heart Association [AHA] if the 5-minute Apgar score is <7) with added room to record (by a checkmark) if any of the following are used: oxygen, positive-pressure ventilation/nasal continuous positive airway pressure, endotracheal tube, chest compressions, and epinephrine. This new score accounts for resuscitative interventions. The definitions from the Neonatal Encephalopathy and Neurologic Outcome report that are recommended for the 5-minute Apgar score for term and late preterm infants are as follows: score of **7 to 10, reassuring**; score of **4 to 6, moderately abnormal**; and score of **0 to 3, low**. The AAP and ACOG recommend an umbilical arterial blood gas sample from a clamped section of the umbilical cord and possibly submitting the placenta for examination by pathology if the infant has an Apgar score of 5 at <5 minutes. Below is a summary of what the Apgar score does and does not do based on the AAP 2015 Policy Statement and the ACOG Task Force on Neonatal Encephalopathy.

What the Apgar Score Does

1. The Apgar score is an acceptable method for reporting the condition of a newborn immediately after birth and the response to resuscitation if necessary. It is affected by multiple factors including normal transition variations, gestational age, maternal medications, maternal sedation, maternal anesthesia, type of delivery, multiple births, maternal infection, resuscitation, neurologic and cardiorespiratory diseases, trauma, any congenital abnormality, and variability in the observer who is scoring the newborn.
2. A low 5-minute score (0–3) strongly correlates with neonatal mortality (report was in large populations). In the Neonatal Encephalopathy and Neurologic Outcome report, an Apgar score of 0 to 3 at ≥5 minutes was felt to be a nonspecific sign of illness. It does not predict neurologic dysfunction in the future. A low 1-minute score does not correlate or predict the outcome of an infant.
3. An Apgar score <5 at 5 and 10 minutes increases the relative risk of cerebral palsy. The majority of infants with a low 5-minute Apgar score do not develop cerebral palsy.
4. If the Apgar score is <3 at 10, 15, and 20 minutes, the population risk of a poor neurologic outcome is increased.
5. If the Apgar score is 0 after 10 minutes of age (no heart rate detectable for 10 minutes), it might be appropriate to discontinue resuscitation of the infant. This decision of stopping or continuing resuscitation should be individualized. A score of 0 at 10 minutes is a strong predictor of mortality and serious morbidity in term and late preterm infants.
6. Low Apgar scores are inversely related to birthweight.
7. A difference in the score from 1 minute to 5 minutes can be useful as an index to the response to resuscitation.
8. If the Apgar score is ≥7 at 5 minutes and the infant has neonatal encephalopathy, it is probably not due to hypoxia-ischemia in the peripartum period.

What the Apgar Score Does Not Do

1. During resuscitation of an infant, the Apgar score is not as accurate as if performed in an infant who was not resuscitated. There are no standards for assigning and reporting an Apgar score if the infant has been resuscitated.

Apgar Score

Gestational age _____ weeks

Sign	0	1	2	1 minute	5 minute	10 minute	15 minute	20 minute
Color	Blue or Pale	Acrocyanotic	Completely Pink					
Heart rate	Absent	<100 minute	>100 minute					
Reflex irritability	No Response	Grimace	Cry or Active Withdrawal					
Muscle tone	Limp	Some Flexion	Active Motion					
Respiration	Absent	Weak Cry; Hypoventilation	Good, Crying					
Total								
Comments:	Resuscitation							
	Minutes	1	5	10	15	20		
	Oxygen							
	PPV/NCPAP							
	ETT							
	Chest Compressions Epinephrine							

FIGURE B-1. Expanded Apgar score reporting form. Scores should be recorded in the appropriate place at specific time intervals. The additional resuscitative measures (if appropriate) are recorded at the same time that the score is reported by using a checkmark in the appropriate box. The comment box is used to list other factors, including maternal medications and/or the response to resuscitation between the recorded times of scoring. ETT, endotracheal tube; PPV/NCPAP, positive pressure ventilation/nasal continuous positive airway pressure. (Based on data from American Academy of Pediatrics Committee on Fetus and Newborn, American College of Obstetricians and Gynecologists Committee on Obstetric Practice. *The Apgar score*. Pediatrics. 2015;136:819-822.)

2. It does not tell you if you need to resuscitate the infant. If an infant needs resuscitation, it should be started before the 1 minute of age score. The score also does not tell you what resuscitation steps are necessary and when to use them.
3. The Apgar score does not predict an infant's morbidity, mortality, or neurologic outcome.
4. The Apgar score does not diagnose, define, measure, or provide evidence of asphyxia.

Appendix C. Blood Pressure Determinations

Table C-1. BLOOD PRESSURE MEASUREMENTS (MM HG) IN PRETERM AND FULL-TERM NEONATES (DAYS 1-7 AND DAY 30)

Postnatal Day	Gestational Age (Noncritically Ill Infants)			
	≤28 Weeks	29-32 Weeks	33-36 Weeks	37 Weeks
1	Systolic: 38-46 Diastolic: 23-29 Mean: 29-35	Systolic: 42-52 Diastolic: 26-38 Mean: 33-43	Systolic: 51-61 Diastolic: 32-40 Mean: 39-47	Systolic: 57-69 Diastolic: 35-45 Mean: 44-52
2	Systolic: 38-46 Diastolic: 24-32 Mean: 29-37	Systolic: 46-56 Diastolic: 29-39 Mean: 35-45	Systolic: 54-62 Diastolic: 34-42 Mean: 42-48	Systolic: 58-70 Diastolic: 36-46 Mean: 46-54
3	Systolic: 40-48 Diastolic: 25-33 Mean: 30-38	Systolic: 47-59 Diastolic: 30-35 Mean: 37-47	Systolic: 54-64 Diastolic: 35-43 Mean: 42-50	Systolic: 58-71 Diastolic: 37-47 Mean: 46-54
4	Systolic: 41-49 Diastolic: 26-36 Mean: 31-41	Systolic: 50-62 Diastolic: 32-42 Mean: 39-49	Systolic: 56-66 Diastolic: 36-44 Mean: 44-50	Systolic: 61-73 Diastolic: 38-48 Mean: 46-56
5	Systolic: 42-50 Diastolic: 27-37 Mean: 32-42	Systolic: 51-65 Diastolic: 33-43 Mean: 40-50	Systolic: 57-67 Diastolic: 37-45 Mean: 44-52	Systolic: 62-74 Diastolic: 39-49 Mean: 47-57
6	Systolic: 44-52 Diastolic: 30-38 Mean: 35-43	Systolic: 52-66 Diastolic: 35-45 Mean: 41-51	Systolic: 59-69 Diastolic: 37-45 Mean: 45-53	Systolic: 64-76 Diastolic: 40-50 Mean: 48-58
7	Systolic: 47-53 Diastolic: 31-39 Mean: 37-45	Systolic: 53-67 Diastolic: 36-44 Mean: 43-51	Systolic: 60-70 Diastolic: 37-45 Mean: 45-53	Systolic: 66-76 Diastolic: 40-50 Mean: 50-58
30	Systolic: 59-65 Diastolic: 35-49 Mean: 42-56	Systolic: 67-75 Diastolic: 43-53 Mean: 52-60	Systolic: 68-76 Diastolic: 45-55 Mean: 53-60	Systolic: 72-82 Diastolic: 46-54 Mean: 55-63

Data from Pejovic B, Peco-Antic A, Marinkovic-Eric J. Blood pressure in non-critically ill preterm and full-term neonates. *Pediatr Nephrol.* 2007;22:249-257.

FIGURE C-1. Mean blood pressure (BP) of all infants 401 to 1000 g during the first 72 hours of life. SD, standard deviation. (Reproduced, with permission, from Fanaroff JM, Wilson-Costello DE, Newman NS, Montpetite MM, Fanaroff AA. Treated hypotension is associated with neonatal morbidity and hearing loss in extremely low birth weight infants. *Pediatrics*. 2006;117:1131-1135.)

Appendix D. Chartwork

Many hospitals are now using electronic medical records (EMR) or electronic health records (EHR). These are often in a preformatted template to be completed electronically. Because there are many different formats, there is no all-inclusive EMR example. The following section provides an overview of the basic history, progress note, admission orders, and discharge summary. Chapter 7 outlines the newborn physical examination.

ADMISSION HISTORY

A. Identification. State the name, age, sex, and weight of the infant. Include whether the patient or mother was transported from another facility or whether the infant was born at home or within the hospital.

Infant James, a 3-hour-old 1800-g white male, is an inborn patient from Baltimore, Maryland.

B. Chief complaint. The major problems of the patient are usually listed in the order of severity of disease process or occurrence.

1. Respiratory distress syndrome
2. Suspected neonatal sepsis
3. Premature birth living child (PBLC)

C. Referring physician. Include the name, address, and telephone number of the referring physician.

Dr. Macaca Mulatta, Benjamin Franklin Medical Center, Chadds Ford, PA; (946) 854-8881.

D. History of present illness. The history of present illness (HPI) is more helpful if it is divided into 4 separate paragraphs.

- 1. Initial statement.** This part of the HPI includes the patient's name, gestational age, birthweight, sex, age of the mother, and the number of times she has been pregnant along with the number of her living children.
- 2. Prenatal history.** Discuss the maternal prenatal care and record the number of prenatal clinic visits. Include any medications the mother was taking, any pertinent prenatal tests done, and the results.
- 3. Labor and delivery.** Include a detailed history of the labor and delivery: type of delivery, type of anesthesia, any medication used, and any fetal monitoring (including results).
- 4. Infant history.** Discuss the initial condition of the infant and the need for resuscitation, and write a detailed description of what occurred. Include the Apgar scores and discuss when the infant became symptomatic or when problems were first noted.

Infant James is an 1800-g white male delivered to a 19-year-old G₂ now P₂, LC₂ married white female.

The mother had excellent prenatal care. She had her first prenatal visit at approximately 8 weeks' gestation and then saw her obstetrician routinely. She was on no medications, and she does not have any history of alcohol or cigarette abuse.

She had rupture of membranes (ROM) at 33 weeks with some mild contractions. At that time, she was seen by her obstetrician, who confirmed the premature ROM. She was admitted to the hospital and started on tocolytic treatment in an attempt to stop the labor. Vaginal-rectal swab for group B Streptococcus (GBS) cultures was obtained. Intravenous (IV) penicillin was initiated. Because of a positive GBS culture, penicillin was continued during tocolysis. External fetal monitoring had been normal until 4 hours after the tocolytic therapy, at which time it showed persistent late decelerations. At this point, an emergency cesarean delivery was performed. General anesthesia was used, and the infant was delivered within 6 minutes.

The infant was delivered depressed at birth, with a 1-minute Apgar score of 4. He required positive-pressure ventilation with 30% oxygen. No medications were needed. The 5-minute Apgar was 7. The infant appeared poorly perfused and had poor color without oxygen. He was stabilized and transported on oxygen to the neonatal intensive care unit.

E. Family history. The family history should include any previous complicated births and their history, miscarriages, neonatal deaths, or premature births. Also include any major family medical problems (eg, hemophilia, sickle cell disease).

Mrs. James had 1 prior uncomplicated vaginal delivery that went to term. There is a history of myelodysplasia in infant James's maternal first cousin.

F. Social history. In the social history, include a brief statement discussing the parent's age, marital status, siblings, occupation, and where they are from.

The parents live in Chadds Ford, Pennsylvania. The mother is a 19-year-old mushroom farm worker and cares for their 2-year-old daughter; the father is 24 years old and works in the local museum as a custodial worker.

G. Physical examination. See Chapter 7.

H. Laboratory data. List the admission laboratory and radiology results.

I. Assessment. State your evaluation of the infant's problems. It can include a list of suspected and potential problems as well as a differential diagnosis.

1. Respiratory distress syndrome: *Because the infant is premature, respiratory distress syndrome must be considered. Pneumonia is also a likely cause because of the maternal history of suspected chorioamnionitis.*

2. Suspected neonatal sepsis: *Because of the positive GBS culture and the premature onset of labor, there is an increased septic risk in this infant. Certain pathogens need to be ruled out. GBS is the most common pathogen in this age group, but Listeria monocytogenes and gram-negative pathogens should be considered.*

3. Premature birth living child: *The infant is at 33 weeks' gestation by Ballard examination.*

J. Plan. Include the therapeutic and diagnostic plans for the infant. (See section titled "Admission Orders.")

PROGRESS NOTES

The most commonly used format for daily progress notes is the *SOAP* method. *SOAP* is an acronym; *S* = subjective, *O* = objective, *A* = assessment, and *P* = plan. Each problem should be discussed in this format. First, state the problems you are to discuss in the order of severity or occurrence and assign a number to them. Then discuss each problem in the *SOAP* format as outlined next.

- A. Subjective (S).** Include an overall subjective view of the patient by the physician.
- B. Objective (O).** Include data that can be objectively gathered, usually in 3 areas:
 1. **Vital signs (temperature, respiratory rate, pulse, blood pressure).**
 2. **Pertinent physical examination.**
 3. **Laboratory data and other test results.**
- C. Assessment (A).** Include evaluation of the preceding data.
- D. Plan (P).** Discuss the medication changes, laboratory orders, and any other new orders as well as the treatment plan.
- E. Example.** The following is an example of part of a progress note using the *SOAP* format.

Problem 1. Respiratory distress syndrome.

S: Infant James is now 4 days old and doing much better. He has been able to wean down to 30% oxygen with good arterial gases.

O: Vital signs: temperature 98.7°F, respirations 52, pulse 140, blood pressure 55/35.

Physical examination: The peripheral perfusion appears good with no obvious cyanosis. There is no grunting or nasal flaring, but the infant has mild substernal and intercostal retractions. The chest sounds slightly wet. Laboratory data and other test results: Arterial blood gases on 30% oxygen—pH 7.32, CO₂ 48, O₂ 67, 97% saturation. Chest radiograph shows mild haziness in both lung fields.

A: Infant James has resolving mild respiratory distress syndrome.

P: The plan is to wean the oxygen as long as his arterial PaO₂ is maintained between >55 and 70 mm Hg.

Problem 2. Suspected neonatal sepsis—Follow with SOAP note.

Problem 3. Premature birth living child (PBLC)—Follow with SOAP note.

ADMISSION ORDERS

The following format is useful for writing admission orders. It involves the mnemonic *A.D.C. VAN DISSEL*: Admit, Diagnosis, Condition, Vital signs, Activity, Nursing procedures, Diet, Input and output, Specific drugs, Symptomatic drugs, Extras, and Laboratory data. Most centers now have online physician ordering templates.

- A. Admit.** Specify the location of the patient (neonatal intensive care unit, newborn nursery) and the attending physician in charge and the house officer along with their paging/phone numbers.
- B. Diagnosis.** List the admitting diagnoses.
 1. *Respiratory distress syndrome*
 2. *Suspected neonatal sepsis*
 3. *Premature birth living child*
- C. Condition.** Note whether the patient is in stable or critical condition.
- D. Vital signs.** State the desired frequency of monitoring of vital signs. Specify rectal or axillary temperature. Rectal temperature is usually done initially to obtain a core temperature and also to rule out imperforate anus. Then, monitor axillary temperature. Other parameters include blood pressure, pulse, and respiratory rate. Weight, length, and head circumference should also be obtained on admission.
- E. Activity.** All are at bed rest, but one can specify “minimal stress or hands-off protocol” here. This notation is used for infants who react poorly to stress by dropping their oxygenation, as in patients with persistent pulmonary hypertension. At most centers, it means to handle the infant as little as possible and record all vital signs off the monitor.

- F. Nursing procedure.** Respiratory care (ventilator settings, chest percussion and postural drainage orders, endotracheal suctioning with frequency). Also require that a daily weight and head circumference be recorded. The frequency of Dextrostix (or Chemstrip-bG) testing is included in this section because it is a bedside procedure.
- G. Diet.** All infants admitted to the neonatal intensive care unit are usually made NPO (nothing by mouth) for at least 6 to 24 hours until they are accessed and stabilized. When appropriate, write specific diet orders.
- H. Input and output.** Request that the nursing staff record accurate input and output (I&O) of each infant. This record is especially important for infants on IV fluids and those just starting oral feedings. Specify how often you want the urine tested for specific gravity and glucose.
- I. Specific drugs.** State drugs to be administered, giving specific dosages and routes of administration. It is useful to also include the milligrams-per-kilogram-per-day dose of the drug to allow cross-checking and verification of the dose ordered. An example is as follows:
Ampicillin 45 mg IV every 12 hours (50 mg/kg/d divided every 12 hours).
For all infants, order the following medications at the time of admission.
 - 1. Vitamin K (see Chapter 155) is given to prevent vitamin K deficiency disease.
 - 2. Erythromycin eye drops (see Chapter 155) are given to prevent gonococcal ophthalmia.
- J. Symptomatic drugs.** These drugs are not routinely used in a neonatal intensive care unit and would include such items as pain and sleep medications.
- K. Extras.** Any other orders required but not included previously, such as roentgenography, electrocardiography, and ultrasonography.
- L. Laboratory data.** Include laboratory data drawn on admission, plus routine laboratory orders with frequency (eg, arterial blood gases every 2 hours, sodium and potassium bid).

DISCHARGE SUMMARY

The following information is written at the time of discharge and provides a summary of the infant's illness and hospital stay.

- A. Date of admission.**
- B. Date of discharge.**
- C. Admitting diagnosis.**
- D. Discharge diagnosis.** List in order of occurrence or severity.
- E. Attending physician and service caring for the patient.**
- F. Referring physician and address.**
- G. Procedures.** Include all invasive procedures.
- H. Brief history, physical examination, and laboratory data on admission.** Use the admission history, physical examination, and laboratory data as a guide.
- I. Hospital course.** The easiest way to approach this section of the discharge summary is to discuss each problem in paragraph form.
- J. Condition at discharge.** A complete physical examination is done at the time of discharge and included in this section. It is important to include the discharge weight, head circumference, and length so that growth can be assessed at the time of the patient's initial checkup. Also include the type and amount of formula the patient is on and any pertinent discharge laboratory values.
- K. Discharge medications.** Include the name(s) of medication(s), the dosage(s), and length of treatment. If the patient is being sent home on an apnea monitor, it is helpful to include the monitor settings and the planned course of treatment.
- L. Disposition.** Note where the patient is being sent (outside hospital, home, foster home).
- M. Discharge instructions and follow-up.** Include instructions to the parents on medications and when the patient is to return to the clinic (and exact location). It is helpful to indicate tests that need to be done on follow-up and any results that need to be rechecked (eg, bilirubin, repeat phenylketonuria screen).
- N. Problem list.** Same list as the discharge diagnosis list.

Appendix E. Immunization Guidelines

For most up to date changes, see <https://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-child-combined-schedule.pdf> (accessed October 24, 2018). This table is approved by the Centers for Disease Control and Prevention, American Academy of Pediatrics (AAP), American Academy of Family Physicians, and American College of Obstetricians and Gynecologists.

IMMUNIZATIONS FOR TERM INFANTS

Term infants follow the recommended immunization schedule for persons aged 0 to 15 months, then 18 months to 18 years (<http://www.immunize.org/cdc/schedules/cdc-child-iz-schedule>; accessed October 24, 2018).

IMMUNIZATIONS FOR PRETERM INFANTS

Misconceptions about the safety and efficacy of vaccinations for preterm infants have led to delays in immunization for these infants. It is important that preterm infants with prolonged hospital stays begin necessary immunizations prior to neonatal intensive care unit (NICU) discharge to allow development of early protection from infectious agents prevalent in the community, especially pertussis. The AAP current recommendations can be summarized as follows:

- “Infants born preterm (at less than 37 weeks of gestation) or of low birthweight (less than 2500 g) [who are clinically stable] should, with few exceptions, receive all routinely recommended childhood vaccines at the same chronologic age as term infants,” even if they are still hospitalized.
- “The same volume of vaccine used for term infants is appropriate for medically stable preterm infants.”
- “The choice of needle lengths used for IM [intramuscular] vaccine administration is determined by available muscle mass of the preterm or low birth weight infant” (Table E-1).
- “Medically stable preterm infants who remain in the hospital at 2 months of chronologic age should receive all inactivated vaccines recommended at that age.”
- All vaccines required at 2 months of age can be given simultaneously to preterm or low birthweight infants, except oral rotavirus vaccine, which should be given at discharge.
- Limit the number of injections at 2 months of age by giving combination vaccines. If there are limited injection sites, give the vaccines at different times, separated by 2-week intervals.

Refer to Table E-2 for immunizations for preterm infants.

Table E-1. SITE AND NEEDLE LENGTH BY AGE FOR INTRAMUSCULAR IMMUNIZATION

Age Group	Needle Length, inches (mm) ^a	Suggested Injection Site
Newborns (preterm and term) and infants <1 month of age	$\frac{5}{8}$ –1 (16–25 mm) ^b	Anterolateral thigh muscle
Term infants, 1–12 months of age	$\frac{5}{8}$ –1 (16–25 mm)	Anterolateral thigh muscle

^aAssumes that needle is inserted fully.

^bIf the skin is stretched tightly and subcutaneous tissues are not bunched. Based on *Red Book* recommendation (2018–2021).

Effectiveness of Immunizations

For the majority of premature infants, their protective antibody responses to immunizations are comparable to those seen in term infants. Although some studies have shown decreased immunity from vaccines in preterm infants weighing <1500 g and born at <29 weeks of gestation, the vast majority of preterm infants, including those receiving steroids for chronic lung disease, will produce sufficient immunity from vaccines to prevent disease.

Immunization Pain Management

Injection pain is often a source of concern among parents and hospital staff. Needle size is addressed earlier. Many simple pain management strategies are effective, particularly breast feeding, feeding sugar solutions, and applying topical anesthetics. Aspiration before injection is not recommended because it may cause more pain, and is not necessary because the anatomy of the injection site does not have any large blood vessel. For term newborns, infants, and children, the application of EMLA (lidocaine 2.5%/prilocaine 2.5%) approximately 60 minutes prior to the administration of vaccinations is an effective pain management strategy. However, the use of acetaminophen prior to vaccinations is not recommended due to possible loss in vaccine effectiveness. Acetaminophen can be used after immunizations to treat pain or fever.

A Cochrane review from 2015 evaluated several studies to determine whether needle size used for administration of vaccinations in healthy infants could reduce pain and local inflammation, while maintaining immunogenicity. In 3 studies, which including >1000 healthy infants, infants were vaccinated in the thigh with 25-gauge/25-mm needles (narrow, long needles), 23-gauge/25-mm needles (wide, long needles), or 25-gauge/16-mm needles (narrow, short needles). Using the World Health Organization guidelines, the needles were inserted at a 90-degree angle into the skin and pushed down into the muscle of the thigh. Using 25-mm needles (either 23 or 25 gauge) for intramuscular vaccination procedures in the anterolateral thigh of infants seemed to reduce the occurrence of local reactions while achieving a comparable immune response to 25-gauge/16-mm needles. Although this review was limited by its use of combination vaccines including diphtheria (D), tetanus (T), whooping cough (pertussis), and *Haemophilus influenzae* type b disease (Hib), it suggests that reducing pain with smaller, narrower needles maintains immunogenicity and reduces local inflammation. The current AAP recommendations for injection site and needle length are included in Table E-1.

Complications of Immunization

Adverse events have been reported after vaccine administration and historically have led to concern, limiting immunization of premature infants. Adverse events may be caused by the vaccine or may occur by chance after immunization. Any event that is considered **serious** or **unexpected** and possibly related to the vaccination should be reported. Serious adverse events include: **apnea, anaphylaxis, abscess formation, encephalitis, acute flaccid paralysis, fever (>40.5°C), persistent screaming, severe local reactions, and seizures.**

Preterm infants are not at higher risk for these types of adverse reactions as compared with term infants. Premature infants generally tolerate immunizations as well as term infants and experience fewer febrile and local reactions to immunizations because of their more immature immune systems. However, **apnea following immunizations** has been observed in infants with previous apneic spells, particularly within the 24 hours prior to immunizations, and those with younger gestational age or weight <2000 g at the time of immunization and a 12-hour Score for Neonatal Acute Physiology II >10. If these infants are hospitalized at the time of immunization, they should be monitored for 48 hours after immunization. Contraindications to immunizations are the same for all infants and include a significant febrile illness, active seizure disorder or encephalopathy, or any known allergies to the vaccine components (eg, eggs).

An increased incidence of apnea with or without bradycardia after immunization with whole-cell DTP was recognized in extremely low birthweight infants <1000 g but has not been reported with DTaP. Cardiorespiratory events (apnea and bradycardia with desaturations) can be seen in preterm infants given combination DTaP, inactivated polio, hepatitis B, and Hib conjugate vaccines but are not reported to have a detrimental effect on the clinical course of immunized infants according to the AAP *Red Book*. A 2008 retrospective study of >16,000 premature infants showed that specific events could not be associated with specific vaccinations; no difference in the frequency of apnea was observed after either pertussis-containing or non-pertussis-containing vaccines. Thus, the incidence of apnea in this age group is more likely to be related to a generalized inflammatory response, rather than a response to the specific vaccine antigens.

Table E-2. IMMUNIZATIONS FOR PRETERM INFANTS

Age	Infection Prevented	Recommended Vaccine
Birth	Hepatitis B ^a	<p>Mother HBsAg positive: Give to all newborns regardless of BW both hepatitis B vaccine and 0.5 mL of HBIG at separate anatomic sites within 12 hours of birth.</p> <p>Mother HBsAg negative:</p> <p>BW ≥2000 g: Give hepatitis B vaccine as routine prophylaxis to all medically stable infants within 24 hours of birth.</p> <p>BW <2000 g: Give hepatitis B vaccine as routine prophylaxis at 1 month of age chronologically or at hospital discharge (whichever occurs first).</p> <p>Mother HBsAg unknown: Give hepatitis B vaccine within 12 hours of birth to all newborns regardless of BW.</p> <p>For HBIG:</p> <p>BW ≥2000 g: Give HBIG within 7 days of birth if maternal status is confirmed positive, or by 7 days of life or at hospital discharge (whichever is first) if maternal status remains unknown.</p> <p>BW <2000 g: Give 0.5 mL of HBIG within 12 hours of birth unless maternal status is confirmed negative by that time.</p>
1–2 months	Hepatitis B ^a	Give the second dose of hepatitis B vaccine at 1–2 months of age.
2 months ^c	Diphtheria, tetanus, pertussis <i>Haemophilus influenzae</i> type b Inactivated poliovirus Pneumococcal conjugate Rotavirus ^d	<p>DTaP^b</p> <p>Hib</p> <p>IPV</p> <p>PCV13</p> <p>Rotavirus vaccine can be given to preterm (clinically stable)/term infants as follows: between 6 weeks and 14 weeks, 6 days of chronologic age, with first dose given at hospital discharge, or after discharge—series should not be started after 15 weeks, 0 days of age.</p>

(Continued)

Table E-2. IMMUNIZATIONS FOR PRETERM INFANTS (*CONTINUED*)

Age	Infection Prevented	Recommended Vaccine
	Meningococcal vaccine (Menveo)	Only for anatomic/functional asplenia, sickle cell disease, HIV infection, persistent complement component deficiency, or infants who live or travel in countries where meningococcal disease is hyperendemic or epidemic. Give at 2, 4, 6, and 12 months of age.
4 months	All of those listed for 2 months	All of those listed for 2 months except hepatitis B: If using monovalent hepatitis B, no vaccine at 4 months. If using a combination vaccine with hepatitis B, then acceptable to have baby receive a total of 4 doses of hepatitis B vaccine.
6 months	All of those listed for 1–2 and 2 months	All listed for 1–2 and 2 months, except: If Pedvax-HIB is administered at 2 and 4 months, a dose at 6 months for Hib not necessary. Only RotaTeq vaccine given at 6 months.
	Influenza vaccine	Inactivated influenza vaccine: 2 doses beginning at 6 months of age, with second dose 1 month later.
	MMR (only international travel)	For international travel only, give 1 dose before departure.
	Hepatitis A vaccination	For infants traveling to countries with high or intermediate endemic hepatitis A.
Hospital discharge	RSV ^e	Appropriately selected preterm infants may benefit from immunoprophylaxis with palivizumab beginning at hospital discharge and then monthly during RSV season. Refer to yearly regional recommendations for guidelines

BW, birthweight; HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; MMR, measles, mumps, rubella; RSV, respiratory syncytial virus.

^aOnly monovalent (single-antigen) hepatitis B vaccine should be used for the dose at birth and any dose given before 6 weeks of age.

^bWhenever possible, the same brand of DTaP should be used at 2, 4, and 6 months.

^cCombination vaccines can be given starting at 2 months of age to minimize the number of injections.

^dDo not use rotavirus if there is a history of intussusception or severe combined immune deficiency. Use precautions when giving rotavirus if the infant has any moderate to severe illness, manifestations of altered immunocompetence, preexisting chronic intestinal tract disease, or bladder exstrophy or spina bifida. Rotavirus can be given the same time as other vaccines or any time a blood product is given. If the infant vomits, regurgitates, or spits up during or after the dose, do not repeat it. Rotarix is a 2-dose series at 2 and 4 months. RotaTeq is a 3-dose series at 2, 4, and 6 months.

^eRSV eligibility includes: Preterm infants with chronic lung disease (CLD) of prematurity (GA <32 weeks, 0 days, and a requirement for >21% oxygen for at least the first 28 days after birth); infants with acyanotic heart disease on medication to control congestive heart failure who require cardiac surgical procedures; infants with moderate to severe pulmonary hypertension; and preterm infants without CLD or CHD if born at <29 weeks, 0 days of gestation.

Based on Kimberlin DW, Long SS, eds. *Red Book: 2018–2021 Report of the Committee on Infectious Diseases*. 31st ed. Elk Grove Village, IL: American Academy of Pediatrics; 2018–2021.

Special Circumstances

There are few data regarding the immunologic responses of extremely preterm infants receiving steroids for the treatment of bronchopulmonary dysplasia/chronic lung disease (BPD/CLD). Therefore, live vaccines should not be administered to babies receiving prednisolone (2 mg/kg/d for >1 week or 1 mg/kg/d for >1 month) or the equivalent dose of dexamethasone. Live vaccines should not be administered while babies are hospitalized in the NICU.

Premature infants >6 months but <2 years of age with a history of BPD/CLD or reactive airway disease should be considered for vaccination against influenza.

Select premature infants are eligible to receive prophylaxis against the respiratory syncytial virus (RSV) as a monthly injection given during RSV season. Eligibility requirements can change yearly. It is recommended that physicians use local references at the beginning of the RSV season for guidance on dosing.

Immunization for Perinatal Hepatitis B Infection

The AAP recently released an updated policy statement for elimination of perinatal hepatitis B infection. Unfortunately, when infants become infected and are not adequately treated, 90% will go on to develop chronic hepatitis B infection. Further, one-quarter of those infants will die of hepatocellular carcinoma or liver cirrhosis. Hepatitis B vaccination is highly effective when given appropriately; hepatitis B vaccine alone is 75% to 95% effective in preventing perinatal hepatitis B transmission if administered within 24 hours of birth. In addition, when postexposure prophylaxis of both hepatitis B vaccine and hepatitis B immune globulin (HBIG) is given correctly and is followed by completion of the infant hepatitis B immunization series, perinatal infection rates can drop below 1%.

Appendix F. Isolation Guidelines

The following table, Table F-1 Transmission-Based Precautions for Perinatal/Neonatal Patients, in conjunction with Standard Precautions (see Chapter 25), is based on current knowledge and practices in the fields of epidemiology, pediatrics, and perinatology. Published resource references are listed immediately after the table. Always follow local guidelines where they exist.

INSTRUCTIONS FOR USING PRECAUTIONS FOR PERINATAL/NEONATAL PATIENTS (TABLE F-1)

- Each disease is considered individually so that only precautions indicated to interrupt transmission for that disease are recommended.
- The column “Maternal Precautions” describes the precautions to be used by staff providing care to the mother.
- The column “Neonatal Precautions” describes the precautions to be used by staff, patients, or visitors in contact with the neonate.
- Staff should assess the mother’s ability to wash hands correctly and comply with precautions when determining the appropriateness of permitting rooming in.
- Precautions should be initiated for suspected as well as confirmed infectious diseases/conditions.

Table F-1. TRANSMISSION-BASED PRECAUTIONS FOR PERINATAL/NEONATAL PATIENTS

Infection/Disease	Maternal Precautions	Neonatal Precautions	Room-in	Mother May Visit in Nursery	Breast Feeding	Additional Considerations
AIDS/HIV positive	Standard	Standard Bathe baby ASAP when stable	Yes	Yes	No HIV may be transmitted through breast milk.	Recommend tuberculosis testing for mother. Due to constant HIV antiretroviral (ARV) treatment option changes, consult with neonatology expert and refer to http://aidsinfo.nih.gov for current ARV treatment options. Follow your local public health department reporting requirements.
Chickenpox (see Varicella)						
<i>Chlamydia trachomatis</i>	Standard	Standard	Yes	Yes	Yes	Topical prophylaxis is ineffective for <i>Chlamydia</i> ophthalmic disease. Treatment for <i>Chlamydia</i> : Even though infants born to mothers with untreated chlamydial infections are at high risk of infection, prophylaxis is not indicated. The recommended treatment of choice for conjunctivitis and pneumonia is oral erythromycin base or ethylsuccinate (50 mg/kg/d in 4 divided doses daily) for 14 days or azithromycin (20 mg/kg as single dose) for 3 days. Due to 80% treatment efficacy, a second course may be required (see <i>Red Book</i> , 2018–2021).
Cytomegalovirus (CMV)	Standard	Standard	Yes	Yes	Yes	No additional precautions for pregnant healthcare workers.

(Continued)

Table F-1. TRANSMISSION-BASED PRECAUTIONS FOR PERINATAL/NEONATAL PATIENTS (CONTINUED)

Infection/Disease	Maternal Precautions	Neonatal Precautions	Room-In	Mother May Visit in Nursery	Breast Feeding	Additional Considerations
Gastroenteritis	Contact precautions for diapered or incontinent persons for the duration of illness or to control outbreaks for gastroenteritis caused by infectious agents such as <i>Clostridium difficile</i>	Contact precautions for the duration of illness to control outbreaks for gastroenteritis/ diarrhea caused by infectious agents such as <i>C. difficile</i>	Yes	Yes	Yes	The most effective method to remove <i>C. difficile</i> spores from contaminated hands is through meticulous hand hygiene with soap and water. Alcohol-based hand hygiene products do not inactivate <i>C. difficile</i> spores. Because <i>C. difficile</i> spores are difficult to kill, most surface disinfectants are ineffective. When outbreaks of <i>C. difficile</i> diarrhea are not controlled by other measures, it is recommended to use a disinfectant with sporicidal activity (eg, hypochlorite).
Gonococcal ophthalmia neonatorum	Standard	Standard	Yes After 24 hours of maternal treatment with antibiotics	Yes After 24 hours of maternal treatment with antibiotics	Yes After 24 hours of maternal treatment with antibiotics	In addition to antimicrobial therapy, treatment should include eye irrigations with saline solution immediately after birth and frequently until discharge stops. (See Chapter 58.)
Group B streptococcal infections	Standard	Standard	Yes	Yes	Yes	In case of a nursery outbreak, cohorting of ill and colonized infants and use of contact precautions are recommended.
Hepatitis A, B, C	Standard	Standard (special attention to wear gloves when removing maternal blood at the time of birth)	Yes	Yes	Yes	Early hepatitis B immunization is recommended for all medically stable infants with birthweight >2 kg, regardless of maternal status. The AAP recommends

that infants born to HBsAg-positive mothers, including preterm and low birth-weight infants, receive the initial dose of hepatitis B vaccine within 12 hours of birth. Report to health department.

<p>Herpes simplex virus (HSV) Neonatal infection or positive culture in absence of disease</p>	<p>Contact (gown and gloves) for active HSV lesions during labor, delivery, and the postpartum period.</p>	<p>Contact (gown and gloves) during incubation for infants born to women with active HSV lesions</p>	<p>Yes If baby is at low risk of infection</p>	<p>Yes If no vesicular herpetic lesion in the breast area and all active skin lesions are covered.</p>	<p>Women with primary HSV infections are more likely to shed the virus and transmit the virus to their newborn infant. The AAP published two algorithms for the evaluation and treatment of asymptomatic neonates following vaginal or cesarean delivery to women with active genital HSV lesions (see Figures 137–1 and 137–2).</p>
<p>Lice (see Pediculosis)</p>					
<p>Measles (rubeola)</p>	<p>Airborne N-95 masks for those susceptible. Labor, delivery, and postpartum recovery should take place in a private room with negative-pressure, nonrecirculating air with door closed. If mother is transferred to the delivery room for the actual delivery, she should wear surgical mask during transfer and delivery.</p>	<p>Standard and airborne For 4 days after the onset of rash in otherwise healthy patients and for duration of illness in immunocompromised patients. Exposed susceptible patients need to be placed in airborne precautions from day 5 after first day of exposure until day 21 after last exposure.</p>	<p>No</p>	<p>No Until mother is noncontagious</p>	<p>Contagious during prodrome and for 4 days after onset of rash. Healthcare personnel who may come in contact with patients with measles should have evidence of immunity to measles through their vaccine records. Follow your local health department reporting requirements.</p>

(Continued)

Table F–1. TRANSMISSION-BASED PRECAUTIONS FOR PERINATAL/NEONATAL PATIENTS (CONTINUED)

Infection/Disease	Maternal Precautions	Neonatal Precautions	Room-In	Mother May Visit in Nursery	Breast Feeding	Additional Considerations
Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA), methicillin-sensitive <i>S aureus</i> (MSSA), vancomycin-intermediate susceptible <i>S aureus</i> (VISA), and vancomycin-resistant <i>S aureus</i> (VRSA)	Contact Gown and gloves	Contact Gown and gloves. For patients with pneumonia, droplet precautions are recommended for the first 24 hours of antimicrobial therapy. Droplet precautions should be maintained throughout the illness for MSSA or MRSA tracheitis with a tracheostomy tube in place. For VISA/VRSA, in addition to contact precautions, wear mask/eye protection or face shield when performing procedures that can generate splash/splatter contaminated materials (eg, wound drainage, blood, bodily fluids, secretions).	Yes	Yes Follow contact precautions	Yes	Apply contact precautions for active infections only. More evidence is needed for recommendations on isolation precautions for patients with known colonization. CDC has issued specific infection control recommendations for VISA and VRSA (http://www.cdc.gov/hai/pdfs/VRSA-Investigation-Guide-05_12_2015.pdf). Follow your local public health department reporting and discharging requirements.
Mumps (infectious parotitis)	Standard and droplet Masks within 3 ft of patient. Private room.	Standard and droplet until 5 days after onset of parotid swelling	No	No	No Until mother is noncontagious	Contagious for 5 days after onset of swelling. Follow your local health department reporting requirements.

Pediculosis (lice)	Contact For 24 hours after effective treatment, gown and gloves	Contact For 24 hours after effective treatment, gown and gloves	Yes	Yes	Yes	Exposed individuals and household contacts should be examined and treated if infected. Bedmates of infested people should also receive prophylactic treatment. Instruct mother to clean breasts before feeding if medication is applied to that area. Stress good hand hygiene with special attention to area under fingernails.
Pertussis (whooping cough)	Standard and droplet for duration of illness as clinically determined by the MD	Standard and droplet for 5 days after initiation of effective therapy and up to 21 days after onset of cough if no treatment given	No	No	No Until mother is noncontagious	Contagious for 5 days after start of effective therapy. Treatment with antimicrobial agents if available for newborns <1 and 2 months of age if the risk of developing severe pertussis and life-threatening complications outweighs the potential risk of developing infantile hypertrophic pyloric stenosis. See <i>Red Book</i> , 2018. Follow local public health department reporting requirements.
Respiratory syncytial virus (RSV)	Standard plus contact for duration of illness, including patients treated with ribavirin	Standard and contact for duration of illness including patients treated with ribavirin	Yes	Yes May visit private room or cohort	Yes	Parent education is essential to avoid transmission of the virus. The importance of hand hygiene should be emphasized in all settings. Prophylaxis to prevent RSV in newborns at increased risk for severe disease, particularly those with bronchopulmonary dysplasia/chronic lung disease receiving medical management on a long-term basis, is available. Refer to <i>Perinatal Guidelines</i> (AAP/ACOG, 2012) and the <i>Red Book</i> (2018).

Contagious for duration of illness.

(Continued)

Table F-1. TRANSMISSION-BASED PRECAUTIONS FOR PERINATAL/NEONATAL PATIENTS (CONTINUED)

Infection/Disease	Maternal Precautions	Neonatal Precautions	Room-In	Mother May Visit in Nursery	Breast Feeding	Additional Considerations
Rubella (German measles) Postnatal	Standard and droplet	Standard and droplet for 7 days after onset of the rash. Contact precautions indicated if suspected congenital rubella until 1 year of age, unless 2 cultures or clinical specimens obtained 1 month apart after 3 months are negative for the rubella virus.	Yes	No	No	Contagious for 7 days after onset of rash. Susceptible persons should stay out of room, if possible.
Rubella (German measles) Maternal	Masks within 3 ft of patient. Private room; masks for those susceptible.					Follow your local health department reporting requirements.
Rubella (German measles) Congenital		Contact Gown and gloves	Yes	Yes	Yes	Contagious until at least 1 year of age, unless 2 cultures or clinical specimens obtained 1 month apart after 3 months of age are negative for rubella virus. Susceptible persons should stay out of room, if possible. Report to health department.
Scabies	Contact For 24 hours after treatment, gown and gloves.	Contact For 24 hours after treatment, gown and gloves.	Yes	Yes	Yes	Treatment of exposed individuals and household contacts is recommended. Instruct mother to clean breasts before feeding if medication is applied to that area. Stress good hand hygiene.

Syphilis	Standard	Standard. Gloves should be worn when caring for patients with congenital, primary, and secondary syphilis with skin or mucous membrane lesions until 24 hours of treatment have been completed.	Yes	Yes	Yes	Treatment for congenital syphilis is available for infants in the first month of life (see <i>Red Book</i> , 2018–2021). Follow your local health department reporting requirements.
Tuberculosis (TB) Mother with recent positive purified protein derivative (PPD) and no evidence of active TB.	Standard	Standard	Yes	Yes	Yes	If the mother is asymptomatic, no separation is required. The newborn infant needs no special evaluation or therapy.
TB Mother with minimal disease or disease has been treated for ≥2 weeks and is determined by pulmonary or infectious disease specialist to be noncontagious at delivery.	Standard	Standard	Yes	Yes	Yes	Management of the newborn infant suspected of congenital TB is based on categorization of the maternal infection. See testing and treatment in the <i>Red Book</i> , 2018–2021. Follow your local health department requirements.

Table F-1. TRANSMISSION-BASED PRECAUTIONS FOR PERINATAL/NEONATAL PATIENTS (CONTINUED)

Infection/Disease	Maternal Precautions	Neonatal Precautions	Room-In	Mother May Visit in Nursery	Breast Feeding	Additional Considerations
TB Mother with current pulmonary or laryngeal active TB and suspected of being contagious at time of delivery.	Airborne N95 respirator for healthcare workers. Labor, delivery, and postpartum care in private room with negative-pressure, nonrecirculating air with door closed. If mother is transferred to the delivery room for the actual delivery, she should wear mask during transfer and delivery.	Standard. Airborne precautions for neonates with congenital TB during procedures involving the oropharyngeal airway (eg, intubation) until effective therapy has been initiated, sputum smears are negative, and cough has been abated.	No Until mother is determined to be noncontagious	No Until mother is determined to be noncontagious	No Until mother is determined to be noncontagious	Management of the newborn infant suspected of congenital TB is based on categorization of the maternal infection. See testing and treatment in the <i>Red Book</i> , 2018–2021. Follow your local health department reporting requirements. Report to health department.
TB Mother has extra-pulmonary spread of TB (eg, military, bone,	Standard	Standard	No Until mother is determined to be noncontagious	No Until mother is determined to be noncontagious	No Until mother is determined to be noncontagious	Management of the newborn infant suspected of congenital TB is based on categorization of the maternal infection. See testing and treatment in the <i>Red Book</i> , 2018–2021. Report to health department.

Varicella (chicken-pox) or herpes zoster in immunocompromised mother or if disseminated maternal infection	Airborne/contact Labor, delivery, and postpartum care in private room with negative-pressure, nonrecirculating air with door closed. If mother is transferred to the delivery room for the actual delivery, she should wear mask during transfer and delivery.	Airborne and contact for neonates born to mothers with varicella; neonates should be placed on airborne and contact precautions from birth until 21 days or from birth or until 28 days of age if VarZIG or IGIV was administered. Mother and infant should be isolated separately until the mother's vesicles have dried.	No Until mother's lesions have crusted	No Until mother's lesions have crusted	No Until mother's lesions have crusted	Consider immunologic titer for neonates <28 weeks' gestational age.
Varicella—newborn or exposure to varicella	Airborne and contact Masks for those susceptible. Private room with negative-pressure, non-recirculating air with door closed. From 8 until 21 days after exposure and until 28 days if VarZIG or IVIG given.	Yes	Yes May visit private room or cohort	Yes Unless mother has lesions	Hospitalized patients should be discharged prior to the 10th day after exposure, if possible. Infants with varicella embryopathy do not require isolation if they do not have active lesions.	

AAP, American Academy of Pediatrics; ACOG, American College of Obstetricians and Gynecologists; AIDS, acquired immunodeficiency syndrome; CDC, Centers for Disease Control and Prevention; HBSAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; IVIG, intravenous immune globulin; MD, physician. EMERGENCY MEDICATIONS FOR NEONATES^a

MEDICATION	INDICATIONS	DOSING RANGE	NOTES	UMBILICAL CATHETER DOSING ^b	
				UAC	UVC
Calcium gluconate (10%) (100 mg/mL)	Hypocalcemia Hyperkalemia	Ca gluconate 60–100 mg/kg/dose slow IV over 10–30 minutes (0.6–1 mL/kg/dose); may repeat in 10 minutes, if needed	Infuse slowly; caution with digitalized patient; tissue necrosis if extravasation. Can also use Ca chloride 20 mg/kg/dose, administer via central access.		Yes
Dextrose	Hypoglycemia	0.2 g/kg/dose IV (2 mL/kg/dose IV of D10W)	D10 = 100 mg/mL; D12.5 = 125 mg/mL; D25 = 250 mg/mL (D25 only in central line)	Yes	Yes
Dobutamine	Cardiogenic shock, hypotension due to refractory CHF	2–20 mcg/kg/min, titrate gradually every few minutes	Mix in D5W, NS, LR		Yes
Dopamine	Hypotension, agonal heart	1–20 mcg/kg/min, titrate gradually every few minutes	Mix in D5W, NS, LR		Yes
Levetiracetam (Keppra)	Anticonvulsant	10–50 mg/kg/dose IV	Adjustment in renal impairment; may cause CNS depression		Yes
Lorazepam	Anticonvulsant	0.05–0.1 mg/kg/dose IV, slow IV over 2–5 minutes	May cause respiratory depression and hypotension; may repeat in 10–15 minutes		Yes
Midazolam	Anticonvulsant	0.05–0.15 mg/kg/dose IV	May cause hypotension, respiratory depression, CNS depression, and myoclonus		Yes
Phenobarbital	Anticonvulsant Most common first line therapy	15–20 mg/kg IV load over 15–30 minutes	Respiratory depression possible, be prepared to provide respiratory support. Follow with maintenance dose.		Yes
Phenytoin/ fosphenytoin	Anticonvulsant	15–20 mg/kg IV load	Phenytoin: Typical infusion rate 0.5–1 mg/kg/min; not to exceed 1 mg/kg/min; INCOMPATIBLE with dextrose containing fluid. Fosphenytoin: Typical infusion rate 1–2 mg/kg/min; not to exceed 2 mg/kg/min.		Yes

^aFor abbreviations, see Appendix A.

^bAvoid infusion of catecholamines into UAC. UVC in good position preferred to administer medications. In emergency situations, a UVC inserted only to the point where blood can be aspirated (at least 2–4 cm; less in preterm infants), but whose position is not verified by radiograph, can be used for volume expanders, epinephrine, and glucose (not >12.5%). Intraosseous access can be used as an alternative route. **Note:** No hypertonic solutions should be used in a catheter that is not confirmed by x-ray.

EMERGENCY MEDICATIONS USED IN THE DELIVERY ROOM, ETT SIZES, CARIOVERSION, AND DEFIBRILLATION^a

MEDICATION	INDICATIONS	DOSING RANGE	NOTES	UMBILICAL CATHETER DOSING ^b	
				UAC	UVC
Epinephrine 0.1 mg/mL (1 mg/10 mL) Never 1 mg/mL!	Asystole, bradycardia, hypotension (acute) Delivery room indication: HR remains <60 bpm after 1. Minimum of 30 seconds of effective PPV that inflates the lungs AND 2. Another 60 seconds of chest compressions with PPV using 100% O ₂	Estimate baby's weight in delivery room. IV preferred or IO: 0.1–0.3 mL/kg of 0.1 mg/mL solution (0.01–0.03 mg/kg). Prepare in a 1 mL syringe. ETT (less effective): 0.5–1 mL/kg of 0.1 mg/mL solution (0.05–0.1 mg/kg). Dilute with NS to 3–5 mL.	Give as quickly as possible. Administer every 3–5 minutes as needed. IV or IO: Flush with 0.5–1 mL NS after the drug is given. ETT: Consider 1 dose while establishing vascular access. Give directly in the tube and give PPV breaths after dose to distribute the drug to the lungs.		Yes
VOLUME EXPANDERS: Indicated if the infant is not responding to resuscitation and there is history of acute blood loss or signs of shock.					
Normal saline (0.9% NaCl)	Volume expansion	10 mL/kg IV or IO over 5–10 minutes; may repeat	Check Hct and glucose before and after dose. Caution with preterm newborns <30 weeks' gestation. For emergency volume administration in the setting of cardiovascular collapse, place a UVC or insert an intraosseous needle.	Yes	Yes
0 Rh-negative packed RBCs	Volume expansion (severe anemia/ blood loss)	10 mL/kg IV or IO over 5–10 minutes; may repeat	If time permits, blood should be cross-matched to the mother. Use emergency non-cross-matched, type O, Rh-negative packed red blood cells if cross-matched blood is not immediately available.	Yes (not preferred)	Yes
Endotracheal tube (uncuffed)	2.5 mm internal diameter (ID) 3.0 mm ID 3.5 mm ID	<1000 g or <28 weeks 1000–2000 g or 28–34 weeks >2000 g or >34 weeks			—
Cardioversion/ defibrillation	VT, VF, SVT, atrial fib/flutter	Cardioversion: Start at 0.5–1.0 J/kg/dose, if ineffective increase to 2 J/kg/dose Defibrillation: start at 2 J/kg, if ineffective increase to 4 J/kg; if biphasic, doses higher than 4 J/kg can be given. Maximum dose for pediatric patients 10 J/kg.	Synch switch off for VF		—

^aFor abbreviations, see Appendix A.

^bAvoid infusion of catecholamines into UAC. UVC in good position preferred to administer medications. In emergency situations, a UVC inserted only to the point where blood can be aspirated (at least 2–4 cm; less in preterm infants), but whose position is not verified by radiograph, can be used for volume expanders, epinephrine, and glucose (not >12.5%). Intraosseous (I/O) access can be used as an alternative route. **Note:** No hypertonic solutions should be used in a catheter that is not confirmed by x-ray.
