GOMELLA'S

NEONATOLOGY

Management, Procedures, On-Call Problems,
Diseases, and Drugs

EIGHTH EDITION

Editor

TRICIA LACY GOMELLA, MD

Assistant Professor of Pediatrics, Part-Time
Johns Hopkins University School of Medicine
Baltimore, Maryland

Senior Associate Editor

FABIEN G. EYAL, MD

Professor of Pediatrics
University of South Alabama Health System
Chief, Division of Neonatology
USA Children's and Women's Hospital
Mobile, Alabama

Associate Editor

FAYEZ BANY-MOHAMMED, MD, FAAP

Clinical Professor of Pediatrics
Program Director
Neonatal-Perinatal Medicine Fellowship Program
University of California, Irvine School of Medicine
UC Irvine Medical Center
Orange, California

New York Chicago San Francisco Athens London Madrid Mexico City
Milan New Delhi Singapore Sydney Toronto

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Contents

Emergency Medications Used in the Delivery Room, ETT Sizes, Cardioversion, and Defibrillation	inside front cover
Emergency Medications for Neonates	inside back cover
Contributors	xvii
In Honor of Dr. M. Douglas Cunningham	xxix
Preface	xxxi
SECTION I. Prenatal, Labor, Delivery, and Transport Management	
1 Fetal Assessment	1
2 Obstetric Anesthesia and the Neonate	13
3 Resuscitation of the Newborn	19
4 Neonatal Transport	31
SECTION II. Basic Management	
5 The Golden Hour	37
6 Gestational Age and Birthweight Classification	42
7 Newborn Physical Examination	59
8 Temperature Regulation	92
9 Respiratory Management	97
10 Fluid and Electrolytes	117
11 Nutritional Management	125
SECTION III. Advanced Management	
12 Imaging Studies	167
13 Management of the Extremely Low Birthweight Infant During the First Week of Life	196
14 Management of the Late Preterm Infant	208
15 Pain in the Neonate	211
16 Newborn Screening	223
17 Genetic and Genomic Testing in the Newborn Period	234
18 Studies for Neurologic Evaluation	239
19 Blood Component Therapy	248
20 Extracorporeal Life Support in the Neonate	256

21	Follow-Up of High-Risk Infants.....	277
22	Complementary and Integrative Medical Therapies in Neonatology	282
23	Neonatal Bioethics.....	289
24	Neonatal Palliative Care.....	295

SECTION IV. Procedures

25	Principles of Neonatal Procedures	301
26	Arterial Access: Arterial Puncture	305
27	Arterial Access: Percutaneous Arterial Catheterization.....	309
28	Arterial Access: Umbilical Artery Catheterization	312
29	Bladder Aspiration (Suprapubic Urine Collection).....	322
30	Bladder Catheterization	325
31	Chest Tube Placement	329
32	Defibrillation and Cardioversion	336
33	Endotracheal Intubation and Extubation.....	339
34	Exchange Transfusion.....	350
35	Gastric and Postpyloric Tube Placement.....	356
36	Heelstick (Capillary Blood Sampling).....	362
37	Laryngeal Mask Airway.....	368
38	Lumbar Puncture (Spinal Tap).....	371
39	Ostomy Care.....	375
40	Paracentesis (Abdominal)	379
41	Pericardiocentesis	382
42	Peripheral Intravenous Extravasation and Infiltration: Initial Management.....	385
43	Therapeutic Hypothermia.....	388
44	Transillumination and Point-of-Care Ultrasound	392
45	Venous Access: Intraosseous Infusion	403
46	Venous Access: Peripherally Inserted Central Catheter	407
47	Venous Access: Peripheral Intravenous Catheterization	413
48	Venous Access: Umbilical Vein Catheterization	417
49	Venous Access: Venipuncture (Phlebotomy).....	423

SECTION V. On-Call Problems

50	Abdominal Distension.....	427
51	Abnormal Blood Gas	431

52	Apnea and Bradycardia (A's and B's): On Call	442
53	Arrhythmia	459
54	Bloody Stool	468
55	Counseling Parents Before High-Risk Delivery	477
56	Cyanosis.....	481
57	Death of an Infant.....	493
58	Eye Discharge and Conjunctivitis	501
59	Gastric Residuals.....	517
60	Gastrointestinal Bleeding from the Upper Tract	524
61	Hematuria	532
62	Hyperbilirubinemia: Conjugated, On Call	537
63	Hyperbilirubinemia: Unconjugated, On Call.....	546
64	Hyperglycemia.....	558
65	Hyperkalemia	566
66	Hypertension	574
67	Hypoglycemia.....	587
68	Hypokalemia	602
69	Hyponatremia.....	608
70	Hypotension and Shock	617
71	Is the Infant Ready for Discharge?	630
72	No Stool in 48 Hours.....	645
73	No Urine Output in 24 Hours	655
74	Pneumoperitoneum	667
75	Pneumothorax.....	676
76	Polycythemia: On Call	686
77	Poor Perfusion	694
78	Postdelivery Antibiotics	701
79	Pulmonary Hemorrhage.....	719
80	Rash and Dermatologic Problems	726
81	Sedation and Analgesia	743
82	Seizure Activity: On Call	749
83	Traumatic Delivery.....	769
84	Vasospasms and Thromboembolism	784

SECTION VI. Diseases and Disorders, General

85	ABO Incompatibility	801
86	Acute Kidney Injury	803
87	Air Leak Syndromes	808
88	Anemia	815
89	Apnea	823
90	Bronchopulmonary Dysplasia/Chronic Lung Disease	827
91	Calcium Disorders (Hypocalcemia, Hypercalcemia)	833
92	Coagulation Disorders	838
93	Common Multiple Congenital Anomalies: Syndromes, Sequences, and Associations	853
94	Congenital Heart Disease	863
95	Disorders of Sex Development	874
96	Eye Disorders of the Newborn	881
97	Hydrocephalus and Ventriculomegaly	885
98	Hyperbilirubinemia: Conjugated	891
99	Hyperbilirubinemia: Unconjugated	902
100	Inborn Errors of Metabolism with Acute Neonatal Onset	915
101	Infant of a Diabetic Mother	937
102	Infant of a Mother with Substance Use Disorder	945
103	Intracranial Hemorrhage	955
104	Intrauterine (Fetal) Growth Restriction	963
105	Magnesium Disorders (Hypomagnesemia, Hypermagnesemia)	976
106	Meconium Aspiration	978
107	Multiple Gestation	984
108	Myasthenia Gravis (Transient Neonatal)	988
109	Necrotizing Enterocolitis	991
110	Neonatal Encephalopathy	997
111	Neural Tube Defects	1005
112	Orthopedic and Musculoskeletal Problems	1013
113	Osteopenia of Prematurity (Metabolic Bone Disease)	1022
114	Patent Ductus Arteriosus	1027

115	Persistent Pulmonary Hypertension of the Newborn	1032
116	Polycythemia and Hyperviscosity	1040
117	Respiratory Distress Syndrome.....	1043
118	Retinopathy of Prematurity	1051
119	Rh Incompatibility.....	1056
120	Seizures	1061
121	Spontaneous Intestinal Perforation.....	1067
122	Surgical Diseases of the Newborn: Abdominal Masses.....	1069
123	Surgical Diseases of the Newborn: Abdominal Wall Defects	1072
124	Surgical Diseases of the Newborn: Alimentary Tract Obstruction	1076
125	Surgical Diseases of the Newborn: Diseases of the Airway, Tracheobronchial Tree, and Lungs.....	1080
126	Surgical Diseases of the Newborn: Retroperitoneal Tumors.....	1085
127	Surgical Diseases of the Newborn: Urologic Disorders	1088
128	Thrombocytopenia and Platelet Dysfunction.....	1092
129	Thyroid Disorders	1097
130	Transient Tachypnea of the Newborn	1107

SECTION VII. Infectious Diseases

131	Chlamydial Infection	1115
132	Cytomegalovirus.....	1117
133	Dengue Infection, Neonatal.....	1121
134	Enteroviruses and Parechoviruses	1123
135	Gonorrhea	1127
136	Hepatitis.....	1128
137	Herpes Simplex Viruses	1136
138	Human Immunodeficiency Virus.....	1143
139	Lyme Disease	1151
140	Meningitis	1154
141	Methicillin-Resistant <i>Staphylococcus aureus</i> Infections	1157
142	Parvovirus B19 Infection.....	1162
143	Pertussis	1165
144	Respiratory Syncytial Virus.....	1168
145	Rubella.....	1171

146	Sepsis	1175
147	Syphilis	1189
148	TORCH (TORCHZ) Infections.....	1196
149	Toxoplasmosis.....	1197
150	Tuberculosis	1202
151	<i>Ureaplasma</i> Infection.....	1206
152	Urinary Tract Infection.....	1207
153	Varicella-Zoster Infections	1211
154	Zika Virus (Congenital Zika Syndrome).....	1215

SECTION VIII. Neonatal Pharmacology

155	Medications Used in the Neonatal Intensive Care Unit.....	1225
156	Effects of Drugs and Substances on Lactation and Infants	1316

Appendices

A	Abbreviations	1345
B	Apgar Score/Expanded Apgar Score.....	1360
C	Blood Pressure Determinations.....	1363
D	Chartwork	1364
E	Immunization Guidelines.....	1368
F	Isolation Guidelines	1372
G	Temperature Conversion Table.....	1382
H	Weight Conversion Table.....	1383

Index	1385

PAST CONTRIBUTOR ACKNOWLEDGMENT

This edition of our book is based on a strong foundation of many contributors from previous editions. The editors of the current edition would like to express our appreciation and thanks in particular to the contributors of the 7th edition:

Hubert Ballard, MD; Michael Bober, MD, PhD; Doug Cunningham, MD; Jennifer Das, MD; Steve Docimo, MD; Cathy Finnegan, MS, NNP-BC; Janet Graber, MD; George Gross, MD; Jose Hamm, Jr, MD; Joseph Iocono, MD; Kathy Isaacs, MSN, RNC-NIC; Shamin Jivabhai, MD; Jamieson Jones, MD; Kathy Keen, MSN, NNP-BC; Chris Lehman, MD; Barbara McKinney, PharmD; Solomania Nino, MD; Paul Noh, MD; Ambadas Pathak, MD; Judith Polak, DNP, NNP-BC; Thomas Strandjord, MD; Christopher Tomlinson, MD; Deborah Tuttle, MD; and Tiffany Wright, MD.

In Honor of Dr. M. Douglas Cunningham

The editor and publisher are pleased to dedicate this edition of *The Lange Clinical Manual of Neonatology* commemorating Dr. Doug Cunningham's career in neonatology and his years of editorial service and leadership on this book.

Dr. Cunningham's interest in the care of preterm infants began during his rotation as an intern in the Premature Infant Nursery of San Francisco General Hospital (SFGH; 1965–1966). His attending physician was Dr. June Brady. With much appreciation, he often recalls her great patience and commitment to teaching and her wealth of information for newborn physiology. He passed his first umbilical vein and artery catheters under her watchful eye and guidance.

His internship year coincided with the earliest efforts for intubating and mechanically ventilating preterm infants with ventilators adapted from adult design. Clearly, Dr. Cunningham's premature infant nursery experience at SFGH ignited his career-long fascination with neonatal pulmonology and mechanical ventilation for sick newborn infants.

His interest in neonatology continued throughout his pediatric residency and service at the US Naval Hospital, San Diego (1967–1972). Upon completion of his residency and military service, he entered the newly formed fellowship in neonatology at the University of California, San Diego, under the mentorship of Dr. Louis Gluck (1970–1972). Those were years of clinical advancement with newly designed infant-specific mechanical ventilators, continuous positive airway pressure support, and improved oxygen monitoring. Arterial blood gas studies became routine, and antenatal amniotic fluid studies for fetal lung maturity became a new focal point of collaboration between neonatologists and obstetricians.

Following his fellowship, he received an academic appointment at the University of Kentucky in the Department of Pediatrics with Dr. Jacqueline Noonan as chairperson. She, as the newly appointed chair of pediatrics, was seeking to develop a division of neonatology and to expand newborn care for sick and preterm infants, a service that would reach many underserved communities of the Appalachian counties of eastern Kentucky. Dr. Nirmala Desai, a recent neonatology fellowship graduate from Boston Children's Hospital, joined him. Coupling Dr. Cunningham's University of California, San Diego, experience with that of Dr. Desai's Harvard Boston background, they became a perfect match for advancing neonatal care with Dr. Noonan's support and guidance. In rapid progression over the next 7 years, a neonatology fellowship program was begun. An expansion of the unit for preterm infants from 24 incubators to a new 50-bed capacity neonatal intensive care unit (NICU) was completed, and ambulance and helicopter sick infant transport was inaugurated. Likewise, preterm infant care took on a completely new look as human milk banking came into service, hyperalimentation was used for supplemented nutrition, and mechanical ventilators designed specifically for newborn infants came into regular use.

In 1988, Dr. Cunningham returned to California as a clinical professor with his former mentor Dr. Louis Gluck, then at the University of California, Irvine (UCI). He participated in the expansion of the UCI neonatology program into a multihospital perinatal regional program for 11 neonatal special care units, spanning 5 southern California counties. Throughout his career in the UCI program, Dr. Cunningham was noted for his teaching efforts. He devoted many hours to teaching rounds with medical students, pediatric house staff, and neonatology fellows.

Nearing retirement in 2011, Dr. Cunningham returned to Lexington, Kentucky, and accepted an invitation to also return to the University of Kentucky neonatology program as professor of pediatrics and interim chief of neonatology. An extensive expansion of the program was underway, requiring recruitment of a permanent chief and expanded faculty, fellowship, and support staff—all to accommodate an under-construction 77-bed NICU and regional perinatal program for the eastern counties of the state.

Today, Dr. Cunningham remains as a University of Kentucky professor of pediatrics (part time) and serves as a consultant, lecturer, and mentor for the neonatology fellowship program. He participates regularly as a lecturer for medical students during their pediatric experience. He also serves as a consultant and advisor for the University of Kentucky neonatology residency program for training physician assistants as advanced practice providers in the NICU.

DR. CUNNINGHAM'S REPLY UPON LEARNING THAT THE 8TH EDITION WAS DEDICATED IN HIS HONOR

It has been a personal pleasure for me to see Tricia's success as the originator and longtime editor of this manual. First published in 1988 and now in its 8th edition, it has had unprecedented worldwide success as a clinical guide for the care of sick newborn infants.

I recall the very humble beginnings of the manual that began with Tricia's insistence that it would be the work product of her fellowship in neonatology at the University of Kentucky, rather than an assigned research project. I challenged her to think otherwise, but she remained insistent that she could bring about a publishable manual based on the practical aspects of daily infant care rounds at the University of Kentucky. The culmination of the challenge began when she presented me with a set of drafted chapters. I recall reading them with great interest and congratulated her on their concise text and considerably logical format. The concept of creating "On Call Problems" for the new trainees entering the NICU for the first time was a novel concept that has now been widely embraced in the field of medicine since she first promoted the concept as a teaching tool. It remains a core element in this book's wide appeal. But I countered Tricia with yet another challenge: Could a publisher be found? I was more than a bit taken aback by her quick reply, "I have one, Appleton and Lange. It will be a good fit in the Lange Clinical Manual series." Admittedly, I was smitten by her pluck and success. The future of the manual was conceived on the spot. I recall the pleasure of being asked to write some of the early chapters and to join the project as one of the co-editors.

Recently, a mutual friend asked for a retrospective of what most defined my career. I noted 2 opportunities: first, to have been a part of the beginning of neonatal intensive care for sick newborn infants and the expansion of neonatology as a medical discipline, and second, to have been an associate editor in the development and ongoing success of *The Lange Clinical Manual of Neonatology*.

I often point out to others, with considerable pride, Dr. Tricia Gomella's accomplishments with the manual, which has achieved worldwide distribution and been translated into 12 languages. I have enjoyed the task of helping to identify authors and editing manuscripts from the many contributors of the editions that have followed. In closing, I wish to express my appreciation for your consideration to dedicate the 8th edition of the manual in recognition of my career. My sincerest thank you.

M. Douglas Cunningham, MD
Professor of Pediatrics (part time)
University of Kentucky College of Medicine
Kentucky Children's Hospital
Lexington, Kentucky

Preface

I am pleased to present the 8th edition of *Neonatology*. The first edition was published in 1988 and was started during my neonatology fellowship at University of Kentucky Medical Center in Lexington. The origins of the manual were fairly simple and started as a series of handouts designed to help students and residents make it through their neonatal intensive care unit rotation. Because of a complicated twin pregnancy during my fellowship, I had to delay my training and complete my required neonatology fellowship time at Johns Hopkins University.

While the roots of this manual can be traced back to the University of Kentucky during my fellowship with Dr. Doug Cunningham, it was ultimately completed while I was a fellow at Johns Hopkins University and working at the newly established Bayview campus in Baltimore under Dr. Fabien Eyal. This has made the book somewhat unique because it was originally written from the perspective of a trainee in 2 different neonatology programs. This simple fact, along with the addition of other authors from around the United States and the world, has brought together a diverse group of contributors. I hope you will agree that this approach provides a comprehensive overview of the field of neonatology.

Dr. Doug Cunningham has worked as associate editor on this manual since its inception 7 editions ago. For this, our 8th edition, he has passed the baton to Dr. Fayeze Mohammed from the University of California, Irvine School of Medicine. Dr. Mohammed has been involved with the manual since the 5th edition and has established himself as one of our most outstanding authors. He has previously contributed multiple chapters with a concise writing style that made him a perfect fit to fill Dr. Cunningham's shoes. I also want to publicly express my thanks to Dr. Cunningham. If it was not for his mentorship, this manual would not be in existence. He gave me special permission to develop the earliest versions of the manual during my dedicated fellowship research time. In a most fitting tribute to his contributions to the field of neonatology and his major longstanding contributions to this manual, we have dedicated this edition to Dr. Doug Cunningham.

In this 8th edition, the table of contents was reformatted to make it more user friendly and hopefully more logical. Section I includes essential prenatal and postnatal topics such as "Fetal Assessment," "Obstetric Anesthesia and the Neonate," "Resuscitation of the Newborn," and "Neonatal Transport." Section II encompasses basic assessment and management of a newborn with a new chapter addressing "The Golden Hour." Section III includes advanced management topics such as the evolving areas of complementary and integrative therapies and 2 new chapters: "Genetic and Genomic Testing in the Newborn Period" and "Neonatal Palliative Care." Section IV includes all the basic and advanced bedside procedures commonly used in neonatology. We have added an entire new section on point-of-care ultrasound in Chapter 44. We have also included point-of-care ultrasound information on pertinent procedures. One of the most popular sections of the book, the "On-Call Problems" section, now includes a total of 35 common neonatal problems with 1 new problem added: "Abdominal Distension." Section VI, "Diseases and Disorders," covers all the common and a few not so common, but clinically important, diseases of the neonate. We have added a new subsection on "Infectious Diseases" to encompass the growing literature on infectious diseases that may be present in a neonate. Two new chapters were added in this section addressing dengue infection and Zika virus. The section on neonatal pharmacology includes significant updates of medications commonly used in neonates. Since there are relatively few medications formally approved for use in neonates, the medication information has been carefully curated by our outstanding group of neonatal PharmDs. We believe it to be the most comprehensive list of medications found in a manual such as ours. The "Effects of Drugs and Substances on Lactation and Infants" chapter has been revised to include the most common medications that might be used by a breast-feeding mother. The appendices include other useful reference

tables and information. A hallmark of our book has been noting areas that are “controversial,” and this edition continues that tradition.

Another exciting and evolving aspect of this manual is its global reach. As our readership has grown worldwide, we have added to our international editorial board. These board members are from many countries: Poland, Jordan, United Arab Emirates, Costa Rica, Saudi Arabia, Peru, French Polynesia, the Netherlands, the Philippines, Finland, India, Israel, Bahamas, Canada, and Australia. These physicians, along with our many international contributors, help to make the manual a useful reference worldwide. The manual has been previously translated into 12 different languages over the past 25 years. These translations include Russian, Spanish, Portuguese, Polish, Chinese (short and long form), Turkish, Greek, Yugoslavian (now Serbian), Italian, Hungarian, and Korean.

I would like to personally thank Dr. Fabien Eyal, my senior associate editor and my fellowship mentor at Johns Hopkins, and Dr. Fayez Bany-Mohammed, my associate editor, for assigning, composing, and reviewing many sections of the manual and for their willingness to always be available for questions. I also want to thank my section editors. Dr. Brooke Vergales, the procedure section editor, spearheaded the procedure chapter updates. I had 3 wonderful PharmDs—Pui-Man (Julia) Ho, Kristin Bohannon, and Valerie Nolt—who worked tirelessly to update the pharmacology and breast-feeding sections, along with their new medication tables, which will enhance several chapters. In addition to their long-term commitment to this manual, the associate editors have brought together outstanding authors from all over the United States and the international community.

I also express appreciation to Louise Bierig, Andrew Moyer, and the editorial and production staff at McGraw-Hill and their colleagues abroad (especially Tania Andrabi) for their extensive assistance during the 2-year journey to complete this new edition. A special thanks to my loving husband Lenny, who helped me extensively concerning matters of editorial content, and my awesome children Patrick, Andrew, Leonard, and Michael (the **PALM team**), who helped troubleshoot computer issues and tolerated many sacrifices while I worked on this and many previous editions of the book over the past 30 years. I owe a debt of gratitude to all of my mother’s caregivers (Edie Brewer, Lynn Finney, Skylar Finney, Meryle Voytilla, Calia Broadus, Anick Biatchon, Veronica Messina, Lillian Colon, and Maria Romero) who took excellent care of my wonderful elderly mother, Nancy Murray Lacy, so I could have the time to work on this edition and to Maisie, our emotional support Bearded Collie, who provided me with humor and love.

Please visit our website, www.neonatologybook.com, for additional information on this manual and for links to enhanced online content for supplemental images, indicated by the symbol [☞] that appears in several chapters. References for each chapter can be accessed from <http://mhprofessional.com/GomellasNeonatology>.

Your suggestions and comments about this manual are always welcome. Readers’ comments have helped shape the content of our manual over the previous 7 editions.

Tricia Lacy Gomella, MD
neonatologyeditor@gmail.com

1 Fetal Assessment

PRENATAL DIAGNOSIS

Prenatal diagnosis refers to those testing modalities used during pregnancy to screen and diagnose fetal aneuploidies and anomalies. Counseling is recommended, ideally in the first trimester, prior to pursuing any type of prenatal screening or diagnostic testing. Screening tests provide risk assessment and determine whether the individual is at increased risk for having a fetus with a genetic condition. Diagnostic testing determines if the fetus is affected by a chromosomal or genetic abnormality by analyzing the fetal DNA through invasive testing. Evolving technology has made the use, interpretation, and choice of appropriate test for each individual challenging for both patients and providers.

FETAL SCREENING TESTS

- I. **Nuchal translucency (NT).** An ultrasound measurement of the amount of fluid behind the neck of the fetus, done between 10 0/7 and 13 6/7 weeks¹ when the crown-rump length (CRL) measures 38 to 45 and 84 mm, respectively. An increased NT is defined as a numerical value of ≥ 3 mm or greater than the 95th to 99th percentile for gestational age. An increase in the NT correlates with an elevated risk for chromosomal abnormalities such as trisomy 21, trisomy 18, and Turner syndrome and other genetic diseases such as Noonan syndrome. In addition, gestations with increased NT have an elevated risk of adverse pregnancy outcomes, including fetal cardiac defects and intrauterine fetal demise, even when karyotype is normal. A measurement of NT alone has a low detection rate for trisomy 21 (64%–70%); therefore, it is not recommended as a sole screening test for aneuploidy.
- II. **Combined first-trimester screening.** NT combined with a measurement of the maternal serum markers, free β -human chorionic gonadotropin (β -hCG) and pregnancy-associated plasma protein A (PAPP-A), is used to calculate the risk for trisomies 18 and 21. It is performed between 10 3/7 and 13 6/7 weeks' gestation. It is an effective screening tool, with a detection rate of 82% to 87% for trisomy 21 at a 5% false-positive screen rate. Free β -hCG is elevated and PAPP-A is decreased in a pregnancy affected by Down syndrome. A Cochrane review comparing the performance of first-trimester ultrasound markers with or without serum markers for Down syndrome screening found that the combination of maternal age, NT, and serum markers (PAPP-A and free β -hCG) performs better than the use of ultrasound markers alone (except nasal bone) with or without maternal age.
- III. **Second-trimester screening.** The **quadruple screen (or quad screen)** involves analyzing levels of 4 maternal circulating factors: maternal serum α -fetoprotein (MSAFP), total hCG, unconjugated estriol, and inhibin A between 15 and 22 6/7 weeks' gestation. The quad screen is used to calculate the risk for trisomies 18 and 21 and open neural tubes defects. For patients who present after 13 6/7 weeks or choose not to undergo first-trimester screening, the quad screen is an option. In a pregnancy affected by Down syndrome, both MSAFP and unconjugated estriol are low and hCG and inhibin A are

¹This nomenclature refers to the number of weeks and the number of days in an incomplete week of gestation.

elevated. The quad screen has a detection rate of approximately 80% for Down syndrome at a 5% false-positive rate. The **penta screen** analyzes the hyperglycosylated hCG plus the 4 quad screen markers and is an alternative for second-trimester screening.

Like first-trimester screening, the quad screen and penta screen require an invasive test to confirm the diagnosis of a chromosomal abnormality (ie, amniocentesis or chorionic villous sampling [CVS]). For patients who chose to undergo first-trimester screening and/or CVS, neural tube defect screening in the form of a second-trimester MSAFP level should be offered. MSAFP is elevated in the presence of an open neural tube defect. Evidence exists that focused ultrasound during the second trimester is an effective tool for detecting an open neural tube defect.

IV. **Integrated screening and sequential screening (independent, stepwise, and contingent).**

These options involve a combination of first- and second-trimester screening.

A. Integrated screen. The NT and maternal serum levels of PAPP-A are obtained in the first trimester, and the quad screen is obtained in the second trimester. When the test does not include an NT measurement, it is called **serum integrated**. With both full-integrated screening and serum screening, the results are reported when all the tests are completed, yielding detection rates for Down syndrome of 94% and 87%, respectively, at a 5% false-positive rate.

B. Sequential screening. NT, PAPP-A, and free β -hCG are measured in the first trimester followed by a quad screen in the second trimester. With the **independent approach**, results are given after the first trimester, and women with an increased risk are offered noninvasive prenatal testing (NIPT) or invasive testing. If there is a low risk, a second-trimester screening is completed and interpreted independently of first-trimester results with a high false-positive rate of 11% at a detection rate of 94%. With the **stepwise approach**, patients determined to be at high risk after the first-trimester screenings are offered NIPT or invasive testing. Otherwise, the second-trimester portion is completed, and the results are given and combined with those from the first trimester. The detection rate is 95% at a 5% false-positive rate. The **contingent approach** begins with the first-trimester portion of the sequential testing and follows with the quad screen when an intermediate risk is noted. Those at high risk are offered NIPT or invasive testing by CVS or amniocentesis. However, those at low risk do not undergo further testing. **The contingent sequential screening has an excellent detection rate and a low false-positive rate, and it is the most cost-effective screening tool for trisomy 21.** A Cochrane review comparing the performance of first- and second-trimester Down syndrome screening suggests that maternal age combined with first-trimester NT and first- and second-trimester serum markers performs better than testing modalities that do not include first-trimester ultrasound or those that include only second-trimester biochemical markers without first-trimester serum markers.

V. Cell-free fetal DNA screening. Cell-free fetal DNA (cffDNA) screening is also known as noninvasive prenatal screening, NIPT, or genomic noninvasive prenatal testing. Fetal cell DNA in maternal blood is analyzed to screen for some chromosomal or genetic abnormalities including trisomies 21 (Down syndrome), 18 (Edwards syndrome), and 13 (Patau syndrome) and sex chromosome abnormalities. The detection rate for trisomy 21 is estimated to be as high as 98% to 99% with a <1% false-positive rate. The American College of Medical Genetics and Genomics (ACMG) states that cell-free DNA screening is the most sensitive screening option for Down syndrome and should be available to all pregnant women. The American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine recommend the test to women at increased risk for fetal aneuploidy, including women with previous pregnancy with a trisomy, advanced maternal age (age 35 years or older), a positive first- or second-trimester maternal screening test, a fetal ultrasound that indicates an increased risk of chromosome abnormality, or a known balanced chromosome translocation in the mother or father. In patients considered to be at low risk for aneuploidy, there is a higher false-positive rate and lower positive predictive value because the

prevalence of aneuploidy is also lower. Like other screening modalities, a positive test requires an invasive test to confirm the diagnosis of a chromosomal abnormality. It can be performed from 10 weeks' gestation to term. Nonreportable testing can be the result of low fetal fraction and high body mass index. However, literature also suggests there is an increased risk for chromosomal abnormalities associated with a low fetal fraction. Patients with a nonreportable result can be offered repeat cell-free fetal DNA test or invasive testing. The test does not provide risk assessment for open neural tube defects, and MSAFP screening should be offered between 16 and 18 weeks' gestation. Cell-free DNA can also be used to determine fetal gender and fetal Rh status in pregnancies at risk for isoimmunization. Some laboratories provide risk assessment for some microdeletions by cell-free DNA (such as 22q11 deletion syndrome). However, its clinical utility remains controversial considering the lack of validation in clinical studies, higher false-positive and false-negative rates, and lower positive predictive value when compared to aneuploidy screening.

DIAGNOSTIC TESTING

- I. **Chorionic villus sampling.** CVS is usually performed between 10 and 13 weeks' gestation. Chorionic villi are withdrawn from the placenta, either through a needle inserted through the abdomen or through a transcervical catheter, and the cells obtained are grown and analyzed for prenatal diagnosis of karyotypic abnormalities or genetic disorders for which testing is available. Pregnancy loss rates after CVS are similar to those for amniocentesis but are highly operator dependent. CVS is not recommended prior to 10 weeks' gestation due to the increased rate of limb anomalies reported.
- II. **Amniocentesis.** Amniotic fluid removed under ultrasound guidance can be analyzed for prenatal diagnosis of karyotypic abnormalities, genetic disorders (for which testing is available), fetal blood type and hemoglobinopathies, and fetal lung maturity; for monitoring the degree of isoimmunization by measurement of the content of bilirubin in the fluid; and for the diagnosis of chorioamnionitis. Testing for karyotypic abnormalities is usually done at 15 to 20 weeks' gestation. The pregnancy loss rate related to amniocentesis is estimated to be 1 in 300 to 1 in 900. Early amniocentesis (before 15 weeks) is generally not recommended because it is associated with a significantly higher rate of fetal loss, preterm premature rupture of membranes, and failed amniotic fluid cultures. Indications for amniocentesis include women at an increased risk of aneuploidy or genetic abnormalities (either by history or abnormal first- or second-trimester screening tests) and fetal structural abnormalities identified on ultrasound.
- III. **Chromosomal microarray.** This test allows the identification of small gains and losses in the DNA in addition to the chromosomal aneuploidies identified by standard karyotype analyses. Microarray does not detect balanced translocations or inversions or low-level mosaicism. Studies indicate that the test would detect 1% to 2% of clinically significant genetic abnormalities not detected by karyotype in fetuses without structural abnormalities and 6% of clinically significant genetic abnormalities in fetuses with structural anomalies detected by ultrasound. Diagnostic testing (by CVS or amniocentesis) with microarray analyses should be offered to women carrying a fetus with a structural anomaly detected by ultrasound and in cases of fetal demise. Counseling is important prior to performing a microarray because it can also detect copy variants of unknown clinical significance in 3.4% of patients (with 1.8% of those being likely benign and 1.6% likely pathogenic), adult-onset disease, nonpaternity, and consanguinity. Mothers undergoing diagnostic testing in whom the fetus has no known structural anomaly can choose between standard karyotype and microarray analysis.
- IV. **Next-generation sequencing (NGS).** NGS is a high-throughput method to accurately determine the nucleotide sequence of a partial or entire genome of an individual. Whole genome sequencing (WGS) evaluates the entire genome including introns (noncoding DNA regions, likely of no clinical significance) and exons (protein coding

regions), whereas whole exome sequencing (WES) focuses on the exon regions of the genome considered to be clinically relevant. NGS is complex, time consuming, and expensive, although costs and sample requirements have all become more reasonable. Prenatal diagnosis by NGS is reserved for clinical research or very selected cases of fetal abnormalities in which a karyotype and microarray have been normal and is only performed after expert genetic counseling.

CARRIER SCREENING

Carrier screening refers to the genetic testing done in asymptomatic patients to determine the presence of a mutation or abnormal gene causing a specific condition, in order to identify couples at risk for passing on such conditions to their offspring.

- I. **Ethnic-specific screening.** Ethnic-specific screening is done based on the ethnic background of the individual. This has become more challenging due to multiracial societies and the difficulty in determining a patient's ancestry.
- II. **Pan-ethnic screening.** Pan-ethnic screening offers carrier screening for multiple disorders regardless of ethnic background, with each condition being assessed by an individual test.
- III. **Expanded carrier screening.** Expanded carrier screening also offers screening for multiple disorders regardless of ethnic background using a single screening panel that detects multiple conditions simultaneously.

Patients should be counseled regarding the availability of prenatal or, ideally, pre-conceptual ethnic-specific, pan-ethnic, and/or expanded carrier screening. Pretest, posttest, and residual risk counseling and reproductive partner testing in identified carrier individuals should be provided to all patients. Society guidelines have been published regarding recommendations for carrier screening. See Table 1–1 for some of the most common society guidelines recommendations. Regarding expanded carrier screening, ACOG recommends that conditions evaluated meet some specific criteria, including a carrier frequency of ≥ 1 in 100, well-defined karyotype, decreased quality of life, early onset in life, need for medical or surgical therapy, available prenatal diagnosis, and opportunity to improve outcome. ACMG has also published criteria similar to ACOG. However, ACMG indicates optional testing for conditions with mild phenotype, variable expressivity, or incomplete penetrance and for adult-onset diseases.

PRENATAL ULTRASOUND

Prenatal ultrasound examination is used in the following circumstances.

- I. **Determination of pregnancy viability.** Once the mean gestational sac diameter is ≥ 25 mm, an embryo should be seen by transvaginal ultrasound. Once the CRL is ≥ 7 mm, fetal heart motion should be seen by transvaginal ultrasound. Ultrasound is also used in the case of a suspected fetal demise later in pregnancy.
- II. **Calculation of gestational age.** Measurement of the CRL up to and including 13 6/7 weeks' gestation allows for the most accurate assessment of gestational age in the first trimester. The pregnancy should be re-dated if there is a difference between the last menstrual period (LMP) and the CRL of >5 days prior to 8 6/7 weeks' gestation and >7 days between 9 0/7 and 13 6/7 weeks' gestation. After the first trimester, a combination of biparietal diameter, head circumference, abdominal circumference, and femur length is used to estimate gestational age and fetal weight. The pregnancy should be re-dated if there is a difference between the LMP and the 4 combined measurements of >7 days between 14 0/7 and 15 6/7 weeks' gestation, >10 days between 16 0/7 and 21 6/7 weeks' gestation, >14 days between 22 0/7 and 27 0/6/7 weeks' gestation, and >21 days after 28 0/7 weeks' gestation.
- III. **Diagnosis of multiple pregnancy and determination of chorionicity and amnionicity.** The determination of chorionicity and amnionicity is made by ultrasound examination of the fetal membranes and is best done as early as possible in the first trimester but

Table 1–1. CARRIER SCREENING

Test/Condition	ACOG	ACMG
Cystic fibrosis	Offer to all women	Same as ACOG
Spinal muscular atrophy	Offer to all women	Same as ACOG
Hemoglobinopathies	All women should have a complete blood count (CBC) with red blood cell (RBC) indices If the mean corpuscular volume (MCV) is low, then hemoglobin electrophoresis (Rule/out β -thalassemia trait) and measurement of serum ferritin (R/O iron deficiency) should be done. If MV low, no evidence of iron deficiency anemia, and β -thalassemia are ruled out, DNA based testing is recommended to rule out α -thalassemia. CBC and hemoglobin electrophoresis in African, Middle Eastern, Mediterranean, Southeast Asian, or West Indian descent	No current guideline
Ashkenazi Jewish	Offer Canavan disease, familial dysautonomy, Tay Sachs disease, and cystic fibrosis. Consider also Bloom syndrome, Fanconi anemia, Gaucher disease, mucopolipidosis type IV, Niemann-Pick disease, familial hyperinsulinemia, glycogen storage disease type 1, Joubert syndrome, maple syrup urine disease, and Usher syndrome	Same as ACOG
Fragile X syndrome	Offer to women with unexplained ovarian failure or insufficiency, elevated FSH at <40 years old, or family history of fragile X or intellectual disability	Offer to women with family history of intellectual disability
Expanded carrier screening	Offer to all women for selected conditions Expert counseling	Offer to all women for selected counseling Expert counseling

ACMG, American College of Medical Genetics and Genomics; ACOG, American College of Obstetricians and Gynecologists; CBC, complete blood count; FSH, follicle-stimulating hormone; MCV, mean corpuscular volume; RBC, red blood cell.

after 6 weeks' and prior to 14 weeks' gestation. (Chorionicity refers to determining in a multiple pregnancy if the fetuses share a common placenta. In the setting of twins, they can be dichorionic [each fetus has a separate placenta and is in a separate chorion] or monochorionic, where the fetuses share a placenta and chorion [signifying identical twins]. In multiple pregnancies, amnionicity refers to the assessment of the amnion to

determine if the fetuses share a common amniotic sac as well as a placenta and chorion. Although the latter sharing situation is rare, it represents a high-risk situation.)

- IV. **Anatomic survey.** A routine ultrasound, ideally between 18 and 22 weeks' gestation, is recommended to evaluate fetal anatomy. A large number of congenital anomalies can be diagnosed reliably by ultrasonography, including anencephaly, hydrocephalus, congenital heart defects, gastroschisis, omphalocele, spina bifida, renal anomalies, diaphragmatic hernia, cleft lip and palate, and skeletal dysplasia. Identification of these anomalies before birth can help determine the safest method of delivery and the support personnel needed at delivery. Ultrasonography can also aid in determining fetal gender for patients in whom this determination impacts the likelihood of a known X-linked genetic disorder.
- V. **Visual guidance.** Ultrasound is used for guidance during procedures such as amniocentesis, CVS, percutaneous umbilical blood sampling (PUBS), and some fetal surgeries (eg, placement of bladder or chest shunts).
- VI. **Assessment of growth and fetal weight.** Ultrasonography is useful to detect and monitor both fetal growth restriction (FGR; defined as an estimated fetal weight <10%) and fetal macrosomia (estimated fetal weight >4000 g or >90%). Evaluation of fetal growth is usually recommended every 3 to 4 weeks. Evidence is accumulating that maternal physical size and race should be considered in customizing the fetal weight for determination of FGR. Estimation of fetal weight is also important in counseling patients regarding expectations after delivering a premature infant. Ultrasound assessment for fetal weight by an experienced sonographer is accurate within 10% to 20% of actual weight.
- VII. **Assessment of amniotic fluid volume.** Amniotic fluid volume may be assessed objectively with ultrasound by measuring the **maximum vertical pocket (MVP)**. **The MVP is preferred to the amniotic fluid index (AFI):** total of cord-free deepest vertical pockets in 4 quadrants in centimeters).
 - A. **Oligohydramnios.** Oligohydramnios is defined as MVP <2 cm. MVP is currently the method of choice compared to AFI methods because it is associated with fewer unnecessary interventions (eg, induction) without an increase in adverse outcomes. Oligohydramnios is associated with increased fetal morbidity and mortality. Spontaneous rupture of membranes is the most common cause. Other causes include placental insufficiency, chronic hypertension, postdate gestation, and fetal anomalies such as renal agenesis, bladder outlet obstruction, cardiac disease, and karyotypic abnormalities.
 - B. **Polyhydramnios.** Polyhydramnios is defined as MVP \geq 8 cm. Causes of polyhydramnios include diabetes, multiple gestations with twin-twin transfusion syndrome, nonimmune hydrops, and fetal anomalies such as open neural tube defects, cardiac diseases, and gastrointestinal obstruction. Most cases of polyhydramnios are idiopathic; however, the risk for fetal anomalies increases with the severity of the polyhydramnios.
- VIII. **Ultrasound assessment of placental location and presence of retroplacental hemorrhage.** This is useful in suspected cases of placenta previa or accreta. Most cases of abruptio placentae are not diagnosed by ultrasonography because abruption is an emergent clinical diagnosis.
- IX. **Assessment of fetal well-being**
 - A. **Biophysical profile (BPP).** Ultrasonography is used to assess fetal movements, fetal breathing, fetal tone, and amniotic fluid volume. See BPP under antepartum tests of fetal well-being (Table 1–2).
 - B. **Doppler ultrasonography.** Doppler ultrasonography of fetal vessels, particularly the **umbilical artery**, is a useful adjunct in the management of high-risk pregnancies, especially those complicated by FGR. Changes in the vascular Doppler pattern (ie, increased systolic/diastolic ratios and absent or reversed end-diastolic flow in the umbilical artery) signal elevations in placental vascular resistance. These abnormalities correlate with an increased risk for perinatal morbidity and mortality. In

Table 1–2. BIOPHYSICAL PROFILE

Variable	Normal Response (2 points)
Fetal breathing	≥1 episode of continuous breathing movement of at least 30 seconds
Fetal gross body movements	≥3 body or limb movements
Fetal tone	≥1 extension of fetal extremity or spine with return to flexion, or opening of fetal hand
Amniotic fluid	≥1 pocket of amniotic fluid of >2 cm in 2 perpendicular planes
Nonstress test	Reactive

high-risk pregnancies, assessment of the **middle cerebral artery** is useful for evaluating for the presence of fetal anemia. The overall use of Doppler ultrasonography has been associated with a 29% decrease in perinatal mortality and fewer inductions of labor and cesarean deliveries in high-risk pregnancies; however, no benefit in using this technique has been demonstrated in screening a low-risk population.

- X. Percutaneous umbilical blood (PUBS).** Under ultrasound guidance, a needle is placed transabdominally into the fetal umbilical artery or vein. Samples of fetal blood can be obtained for karyotype, viral studies, fetal blood type, hematocrit, or platelet count. This also provides a route for in utero transfusion of red blood cells or platelets. PUBS is most often used in cases of severe hemolytic disease of the fetus with or without hydrops, such as that due to Rh or atypical antibody isoimmunization.

ANTEPARTUM TESTS OF FETAL WELL-BEING

Antepartum testing refers to those testing modalities used during pregnancy to assess fetal health and identify fetuses at risk for poor pregnancy outcome.

- I. Nonstress test (NST).** The NST is a simple noninvasive test used to check fetal well-being by measuring the heart rate in response to fetal movements, preferably with the mother lying in a semi-Fowler's position (lying supine on the bed, which is inclined at an angle from 30–45 degrees). Fetal well-being is confirmed if the baseline heart rate is normal and there are periodic accelerations in the fetal heart rate. The following guidelines can be used, although there may be variations between institutions.
 - A. Reactive NST.** In a 20-minute monitoring period, there are ≥2 accelerations of the fetal heart rate 15 beats/min above the baseline, each lasting at least 15 seconds. In a fetus <32 weeks' gestation, the accelerations must reach 10 beats/min above the baseline and last at least 10 seconds. The perinatal mortality within 1 week after a reactive NST is ~1.9 per 1000.
 - B. Nonreactive NST.** Fetal heart rate does not meet the established criteria during a prolonged period of monitoring (usually at least 40 minutes). There are many causes of a nonreactive NST besides fetal compromise, including fetal sleep cycle, chronic maternal smoking, and exposure to medications such as central nervous system depressants and propranolol. Because of this low specificity (the false-positive rate is ~75%–90%), a nonreactive NST should be followed by more definitive testing such as a BPP or a contraction stress test.
- II. Biophysical profile.** The BPP involves performing an NST to assess fetal heart rate and ultrasound over 30 minutes to assess fetal breathing movements, gross body movements, tone, and amniotic fluid volume. Two points are given for each variable if present and 0 points if absent during the observation period (see Table 1–2). A score of 8 to 10 is considered normal, 6 is equivocal and warrants a repeat BPP

in 24 hours, and 0 to 4 is abnormal with delivery usually indicated. Changes in the BPP parameters are due to fetal hypoxemia. Caution is needed since the BPP can also be affected by other factors such as gestational age, medications, and improper technique. The BPP is widely used among institutions to monitor high-risk pregnancies. However, evidence from randomized clinical trials does not support its use to monitor complicated pregnancies. Institutional variation exists regarding gestational age for performance of BPP, starting as low as 24 weeks, even when its utility has only been studied at higher gestational ages.

A. Modified biophysical profile. The BPP scoring system has been modified to shorten testing time. The most common combination includes an evaluation of only an NST and amniotic fluid volume. In some cases, the modified BPP is used as an initial test, and if abnormal, it is followed by additional testing including a full BPP. The stillbirth rate within 1 week of a normal BPP or a modified BPP is the same, at 0.8 per 1000.

III. Contraction stress test (CST). The CST is used to assess a fetus at risk for uteroplacental insufficiency (UPI). The fetal heart rate and uterine contractions are continuously monitored. An adequate test consists of 3 40-second contractions within a period of 10 minutes. If sufficient contractions do not occur spontaneously, oxytocin or nipple stimulation may be used. If late decelerations occur during or after contractions, UPI may be present. The CST may be contraindicated in patients with placenta previa, those who have had a previous cesarean section with a vertical incision, and those with high-risk factors for preterm delivery (eg, premature rupture of membranes or cervical insufficiency). CST results are interpreted as follows:

A. Negative (normal) test. No late or significant variable decelerations occur. This result is associated with a very low perinatal mortality rate of 0.3 per 1000 in the week following the test.

B. Positive (abnormal) test. Late decelerations occur with at least 50% of the contractions. This result is associated with an increased risk of perinatal morbidity or mortality and indicates that delivery is usually warranted.

C. Equivocal (suspicious) test. Late or significant variable decelerations occur but with <50% of the contractions. Prolonged fetal monitoring is usually recommended, and the CST should be repeated in 24 hours.

D. Equivocal. Deceleration occurs in the presence of tachysystole (contractions >2 minutes apart lasting >90 seconds).

E. Unsatisfactory. Unsatisfactory indicates there are <3 contractions in 10 minutes or inability to interpret tracing.

IV. Doppler studies. Antepartum Doppler studies are discussed under the earlier prenatal diagnosis section.

V. Fetal movement counting. Maternal perception of fetal movement has been proposed as a tool to evaluate fetal well-being. Different methods have been evaluated including “the count to 10,” which involves counting 10 fetal movements over 2 hours during maternal rest. The utility of maternal kick counts to predict stillbirth is **controversial** in the literature. Maternal reports of abnormal fetal counting warrant further evaluation.

INTRAPARTUM TESTS OF FETAL WELL-BEING

Intrapartum testing refers to those testing modalities used during labor to identify fetuses at risk for acidosis, adverse neonatal outcome, or death.

I. Electronic fetal heart rate monitoring (EFM). Although EFM has become widely used, its benefits over intermittent auscultation of the fetal heart rate have been **controversial**. It was not until recently that EFM was associated with a decrease in early infant and neonatal mortality, a decreased risk for Apgar scores <4 at 5 minutes, and a decreased risk of neonatal seizures. EFM is associated with an increase in the rates of both cesarean sections and operative vaginal deliveries. Fetal heart rate monitoring may be **internal**, with an electrode attached to the fetal scalp, or **external**, with a

monitor attached to the maternal abdomen. The nomenclature and interpretation of EFM are based on the 2008 National Institute of Child Health and Human Development (NICHD) workshop report and are as follows:

- A. Baseline fetal heart rate (FHR).** Baseline FHR is the rate maintained for at least 2 minutes apart from periodic variations, rounded to the nearest 5 beats/min over a 10-minute period. The normal FHR is 110 to 160 beats/min. Fetal tachycardia is present at >160 beats/min and fetal bradycardia at <110 beats/min. Causes of fetal tachycardia include maternal or fetal infection, fetal hypoxia, thyrotoxicosis, and maternal use of drugs such as parasympathetic blockers or α -mimetic agents. Causes of fetal bradycardia include hypoxia, complete heart block, and maternal use of drugs such as β -blockers.
- B. Variability.** In the normal mature fetus, there are rapid fluctuations in the baseline FHR. This variability indicates a functioning sympathetic–parasympathetic nervous system interaction and is the most sensitive indicator of fetal well-being.
 - 1. Moderate variability.** An amplitude range from peak to trough of 6 to 25 beats/min indicates moderate variability and suggests the absence of fetal hypoxia. Marked variability occurs when >25 beats/min is noted.
 - 2. Minimal variability.** Minimal variability is quantified as <5 beats/min.
 - 3. Absent variability.** Absent variability refers to an amplitude range that is undetectable.
 - 4. Decreased variability.** Decreased variability may be caused by severe hypoxia, anencephaly and other fetal neurologic abnormalities, complete heart block, and maternal use of drugs such as narcotics or magnesium sulfate. In addition, variability is decreased during normal fetal sleep cycles.
- C. Accelerations.** Accelerations are often associated with fetal movement and are an indication of fetal well-being. The presence of accelerations suggests the absence of any acidosis.
- D. Decelerations.** There are 3 types of decelerations (Figure 1–1).
 - 1. Early decelerations.** Early decelerations result from physiologic head compression and occur secondary to an intact vagal reflex tone, which follows minor, transient fetal hypoxic episodes. These are benign and are not associated with fetal compromise. They appear as mirror images of the contraction pattern.
 - 2. Late decelerations.** Late decelerations are a result of UPI and indicate the presence of fetal hypoxia. Potential causes include maternal hypotension, sometimes as a result of supine positioning or regional anesthesia, as well as uterine hyper-tonicity. More chronic causes of UPI, such as hypertension, postdate gestation, and preeclampsia may predispose a fetus to the development of late decelerations. Although by themselves they reflect only a decreased oxygen tension for the fetus, their persistence may lead to the development of fetal acidemia and eventual compromise. The nadir occurs after the contraction peaks, with the shape demonstrating a gradual decrease and slow return to baseline.
 - 3. Variable decelerations.** Variable decelerations result from abrupt compression of the umbilical cord. They can also be seen as a consequence of cord stretch, as in phases of rapid fetal descent, and with a cord prolapse. Variable decelerations tend to increase in the setting of oligohydramnios. The majority of these decelerations are benign and not predictive of an acidemic fetus. However, severe variable decelerations (those lasting >60 seconds), especially in the setting of decreased variability and/or tachycardia, may portend a compromised fetus. They have a “V” or “W” nonuniform shape with a rapid descent and return to baseline: time from baseline to the nadir of the deceleration is 30 seconds.
- E. Interpretation of electronic fetal monitoring.** FHR patterns can be classified in 1 of 3 categories: I (normal), II (indeterminate), or III (abnormal).
 - 1. Category I FHR pattern.** This pattern has 4 characteristics: normal baseline rate (110–160 beats/min), moderate variability (6–25 beats/min), absence of late or

FIGURE 1-1. Examples of fetal heart rate monitoring. CC, cord compression; FHR, fetal heart rate (beats/min); HC, head compression; UC, uterine contraction (mm Hg); UPI, uteroplacental insufficiency. (Modified with permission from McCrann DJ Jr, Schifrin BS: *Fetal monitoring in high-risk pregnancy*, Clin Perinatol. 1974 Sep;1(2):229-252.)

variable decelerations, and absence or presence of early decelerations or accelerations. In the setting of these findings, there is a high likelihood of a normally oxygenated fetus. Category I FHR is considered normal, and no intervention is needed.

- 2. Category II FHR pattern.** Comprises all FHR patterns not in category I or III. Category II tracings are not predictive of abnormal fetal acid-base status. When a category II tracing is identified, a fetal scalp stimulation test may help identify fetuses in which acid-base status is normal. FHR category II pattern requires evaluation, in utero resuscitation with management of possible underlying cause (if identified), and reevaluation. If persistent or progression to category III occurs, urgent delivery should be considered.
- 3. Category III FHR pattern.** Category III FHR pattern is abnormal and requires prompt evaluation and initiation of in utero resuscitation while in preparation

for prompt delivery, if the condition does not improve. There are 4 FHR patterns predictive of abnormal fetal acid-base status grouped in category III.

- a. **Sinusoidal pattern.** These include a sinusoidal heart rate, defined as a pattern of regular variability resembling a sine wave, with fixed periodicity of 3 to 5 cycles/min and amplitude of 5 to 40 beats/min. A sinusoidal pattern may indicate fetal anemia caused by fetomaternal hemorrhage or alloimmunization.
 - b. **Baseline FHR variability is absent.** The other 3 abnormal FHR patterns in category III are diagnosed when baseline FHR variability is absent and any 1 of the following is present:
 - i. **Recurrent late decelerations**
 - ii. **Recurrent variable decelerations**
 - iii. **Bradycardia**
- II. **Fetal scalp blood sampling (FSB).** FSB had been used during labor to determine the fetal acid-base status when the FHR tracing was nonreassuring or equivocal. The test requires that there is rupture of membranes and the cervix is at least 3 cm dilated. Expedited delivery is recommended if the scalp pH is <7.2 or lactate is >4.8 mmol/L. A Cochrane review indicates that “fetal scalp blood lactate estimation is more likely to be successfully undertaken (requires a smaller amount of blood) than pH estimation. Data is controversial in the literature regarding the utility and benefit of fetal blood sampling. Some studies have suggested a decrease in the need for operative delivery with no improved neonatal outcome, while others suggested an increased in instrumental deliveries but less neonatal acidosis.” Noninvasive methods (vibroacoustic and fetal scalp stimulation) provide similar reassurance, FSB has been associated with some complications, and evidence to support its use is limited. Therefore, it is not commonly used in clinical care.
- III. **Scalp stimulation/vibroacoustic stimulation.** An acceleration in FHR in response to either manual stimulation of the fetal presenting part or vibroacoustic stimulation through the maternal abdomen has been associated with a fetal pH of >7.20 . These tests are often used in labor to determine fetal well-being; however, a lack of fetal response to stimulation is not predictive of acidemia.
- IV. **Fetal pulse oximetry.** This technique was designed as an adjunct to FHR monitoring in labor and involves the placement of a fetal pulse oximeter transcervically next to the fetal cheek. Normal fetal oxygen saturation as measured by pulse oximetry (SpO_2) is 30% to 70%. Due to the lack of clinical significance in the trials in which it was studied, it is currently not recommended.

TESTS OF FETAL LUNG MATURITY

Fetal lung maturity (FLM) testing is rarely used in current clinical practice because patients are managed based on clinical criteria. The statement by the joint workshop between the Eunice Kennedy Shriver National Institute of Child Health and Human Development and the Society for Maternal-Fetal Medicine states: “The rationale that if significant maternal or fetal risks exist, delivery should occur regardless of biochemical maturity and if delivery could be deferred owing to absence of pulmonary maturity there is not a stringent indication for prompt delivery.” FLM is discouraged if delivery is clinically indicated for maternal or fetal reasons because delaying delivery due to an immature result will place the mother and/or fetus at risk. However, a mature result does not reflect maturity in the other organs and can still be associated with adverse neonatal outcome at <39 weeks. ACOG states that when considering delivery in a woman with suboptimally dated pregnancy, late-term delivery is indicated at 41 weeks’ gestation when the gestational age is not known. Some disorders are associated with delayed lung maturation, including diabetes mellitus and Rh isoimmunization complicated by fetal hydrops. Acceleration of FLM is seen in sickle cell disease, maternal narcotic addiction, prolonged rupture of membranes, chronic maternal hypertension, FGR, and smoking. Differences may also occur in various racial groups. FLM is mentioned here for historic purposes only. Different testing modalities for FLM are available (Table 1–3).

Table 1–3. COMMON FETAL LUNG MATURITY TESTS

Test	Results Predicting Maturity	Test Considerations
Lecithin-sphingomyelin (L-S) ratio	≥2	Affected by blood or meconium Testing from vaginal pool not possible Costly, difficult to perform, time consuming
Phosphatidylglycerol (PG)	Present (indicates low risk of RDS)	Not affected by blood, meconium, or vaginal infection Testing from vaginal pool possible
Surfactant-albumin ratio (TDx FLM II)	≥55 mg/g	Affected by blood and meconium Testing from vaginal pool not possible Product recently withdrawn from market
Lamellar body count (LBC)	>30,000–50,000/μL	Affected by blood Testing from vaginal pool not possible
Quantus FLM	Low risk or high risk for neonatal respiratory morbidity	Ultrasound cardiac 4-chamber view of the fetal thorax and web-based analysis

RDS, respiratory distress syndrome.

- I. **Lecithin-sphingomyelin (L-S) ratio.** The L-S ratio compares levels of lecithin (principal active component of surfactant), which gradually increase after 28 weeks, to levels of sphingomyelin, which remain constant. **An L-S ratio ≥2:0 is considered mature.**
- II. **Phosphatidylglycerol (PG).** PG appears in amniotic fluid at ~35 weeks, and levels increase at 37 to 40 weeks. This substance is a useful marker for lung maturation late in pregnancy because it is the last surfactant to appear in the fetal lung. It is reported as either **present or absent**, and its presence is a strong marker that respiratory distress syndrome will not occur.
- III. **Surfactant-albumin ratio by TDx fetal lung maturity (TDx FLM II).** This test (Abbott Laboratories, Abbott Park, IL) measures the relative concentrations of surfactant and albumin (milligrams of surfactant per gram of albumin) in amniotic fluid, which increases with increasing lung maturity. This test has been discontinued by the manufacturer.
- IV. **Lamellar body count (LBC).** After its secretion by type II pneumocytes, surfactant is packaged into storage granules called lamellar bodies. This test uses a standard hematology cell counter to count these lamellar bodies. A count of >50,000/μL suggests lung maturity. However, the optimal cutoff is controversial, with data in the literature ranging from >30,000 to 50,000/μL.
- V. **Quantus FLM (Transmural Biotech, Barcelona, Spain).** This test is the first non-invasive FLM test based on the analysis of an ultrasound images of the fetal lung. A conventional semilateral axial ultrasound section at the level of the cardiac 4-chamber view of the fetal thorax in Digital Imaging and Communications in Medicine (DICOM) format is obtained and uploaded to a web application. The published results are comparable to those of current tests on amniotic fluid (sensitivity 86%, specificity 86%, positive predictive value 62%, negative predictive value 96%.) This test categorizes the risk of developing neonatal respiratory morbidity into 2 levels (high risk or low risk).

CORD BLOOD BANKING

Stem cells from the umbilical cord are collected after the baby is born and are stored by private or public cord blood banks. The family is given a collection kit to bring on the day of delivery. The delivering provider typically collects the blood after the baby is delivered.

After the umbilical cord has been clamped, the blood is drawn with a needle that transfers the blood into a bag that is sealed after the collection is completed. The sample is then taken to the cord blood bank. Parents can opt for cord blood banking, understanding the benefits and limitations; however, it is not universally recommended. Private cord blood banking should be considered when there is a family member with a known condition that can be treated with a hematopoietic transplant. The cells can potentially be used to treat some diseases with an estimated chance of an individual using his or her own cells of 1 in 2700. However, some diseases, including inborn errors of metabolism and genetic diseases, cannot be treated in the same individual because the cells contain the mutation.

2 Obstetric Anesthesia and the Neonate

During birth, the fetal status can be influenced by obstetric analgesia and anesthesia. Care in choosing analgesic and anesthetic agents can often prevent complications such as respiratory depression in the newborn.

I. Placental transfer of drugs. Drugs administered to the mother may affect the fetus via placental transfer or may cause a maternal disorder that affects the fetus (eg, maternal drug-induced hypotension producing fetal hypoxia). All anesthetic and analgesic drugs cross the placenta to some degree, usually through flow-dependent passive diffusion. Most anesthetic and analgesic drugs have a high degree of lipid solubility, low molecular weight (<500), and variable protein-binding and ionization capabilities. These characteristics lead to rapid placental transfer.

II. Analgesia in labor

A. Inhalation analgesia. Inhalation analgesia is not commonly used in the United States because neuraxial (regional) analgesia is widely available. Although not as effective, a mixture of 50% oxygen and 50% nitrous oxide, either premixed (Entonox in Europe) or administered with a blender device (Nitronox in the United States), can be used to lessen the perception of pain. Although placental transfer is rapid, there is no evidence of neonatal respiratory depression or altered neurobehavioral scores. Several problems with inhalational anesthesia limit its routine use:

1. **The need for specialized vaporizers**
2. **Concern for environmental pollution**
3. **Incomplete analgesia**
4. **Maternal childbirth amnesia**
5. **Possible loss of maternal protective airway reflexes**

B. Pudendal block and paracervical block. Paracervical blocks are rarely used today because they may precipitate severe fetal bradycardia from reduced uteroplacental and/or fetoplacental perfusion. This occurs because of an increase in uterine activity and/or a direct vasoconstrictive effect of the local anesthetic. If a paracervical block is performed, the fetal heart rate (FHR) must be monitored continuously. Paracervical blocks are effective in the first stage of labor, and pudendal blocks are effective during the second stage. Pudendal blocks have little direct effect on the fetus.

C. Opioids. All intravenously (IV) administered opioids are rapidly transferred to the fetus, resulting in dose-related respiratory depression and alterations in Apgar and neurobehavioral scores.

1. Meperidine. Meperidine can cause severe neonatal depression including respiratory acidosis, low oxygen saturation, decreased minute ventilation, and increased time to sustained respiration. The risk is least if administered intramuscularly

(IM) within 1 hour of delivery and greatest if given 3 to 5 hours before delivery. Fetal normeperidine, a long-acting meperidine metabolite and significant respiratory depressant, accumulates after multiple doses or a prolonged dose-delivery interval.

2. **Morphine.** Morphine has a delayed onset of action and may generate greater neonatal respiratory depression than meperidine.
 3. **Butorphanol and nalbuphine.** These are mixed agonist-antagonist opioid agents that may be safer than morphine because they demonstrate a ceiling effect for respiratory depression with increasing doses. Unlike butorphanol, maternal administration of nalbuphine can result in decreased FHR variability and, rarely, a sinusoidal FHR pattern.
 4. **Fentanyl and remifentanyl.** These are synthetic opioids, best administered via patient-controlled analgesia. Both are short acting and have no active metabolites. Fentanyl may cause low 1-minute Apgar scores, but neonatal neurobehavioral scores are normal. Remifentanyl requires careful monitoring and 1-on-1 nursing care because maternal sedation and respiratory depression are very common.
- D. Opioid antagonist (naloxone).** For respiratory depression after maternal opioid exposure for pain in the laboring mother, positive pressure ventilation is recommended. For prolonged apnea, insertion of an endotracheal tube or laryngeal mask may be necessary. Naloxone is not recommended in this setting as there is concern for complications (seizures, pulmonary edema, and cardiac arrest).

E. Sedatives and tranquilizers

1. **Barbiturates.** Barbiturates cross the placenta rapidly and can have pronounced neonatal effects (eg, somnolence, flaccidity, hypoventilation, failure to feed) that may last for days. Effects are intensified if opioids are given simultaneously. Barbiturates rapidly redistribute into maternal tissues before placental transfer; after transfer, they are preferentially uptaken by the fetal liver.
 2. **Benzodiazepines (diazepam, lorazepam, midazolam).** These agents promptly cross the placenta and equilibrate within minutes after IV administration. Diazepam accumulates in the fetus; large doses (>10 mg) may persist for days and can result in hypotonia, lethargy, poor feeding, impaired thermoregulation, and an abnormal stress response. Benzodiazepines may also induce maternal childbirth amnesia.
 3. **Phenothiazines.** Phenothiazines are rarely used today because they may cause hypotension via central α -blockade and unwanted extrapyramidal movements; they are sometimes combined with a narcotic (neuroleptanalgesia).
 4. **Ketamine.** Ketamine induces dissociative analgesia. Doses >1 mg/kg may cause uterine hypertonia, neonatal depression, and abnormal neonatal muscle tone. Doses used in labor (0.1–0.2 mg/kg) produce minimal maternal or neonatal effects.
- F. Lumbar epidural analgesia.** Lumbar epidural analgesia is the most frequently used neuraxial analgesic technique for childbirth. In fact, early epidural placement is encouraged in the most recent American Society of Anesthesiologists (ASA) Practice Guidelines for Obstetric Anesthesia when the service is available. Local anesthetic (eg, bupivacaine, ropivacaine) with or without an opioid is injected incrementally or continuously through an epidural catheter placed in a lumbar (L2–3, L3–4, L4–5) interspace to block the T10 to L1 and S2 to S4 spinal cord segments. Maternal pain and catecholamine levels are reduced, decreasing maternal hyperventilation and improving fetal oxygen delivery. A dilute concentration of local anesthetic plus opioid may lower the amount of local anesthetic needed, enhance the quality of analgesia, and minimize motor block. Infusion of the local anesthetic–opioid combination via a patient-controlled approach (patient-controlled epidural analgesia) rather than at a fixed rate may reduce the dosage of local anesthetic further. Drug accumulation and subsequent neonatal respiratory depression are rare. Maternal hypotension from sympathetic blockade is easily treated with fluid administration and IV ephedrine or preferentially phenylephrine because of improved fetal acid-base status. Unfortunately, labor epidural

analgesia is associated with a gradual increase in maternal temperature of up to 1°C. The etiology appears to be inflammatory, not infectious, but may lead to unnecessary neonatal sepsis evaluations. Efforts to lower maternal temperature are prudent because fever, whatever the cause, may be detrimental to the fetal brain.

- G. Intrathecal opioid analgesia/combined spinal epidural (CSE).** Intrathecal opioids (sufentanil or fentanyl ± morphine) provide rapid labor analgesia with minimal motor and sympathetic blockade. They are usually administered in combination with an epidural (CSE) via a “needle-through-needle” technique (spinal needle through epidural needle, opioid injected, epidural catheter placed). When intrathecal analgesia recedes, epidural analgesia takes over. Indications include early first-stage labor (opioid alone), if labor is advanced and progressing rapidly (opioid + bupivacaine), or if there is a reasonable possibility of operative delivery. Transient FHR bradycardia occurs in approximately 10% to 15% of cases, possibly from a rapid decrease in maternal catecholamines and an unopposed oxytocin effect. This may lead to uterine hypertonus or tachysystole and lower fetal perfusion. Therefore, the ASA Practice Guidelines for Obstetric Anesthesia strongly agree that the FHR should be monitored before and after administration of neuraxial analgesia.
- H. Caudal epidural analgesia.** Caudal epidural analgesia blocks the sacral nerve roots and provides excellent pain relief in the second stage of labor. Use is limited during the first stage because the larger doses of local anesthetic needed increase pelvic muscle relaxation and impair fetal head rotation. Fetal intracranial local anesthetic injection can occur also.
- I. Continuous spinal analgesia.** A catheter is placed directly into the subarachnoid (spinal) space either through or over the top of an introducer needle. Usually the introducer is large, making the incidence of spinal headache unacceptably high. An infusion of opioid (fentanyl or sufentanil) with or without bupivacaine is maintained throughout labor.
- J. Local anesthetics.** All of the neuraxial anesthetic/analgesic techniques and local blocks use local anesthetic agents.
- 1. Lidocaine.** Placental transfer of lidocaine is significant, but Apgar scores are not affected in healthy neonates. Acidotic fetuses accumulate larger amounts of lidocaine through pH-induced ion trapping.
 - 2. Bupivacaine.** Bupivacaine is theoretically less harmful for the fetus because the higher degree of ionization and protein binding limits placental transfer. Maternal toxicity leading to convulsions and cardiac arrest has been reported after inadvertent intravascular injection. Bupivacaine, in low concentrations, is the most commonly used local anesthetic agent for continuous labor analgesia because it provides excellent sensory analgesia with minimal motor blockade.
 - 3. 2-Chloroprocaine.** After systemic absorption, 2-chloroprocaine is rapidly broken down by pseudocholinesterase, so very little reaches the placenta or fetus. However, because of its short duration and significant motor blockade, 2-chloroprocaine is not useful for continuous labor analgesia.
 - 4. Ropivacaine** is similar to bupivacaine but produces less motor block and less maternal cardiotoxicity. Neurobehavioral scores are slightly better in infants whose mothers received epidural ropivacaine compared with bupivacaine.
 - 5. Levobupivacaine** is the purified levorotary isomer (*S*-enantiomer) of racemic bupivacaine. Like ropivacaine, it has less potential for cardiotoxicity.
- K. Psychoprophylaxis.** The **Lamaze technique** of prepared childbirth involves class instruction for prospective parents. The process of childbirth is explained, and exercises, breathing skills, and relaxation techniques are taught to help relieve labor pain. However, the assumption that the neonate benefits if the mother receives no drugs during childbirth is questionable. Approximately 50% to 70% of women who have learned the Lamaze method request IV/IM pain medication or a neuraxial analgesic during labor. Other techniques include transcutaneous electrical nerve stimulation (TENS), hypnosis, and acupuncture.

III. Anesthesia for cesarean delivery. Aortocaval compression may decrease placental perfusion if the mother is positioned supine, so a wedge is placed under the right hip to attain a tilt of 15 to 30 degrees. Neuraxial techniques are chosen in preference to general anesthesia for most cesarean deliveries because it is usually safer for mother and baby. However, if emergent delivery is indicated, general anesthesia has the shortest induction time.

- A. Spinal anesthesia.** Spinal anesthesia (injection of local anesthetic \pm opioid directly into the cerebrospinal fluid) requires one-tenth of the drug needed for epidural anesthesia. Maternal and fetal drug levels are extremely low. Hypotension occurs rapidly but can be attenuated by administering 1.5 to 2.0 L of a balanced salt solution IV (preload or co-load) and/or treating with IV ephedrine or phenylephrine. Better quality anesthesia, more rapid placement, and faster onset make spinal anesthesia preferred over epidural anesthesia. In addition, fewer abnormalities in neonatal neurobehavioral scores occur after spinal anesthesia compared with general anesthesia.
- B. Lumbar epidural anesthesia.** Epidural anesthesia is less profound than spinal anesthesia, and a larger dose of local anesthetic is required. Consequently, placental transfer occurs to a small degree, although drug effects can only be detected by neurobehavioral testing. Maternal hypotension occurs more slowly and is less significant because the epidural is dosed incrementally.
- C. Combined spinal epidural.** If a cesarean delivery of prolonged duration is anticipated, a CSE is used. Rapid, intense spinal anesthesia is obtained with the ability to initiate epidural anesthesia when the spinal anesthesia wanes.
- D. General anesthesia.** General anesthesia is used in the following circumstances: strong patient preference, emergency delivery, and contraindications to neuraxial anesthesia. After induction, anesthesia is maintained with a combination of nitrous oxide in oxygen and low doses of inhaled halogenated agents or IV medications.

1. Agents used for general anesthesia

- a. Premedication.** Administration of medications that reduce gastric acid secretion and volume (H_2 receptor antagonists), increase gastric pH (sodium citrate), and speed gastric emptying (metoclopramide) are recommended (ASA Practice Guidelines for Obstetric Anesthesia) to help prevent aspiration. The neonate is not affected by these agents.
- b. Thiopental.** Thiopental (4–5 mg/kg), a common induction agent, is no longer available in the United States. Rapid redistribution into maternal tissues and preferential uptake by the fetal liver confer low fetal brain concentration and minimal neonatal depression.
- c. Propofol.** Propofol (2–2.5 mg/kg), although not approved during pregnancy (there are no well-controlled human studies), is the most widespread induction agent in the United States. It rapidly crosses the placenta and distributes into the fetus. Propofol causes more maternal hypotension than thiopental, which may lead to decreased uteroplacental blood flow, but most investigators have reported no difference in neonatal neurobehavioral scores.
- d. Ketamine.** Ketamine (1 mg/kg) is mainly reserved for induction in severe asthmatics (bronchodilator properties) and in patients with mild to moderate hypovolemia (sympathomimetic properties) when cesarean delivery is emergent. Neonatal neurobehavioral scores are similar to those with thiopental.
- e. Etomidate.** Etomidate (0.2–0.3 mg/kg) is used to induce parturients who are hemodynamically unstable because it produces minimal effects on cardiorespiratory function. A transient decrease in maternal and neonatal cortisol production may occur after administration.
- f. Muscle relaxants.** Muscle relaxants are highly ionized, cross the placenta only in small amounts, and have little effect on the neonate.
- i. Succinylcholine (1–1.5 mg/kg).** In twice-normal doses, succinylcholine is detectable in the fetus, but no respiratory effects are seen until the dose is 5 times normal or both mother and fetus have abnormal pseudocholinesterase levels or activity.

- ii. **Rocuronium (1 mg/kg), atracurium, cisatracurium, vecuronium.** These are medium-duration nondepolarizing muscle relaxants. In clinical doses, they do not affect the neonate.
 - g. **Nitrous oxide.** Nitrous oxide undergoes rapid placental transfer. Prolonged administration of high (>50%) concentrations can result in low Apgar scores because of neonatal anesthesia and diffusion hypoxia. Concentrations of up to 50% are safe, but neonates may need supplemental oxygen after delivery.
 - h. **Halogenated anesthetic agents (isoflurane, enflurane, sevoflurane, desflurane, halothane).** These agents are used to maintain general anesthesia. Beneficial effects include decreased maternal catecholamines, increased uterine blood flow, and improved maternal anesthesia compared with nitrous oxide alone. Low concentrations rarely cause neonatal anesthesia and are readily exhaled. High concentrations may decrease uterine contractility. The lowest effective concentration is chosen, and the agent is usually discontinued after delivery.
 - i. **Opioids.** All opioids readily cross the placenta and are commonly avoided until after delivery.
2. **Neonatal effects of general anesthesia.** Maternal hypoxia resulting from aspiration or failed endotracheal intubation can cause fetal hypoxia. Maternal hyperventilation ($\text{PaCO}_2 < 20$ mm Hg) decreases placental blood flow and shifts the maternal oxyhemoglobin dissociation curve to the left, which can also lead to fetal hypoxia and acidosis.
3. **Interval between incision of the uterus and delivery.** Incision and manipulation of the uterus produce reflex uterine vasoconstriction and may result in fetal acidosis or asphyxia. A long interval between uterine incision and delivery (>90 seconds) is associated with significantly lower Apgar scores, especially if >180 seconds, and is more important when general anesthesia is employed. Neuraxial anesthesia decreases reflex vasoconstriction, so the interval is less significant.
4. **Neuraxial versus general anesthesia**
- a. **Apgar scores.** Early studies showed that neonates had higher Apgar scores at 1 and 5 minutes when neuraxial anesthesia was used. However, newer general anesthetic techniques lower Apgar scores at 1 minute only. This represents transient sedation, not asphyxia. If the interval between induction and delivery is short, the difference in Apgar scores is smaller. Nevertheless, low Apgar scores from sedation do not have the negative prognostic value that those from asphyxia do, provided the neonate is adequately resuscitated.
 - b. **Acid-base status.** The differences in acid-base status are minimal and probably not significant. Infants of diabetic mothers may be less acidotic with general anesthesia because neuraxial anesthesia-induced hypotension may exacerbate any existing uteroplacental insufficiency.
 - c. **Neurobehavioral examinations.** These tests are performed to examine the relationship between motor, neurologic, and behavioral functioning; to detect early central nervous system dysfunction; to predict future outcomes; to evaluate longitudinal development; and to determine the impact of interventions. Detecting atypical development is essential to target early interventions for those most at risk, but also to prevent unnecessary intervention for those who are unlikely to have neurodevelopmental impairment. However, it is important not to administer the tests too early. Xu and colleagues recommend 20 hours after delivery as the earliest appropriate time to obtain results that are not influenced by the acute effects of labor and delivery and thus most accurately represent newborn neurobehavior. Eight assessments appropriate for preterm infants up to 4 months of corrected age are listed in Table 2–1. They include observation of antigravity postures, quality of spontaneous movements, infant motor patterns, reflexes, muscle tone, attention, visual or auditory responses, color, vital signs, and irritability or consolability.

Table 2–1. NEWBORN NEUROBEHAVIORAL ASSESSMENTS

Tool	Age Range	Purposes	Components Tested
APIB (Assessment of Preterm Infants' Behavior)	28 weeks to 1 month	Documentation of the spectrum of preterm/term infants' neurobehavioral functioning/competence	Autonomic, motor, state, attention/interaction, self-regulation
Dubowitz (Dubowitz Neurological Assessment of the Preterm and Full-Term Newborn Infant)	30 weeks to 4 months	Detailed profile of neurologic status; identifies infants with neurologic abnormalities	Posture and tone, reflexes, movements, neurobehavioral responses
GMs (Prechtl's Assessment of General Movements)	Preterm to 4 months	Records spontaneous movements to identify early central nervous system dysfunction	Movement patterns
NAPI (Neurobehavioral Assessment of the Preterm Infant)	32 weeks until term	Measurement of the progression of neurobehavioral performance	Motor development and vigor, scarf sign, popliteal angle, attention/orientation, % asleep, irritability, vigor of cry
NBAS (Brazelton Neonatal Behavioral Assessment Scale)	36 weeks until 6 weeks post term	Identifies individual neurobehavioral functioning and identifies areas of difficulty	Autonomic, motor and reflexes, state, social/attentional
NMBA (Neuromotor Behavioral Assessment)	30 to 36 weeks	Identifies preterm infants who may be developmentally at risk	Neurologic (eg, tone, reflexes), behavioral, autonomic, motor functions
NNNS (Neonatal Intensive Care Network Neurobehavioral Scale)	30 weeks up to 4 months (46/48 weeks post term)	Assesses at-risk infants (eg, substance exposed); documents neurologic integrity and behavioral functioning	Neurologic (tone, reflexes), behavioral, stress/abstinence items
TIMP (Test of Infant Motor Performance)	32 weeks to 4 months	Assesses motor control and organization of posture and movement for functional activities	Orientation of the infant's head in space, auditory and visual stimuli responses, body alignment, limb movements

Note. For clinical purposes, the neurobehavioral assessments GMs, Dubowitz, NAPI, NBAS, and TIMP are suitable, but for research purposes the APIB and NNNS are the assessments of choice. The GMs and TIMP can be used across both settings, having both excellent utility and psychometric properties; they show the strongest associations with neurodevelopmental outcome.

3 Resuscitation of the Newborn

Approximately 10% of all newborns need help with breathing at the time of birth, and 1 in 1000 newborns require resuscitation with chest compressions and cardiac medications. Given the high frequency of newborn resuscitation, it is vital that all neonatal healthcare workers are trained and competent to provide resuscitation to babies in need. Newborn resuscitation cannot always be anticipated in time to transfer the mother before delivery to a facility with specialized neonatal support. Therefore, every hospital with a delivery suite should have a skilled resuscitation team (see Chapter 4, “Neonatal Transport”) and appropriate equipment available (Table 3–1).

- I. **Normal physiologic events at birth.** Normal transition at birth begins with lung expansion, generally requiring large negative intrathoracic pressures, followed by a cry (expiration against a partially closed glottis). Umbilical cord clamping is accompanied by a rise in systemic blood pressure and stimulation of the sympathetic nervous system. With the onset of respiration and lung expansion, pulmonary vascular resistance decreases, followed by a gradual transition (over minutes to hours) from fetal to adult circulation, with the closure of the foramen ovale and ductus arteriosus.
- II. **Abnormal physiologic events at birth.** The asphyxiated newborn undergoes an abnormal fetal to neonatal transition. With asphyxiation, the fetus develops *primary apnea*, during which spontaneous respirations can be induced by appropriate sensory stimuli such as drying. If the asphyxial insult persists, the fetus develops deep gasping, followed by a period of *secondary apnea*, during which spontaneous respirations cannot be induced by sensory stimuli. Death occurs if secondary apnea is not reversed by ventilatory support within several minutes. Because one can never be certain whether an apneic newborn has primary or secondary apnea, resuscitative efforts should proceed as though secondary apnea is present.
- III. **Preparation for high-risk delivery.** Preparation for a high-risk delivery is the key to a successful outcome. Cooperation between the obstetric, anesthesia, and pediatric staff is important. As noted in Figure 3–1, each resuscitation should begin with a team briefing and equipment check. Knowledge of potential high-risk situations and appropriate interventions is essential (Table 3–2). It is useful to have an estimation of weight and gestational age (Table 3–3) for calculating drug dosages and equipment size. The team briefing prior to delivery is used for assigning team member roles and reviewing expected resuscitation measures in order to establish a shared mental model within the resuscitation team. Antenatal counseling should be provided to the parents prior to the birth, especially when the fetus is at the limit of viability or when life-threatening anomalies are anticipated.
- IV. **Assessment of the need for resuscitation.** The Apgar score is assigned at 1, 5, and, occasionally, 10 to 20 minutes after delivery. It gives a fairly objective idea of how much resuscitation was required at birth and the infant’s response to resuscitative efforts. It is, however, not useful during resuscitation. During resuscitation, simultaneous assessment of respiratory activity and heart rate provides the quickest and most accurate evaluation of the need for continuing resuscitation.
 - A. **Respiratory activity.** Respiratory activity is assessed by observing for chest movement. If there is no respiratory effort or the effort is poor, the infant needs respiratory assistance with positive-pressure ventilation (PPV).
 - B. **Heart rate.** The heart rate is best evaluated initially by auscultation. Palpation of the umbilical cord is less accurate. The evaluator should tap out each beat so that all team members can hear it or verbally call out the heart rate. If the heart rate is difficult to detect, then a pulse oximetry that displays a heart rate or a 3-lead electrocardiogram (ECG) should be used. A 3-lead ECG may be more reliable than a pulse oximeter in cases of poor systemic perfusion.

Table 3–1. NEWBORN RESUSCITATION EQUIPMENT CHECKLIST

Warm	<input type="checkbox"/> Preheated warmer <input type="checkbox"/> Warm towels or blankets <input type="checkbox"/> Temperature sensor <input type="checkbox"/> Plastic wrap or bag (<32 weeks) <input type="checkbox"/> Chemical warming blanket (<32 weeks) <input type="checkbox"/> Hat
Clear airway	<input type="checkbox"/> Bulb syringe <input type="checkbox"/> 10F or 12F suction catheter with 80–100 mm Hg wall suction <input type="checkbox"/> Meconium aspirator
Auscultate/electrocardiogram (ECG)	<input type="checkbox"/> Stethoscope <input type="checkbox"/> Electronic cardiac monitor (ECG) and ECG leads
Ventilate	<input type="checkbox"/> Flowmeter set at 10 L/min <input type="checkbox"/> Oxygen blender set at 21% if >35 weeks, 21%–30% if <35 weeks <input type="checkbox"/> Positive-pressure device connected to a blender (positive end-expiratory pressure and peak inspiratory pressure set) <input type="checkbox"/> Term and preterm masks <input type="checkbox"/> 8F feeding tube and syringe <input type="checkbox"/> Oral airway
Oxygenate	<input type="checkbox"/> Equipment to give free-flow oxygen <input type="checkbox"/> Pulse oximeter probe sensor and monitor <input type="checkbox"/> Target oxygen saturation table
Intubate	<input type="checkbox"/> Laryngoscope, size 0 and 1 straight blades with bright light (size 00 optional) <input type="checkbox"/> Stylet (optional) <input type="checkbox"/> Endotracheal tubes (2.5, 3.0, and 3.5) <input type="checkbox"/> End-tidal carbon dioxide detector <input type="checkbox"/> Measuring tape and/or endotracheal tube insertion depth table <input type="checkbox"/> Endotracheal tube securing device or waterproof tape and scissors <input type="checkbox"/> Laryngeal mask airway, size 1, with 5-mL syringe
Medicate	Access to: <ul style="list-style-type: none"> <input type="checkbox"/> 1 mg/10 mL (0.1 mg/mL) epinephrine <input type="checkbox"/> Normal saline <input type="checkbox"/> Code sheet for documentation <input type="checkbox"/> Supplies for placing an emergency umbilical vein catheter and giving medications <input type="checkbox"/> Intraosseous supplies (optional)

V. Neonatal resuscitation at the time of birth. The American Heart Association (AHA) and American Academy of Pediatrics' (AAP) *Textbook of Neonatal Resuscitation* (7th edition) and the Neonatal Resuscitation Program (NRP) course provide the standard of care for the resuscitation of newborns in the United States and many other countries (see Figure 3–1).

A. Initial steps of newborn care. In vigorous term and preterm newborns with intact placental circulation, delaying umbilical cord clamping for 30 to 60 seconds is recommended. In nonvigorous term and preterm newborns with intact placental circulation, it is unclear whether or not there is a benefit from delayed cord clamping. Delayed cord clamping is not recommended in cases where placental circulation is

FIGURE 3-1. The 2015 Neonatal Resuscitation Program (NRP) neonatal resuscitation flow diagram. Chicago, IL: American Heart Association and American Academy of Pediatrics Chicago; 2016.)

Table 3–2. SOME HIGH-RISK SITUATIONS IN WHICH RESUSCITATION CAN BE ANTICIPATED

High-Risk Situation	Possible Intervention Needed
Perinatal asphyxia	PPV, intubation, chest compressions, emergency umbilical catheter placement, epinephrine administration
Preterm delivery	Thermal support, CPAP, intubation, surfactant administration
Acute fetal or placental hemorrhage	Emergency umbilical catheter placement, volume expansion
Hydrops fetalis	Intubation, thoracentesis, and paracentesis
Polyhydramnios: gastrointestinal obstruction	Nasogastric suction
Congenital diaphragmatic hernia	Intubation, nasogastric suctioning
Tracheal obstruction with meconium	Endotracheal suction

CPAP, continuous positive airway pressure; PPV, positive-pressure ventilation.

not intact such as cord avulsion, placental abruption, and bleeding placenta previa or vasa previa.

After birth, the newborn should be rapidly evaluated to determine if he/she can stay with its mother or if he/she should be moved to the radiant warmer for further evaluation. A rapid evaluation can be done by answering 3 key questions:

1. **Does the baby look term?**
2. **Does the baby have good muscle tone?**
3. **Is the baby breathing or crying?**

If the answer to all 3 questions is yes, the newborn can stay with its mother to continue the newborn transition. If the answer to any of the questions is no, the newborn should be moved to the radiant warmer for further evaluation by the neonatal resuscitation team.

The following interventions should be done within approximately 60 seconds after birth (eg, “**the golden minute**”): warm the infant, clear secretions, dry and

Table 3–3. EXPECTED BIRTHWEIGHT (50TH PERCENTILE) AT 24 TO 38 WEEKS’ GESTATION

Gestational Age (weeks)	Birthweight (g)

stimulate, and provide assisted ventilation if the infant is apneic, gasping, or has a heart rate <100 beats/min.

- B. Temperature regulation.** The goal temperature for a newborn undergoing resuscitation is between 36.5°C and 37.5°C. Thermal regulation is especially important in the preterm infant. In cases where there is a concern for hypoxic-ischemic encephalopathy, normothermia should be maintained during resuscitation in order to optimize the effect of epinephrine and avoid hypothermia-induced bradycardia. **Therapeutic hypothermia should only start after the resuscitation** if clinically indicated.

Heat loss during resuscitation may be prevented by the following measures:

1. **Dry the infant thoroughly immediately after birth.**
2. **Maintain a warm delivery room.** For preterm newborns, ≤32 weeks' gestation, the temperature in the delivery room should be between 74°F and 77°F (23°C–25°C).
3. **Place the infant under a prewarmed radiant warmer.**
4. **Swaddle the infant in a warm cloth and place in skin-to-skin contact with the mother (eg, “kangaroo care”).**
5. **For preterm infants born at <32 weeks, place a thermal mattress under the newborn, cover the newborn with plastic wrap or in a clean food-grade plastic bag up to the level of the neck, and place a hat on the newborn's head.** Warmed humidified resuscitation gases also should be used. Using a temperature sensor and a warmer with a servo-control mechanism can avoid overheating.
6. **The temperature at the time of admission to the nursery or neonatal intensive care unit (NICU) should be recorded in all newborns.**

C. Ventilatory resuscitation

1. General measures

- a. Suctioning.** Oropharyngeal and nasal suctioning using either a bulb syringe or a suction catheter should be performed if the infant is not breathing, is gasping, has poor tone, has signs of airway obstruction, or is having difficulty clearing the secretions or if PPV is anticipated. The mouth should be suctioned before the nose to ensure the newborn does not aspirate something in the mouth if it gasps during nasal suctioning. **Deep suctioning of the airway with a suction catheter should be avoided.** Deep suctioning can result in reflex bradycardia due to vagal nerve stimulation.

- b. Positive-pressure ventilation. Ventilation of the lungs is the most critical action in neonatal resuscitation.** PPV is indicated in newborns who are apneic, gasping, or have a heart rate <100 beats/min. Most infants can be adequately ventilated with a bag and mask provided that the mask is the correct size with a good seal around the mouth and nose and there is an appropriate flow of gas (Figure 3–2). The positioning of the head and neck to open the airway is critical to successful PPV. The correct position of the head and neck is called the “sniffing position,” which involves 35 degrees of flexion of the neck and 15 degrees of extension of the head. A T-piece resuscitator is an alternative method to provide PPV that controls peak inspiratory pressure (PIP) and positive end-expiratory pressure (PEEP) and can deliver continuous positive airway pressure (CPAP) (Figure 3–3). When giving PPV, an initial PIP of 20 to 25 cm H₂O and PEEP of 5 cm H₂O are recommended. **During PPV, a rate of 40 to 60 breaths/min should be used to mimic the normal respiratory rate of a newborn.**

Chest wall movement is the best method to confirm effective ventilation of the lungs. The mnemonic **MR. SOPA** is used by the NRP to highlight the airway corrective steps to take when chest movement is not initially achieved with PPV. The 6 airway corrective steps of MR. SOPA include: (1) **M**ask reapplication, (2) **R**eposition the head, (3) **S**uction the airway, (4) **O**pen the mouth, (5) increase the **PIP**, and (6) place an **A**dvanced airway. In most cases,

FIGURE 3-2. Bag-and-mask ventilation of the neonate.

FIGURE 3-3. T-piece resuscitator used to provide positive-pressure ventilation with consistent peak inspiratory pressure and positive end-expiratory pressure (PEEP).

chest movement with PPV can be achieved with the completion of the first 2 steps of the pneumatic MR.SOPA.

- c. **Supplemental oxygen.** Oxygen should be used appropriately during neonatal resuscitation. Supplemental oxygen should be titrated to keep preductal (right hand) oxygen saturation in the target range (see Figure 3-1). In newborns born at ≥ 35 weeks' gestation, PPV should start with 21% oxygen. In newborns born earlier than 35 weeks' gestation, PPV can begin with 21% to 30% oxygen, depending on local practice. Supplemental oxygen can be started at 30%, and titrated as needed, in newborns who are breathing but not maintaining oxygen saturations within the target range. Oxygen should be increased to 100% with the start of chest compressions to maximize systemic oxygen delivery.
 - d. **Pulse oximetry.** Pulse oximetry should be used to guide treatment when resuscitation is anticipated, to confirm cyanosis, if supplemental oxygen is given, and if PPV is required. **The pulse oximeter probe should be placed on the right hand or wrist of the newborn** in order to measure preductal oxygen saturations. The sensor must be oriented so that it detects the transmitted red light. When applied appropriately, the pulse oximeter will accurately detect the heart rate and oxygen saturations within 1 to 2 minutes. It may be helpful to shield the pulse oximetry probe from the light or adjust the probe location if it is not providing a consistent reading.
 - e. **Continuous positive airway pressure.** CPAP is a type of respiratory support used to keep the airways open with continuous pressure. In the delivery room, CPAP is applied via a face mask using either a T-piece resuscitator or a flow-inflating bag. **CPAP cannot be given with a self-inflating bag.** CPAP is used in newborns who are spontaneously breathing with a heart rate of >100 beats/min who have either respiratory distress or low oxygen saturations. Resuscitation of a premature infant with respiratory distress syndrome is a common indication for CPAP in the delivery room.
 - f. **Endotracheal tube intubation and laryngeal mask airway.** Placement of an endotracheal tube (ETT) or laryngeal mask airway (LMA) is indicated in newborns with persistent apnea, gasping, or a heart rate ≤ 60 beats/min despite effective PPV via a face mask or when face mask ventilation is unsuccessful after completion of the MR. SOPA steps. As seen in Figure 3-1, **ETT or LMA is recommended before starting chest compressions during neonatal resuscitation.** This is because in some cases ventilation through the ETT or LMA can result in a rise in heart rate, thus avoiding the need for chest compressions.
 - i. **Endotracheal tube intubation.** The steps involved in placing an ETT are outlined in Chapter 33. Once the endotracheal tube is placed, auscultation of breath sounds and a carbon dioxide (CO_2) detector should be used to confirm tube placement in the trachea. Correct ETT depth can be found in Table 33-3 or by measuring the newborn's nasal-tragus length and adding 1 cm.
 - ii. **Laryngeal mask airway.** Placement of an LMA is indicated when tracheal intubation is not feasible due to lack of trained personnel or not successful after a few attempts. LMAs are recommended for the resuscitation of newborns ≥ 34 weeks' gestation and weighing ≥ 2000 g. LMAs have not been evaluated during chest compressions or the administration of emergency medications. However, it is reasonable to start compressions with the LMA in place if intubation is not feasible or has been unsuccessful after several attempts. See Chapter 37 for details on LMA placement.
2. **Specific resuscitation circumstances**
 - a. **Preparation of the parents for resuscitation.** Initial resuscitation usually occurs in the delivery room with 1 or both parents present. It is helpful to

prepare the parents in advance, if possible. Describe what will be done, who will be present, who will explain what is happening, where the resuscitation will take place, where the father should stand, why crying may not be heard, and where the infant will be taken after stabilization. Details on the process of counseling parents before a high-risk delivery takes place are outlined in Chapter 55.

- b. Meconium-stained amniotic fluid (MSAF).** Infants born with MSAF may aspirate meconium in utero, during delivery, or immediately after birth. The sickest of these infants have usually aspirated in utero and generally also have reactive pulmonary vasoconstriction. In the past, the AAP and the AHA recommended endotracheal suctioning in cases of MSAF when the infant was not vigorous at birth. However, due to insufficient evidence, **routine endotracheal suctioning of nonvigorous newborns with MSAF is no longer recommended.** Management depends on whether the infant is vigorous or nonvigorous.
- i. Vigorous.** If the infant is vigorous (good respiratory effort and muscle tone), simply use a bulb syringe to clear meconium-stained secretions from the mouth (first) and nose. The infant can stay with the mother to receive newborn care.
 - ii. Nonvigorous.** If the infant is nonvigorous (depressed respirations and poor muscle tone), take the infant to the radiant warmer. Use a bulb syringe to clear meconium-stained secretions from the mouth (first) and the nose. If the infant is apneic, gasping, or has a heart rate <100 beats/min, begin PPV. Routine endotracheal intubation is not recommended for tracheal suction. Endotracheal suctioning should be considered in infants born through MSAF if there is a concern for **tracheal obstruction** with meconium. Meconium aspiration is discussed in detail in Chapter 106.
- D. Perinatal asphyxia.** If the infant is nonvigorous (poor tone and not crying), a brief period of tactile stimulation by rubbing the back and/or tapping the soles of the feet can be used, followed immediately by evaluating respirations and heart rate. **A term infant with a heart rate of <100 beats/min or no spontaneous respiratory activity requires PPV.** PPV should be initiated at 40 to 60 breaths/min, and chest wall movement should be used to confirm effective ventilation of the lungs. If mask ventilation is ineffective at moving the chest, the MR, SOPA steps should be completed. If mask ventilation remains ineffective or prolonged PPV is necessary, endotracheal intubation or placement of an LMA is indicated (see Chapters 33 and 37).
- E. Preterm newborn.** Preterm infants often require immediate lung expansion in the delivery room. Although high PIP may initially be needed to expand the lungs, as soon as the lungs “open up,” the pressure should be decreased if the clinical course permits. CPAP administered with a T-piece resuscitator or a flow-inflating bag-and-mask system, providing a pressure of 4 to 6 cm H₂O, may be sufficient to expand the lungs of a preterm infant and improve ventilation. Because many preterm infants can be supported with CPAP alone and do not require intubation or mechanical ventilation, routine use of **prophylactic surfactant for respiratory distress syndrome is not recommended** (see Chapters 9 and 117).
- F. In extremely premature infants** who require intubation at delivery because of severe respiratory distress syndrome, surfactant should be given after initial stabilization. Surfactant administration is not a component of the initial resuscitation and should be delayed until the newborn has a stable heart rate. The surfactant is administered via the ETT and distributed into the lungs using PPV breaths. Prior to giving surfactant, appropriate ETT location should be confirmed by auscultation of equal bilateral breath sounds or chest x-ray. In some cases, the ETT can be removed immediately after surfactant is given using a technique called **INSURE** (INtubate, SURfactant, and Extubate). After the extubation, these infants should

be placed on CPAP for continued respiratory support. In premature infants initially maintained on CPAP, surfactant can be given if the infant fails CPAP (see Chapters 13 and 117).

- G. Opioid-exposed newborn.** Newborns of mothers who have recently received opioid analgesics or who have used illicit opioids may have respiratory depression and apnea at birth. **The narcotic antagonist naloxone is not recommended to treat apnea in opioid-exposed newborns.** Some studies have linked naloxone use in newborns to seizures, pulmonary edema, and cardiac arrest. The treatment for a newborn with respiratory depression from opioids is respiratory support with PPV and possible LMA placement or endotracheal intubation if the apnea is prolonged.
- H. Air leak or pleural effusion.** A collection of air or fluid in the chest cavity of a newborn can result in severe respiratory distress and persistent bradycardia. Rapid identification of a pneumothorax or pleural effusions is key to effective treatment. In most cases of pneumothorax, there is no time to obtain a chest x-ray to confirm the diagnosis. Therefore, clinical exam findings such as auscultation of decreased breath sounds and transillumination are the primary means of diagnosis. In most cases of pleural effusion, the issue has been identified prior to birth by prenatal ultrasound. In these cases, the delivery team should be prepared to perform needle thoracentesis for emergency air or fluid evacuation. (See Chapter 31.)
- I. Airway obstruction.** Obstruction of the airway with meconium, vernix, mucus, or other materials can make it impossible to provide effective mask ventilation. Airway obstruction should be suspected in newborns who do not have chest wall movement with PPV after completing the first 5 steps of MR. SOPA. Clearance of the airway can be performed by placing an ETT in the trachea and using a meconium aspirator to suction the airway. This is often more effective than attempting to suction the airway with a bulb syringe or suction catheter (8–10F) since the ETT diameter is larger and more suction pressure can be provided. A negative pressure of 80 to 100 mm Hg is recommended in such cases. (See Chapters 33 and 106.)
- J. Hypovolemic shock.** Hypovolemic shock at birth can result from a variety of peripartum and intrapartum causes including fetal-maternal hemorrhage, bleeding vasa previa, placental laceration, umbilical cord prolapse, tight nuchal cord, and umbilical cord avulsion. Newborns with hypovolemic shock may have a persistent low heart rate that does not improve with resuscitative efforts. Clinical signs of hypovolemic shock include pale skin, delayed capillary refill, and weak pulses. Treatment of hypovolemic shock in the delivery room is placement of an emergency umbilical catheter and volume expansion with 0.9% NaCl (normal saline) or emergency, non-cross-matched, type-O, Rh-negative packed red blood cells in aliquots of 10 mL/kg given over 5 to 10 minutes. (See Chapter 70.)
- VI. Cardiac resuscitation.** During delivery room resuscitation, efforts should be directed first to assisting ventilation because in the vast majority of cases that is all that is needed.
- A. Chest compressions.** **If the heart rate continues to be <60 beats/min after 30 seconds of effective positive-pressure ventilation that moves the chest, chest compression should be initiated.** During neonatal chest compressions, the thumbs are placed on the lower third of the sternum, between the xiphoid and the line drawn between the nipples (Figure 3–4). The sternum is compressed a third of the anteroposterior diameter of the chest at a regular rate of 90 compressions/min while ventilating the infant at 30 breaths/min, synchronized such that every 3 compressions are followed by 1 breath. Chest compression should be synchronized with ventilations in a 3:1 ratio, regardless of the presence of an advanced airway. The compressor can administer chest compressions from the head of the newborn in order to allow another provider space to place an emergency umbilical catheter. The preferred method for assessing heart rate after chest compressions

FIGURE 3-4. Technique for chest compressions in the neonate. Note the position of the thumbs on the lower third of the sternum, between the xiphoid and the line drawn between the nipples.

have started is a 3-lead ECG. **The heart rate should be checked every 60 seconds during chest compressions.** Chest compression should be discontinued when the heart rate is >60 beats/min.

B. Stopping resuscitation. An infant with no heart rate at birth who does not respond to resuscitation efforts may be considered stillborn. Prolonged resuscitative efforts are a matter for ethical consideration. The AAP and AHA state that **if there is no heart rate after 10 minutes of adequate resuscitation efforts, discontinuation of resuscitation efforts may be reasonable.** However, the decision to continue or discontinue resuscitative efforts must be individualized.

VII. Drugs used in resuscitation. (See also Emergency Medications and Therapy for Neonates, inside the front and back covers, and Chapter 155 for more details.) According to the NRP, 2 medications can be used during neonatal resuscitation: epinephrine and normal saline. Epinephrine is recommended if the heart rate remains <60 beats/min despite adequate ventilation and chest compressions for a minimum of 30 seconds. Volume expansion is recommended if there is a concern for acute hypovolemia or hypovolemic shock.

A. Route of administration

1. **The umbilical vein** is the preferred route for drug administration in the delivery room. A 3.5F or 5F umbilical catheter should be inserted until blood is easily withdrawn (usually 2–4 cm); this shallow placement avoids inadvertent placement in the hepatic or portal vein. Umbilical vein catheterization is discussed in Chapter 48.
2. **The endotracheal tube** is an alternative route for administration of epinephrine in the delivery room and can be used while vascular access is being obtained. Absorption of medication via the endotracheal route is variable. If the first dose of epinephrine is given through the ETT, a repeat intravenous dose should be given immediately after vascular access is established.
3. **Alternate routes** of administration include **intraosseous needle** (see Chapter 45) and **peripheral venous catheter** (see Chapter 47).

B. Medications used in neonatal resuscitation

1. **Epinephrine.** Epinephrine may be necessary during resuscitation when adequate ventilation, oxygenation, and chest compression have failed and the heart rate is still <60 beats/min. The primary mechanism of action of epinephrine during cardiac arrest is thought to be via peripheral vasoconstriction resulting in increased afterload to the heart and retrograde filling of the coronary arteries. **The dose of epinephrine is 0.01 to 0.03 mg/kg (0.1–0.3 mL/kg) of 1:10,000 (1 mg/10 mL) solution given intravenously, or 0.05 to 0.1 mg/kg (0.5–1 mL/kg) given by the ETT.** This may be repeated every 3 to 5 minutes.
2. **Volume expanders.** Hypovolemia should be suspected in an infant requiring resuscitation when there is evidence of acute blood loss with pallor, poor peripheral pulses, long capillary refill times, or poor response to resuscitative efforts. **Appropriate volume expanders include normal saline or uncrossmatched type O-negative packed red blood cells.** Volume expanders are given in 10-mL/kg doses over 5 to 10 minutes.
3. **Sodium bicarbonate is no longer part of the NRP treatment algorithm.** This is due to a concern that CO₂ is produced when sodium bicarbonate mixes with acid in the blood and that the excess CO₂ may worsen acidosis in infants with impaired ventilation. In addition, rapid administration of sodium bicarbonate has been linked to intraventricular hemorrhage in preterm newborns. **Sodium bicarbonate is still part of the European and UK neonatal resuscitation guidelines** because there is some evidence that using alkali to reverse intracardiac acidosis may sometimes restore the heart rate when all else fails.

VIII. Newborn resuscitation ethics. A consistent and coordinated approach by the obstetric and neonatal teams with the prenatal involvement of parents is important in making decisions regarding potentially withholding resuscitation efforts. Neonatal resuscitation is not ethical and should not be offered in cases where there is no chance for survival. Examples of such cases include birth at <22 weeks' gestation and some congenital malformations and chromosomal anomalies. Neonatal resuscitation may be offered in cases where there is a high risk of morbidity and survival is uncertain. In these cases, prenatal counseling regarding resuscitation should include the parents, and the parents' desires should determine the resuscitation plan. Examples of such cases include birth between 22 and 24 weeks' gestation and some chromosomal anomalies and congenital malformations. (See Chapter 23.)

IX. Neonatal resuscitation after the time of birth. Neonatal resuscitation guidelines taught in the NRP course (see Figure 3–1) apply to newborns at the time of birth and can also be used during the initial hospital stay in the NICU. Neonates in the NICU, however, have a variety of complex medical conditions that place them at risk for cardiopulmonary arrest from a variety of etiologies not commonly encountered in the delivery room. This has prompted some to question whether Pediatric Advanced Life Support (PALS) guidelines from the AHA should be followed in the NICU in

some cases. One of the key differences between neonatal and pediatric resuscitation guidelines is the chest compression-to-ventilation ratio (neonatal guidelines = 3:1 coordinated compressions to ventilations, versus pediatric guidelines = 15:2 coordinated compressions to ventilations during 2-person resuscitation without an advanced airway, and continuous chest compressions at 100–120 compressions per minute without pausing for ventilations when an advanced airway is present). Because there are no scientific data to resolve this issue, according to the AHA, the resuscitation approach and compression-to-ventilation ratio most commonly used in a provider's practice environment should be used for intubated term or near-term newborns within the first month of life. PALS compression-to-ventilation ratio should be used for intubated newborns who require resuscitation in nonneonatal settings (eg, prehospital, emergency department, and pediatric intensive care unit [PICU]) and those with a cardiac etiology of arrest, regardless of location. Investigations of resuscitation practices in the NICU, PICU, and cardiac intensive care unit (CICU) indicate that the resuscitation guidelines used are primarily determined by patient location rather than age or arrest etiology, with NRP guidelines followed in the NICU and PALS guidelines in the PICU and CICU. Some authors have proposed the creation of advanced neonatal resuscitation guidelines that apply to the special resuscitation needs of newborns in the NICU.

- X. **Postresuscitation debriefing.** Postresuscitation debriefing is a facilitated discussion of a clinical event focused on learning and performance improvement. Debriefing enhances communication and teamwork and reduces the frequency of equipment-related problems. Both the AHA and NRP recommend postresuscitation debriefing as standard practice. The structure of the debriefing conversation typically follows the **Gather, Analyze, Summarize** approach, with the discussion focusing on the key behavioral skills of neonatal resuscitation. Using this structure, the facilitator starts the conversation with a team member or the team leader, giving a summary of the clinical event in order to establish a shared mental model of what happened (**gather**). The team then self-examines their performance (**analyze**). During the analysis phase, actual performance is compared to ideal performance using the **plus-delta technique**, which focuses on what went well (**plus**) and what could be improved (**delta**). The debriefing ends with a summary of what should be done differently in the future and identification of issues that require further follow-up (**summarize**). Developing a culture that supports postresuscitation debriefing is essential for neonatal care teams to improve neonatal resuscitation performance and clinical outcomes.
- XI. **Postresuscitation care.** Infants who require resuscitation at birth should be admitted to the NICU for postresuscitation care. Two important considerations during this period are glucose control and therapeutic hypothermia.
 - A. **Glucose regulation.** Glucose levels should be maintained within an acceptable range following resuscitation. To prevent hypoglycemia, intravenous glucose administration with dextrose 10% in water or parenteral nutrition should be started as soon as possible after the resuscitation. Glucose levels should be checked frequently following resuscitation to monitor for hypo- and hyperglycemia. For additional information on glucose control, see Chapters 64 and 67.
 - B. **Therapeutic hypothermia.** Therapeutic hypothermia should be started after resuscitation in newborns >36 weeks' gestation with clinical and laboratory evidence of moderate to severe hypoxic ischemic encephalopathy (HIE). In resource-limited areas, this may require transport of the infant to another center. **When initiating therapeutic hypothermia for HIE, it is critical to wait to start cooling until after the resuscitation is complete.** Starting hypothermia during the resuscitation is counterproductive. Hypothermia induces bradycardia and will make it more difficult to achieve a normal heart rate and return of spontaneous circulation. For additional information on therapeutic hypothermia, see Chapter 43.

4 Neonatal Transport

Many infants are born in a location where definitive care is not available for their condition. These infants subsequently require transportation to a higher level of care. The conditions requiring transport range from prematurity or hyperbilirubinemia to surgical emergencies, need for extracorporeal membrane oxygenation, or therapeutic hypothermia for hypoxic ischemic encephalopathy. The transport of neonates requires specialized providers and equipment in defined neonatal teams (NNTs). There are many different configurations for transport teams. Of 956 neonatal intensive care units (NICUs) identified by Karlsen et al, 398 offered neonatal transport services. Of 335 respondents in this study, 68% were unit-based teams, and the remainder were dedicated teams, either stand alone or hospital affiliated.

- I. Resource mobilization.** Regardless of team type or configuration, efforts should be made to streamline the dispatch process and improve ease of use for referring facilities and physicians. A single contact number for referring facilities or physicians to arrange for transport of ill neonates as well as to obtain consultation when necessary allows open communication as well as rapid mobilization of the NNT.

Timing of NNT mobilization is an important factor to consider. Research has demonstrated that effective resuscitation and stabilization of critically ill neonates is most successful when performed by specially trained retrieval teams. Rapid mobilization of the NNT for high-risk deliveries may not only impact neonatal morbidity and mortality, but also allow for continuous quality improvement and education of local hospital staff through active involvement in the resuscitation and stabilization. Regardless of team type, many variables have to be considered.

A. Team composition.

- 1. Teams usually have 2 to 4 providers.**
- 2. State neonatal transport team requirements can vary.** As an example, the state of Maryland requires 2 licensed providers (physicians, nurse practitioners, nurses, respiratory therapists, paramedics) and 1 emergency medical technician to operate the vehicle.
- 3. Neonatal teams are most often an interdisciplinary collaborative practice comprised of a registered nurse working with another nurse, respiratory care provider, or paramedic.** Some teams incorporate physicians (eg, pediatric residents, neonatal fellows, or neonatologists) or advanced practice nurses (eg, neonatal nurse practitioners [NNPs]) routinely or based on the perceived acuity of the infant being transported. Studies have found no difference in mortality or long-term outcomes between physician-nurse and nurse-only teams and have shown that nonphysician personnel can be trained to provide equally safe care and similar outcomes.

- B. Supervision and standard of care.** Medical oversight of emergency medical services (EMS) and interfacility transport is contingent upon federal, state, and local regulations. A transport services typically must have a medical director who is responsible for the overall care provided by the team. Because neonatal transport is a specialized form of interfacility transport, typically service medical directors work closely with a neonatologist to ensure quality care. Specialty care physicians may provide indirect (offline) medical consultation in the form of protocol development and quality case reviews as well as direct (online) consultation in the form of telephone or radio orders.

NNTs should have standing orders in the form of protocols or guidelines to facilitate the provision of care until online medical control can be established. Protocols for the management of emergencies (eg, airway compromise or respiratory failure, shock) should be established. Following emergent stabilization, NNTs traditionally established online medical control to discuss the birth history, hospital

course, recent results, assessment findings, and their plan of care. Medical command physicians may ask and answer questions and help establish an ongoing plan of care. The receiving hospital team is often provided an updated estimated time of arrival and apprised of any changes in the neonate's needs (eg, drips/ventilator requirements).

C. Team member training.

1. **Transport team members have various required certifications.** The most commonly required certifications are Basic Life Support (BLS) and Neonatal Resuscitation (NRP), followed by the S.T.A.B.L.E. program. Providers of transport services usually require some, but not always all, of the following:

a. **Basic Life Support**

b. **Neonatal Resuscitation**

c. **The S.T.A.B.L.E. program.**

i. **S.T.A.B.L.E. is a widely implemented education program** that focuses exclusively on the postresuscitation/pretransport stabilization care of sick infants.

ii. **Based on a mnemonic to optimize learning, retention, and recall of information**, S.T.A.B.L.E. stands for Sugar, Temperature, Airway, Blood pressure, Lab work, and Emotional support. A seventh module, Quality Improvement, stresses the responsibility of improving and evaluating care provided to sick infants (<https://stableprogram.org/>).

d. **Pediatric Advanced life Support (PALS)**

e. **Advanced Cardiac Life Support (ACLS)**

2. **Scope of practice.**

a. **After receiving specialized training and release, transport team members often provide care outside the traditional in-patient scope of practice.** NNT team member scope of practice is defined by the medical director within the constraints of federal, state, and local regulations.

b. **Transport team members must be able to provide safe and effective care in the field.** A method for establishing initial and ongoing clinical and procedural competency is essential. Training typically includes clinical experiences in the NICU as well as skills labs and clinical simulation sessions.

3. **Quality improvement.** All transports have to have individuals responsible for quality improvement. Some institutions and teams adhere to publicly available metrics; others develop their own.

D. Mode of transportation.

1. **This may include ground (ambulance) transportation**, helicopters, or fixed-wing aircraft.

2. **Mode of transportation may be decided by distance, severity of illness**, regional differences, and availability.

a. **Dedicated teams are more likely to use all 3 modes.**

b. **Ground transport is more likely to be used for transports <100 miles;** helicopters are more likely used for 1-way transports of 100 to 200 miles.

II. **Care of the infant and family.** It is optimal for the transport team to have a pretransport briefing prior to departure or while in transit to the referring hospital to establish a plan of care based on known information and ensure that the correct equipment is brought for the transport if it does not regularly reside in the ambulance. It is important for those involved to remember that situations may change and the infant may present differently once on scene.

The transport teams must be self-sufficient, with all medications and equipment required for the initiation of definitive care for the infant's condition. Although neonatal transport does not follow the traditional "swoop and scoop" transport methodology of adult EMS services and initial stabilization of the neonate is expected, care should be taken not to excessively prolong scene time because this increases the time interval to definitive care for the neonate.

It is important for the transport team to communicate with the family regarding the transport, the hospital they are going to transport the neonate to, and the neonate's current condition. It is very important to provide emotional support for parents and families during this stressful time. It is also important for the transport team to allow parents to see and touch their infant prior to departure and allow pictures as conditions allow. On arrival after transport, the transport team should notify parents of their arrival. Transport team members should refrain from stating definitive outcomes, plans of care, consults, or procedures that will occur once at the tertiary care center because this may result in unrealistic expectations in families.

- III. Treatment and transport consent.** Consent for transport is typically obtained by the referring hospital when the referring physician informs the family of the need to transport their infant. NNTs should ideally obtain written consent for treatment during the actual transport as well as permission to disclose obtained health information. Transport should not be delayed to obtain firsthand consent if the infant requires emergent care.
- IV. Care of the neonate.**
- A. On arrival,** the team should make the decision as to whether the patient requires any emergency treatment (eg, ongoing cardiopulmonary resuscitation) and tend to these needs.
 - B. If no emergency treatment is needed,** the team should obtain a thorough history from the personnel (usually the physician or NNP) at the referring facility.
 - C. Proceed to examination of the neonate;** obtain vital signs (temperature, respiratory rate, heart rate, blood pressure, oxygen saturation [SpO_2]), weight, and gestational age, and determine the plan of care.
 - D. Check any pertinent laboratory tests** (blood glucose, hematocrit, arterial blood gas levels, any other tests).
 - E. Check ventilation and oxygenation** after accessing pulse oximetry and arterial blood gases.
 - F. Make sure the infant has a line** (intravenous, umbilical venous, or arterial) for fluids or possible emergency medications.
 - G. Once the infant is stable and almost ready to go,** discuss the infant's condition with the parents, answer any questions, obtain signed permits, and reassure parents.
 - H. Obtain copies of the mother's and infant's charts,** any radiographs, and any other copies of studies.
 - I. It is helpful to have protocols in place to aid in decision making and care provision** that are consistent with that of the tertiary care center to which the neonate will be transported. The transport team should contact their medical command physician to give a report and for any help in decision making or planning care that may be needed, as well as notify the receiving hospital of estimated arrival time and any drip or ventilator requirements or other needs that may be needed on arrival.
 - J. Once the infant is in the transport incubator,** efforts should be made to limit opening the incubator on transport due to potential for temperature loss.
- V. Management of some common neonatal transport diagnoses**
- A. Choanal atresia**
 - 1. Being obligate nasal breathers, newborns with choanal atresia** will require some intervention.
 - 2. Begin with placing an oral airway.** Consider endotracheal intubation if the oral airway is not sufficient to maintain saturations and respiratory status when calm.
 - B. Pierre-Robin sequence**
 - 1. Infants present with varying degrees of retro-/micrognathia.**
 - 2. Prone positioning is the first therapy.** Oral airway may be needed.
 - 3. If intubation is required because previously mentioned therapies have failed,** this would be considered a difficult airway and would be a good use of laryngeal mask airway.

C. Esophageal atresia/intestinal obstruction

1. **Place sump catheter** to suction in proximal esophageal pouch if esophageal atresia or in stomach if more distal obstruction.
2. **Do not place regular feeding tube** to suction due to the risk of this tubing getting attached to gastric or esophageal mucosa and forming an ulcer, erosion, or perforation.

D. Persistent pulmonary hypertension (PPHN)

1. PPHN is associated with hypoxemic ischemic encephalopathy, meconium aspiration syndrome, sepsis, congenital diaphragmatic hernia, premature ductal closure, pulmonary hypoplasia, and acidosis.
2. **Obtain pre- and postductal oxygen saturations.** A >10% split with lower postductal saturations is consistent with PPHN.
3. **Optimize ventilation and oxygenation.**
4. **Follow medical command** for individual NICU protocols and oxygenation/ blood gas and blood pressure goals.
5. **Be prepared to start inhaled nitric oxide (iNO).**

E. Congenital diaphragmatic hernia

1. **Mask ventilation of these infants should be avoided** because this will distend the bowels within the chest cavity.
2. **Infants should be intubated**, ideally prior to arrival of the transport team.
3. **Attempt to place a catheter** to suction in stomach and to decompress bowels.
4. **These infants are at high risk for persistent pulmonary hypertension and pneumothorax.** Be prepared to initiate iNO or needle decompression/chest tube placement.

F. Open lesions such as gastroschisis or myelomeningocele.

These should be kept moist and wrapped per protocol of the receiving institution to minimize insensible fluid losses, but contamination from fecal matter should be avoided.

VI. Initiation of definitive therapies on transport.

Some conditions for which a neonate is being transported to a higher level of care are amenable to treatment prior to and during transport, in this way accelerating the provision of definitive care.

A. Pneumothorax

1. **The providers at the referring facility will probably have already needle decompressed a tension pneumothorax.** If there is reaccumulation, the team must be prepared to insert a chest tube.
2. **A nontension pneumothorax in an otherwise stable neonate may be followed clinically if the patient is being transported by ground.** However, if the neonate is being flown, flight physiology must be taken into account.
3. **A chest tube may be required in a patient with a clinically insignificant pneumothorax** because the volume of the pneumothorax increases by an estimated 12% to 16% for every 500-ft change in altitude. Many programs use a 20% to 30% pneumothorax volume as a cutoff for requiring decompression prior to flight, and medical command should be consulted in these cases.

B. Sepsis

1. **Antibiotics** should be part of the medication pack of any neonatal transport team.
2. **After cultures are drawn, antibiotics should be started** in any cases of suspected infection. Time to administration of antibiotics is significantly shorter in this case than when antibiotics are administered on return, thereby improving outcomes.

C. Respiratory distress syndrome

1. **Premature infants with respiratory distress syndrome** benefit from earlier surfactant administration.
2. **Neonatal transport teams should carry surfactant** and be prepared to administer it per recommended dose.

3. **If the infant is already intubated, correct placement of an endotracheal tube should be verified** to avoid 1-sided delivery of surfactant, and if the transport team intubates the infant, a chest x-ray should be obtained prior to surfactant administration.
 4. **Ventilator pressures and settings may need to be weaned quickly** after surfactant administration to accommodate improved compliance.
- D. **Prostaglandin E (PGE) administration for ductal-dependent congenital heart disease**
1. **The team must be able to initiate or continue PGEs on transport.**
 2. **If the team initiates PGEs, one of the side effects is apnea.** This is most likely to occur in premature infants, when PGEs are started at a large dose, and within the first 30 minutes of initiation.
 3. **It is no longer recommended to intubate an infant on PGEs only for transport or for PGE-associated apnea.** Current recommendations are to give a bolus dose of caffeine 20 mg/kg intravenously (IV) if apnea is a concern or if the infant is to be transported immediately after initiation of PGE.
 4. **A second access point must be in place before departure if PGEs** are being administered via peripheral IV.
- E. **Hyperbilirubinemia**
1. **A biliblanket should be available to the transport team** if it is not owned by the team and kept on the ambulance, and it should be brought on all transports for hyperbilirubinemia.
 2. **Research has shown that phototherapy started on transport,** even for a relatively short duration, decreases need for exchange transfusion.
 3. **Maintenance IV fluids should be used in conjunction with phototherapy.**
- F. **Therapeutic hypothermia**
1. **Once it is determined that a neonate qualifies for therapeutic hypothermia,** referring physicians can be encouraged to start passive cooling, but caution must be used and temperatures closely monitored because there is a risk of overcooling even with passive cooling (ie, turning off temperature support, not surrounding infants with ice packs).
 2. **Once the transport team has arrived, active cooling can begin, or the team can continue passive cooling.** This decision should be institution or team based.
 3. **Benefits of active cooling are many,** whether with servo-controlled cooling equipment or manipulation of transport incubator temperatures with continuous temperature measurements. Neonates with active cooling on transport were more likely to reach the destination at the correct temperature for therapeutic hypothermia, and the temperature range at which they arrived was narrower. As therapeutic hypothermia within 6 hours is the goal, starting cooling on transport increases the likelihood that the correct temperature is reached within the time interval, especially in more rural areas where both distances and time to definitive care are greater than in more urban settings.
- G. **Hypoglycemia.** If >12.5% dextrose is anticipated, the patient should have central access, or the team should be prepared to insert an umbilical vein catheter due to the risk of electrolyte disturbances if an increased infusion rate is used instead of a higher dextrose concentration.
- VII. **Special neonatal transport considerations**
- A. **Care must be taken to secure the neonate in the transport incubator,** using commercial securing devices so that the infant is not injured during the transport.
 - B. **The greatest cerebral pressure changes can be seen with acceleration and deceleration.** Care must be taken with all infants, but especially with all preterm infants and infants with extremely low birthweight. Exertional forces are greatest in takeoff and landing during rotor transport, but otherwise remain stable and low, whereas exertional forces occur with all decelerations and accelerations in ground transport, which may impact choice of mode.

- C. **Temperature must be carefully maintained, and excessive insensitve losses should be avoided.** It is helpful to wrap neonates <1000 g in clear plastic film, exposing only those areas (mouth/nose/IV access) required for care. Incubator temperature should be set appropriately for the weight of the baby, and hyperthermia should be avoided at all costs.
- D. **Rotor wing transport is generally considered faster.** However, it can potentially limit the provision of emergency care or procedures during flight due to space and safety concerns.
- E. **Mixed modal transport can be considered if the greatest imperative is providing needed equipment and skills to a bedside.** In these cases, transport the team via rotor wing to speed stabilization of the neonate. Then the team and patient may be able to safely return by ground, allowing greater flexibility for care and procedures in route.
- F. **Chemical warming mattresses are designed to be started at normal room temperature.** If the mattresses are being kept in a cold environment, they will not achieve optimal temperature and will actually lead to heat loss in the infant, whereas thermal burns can occur if they are stored in a warmer or hot environment and subsequently overheat when started.
- G. **When using helicopter or fixed-wing transport, it is important to provide ear protection** because noise levels can exceed 85 dB.
- H. **Special consideration must be given to decompressing and venting the stomach,** with placement of nasogastric or orogastric tube prior to departure.
- I. **The transport mode should be discussed** in neonates with conditions with contained air, including but not limited to pneumothorax, pneumoperitoneum, anal atresia without fistula, and tracheoesophageal fistula with anal atresia, due to pressure changes in flight because aircraft (rotor and fixed) are not pressurized to sea level, and trapped air could expand and compromise the neonate. Also consider the hypoxemic patient or those with significant oxygen needs because FiO_2 may need to be increased to compensate for altitude.

VIII. Hand-off of care

- A. **If there is no emergency to move the patient on arrival to the NICU,** a complete set of vital signs including temperature should be performed prior to moving the patient, and a thorough hand-off of care should be given to the receiving team.
- B. **The team should be using the same hand-off procedures, medication concentrations, and equipment** as their base NICU to minimize errors.
- C. **The team should call the parents** to notify them of the safe arrival of their neonate.

5 The Golden Hour

First described in the field of emergency medicine, the “golden hour” refers to the first 60 minutes following an injury. It was discovered that the sooner trauma patients received definitive care, the better their outcomes. In neonatology, the term “golden hour” refers to the initial 60 minutes of an infant’s life following delivery when a critical transition period of adaptation takes place. Particularly for high-risk neonates, optimizing thermoregulation, glycemic control, cardiorespiratory support, and nutrition during this time is critical to achieving successful long-term outcomes. The golden hour provides opportunity for an evidence-based standardized approach to achieve these goals. Evidence shows that implementation of a golden hour protocol decreases mortality as well as the incidence of hypothermia, chronic lung disease, intraventricular hemorrhage, and retinopathy of prematurity.

I. Golden hour for the term infant

A. The golden hour protocol for a term newborn is composed of delayed cord clamping, maintaining thermoregulation, and the initiation of early breast feeding.

B. Counseling/team briefing

- 1. If there is risk a term newborn will require interventions immediately after birth**, the parents should be counseled and the management plan explained prior to delivery.
- 2. As with all neonatal resuscitations, clear roles and responsibilities should be established** among the team members and all resuscitation equipment prepared.
- 3. For an anticipated admission to the neonatal intensive care unit (NICU)**, staff should be notified.

C. Delayed cord clamping (DCC)

- 1. Per American College of Obstetricians and Gynecologists (ACOG) and Neonatal Resuscitation Program (NRP)**, clamping of the umbilical cord should be done after at least 30 to 60 seconds. World Health Organization (WHO) guidelines are 1 to 3 minutes after birth.
- 2. Delayed clamping for 1 minute** leads to a transfer of approximately 80 mL of extra blood to the term neonate.
- 3. NRP recommends using DCC for all term infants** who do not require resuscitation after birth.
- 4. Benefits include higher hemoglobin at 2 to 12 months of age** and an increase in total body iron during the first year of life.
- 5. DCC may increase the risk for jaundice** and need for phototherapy.
- 6. Umbilical cord milking is an alternative to DCC** but currently not recommended by the NRP.

D. Preventing hypothermia

- 1. Normal temperature** in a newborn is between 36.5°C and 37.5°C.
- 2. Neonatal hypothermia** has been shown to increase neonatal mortality.
- 3. The highest risk of neonatal hypothermia** is immediately after birth due to the difference in in utero and environmental temperature.
- 4. Interventions to prevent hypothermia** include raising the temperature of the delivery room, using a radiant warmer, and early initiation of skin-to-skin contact.
 - a. The newborn should be received in warm blankets** and skin-to-skin contact should be started immediately if no resuscitation is required.
 - b. The delivery room temperature** should be kept between 23°C and 26°C (74°F and 77°F).

E. Respiratory support

1. Oxygen support and pulse oximeter

- When resuscitation is needed**, a pulse oximeter should be placed on the right upper hand or wrist.
- Resuscitation of a term newborn** should start in room air (21% oxygen) and be titrated to achieve the targeted saturation range per NRP.
- If positive pressure is needed**, use T-piece resuscitator to provide consistent peak inspiratory pressure (PIP) and positive end-expiratory pressure (PEEP).
- Confirm endotracheal tube placement** by carbon dioxide (CO₂) detector.

F. Initiation of breast feeding

- Well term newborns** should initiate breast feeding as soon as possible.
- The Baby Friendly Hospital Initiative** recommends immediate skin-to-skin contact and breast-feeding initiation within the first half hour after birth.
- Skin-to-skin contact** is associated with increased breast-feeding rates and duration.

G. Preventing hypoglycemia

- Newborns at greatest risk for hypoglycemia** after birth include large for gestational age infants, infants of diabetic mothers, small for gestational age infants, and infants with intrauterine growth restriction.
- These infants should be monitored for hypoglycemia** with regular blood sugar measurement for the first 12 to 24 hours.

H. Therapeutic hypothermia for asphyxia (see Chapter 43)

- This is a standard of care** for asphyxiated term and near-term newborns with moderate to severe neonatal encephalopathy.
- Should be started within 6 hours of birth** and continued for 72 hours followed by gradual rewarming.
- Therapeutic hypothermia** reduces mortality and improves neurodevelopmental outcomes.
- Turn off radiant warmer and monitor temperature closely** for neonates who potentially need therapeutic hypothermia.

II. Golden hour for the preterm infant

A. Counseling/team briefing

- Plan of management and expected complications** should be explained to the parents prior to the birth of a preterm neonate.
- The chance that a preterm infant will require resuscitation** is significantly higher than that of a full-term infant. An experienced and skilled resuscitation team should be present for the delivery of very low birth weight (VLBW) and extremely low birth weight (ELBW) infants. Roles should be assigned to the members of the resuscitation team by the team leader. Equipment should be prepared. The use of preresuscitation check lists that include all the necessary equipment simplifies and streamlines preparation.

B. Delayed cord clamping (DCC)

- ACOG and NRP recommend clamping of the umbilical cord after at least 30 to 60 seconds.** WHO guidelines are 1 to 3 minutes after birth.
- NRP recommends using DCC for all preterm infants** who do not require resuscitation after birth.
- DCC is associated with** less need for vasopressors, lower blood transfusions for anemia, less intraventricular hemorrhage (IVH), and lower risk of necrotizing enterocolitis and sepsis.
- Umbilical cord milking** may be an alternative to DCC, but the current NRP guidelines do not support its use.

C. Preventing hypothermia

- Hypothermia** in the neonate refers to temperature <36.5°C.
- VLBW infants** are prone to hypothermia given their large body surface area, poorly developed skin barrier, and thin layer of subcutaneous fat compared to that of term infants.

3. **Admission temperature** is a strong predictor of neonatal mortality.
 - a. **Hypothermia** leads to increase in mortality, IVH, late-onset sepsis, hypoglycemia, and respiratory distress.
 - b. **Every 1°C below 36°C on admission temperature** is associated with a 28% increase in mortality risk.
 4. **The delivery room temperature** should be kept between 23°C and 25°C (74°F and 77°F).
 5. **Preheat the radiant warmer** well before the baby is born.
 6. **Polyethylene wrap**
 - a. **Immediately after birth, the neonate should be covered** without drying.
 - b. **Keep the baby fully covered during resuscitation and stabilization.**
 - c. **If umbilical venous catheter is required**, cut a small hole in the plastic and pull the umbilical cord. Do not uncover the baby to place umbilical lines.
 - d. **The wrap should be removed once the infant is stabilized** in the nursery.
 7. **Thermal mattress**
 - a. **A thermal mattress releases heat** when a chemical gel inside the mattress is activated to form crystals.
 - b. **Squeeze the pad to activate the gel** at least 5 minutes before the baby is born.
 - c. **Cover the thermal mattress with a blanket** to prevent burns.
 - d. **It is equally as effective as polyethylene wrap or vinyl bag.**
 - e. **It maintains body temperature during transport** of a VLBW neonate.
 8. **The combined use of a polythene wrap and thermal mattress** is more effective in extreme premature infants (<32 weeks' gestation). The temperature should be monitored more closely if the combination is used because this may increase risk for hyperthermia.
 9. **Covering heads with hats** is effective in reducing heat losses.
 10. **A servo-controlled radiant warmer and a temperature sensor probe** should be present in the delivery room.
 11. **Heated humidified gases** with a blender for respiratory support.
 12. **Use an incubator** for transport and upon arrival to the nursery.
 - a. **Incubator should be rewarmed and double-walled, with humidity.**
 - b. **Incubator minimizes heat loss** by conduction, convection, evaporation, and radiation.
- D. Respiratory support**
1. **Immediate goals** are to achieve early functional residual capacity, achieve appropriate minute ventilation, and avoid invasive ventilation when possible. If the baby is breathing spontaneously and the heart rate is >100 beats/min, positive-pressure ventilation is not required. If the baby has respiratory distress or oxygen saturation remains below the target range, continuous positive airway pressure (CPAP) may be helpful.
 2. **Sustained inflation**
 - a. **Positive-pressure inflation** (15–25 cm H₂O) from 5 to 15 seconds.
 - b. **Establishes functional residual capacity (FRC)**, achieves better lung recruitment, helps move fluid from the alveoli to the interstitium, and improves lung expansion.
 - c. **Sustained inflation has been shown to reduce the need for mechanical ventilation** in the first 3 days of postnatal life in preterm infants. However, the use of sustained inflation in the delivery room is controversial and not a part of NRP.
 3. **Targeted oxygen saturation**
 - a. **NRP recommends pulse oximetry** be used when resuscitation is anticipated, during positive-pressure ventilation (PPV), when supplementary oxygen is administered, or when central cyanosis persists beyond the first 5 to 10 minutes of life.

- b. **Resuscitation of preterm newborns** (<35 weeks' gestation) should be initiated with 21% to 30% oxygen, and this should be titrated to achieve the minute-by-minute saturation goals.
 - i. **1 minute, 60% to 65%**
 - ii. **2 minutes, 65% to 70%**
 - iii. **3 minutes, 70% to 75%**
 - iv. **4 minutes, 75% to 80%**
 - v. **5 minutes, 80% to 85%**
 - vi. **10 minutes, 85% to 95%**
 - c. **Preductal oxygen levels should be targeted**, so the pulse oximeter should be placed on the right hand or wrist.
 - d. **Oxygen saturation should also be monitored** and maintained within the target range using blended oxygen while transporting neonates to the NICU.
4. **CPAP**
- a. **Since the initial respiratory care given to VLBW and ELBW infants contributes to their long-term respiratory outcomes**, maximizing noninvasive ventilation is critical.
 - b. **Seventy percent of VLBW and ELBW infants** can be managed by CPAP in the delivery room.
 - c. **The goal of initial respiratory support** is to establish FRC quickly and efficiently with minimal lung trauma.
 - d. **CPAP may be given in the delivery room** by flow-inflating bags and T-piece resuscitators.
 - i. **Early initiation of CPAP in the delivery room** may reduce the need for intubation and surfactant administration and the total number of ventilator days.
 - ii. **Use of CPAP compared to invasive ventilation in the delivery room** reduces bronchopulmonary dysplasia and death at 36 weeks' post-menstrual age.
5. **Invasive ventilation**
- a. **Preterm infants may require invasive ventilation** due to poor respiratory drive or severe respiratory distress.
 - b. **If PPV is required**, use the lowest PIP to achieve and maintain the heart rate >100 beats/min. An initial PIP of 20 to 25 cm H₂O is adequate for most preterm infants. While using face-mask ventilation, limit PIP to 30 cm H₂O.
 - c. **Intubation should be performed** by a person who is experienced in performing intubations of VLBW and ELBW infants.
 - d. **No more than 2 attempts per intubator should be attempted.**
 - e. **Intubation should be completed by 30 seconds.**
 - f. **Endotracheal tube placement should be confirmed by a CO₂ detector.**
 - g. **Caution should be used to avoid giving high tidal volumes**, since this may lead to decreased action of exogenous surfactant and overall greater lung injury with thickened alveolar septa.
 - h. **T-piece resuscitator should be used** to provide consistent PIP, PEEP, and tidal volume.
6. **Surfactant**
- a. **Surfactant deficiency in preterm newborns results in increased surface tension and atelectasis**, which ultimately results in lung injury.
 - b. **Incidence of respiratory distress syndrome (RDS)**
 - i. **<5% after 34 weeks' gestation**
 - ii. **30% between 28 and 34 weeks' gestation**
 - iii. **60% prior to 28 weeks' gestation**
 - c. **Although there is no benefit to prophylactic surfactant administration**, surfactant given within 2 hours of life may be beneficial, since surfactant works synergistically with CPAP to establish and maintain FRC.

- d. **Surfactant administration is not a component of initial resuscitation** and should be delayed until there is a stable heart rate.
 - e. **INSURE (INTubation, SURfactant, EXTubation) technique**
 - i. **For preterm neonates on CPAP**, this technique involves early surfactant administration followed by extubation.
 - ii. **This technique allows for avoidance of continuous mechanical ventilation.**
 - iii. **Preterm infants who develop RDS** should be given surfactant within the golden hour via the INSURE technique and then continued on CPAP support.
- E. Cardiovascular support**
- 1. **Immediately assess the heart rate.**
 - 2. **An electrocardiogram monitor** with 3 chest leads or limb leads provides a rapid and reliable method of monitoring heart rate.
 - 3. **Maintain normal perfusion and blood pressure**
 - 4. **Per NRP guidelines, chest compressions should be avoided** until adequate ventilation is achieved.
 - 5. **Causes of hypotension in the delivery room**
 - a. **Asphyxia**
 - b. **Sepsis**
 - c. **Air leak syndrome**
 - d. **Maternal anesthesia**
 - e. **Fetal arrhythmias**
 - f. **Fetal blood loss (hemorrhage, twin-twin transfusion syndrome)**
 - 6. **During the golden hour, the goal is to detect shock early in order to begin early management** including intravenous access and use of fluid resuscitation and vasopressors if needed.
- F. Prevention of neurologic injury**
- 1. **Preterm infants (<32 weeks' gestation) are prone to IVH** due to a fragile network of blood vessels in their brain. Obstruction of venous drainage from the head or rapid changes in blood pressure, blood volume, or PaCO₂ may increase the risk of IVH in extremely premature infants. Consider the following precautions while managing extremely premature infants during the golden hour:
 - a. **Gently handle the baby.**
 - b. **Do not position the baby's head lower than the legs.**
 - c. **Our institutional practice is to keep head of the baby in midline position** to prevent obstruction of venous drainage from the brain.
 - d. **Avoid high PIP and PEEP during PPV or CPAP.** Excessive PIP or PEEP can increase intrathoracic pressure and decrease venous return from the head.
 - e. **Avoid rapid changes in PaCO₂.** Rapid fluctuation in CO₂ levels can alter cerebral blood flow and increase risk of IVH.
 - f. **Avoid rapid infusion of intravenous fluids.** If volume expansion is required, infuse over 5 to 10 minutes.
- G. Early initiation of nutrition**
- 1. **Total parenteral nutrition (TPN) and enteral nutrition**
 - a. **Early nutritional support leads to better growth and neurodevelopmental outcomes**, and providing this nutrition should be a priority in the golden hour.
 - b. **Initiation of TPN during the golden hour** helps to support nitrogen balance, growth, and overall health.
 - c. **Early administration of parenteral amino acids** prevents protein catabolism and metabolic shock and buffers against hyperglycemia by initiating endogenous insulin secretion.

- d. **Stable preterm infants may be started on enteral feeds**, preferably with maternal breast milk.
- 2. **Preventing hypoglycemia**
 - a. **Preterm infants <1000 g** have a primary failure to produce or store glycogen.
 - b. **The goal during golden hour management** is to measure the serum glucose within 1 hour and start an infusion of dextrose immediately once access by peripheral intravenous line or central umbilical line is secured.
- H. **Infection prevention**
 - 1. **Preterm infants are at risk for neonatal sepsis.**
 - 2. **If a neonate will be treated for suspected sepsis**, a blood culture should be obtained and the first dose of antibiotics should be administered within the golden hour.
- I. **Laboratory tests**
 - 1. **The necessary tests** (blood culture, glucose, blood gas, and chest x-ray) should be done during the golden hour to minimize handling later on.
- J. **Monitoring/timing**
 - 1. **The timing of the above interventions should be recorded** including documentation of resuscitation, birth weight, and temperature upon admission to the nursery; timing of surfactant administration; timing of umbilical catheter placement; and timing of antibiotic administration.
- K. **Communication with parents**
 - 1. **The parents should be informed about the condition of the neonate**, chances of survival, expected morbidities, duration of stay, and further management plan.

6 Gestational Age and Birthweight Classification

Gestation is the period of fetal development from the time of conception to birth. **Gestational age** (or menstrual age), as defined by the American Academy of Pediatrics (AAP), is the “time elapsed between the first day of the last menstrual period (LMP) and the day of delivery.” It is expressed in completed weeks (26-week and 4-day-old fetus is expressed as a 26-week fetus). Gestational age is important information for the obstetrician to provide obstetric care. It is critical information for the neonatologist for evaluation of the infant and to anticipate high-risk infants and complications. Gestational age and birthweight classification help the neonatologist to categorize infants, guide treatment, and assess risks for morbidity and mortality. Neonates can be classified based on **gestational age** (preterm, late preterm, early term, full or late term, post term), **birthweight** (eg, extremely low birthweight, very low birthweight, low birthweight), and **gestational age and birthweight combined** (small for gestational age [SGA], appropriate for gestational age [AGA], large for gestational age [LGA]). **The AAP recommends that all newborns be classified by birthweight and gestational age.**

- I. **Gestational age assessment.** Gestational age can be determined prenatally in the fetus and postnatally in the newborn. Gestational age is determined by the “best obstetric estimate,” which is based on 4 parameters: first day of LMP, physical examination of the mother, prenatal ultrasound, and history of assisted reproduction. The American College of Obstetricians and Gynecologists, the American Institute of Ultrasound in Medicine, and the Society for Maternal-Fetal Medicine indicate that **antenatal first-trimester**

ultrasonography is the most accurate method to establish gestational age in a pregnancy not achieved through assisted reproductive technologies. The methods they recommend in the first trimester (ultrasound, LMP data) represent the best obstetric estimate for clinical care, and this date should be recorded on the birth certificate. Some feel that the most accurate estimation of gestational age is based on the prenatal estimation (using ultrasound and LMP) in combination with the postnatal assessment using physical and neurologic maturity. Gestational age can also be determined postnatally using various examinations including assessment of physical and neuromuscular maturity. It is done if the best obstetric estimate is inaccurate. Postnatal gestational assessment is important, especially in cases where there is no prenatal care, LMP is unknown, and no ultrasounds were done.

A. Prenatal gestational age assessment. Determined by a combination of date of the LMP and prenatal ultrasound examination. Based on these, the obstetrician is able to give his or her “best estimate” of gestational age, since variability up to 2 weeks can occur. Use of quickening and physical examination of the mother are not very accurate and are not used if ultrasound is available.

1. Maternal history

- a. **First day of the last menstrual period (LMP).** This clinical estimate is very reliable if dates are remembered but depends on an accurate menstrual history and normal maternal physiology. The first day of the LMP is about 2 weeks before ovulation and about 3 weeks before blastocyst implantation. This method can be inaccurate if the incorrect date is reported, with recent use of contraceptives that may affect ovulation, after conception spotting misinterpreted as a period, with variability in ovulation timing, and if the menstrual cycle length is not regular. Studies indicate that using the LMP usually overestimates the gestational age at term. If the **menstrual dates are uncertain**, gestational age is based on the first-trimester ultrasound. If the **menstrual dates are known**, then the LMP can be used for the gestational age and the ultrasound can be done at 18 to 20 weeks to confirm the date when performing an anatomic survey.
- b. **Assisted reproductive technology (ART).** If pregnancy resulted from ART, the ART-derived gestational age should be used to assign the estimated due date. In vitro fertilization pregnancies have a known date of conception, and the gestational age can accurately be predicted within 1 day. If pregnancy was achieved using ART, the gestational age is calculated by adding 2 weeks to the chronologic age (time elapsed from birth). Intrauterine insemination may have a few days' delay.
- c. **Perception of fetal movement by the mother (termed quickening).** Date of first reported fetal activity by the mother (18–20 weeks for a primigravida, 16–18 weeks for a multigravida).
- d. **As soon as data from the LMP, the first accurate ultrasound, or both are obtained,** the gestational age and estimated due date should be determined.

2. Clinical examination

- a. **Pelvic examination.** Uterine size by bimanual examination in the first trimester can be accurate within 2 weeks. At 6 to 8 weeks, the uterus is the size of a plum; at 8 to 10 weeks, the size of an orange; and at 10 to 12 weeks, the size of a grapefruit.
- b. **Symphysis–fundal height (SFH), fundal height, or McDonald’s rule.** This is a measure of the size of the uterus, which corresponds to the gestational age in weeks between 12 and 36 weeks for a vertex fetus. Palpate the superior edge of the pubis symphysis to the palpable top of the uterus to obtain the fundal height. This measurement can be incorrect if there are uterine fibroids, a full bladder, multiple pregnancy, oligo-/polyhydramnios, SGA/LGA infant, or breech position. In resource-poor countries, gestational age can be estimated from serial measurements of pubis symphysis pubis fundal height. It

is only accurate within 4 weeks. Cochrane review states there is insufficient evidence to evaluate the use of SFH measurements during antenatal care and to determine whether SFH measurement is effective in detecting problems with fetal growth (intrauterine growth restriction [IUGR]). **McDonald's rule** (fundal height) relies on the height of the fundus to calculate the duration of pregnancy in weeks or months. To calculate in months: fundal height measurement (in cm) $\times 2/7$ = duration of pregnancy in months. To calculate in weeks: fundal height measurement (in cm) $\times 8/7$ = duration of pregnancy in weeks.

- i. **12 weeks:** uterine fundus at the pubic symphysis
 - ii. **16 weeks:** uterine fundus between the umbilicus and pubis symphysis
 - iii. **20 weeks:** uterine fundus at the umbilicus
 - iv. **20–34 weeks:** the fundal height in centimeters equals the gestational age in weeks
 - v. **36 weeks:** uterine fundus at the xiphoid process of sternum
- c. **Ultrasound examinations. Listed below are the most commonly used ultrasound assessments.** Less common parameters used are binocular distance, transverse cerebellar diameter, fetal foot length, clavicle length, cranial ultrasound assessment, fetal scapular length, corpus callosum measurements, head and midarm circumference, and epiphyseal ossification centers.
- i. **First fetal heart tones by Doppler ultrasound** heard as early as 8 to 12 weeks.
 - ii. **Fetal heart motion/beat by ultrasound.** Cardiac activity on ultrasound is detectable at 5.5 to 6.5 weeks by vaginal ultrasound and at 6.5 to 7 weeks by fetal ultrasound.
 - iii. **First-trimester examination** (up to and including 13 6/7 weeks' gestation) by ultrasound measurement of the fetus is the most accurate method to establish gestational age. Cochrane review found that early ultrasound (before 24 weeks) may result in fewer inductions for postmaturity because of improved gestational dating.
 - (a) **Crown-rump length (CRL) is the most reliable measurement of gestational age up to and including 13 6/7 weeks' gestation,** is accurate within 5 to 7 days, and is most accurate if performed early in the first trimester. It measures the embryo at the tip of the cephalic pole to the tip of the caudal pole. Three measurements should be obtained. Accuracy of gestational age assessment decreases if the CRL measurement is >84 mm (approximately 14 0/7 weeks).
 - (b) **Mean sac diameter (MSD)** is no longer recommended for estimating the due date.
 - iv. **Second-trimester examination (between 14 0/7 and 27 6/7 weeks' gestation).** Ultrasound measurement of the fetus in the second trimester is based on formulas that use biparietal diameter (BPD), head circumference, abdominal circumference, and femur length.
 - (a) **Ultrasound done between 14 0/7 and 22 6/7 weeks:** gestational age accuracy of 7 to 10 days.
 - (b) **Ultrasound done between 22 0/7 and 27 6/7 weeks:** gestational age accuracy of 10 to 14 days.
 - v. **Third-trimester examination (28 0/7 weeks' gestation and beyond)** is the least reliable measurement of gestational age. The same parameters are used as in the second trimester. Accuracy is within 21 to 30 days.
3. **Laboratory data.** There are multiple biochemical parameters that can aid in the estimation of gestational age and fetal maturity. These include amniotic fluid creatinine concentration, lecithin-to-sphingomyelin ratio, total protein, uric acid, bilirubin, and fetal fat staining cells. The 2 best parameters are amniotic creatinine

(fetal kidney maturity) and lecithin (fetal lung maturity). There are multiple risks of obtaining amniotic fluid by amniocentesis including infection, hemorrhage, and fetal loss.

B. Postnatal gestational age assessment. Clinicians usually perform a postnatal gestational assessment on every infant. It is important to perform this assessment, because some prenatal estimates of LMP are incorrect, and an ultrasound (especially first trimester) may not have been done. Another benefit is that it can confirm the obstetrician's date and may provide additional information relevant to the developmental stage. There are many methods to assess gestational age, including rapid assessment of gestational age at delivery, direct ophthalmoscopy of the lens of the eye, and various examinations including assessment of physical and neuromuscular maturity. Metabolic gestational age dating has been studied using newborn screening metabolic profile measurements for use in resource-poor countries.

1. Rapid assessment of gestational age in the delivery room. There are multiple methods for rapid assessment of gestational age. Most include some of the following physical characteristics: skin texture, skin color, skin opacity, edema, lanugo hair, skull hardness, ear form, ear firmness, genitalia, breast size, nipple formation, and plantar skin creases. One method for rapid gestational age assessment includes the **most useful clinical signs in differentiating among premature, borderline mature, and full-term infants, which are as follows (in order of utility):** creases in the sole of the foot, size of the breast nodule, nature of the scalp hair, cartilaginous development of the earlobe, scrotal rugae, and testicular descent in males. These signs and findings are listed in Table 6–1.

2. Direct ophthalmoscopy of the lens is another method for determination of gestational age at 27 to 34 weeks only. It is based on the normal embryologic process of the gradual disappearance of the anterior lens capsule vascularity between 27 and 34 weeks of gestation. Before 27 weeks, the cornea is too opaque to allow visualization; after 34 weeks, atrophy of the vessels of the lens occurs. This method is reliable to ± 2 weeks. The pupil must be dilated under the supervision of an

Table 6–1. CRITERIA FOR RAPID GESTATIONAL ASSESSMENT AT DELIVERY

Feature	36 Weeks and Earlier	37–38 Weeks	39 Weeks and Beyond
Creases in soles of feet	1 or 2 transverse creases; posterior three-fourths of sole smooth	Multiple creases; anterior two-thirds of heel smooth	Entire sole, including heel, covered with creases
Breast nodule ^a	2 mm	4 mm	7 mm
Scalp hair	Fine and woolly; fuzzy	Fine and woolly; fuzzy	Coarse and silky; each hair single stranded
Earlobe	No cartilage	Moderate amount of cartilage	Stiff earlobe with thick cartilage
Testes and scrotum	Testes partially descended; scrotum small, with few rugae	?	Testes fully descended; scrotum normal size with prominent rugae

^aThe breast nodule is not palpable before 33 weeks. Underweight full-term infants may have retarded breast development.

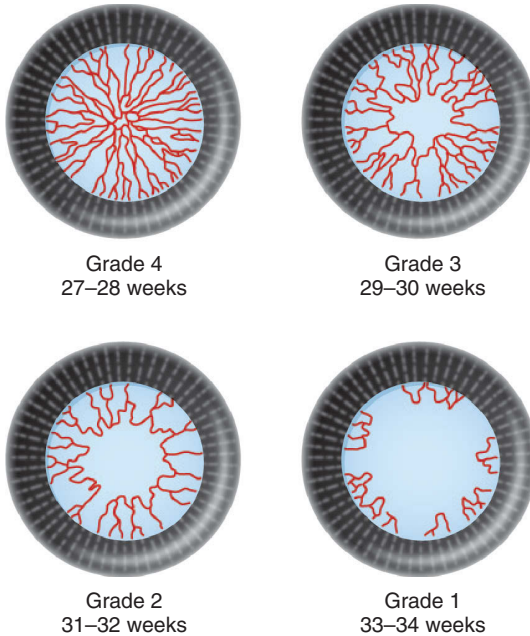

FIGURE 6-1. Grading system for assessment of gestational age by examination of the anterior vascular capsule of the lens. (Reproduced with permission from Hittner HM, Hirsch NJ, Rudolph AJ: *Assessment of gestational age by examination of the anterior vascular capsule of the lens*, J Pediatr. 1977 Sep;91(3):455-458.)

ophthalmologist, and the assessment must be performed within 48 hours of birth before the vessels atrophy. This method is highly accurate and is not affected by alert states or neurologic deficits. The following grading system is used, as shown in Figure 6-1.

- a. **Grade 4 (27–28 weeks).** Vessels cover the entire anterior surface of the lens, or the vessels meet in the center of the lens.
 - b. **Grade 3 (29–30 weeks).** Vessels do not meet in the center but are close. Central portion of the lens is not covered by vessels.
 - c. **Grade 2 (31–32 weeks).** Vessels reach only to the middle-outer part of the lens. The central clear portion of the lens is larger.
 - d. **Grade 1 (33–34 weeks).** Vessels are seen only at the periphery of the lens.
3. **Examinations based on physical and neuromuscular maturity.** These include the **Dubowitz method**, **Ballard maturational score**, and **new Ballard score**. These approaches have used physical and neuromuscular maturity to assess gestational age. Physical criteria alone are more accurate than neurologic criteria alone, with the combination providing the best estimate of gestational age. It is important to note that, in recent studies, gestational assessment in the community in low-resource areas had poor diagnostic accuracy and neonatal anthropometrics were poor for classifying preterm infants in areas with high rates of fetal growth restriction.
- a. **Dubowitz method.** Dubowitz et al. (1970) originally described a method that included a total of 21 physical and neurologic assessments. The test was widely used but became difficult and time consuming (up to 7 minutes) in performing

the assessment, especially on extremely premature and sick infants, and the method overestimated gestational age in premature infants.

b. Ballard maturational score. The Ballard method (1979) shortened the Dubowitz method (now only 3.5 minutes) and had only 6 physical and 6 neurologic criteria. This method was considered inaccurate at assessing gestational age in preterm neonates and postterm and small for gestational age infants.

c. New Ballard score. Ballard et al. (1991) later refined and expanded their test to include the assessment of extremely premature infants (20 weeks). **This is the most commonly used scoring system for assessing gestational age.**

i. New Ballard score. The score spans from 10 (correlating with 20 weeks' gestation) to 50 (correlating with 44 weeks' gestation). It is best performed at <12 hours of age if the infant is <26 weeks' gestation. If the infant is >26 weeks' gestation, there is no optimal age of examination up to 96 hours.

(a) Accuracy. The examination is accurate whether the infant is sick or well to within 2 weeks of gestational age. It overestimates gestational age by 1.3 to 3.3 weeks in infants who are 22 to 28 weeks' gestation. It overestimates gestational age by 2 to 4 days in infants between 32 and 37 weeks' gestation.

(b) Criteria. The score consists of 6 neuromuscular and 6 physical criteria. The neuromuscular criteria are based on the understanding that passive tone is more useful than active tone in indicating gestational age.

(c) Procedure. The examination is administered twice by 2 different examiners to ensure objectivity, and the data are entered on the chart (Figure 6–2). This form is available in most nurseries and online sites. The examination consists of 2 parts: neuromuscular maturity and physical maturity. The 12 scores are totaled, and the **maturity rating** is expressed in weeks of gestation (**gestational age**), estimated by using the chart provided on the form.

(d) Neuromuscular maturity

(i) Posture. Score 0 if the arms and legs are extended, and score +1 if the infant has beginning flexion of the knees and hips, with arms extended; determine other scores based on the diagram.

(ii) Square window. Flex the hand on the forearm between the thumb and index finger of the examiner. Apply sufficient pressure to achieve as much flexion as possible. Visually measure the angle between the hypothenar eminence and the ventral aspect of the forearm. Determine the score based on the diagram.

(iii) Arm recoil. Flex the forearms for 5 seconds and then grasp the hand and fully extend the arm and release. If the arm returns to full flexion, give a score of +4. For lesser degrees of flexion, score as noted in the diagram.

(iv) Popliteal angle. Hold the thigh in the knee-chest position with the left index finger and the thumb supporting the knee. Then extend the leg by gentle pressure from the right index finger behind the ankle. Measure the angle at the popliteal space and score accordingly.

(v) Scarf sign. Take the infant's hand and try to put it around the neck posteriorly as far as possible over the opposite shoulder, and score according to the diagram.

(vi) Heel to ear. Keeping the pelvis flat on the table, take the infant's foot and try to put it as close to the head as possible without forcing it. Grade according to the diagram.

(e) Physical maturity. These characteristics are scored as shown in Figure 6–2.

FIGURE 6-2. (Continued)

- (i) **Skin.** Carefully look at the skin, and grade according to the diagram. Extremely premature infants have sticky, transparent skin and receive a score of +1.
- (ii) **Lanugo hair.** Examine the infant's back and between and over the scapulae.
- (iii) **Plantar surface.** Measure foot length from the tip of the great toe to the back of the heel. If the result is <40 mm, give a score of -2. If it is between 40 and 50 mm, assign a score of -1. If the measurement is >50 mm and no creases are seen on the plantar surface, give a score of 0. If there are creases, score accordingly.
- (iv) **Breast.** Palpate any breast tissue and score.
- (v) **Eye and ear.** This section has been expanded to include criteria that apply to the extremely premature infant. Loosely fused eyelids are defined as closed, but gentle traction opens them (score as -1). Tightly fused eyelids are defined as inseparable by gentle traction. Base the rest of the score on open lids and the examination of the ear.
- (vi) **Genitalia.** Score according to the diagram.

4. **Metabolic gestational age dating.** Prediction models have been developed using newborn metabolic profile, hemoglobin levels, and analyte data from the newborn metabolic screening profiles. The results were very favorable, and one study predicted gestational age within 1 week of the actual gestational age in two-thirds of the infants. This method is accurate and may be useful in resource-poor countries where ultrasound is not readily available. DNA methylation on cord blood and blood spot samples has also been studied and accurately estimates gestational age.

C. **Newborn classification based on gestational age.** Infants can be classified based on their gestational age. The major classification categorizes the infant as **preterm, term, or postterm**. It is based on the weeks of gestation, completed weeks of gestation, or days. (See Table 6-2 for a full description.) Both **preterm and term** have been further subclassified. **Preterm** has been categorized into **extremely preterm, very preterm, or moderate to late preterm (moderately preterm and late preterm)**. Note that the recommendations from the Defining "Term" Pregnancy Workgroup have redefined the **definition of term** pregnancy and recommend subcategorization of the 6-week period from 37 to 42 weeks (**early term, full term, and late term**). They did this because maternal and neonatal outcomes are very different across this 6-week gestational period. They discourage the use of the word "term." (See Table 6-2 for a full description.)

II. **Birthweight classification.** Infants can be classified by birthweight; some of the common terminology classifications used are as follows:

- A. **Micro preemie.** <800 g or 1 lb 12 oz.
- B. **Extremely low birthweight (ELBW).** <1000 g or 2 lb 3 oz.
- C. **Very low birthweight (VLBW).** <1500 g or 3 lb 5 oz.
- D. **Low birthweight (LBW).** <2500 g or 5.5 lb.
- E. **Normal birthweight (NBW).** From 2500 g (5 lb 8 oz.) to 3999 g (8 lb 13 oz.).
- F. **High birthweight (HBW).** From 4000 g (8 lb 13.1 oz.) to 4500 g (9 lb 14 oz.).
- G. **Very high birthweight (VHBW).** >4500 g (9 lb 14 oz.).

III. **Classification by birthweight and gestational age combined.** Newborns can be classified by assessing their gestational age and obtaining their birthweight and plotting these against standardized intrauterine growth charts. This allows categorization as SGA (small for gestational age), AGA (appropriate for gestational age), or LGA (large for gestational age). These refer to the size of the infant at birth and not fetal growth.

A. **How to decide whether the infant is SGA, AGA, or LGA.** Plot gestational age assessment against weight, length, and head circumference on an intrauterine growth chart to determine whether the infant is SGA, AGA, or LGA. There are multiple intrauterine growth charts available based on different populations, including those by

Table 6–2. DEFINITIONS OF POSTNATAL GESTATIONAL AGE

	Weeks of Gestation (number of weeks after the first day of the mother's last menstrual period)	Completed Weeks (number of 7-day intervals after the first day of the mother's last menstrual period)	Days (common medical terminology)
Extremely preterm	<28 weeks	On or before the end of the last day of the 28th week	<197 days
Very preterm	28 0/7 to 31 6/7 weeks	On or after the first day of the 29th week through the last day of the 32nd week	197–224 days
Moderately preterm	32 0/7 to 33 6/7 weeks	On or after the first day of the 33 weeks through the last day of the 34th week	225–238 days
Preterm	<37 weeks	On or before the end of the last day of the 37th week	<260 days
Late preterm	34 0/7 to 36 6/7 weeks	On or after the first day of the 35th week through the end of the last day of the 37th week	239–259 days
Early term	37 0/7 to 38 6/7 weeks	On or after the first day of the 38th week through the end of the last day of the 39th week	260–273 days
Full term	39 0/7 to 40 6/7 weeks	On or after the first day of the 40th week through the end of the last day of the 41st week	274–287 days
Late term	41 0/7 to 41 6/7 weeks	On or after the first day of the 42nd week through the end of the day of the 42nd week	288–294 days
Post term	42 0/7 weeks or more	On or after first day of the 43rd week	≥295 days

Definitions of postnatal gestational age are based on **conventional medical definitions** (day of birth counted as day 1) by the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, and the World Health Organization.

Data from Engle WA, Tomashek KM, Wallman C, et al: "Late-preterm" infants: a population at risk, *Pediatrics*. 2007 Dec;120(6):1390-1401; Spong CY: Defining "term" pregnancy: recommendations from the Defining "Term" Pregnancy Workgroup, *JAMA*. 2013 Jun 19;309(23):2445-2446.

Battaglia and Lubchenco (United States, 1966, 1967), Usher and McLean (Canada, 1969), Beeby (South Wales, 1996), Niklasson (Sweden, 1991), Fenton (South Wales, Sweden, Canada, 2003, revised 2013), Olsen (United States, 2010), and now Boghossian (United States, 2016).

Which chart to use? The original charts were the Battaglia and Lubchenco charts (Figure 6–3). The first Fenton chart (2003) was the Babson and Benda's chart updated with a new format and new data. The revised Fenton Chart (2013) includes the World Health Organization growth standard and reflects actual age to improve preterm infant growth monitoring (Figure 6–4). The Olsen charts are gender-specific intrauterine growth charts that include more infant sizes and new preterm infant growth curves, and they more accurately represent the current ethnically diverse US population (Figure 6–5). Boghossian et al. (2016) have published new sex-specific weight and head circumference for gestational age charts for infants born between 22 and 29 weeks' gestation using data from >156,000 infants from the Vermont Oxford Network database (Figure 6–6). Deciding which chart to use usually depends on the preference of the neonatal intensive care unit.

B. Definitions and characteristics of AGA, SGA, and LGA

1. **Appropriate for gestational age (AGA).** Defined as a birthweight between the 10th and 90th percentiles for the infant's gestational age.

2. **Small for gestational age (SGA).** Defined as birthweight 2 standard deviations below the mean weight for gestational age or below the 10th percentile for gestational age. SGA refers to the size of the infant at birth and not fetal growth. SGA is typically associated with **maternal factors** (eg, chronic disease, malnutrition, multiple gestation, high altitude, or conditions affecting the blood flow and oxygenation in the placenta [hypertension, preeclampsia, smoking]), **placental factors** (eg, infarction, previa, abruption, anatomic malformations), **fetal factors** (usually symmetric; birthweight, length, and head circumference all depressed the same), congenital infections (eg, TORCH [toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus]; see Chapter 148), chromosomal abnormalities, and congenital malformations (eg, dysmorphic syndromes and other congenital anomalies, fetal diabetes mellitus, familial causes, multiple gestation, constitutional). **IUGR** and **constitutionally small fetus** should be included when discussing SGA infants.

a. **Intrauterine growth restriction (fetal growth restriction).** (See Chapter 104.)

IUGR is a reduction in the expected fetal growth of an infant. The failure to obtain optimal intrauterine growth is due to an in utero insult. There is no standard definition, but a fetus at <10th percentile weight for age or with a ponderal index <10% is sometimes used to classify an infant as IUGR. (**Note:** SGA and IUGR are related but not synonymous. All infants born SGA may not be small as a result of IUGR. All infants born IUGR may not be SGA. SGA is a clinical finding, and IUGR is an ultrasound finding.)

b. **Constitutionally small infants.** Includes 70% of infants with a birthweight below the 10th percentile. They have no increased obstetrical or neonatal risks. They are constitutionally small, anatomically normal, well proportioned, and have normal development. They grow parallel to the lower percentiles throughout pregnancy. Mothers are usually slim, petite women. The infants are small because of constitutional reasons: maternal ethnicity, female sex, body mass index, and others.

3. **Large for gestational age (LGA).** Defined as birthweight 2 standard deviations above the mean weight for gestational age or above the 90th percentile for gestational age. LGA can be seen in infants of diabetic mothers (maternal or gestational), infants with Beckwith-Wiedemann syndrome or other syndromes, constitutionally large infants with large parents, postmature infants (gestational age >42 weeks), and infants with hydrops fetalis. LGA infants are also associated with increased maternal weight gain in pregnancy, multiparity, male sex,

(Data from Boghossian NS, Geraci M, Edwards EM, et al: *Anthropometric Charts for Infants Born Between 22 and 29 Weeks' Gestation*, Pediatrics. 2016 Dec;138(6).)

congenital heart disease, especially transposition of the great arteries (“happy chubby blue male infant”), islet cell dysplasias, and certain ethnicities (Hispanic). LGA infants are sometimes referred to as infants with macrosomia.

a. Macrosomia means “large body.” Hispanic women have a higher risk of fetal macrosomia when compared to Asian, African American, and white women. Because males weigh more at birth, it is also more common in males. It is associated with diabetes (gestational and maternal), maternal obesity, and a longer duration of gestation. Macrosomia has multiple definitions in the literature.

i. Birthweight >4000 g or >4500 g regardless of gestational age.

ii. Large for gestational age (LGA). Birthweight $\geq 90\%$ for gestational age.

iii. Weight is above a defined limit at any gestational age.

IV. Other age terminology (recommended terms by the AAP) used to describe the age and gestation of an infant:

A. Chronologic age (or postnatal age). The time elapsed since birth expressed in days, weeks, months, or years.

B. Postmenstrual age. Gestational age plus chronologic age. It is expressed in weeks and is the preferred term to describe premature infants in the perinatal period while the infant is in the hospital.

C. Corrected age (or adjusted age; only used in children born preterm <3 years old). Corrected age is the chronologic age minus the number of weeks born before 40 weeks’ gestation and is the preferred term to describe the age of preterm infants after the perinatal period. It is expressed in weeks or months.

D. Conceptional age is the time elapsed between the day of conception and the day of delivery. If pregnancy was achieved by assisted reproductive technology (ART), then a precise conceptional age can be calculated. Typically when the date of conception is known, gestational age is calculated by adding 2 weeks to the conceptional age. Gestational age is the preferred term to be used in clinical pediatrics and conceptional and postconceptional age are no longer recommended terms. Conceptual age and postconceptual age are incorrect terms and should never be used.

7 Newborn Physical Examination

Newborns are examined immediately after birth to quickly assess their respiratory effort, circulation, and temperature; to identify any major congenital abnormalities; and to check for any infectious or metabolic disease that requires immediate treatment. This exam is critical to ensure the transition to extrauterine life proceeds without difficulty. The infant should then undergo a complete physical examination within 24 hours of birth and again at discharge. Specific findings in an infant who has experienced a traumatic birth are reviewed in detail in Chapter 83.

It is best to perform a routine newborn physical exam under a radiant warmer with the lights on. Before even touching the infant, observe and assess color, activity, posture, maturity, and respirations. Perform the examinations that cause the least amount of disturbance first. It is easier to listen to the heart and lungs first and feel the pulses when the infant is quiet. Warming the hands and stethoscope before use decreases the likelihood of making the infant cry.

In addition to examination of the infant, the complete maternal history, including prenatal, perinatal, labor and delivery, family, and social history, should be reviewed. (See Appendix D, “Chartwork.”)

I. Vital signs

- A. Temperature.** Indicate whether the temperature is rectal (which is usually 1° higher than oral), oral, or axillary (which is usually 1° lower than oral). Axillary temperature is usually measured in the neonate, with rectal temperature done if the axillary temperature is abnormal. Normal axillary temperature in a newborn ranges from 97.5°F to 99.3°F (36.5–37.4°C).
- B. Respirations.** The normal respiratory rate in a newborn is 30 to 60 breaths/min. Periodic breathing (≥ 3 apneic episodes lasting >3 seconds within a 20-second period of otherwise normal respirations) is considered normal and common in newborns.
- C. Blood pressure.** Blood pressure correlates directly with gestational age, post-natal age of the infant, and birthweight. (For normal blood pressure curves, see Appendix C.)
- D. Heart rate.** The normal heart rate is 70 to 190 beats/min in the newborn (usually 120–160 beats/min when awake, >170 beats/min with activity or crying, and decreasing to 70–90 beats/min when asleep). In the healthy infant, the heart rate increases with stimulation. See Table 53–1, page 460.
- E. Pulse oximetry.** Pulse oximetry in the neonatal intensive care unit (NICU) has become standard of care and is sometimes referred to as the “fifth vital sign.” (**Note:** Pain assessment has also been referred to as the “fifth vital sign” by some.) It is a simple, painless noninvasive tool used to measure arterial oxygen saturation by measuring the absorption of light in tissue beds. It is commonly used in the NICU as a monitoring tool during oxygen supplementation, during sedation for procedures, perioperatively, in high-risk infants, in the delivery room, and during transport. Pulse oximetry is also used diagnostically in persistent pulmonary hypertension and to screen for critical congenital heart disease (CCHD). Screening pulse oximetry for critical cyanotic heart disease is recommended for all infants before discharge.

1. Screening pulse oximetry for critical congenital cyanotic heart disease.

Congenital heart disease is a common birth defect, occurring in approximately 1% of all newborns. CCHD, occurring in approximately 18 in 10,000 infants, is a life-threatening condition with significant morbidity and mortality in the newborn period. These conditions may require heart surgery or catheter-based intervention within the first year of life to prevent end-organ damage or death. As of 2011, universal pulse oximetry screening is recommended for all newborns because low blood oxygen saturation may detect CCHD. This screening has been endorsed by the American College of Cardiology Foundation, March of Dimes, Newborn Foundation, American Heart Association, and American Academy of Pediatrics (AAP). An expert panel was convened again in 2015 to rereview practices and identify areas of improvement. Infants who test positive (up to 79%) can have CCHD or another non-CCHD cause of hypoxemia. Most states in the United States have followed this AAP-endorsed protocol, with New Jersey and Tennessee adopting different algorithms. See Figure 7–1 for the AAP-endorsed CCHD pulse oximetry screening algorithm from the Centers for Disease Control and Prevention (CDC).

a. Twelve heart conditions that are detected by screening for CCHD with pulse oximetry include the following.

- i. **Core/primary targets for CCHD screening (7 most common critical lesions that present with hypoxemia):** Hypoplastic left heart syndrome, pulmonary atresia with intact ventricular septum, tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, and truncus arteriosus.
- ii. **Additional/secondary targets for CCHD screening (5 critical lesions that either are less common but present with hypoxia or are more**

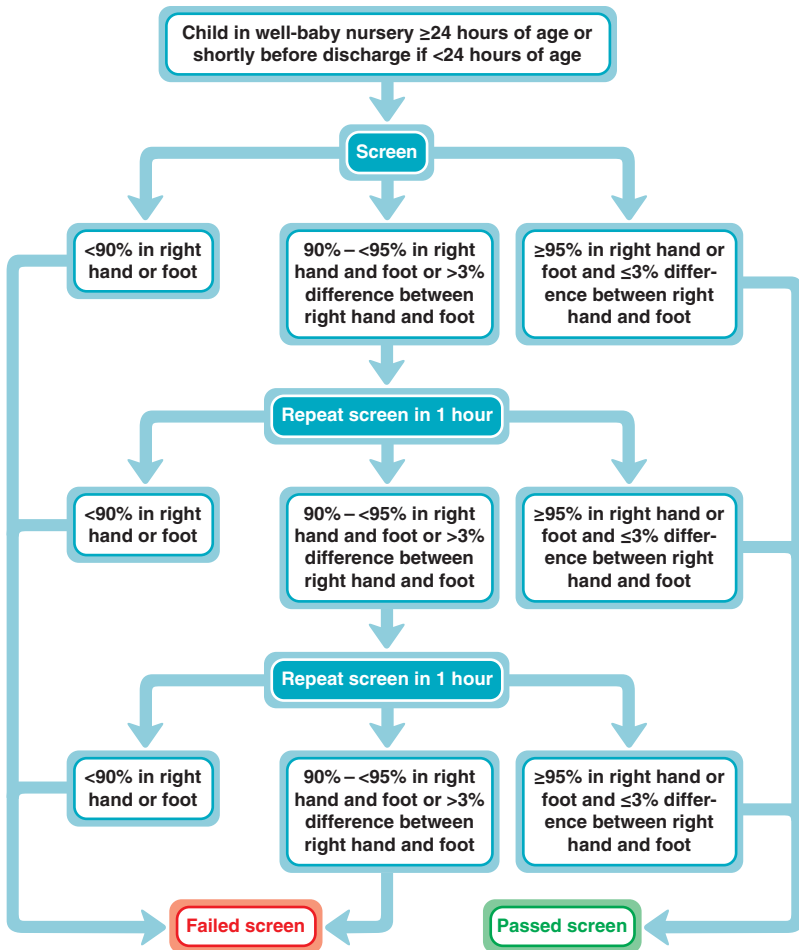

FIGURE 7-1. Screening algorithm for critical congenital heart disease using pulse oximetry. (Reproduced with permission from Kemper AR, Mahle WT, Martin GR, et al: *Strategies for implementing screening for critical congenital heart disease*, Pediatrics. 2011 Nov;128(5):e1259-e1267.)

common and do not present with hypoxia): Coarctation of the aorta with patent ductus arteriosus (PDA), double outlet right ventricle, Ebstein anomaly, interrupted aortic arch/aortic atresia, and single ventricle physiology.

- b. Three heart conditions that are potentially screenable by pulse oximetry:** Pulmonary stenosis, aortic stenosis with PDA, and complete atrio-ventricular canal.
- c. Heart conditions that are not screenable by pulse oximetry:** Aortic stenosis without PDA, Ebstein anomaly without right to left shunt, coarctation of the aorta without a PDA, and any other left to right shunting lesions.

- d. **Secondary conditions (non-CCHD conditions) that are detected by screening by pulse oximetry:** Hypothermia, infections (including sepsis), hemoglobinopathy, congenital or acquired lung disease, persistent pulmonary hypertension, transient tachypnea of the newborn, a noncritical congenital heart defect, and other hypoxemic conditions.
2. **Newborn nursery/intermediate nursery pulse oximetry screening guidelines**
- a. **Screen all healthy newborn infants.** It is best to screen when alert. The only infants who do not need to be screened are those who have already been diagnosed with CCHD, those who have already had an echocardiogram, or those with serious medical conditions in whom no intervention would be done if CCHD was diagnosed.
- b. **Use only hospital-grade, motion-tolerant pulse oximeters** designed for use in neonates. Confirm that the probes are correct for the machine and are appropriate for use in neonates. Disposable or reusable pulse oximetry probes may be used. If only using 1 pulse oximeter, test one right after the other.
- c. **Screen at 24 to 48 hours of age** or as late as possible for early discharge.
- d. **Obtain oxygen saturation in the right hand and either foot.**
- e. **Failed screen. Is the infant hemodynamically stable? Perform a comprehensive evaluation for hypoxia.** Rule out other reasons for hypoxia (infectious and pulmonary causes). **CCHD needs to be excluded with a diagnostic echocardiogram.** If no obvious cause is found, a pediatric cardiology consultation (if possible) is obtained prior to obtaining a diagnostic echocardiogram.
- f. **Passed screen.** False positives and false negatives may occur. A passed test does not mean the infant does not have CCHD. This test does not detect all cases of congenital heart defects.
3. **NICU screening guidelines.** Screening in the NICU can give higher false-positive rates because premature infants have lower saturations than term infants. Many units follow the standard AAP protocol, some modify it, and some do not screen at all. As noted earlier, **it is recommended that all infants should be screened for CCHD.** One recommendation is to wait until the infant is off oxygen to do the test or, if on oxygen at discharge, obtain an echocardiogram.
4. **Out of hospital births.** All newborns should be screened regardless of the location of birth. Birthing centers and those who perform home births should have a protocol for the infant to be screened.
5. **High altitude.** Infants at a higher altitude have a lower oxygen saturation than those at sea level. Therefore, oxygen saturation thresholds for a positive screening may vary at high altitudes. Adapting the protocol for hospitals at elevations >6800 feet include obtaining an echocardiogram and repeating the pulse oximetry test every 4 hours until the echocardiogram results are obtained, placing the infant in an oxygen hood to replicate sea level, and testing at 30 hours to allow a transition time.
- II. **Head circumference, length, weight, chest circumference, abdominal circumference, and gestational age.** (For intrauterine growth charts, see Chapter 6). For standard infant/child growth charts based on CDC and World Health Organization (WHO) data from birth to 36 months, see <http://www.cdc.gov/growthcharts/>.
- A. **Head circumference and percentile.** Determine the occipital-frontal circumference by placing the measuring tape around the front of the head (above the brow [the frontal area]) and the occipital area. The tape should be above the ears. This is normally 32 to 37 cm at term; percentile is determined by the CDC/WHO table.

- B. Length and percentile.** Normal length is 48 to 52 cm, with the percentile determined by the CDC/WHO table.
 - C. Chest circumference.** With the infant supine, measure the circumference of the chest at the level of the nipples during normal breathing. This is a good indicator of low birthweight. Normal is 30 to 35 cm (head circumference is typically 2 cm larger than chest circumference).
 - D. Abdominal circumference** is usually not measured unless there is abdominal distension, but a baseline can be valuable because if there is a question of a change in abdominal distension, a measurement is available to compare. Measure the distance 1 cm above the umbilicus in the supine position, not at or below the umbilicus (a full bladder may interfere with the measurement). Multiple variables can affect the measurement: birthweight, time of last feeding and time of last stool, resistance of the abdominal wall, phase of breathing, and amount of abdominal fat. Increases of abdominal circumference of <1.5 cm occur normally and should not be a cause of concern, especially if there are no other abnormal clinical signs. An increase in abdominal girth >2 cm may be considered abnormal, but studies have shown that abdominal circumference may vary by 3.5 cm in one feeding cycle in normal premature infants.
 - E. Gestational age and birthweight classification.** See Chapter 6. The AAP recommends all newborns be classified by both birthweight and gestational age. Assess gestational age by using the new Ballard examination and classify as preterm, late preterm, etc. Classify by birthweight, if extremely low birth weight (ELBW), low birth weight (LBW), etc. Determine if small, appropriate, or large for gestational age based on weight and gestational age.
- III. General appearance.** Observe the infant and record the general appearance (eg, activity, skin color, respirations, posture, obvious congenital abnormalities). Much of the newborn examination is done through observation. **The normal resting posture of a term newborn is in flexion; the normal posture of a preterm baby is in extension at rest.** For an infant born in breech presentation, the infant may have fully flexed hips and knees, feet may be near the mouth, or legs and feet may be to the side of the baby. Note if the general movements are normal, note the skin color, look at chest and note respirations and see if breathing is normal or labored, and look for any obvious major congenital anomalies. Are there any signs or symptoms of infection (fever, lethargy, hypothermia, rashes, tachypnea, abdominal distension, irritability, vomiting) or metabolic disease (growth restriction, rash, jaundice, seizures, hepatosplenomegaly, microcephaly, failure to thrive, anomalies)?
- IV. Abnormal odor.** Does the infant have an abnormal odor? Abnormal odors suggest an inborn error of metabolism or infection.
- A. Odor of maple syrup or burnt sugar, sweet odor of the urine:** Maple syrup urine disease.
 - B. Odor of sweaty feet:** Isovaleric acidemia, glutaric acidemia type II.
 - C. Odor of cat urine:** 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) lyase deficiency.
 - D. Odor of cabbage:** Tyrosinemia type 1.
 - E. Odor of rotten or decaying fish:** Primary trimethylaminuria (seen in preterm neonates fed a choline-containing formula).
 - F. Odor of unpleasant musty smell or mousy body odor:** Phenylketonuria (PKU; due to phenylacetic acid in the urine and stool).
 - G. Fruity breath smell:** Diabetic ketoacidosis.
 - H. Odor of rotten egg:** Smell of hydrogen sulfide, suspect neonatal sulfhemoglobinemia either from drugs or intestinal microbiota.
 - I. Foul/stinky urine:** The smell can be from intestinal bacteria that have entered the urine or bacteria producing ammonia, and it may be a symptom of urinary tract infection (especially in an infant with a fever).
- V. Skin.** See also Chapter 80.

- A. Color.** Regardless of race, skin color is normally reddish-purple and changes to a pinkish red in about 24 hours after birth.
- 1. Plethora (deep, rosy red [ruddy] color).** Plethora beyond 24 hours after birth is more common in infants with polycythemia but can be seen in an overoxygenated or overheated infant. It is best to obtain a central hematocrit on any plethoric infant.
 - 2. Jaundice (yellowish color if secondary to indirect hyperbilirubinemia; greenish color if secondary to direct hyperbilirubinemia).** With jaundice, bilirubin levels are usually >5 mg/dL. This condition is abnormal in infants <24 hours of age and may signify Rh incompatibility, sepsis, and TORCH (toxoplasmosis, other, rubella, cytomegalovirus, and herpes simplex virus) infections. After 24 hours, it may result either from these diseases or from such common causes as ABO incompatibility or physiologic causes.
 - 3. Pallor (washed-out, whitish appearance).** Pallor reflects poor perfusion. It may be secondary to anemia, birth asphyxia, shock, sepsis, or PDA. *Ductal pallor* is the term sometimes used to denote pallor associated with PDA.
 - 4. Poor perfusion.** Some descriptors include “infant doesn’t look good” or “looks mottled.” Poor perfusion is inadequate blood flow to the skin tissues. Check capillary refill time by pressing on the sternum for 5 seconds with a finger and noting the time needed for the color to return. See Chapter 77.
 - 5. Excessive pigmentation.** Infants with more melanin can have increased pigment in the following places: in the axilla, over the scrotum or labia, over the helices of the ear, at the base of the nails, and around the umbilicus. The skin color of the parents and maternal hormones in utero will affect the pigmentation of the infant. The *linea nigra* (dark line down the middle of the abdomen) is from exposure to maternal hormones, is more common in females, and usually resolves spontaneously.
 - 6. Cyanosis** (desaturation of >3 – 5 g/dL of hemoglobin is usually necessary for one to note a bluish color)
 - a. Central cyanosis (bluish skin, including the tongue, mucosal membranes, and lips). Low partial pressure of oxygen (PaO_2) and low arterial oxygen saturation (SaO_2).** Caused by low oxygen saturation in the blood. Rule out cardiac, lung, central nervous system (CNS), metabolic, or hematologic diseases.
 - b. Peripheral cyanosis (bluish skin, especially distal extremities with pink lips, mucous membranes, and tongue). Normal oxygen saturation (normal PaO_2).** It is secondary to an increase in deoxygenated blood on the venous side because of increased oxygen extraction by the tissues. It is best noted in the nail beds and can be associated with all the common causes of central cyanosis (eg, methemoglobinemia). Causes of peripheral cyanosis include vasomotor instability, venous obstruction (venous thrombosis), polycythemia, low cardiac output, shock, sepsis, vasoconstriction secondary to cold exposure, and elevated venous pressure.
 - c. Acrocyanosis (bluish hands and feet only). Normal oxygen saturation (normal PaO_2).** Peripheral cyanosis of the extremities. This may be normal immediately after birth or within the first few hours after birth or with cold stress. Spasm of smaller arterioles can cause this (up to 24–48 hours of life). In a normothermic older infant, consider hypovolemia.
 - d. Perioral cyanosis (bluish color around the lips and philtrum [nose to upper lip]). Normal oxygen saturation at birth.** Common after birth, due to the close proximity of the blood vessels to the skin (infants have a superficial perioral venous plexus). It is not a sign of peripheral or central cyanosis and usually resolves after 48 hours.
 - e. Traumatic cyanosis. Normal oxygen saturation (normal PaO_2).** This is cyanosis of the head and face, usually with petechiae, that results from

venous congestion. It occurs due to a birth face presentation or an umbilical cord around the neck.

- f. **Pseudocyanosis. Normal oxygen saturation (normal PaO₂).** Bluish color of the skin without hypoxemia, hemoglobin abnormality, or peripheral vasoconstriction. The mucous membranes of the mouth are pink. Pressure on the skin fails to blanch. This can mimic peripheral cyanosis except there is no blanching of the skin when pressure is applied. In neonates, it is commonly caused by fluorescent lighting. It can also be due to drug exposure (amiodarone).
 - g. **Differential cyanosis.** The upper part of the body is pink, and the lower body is cyanotic, or vice versa.
 - i. **Differential cyanosis (most common).** Occurs in infants with a PDA with a right to left shunt. The preductal part of the body (upper) is pink, and the postductal body part (lower) is cyanotic. Oxygen saturation in the right hand is greater than in the foot. Seen in severe coarctation of aorta or interrupted aortic arch or in a newborn with a structurally normal heart, it can occur with severe persistent pulmonary hypertension with right to left shunting through the ductus arteriosus.
 - ii. **Reverse differential cyanosis.** This is a **newborn cardiac emergency**. The preductal part of the body (upper part) is cyanotic (blue), and the postductal part (lower part) is pink. This occurs when oxygen saturation is lower in the upper extremity (right hand) than in the lower extremity (foot). This occurs with complete transposition of the great arteries with PDA and persistent pulmonary hypertension or in transposition of the great arteries with PDA and preductal coarctation or aortic arch interruption and supracardiac total anomalous pulmonary venous connection. The ductus allows saturated blood to perfuse the lower body.
 - h. **Cyanosis with asphyxia stages after birth (historical degrees of severity)**
 - i. **Asphyxia livida (early stage).** The phase during asphyxia when primary apnea occurs (heart rate decreases, respiratory efforts may be present, blood pressure rises then drops, arterial partial pressure of carbon dioxide [PaCO₂] and pH increase). The infant is **cyanotic**, has some muscle tone, and has adequate circulation.
 - ii. **Asphyxia pallida (late stage).** The phase during asphyxia when secondary apnea occurs (heart rate and blood pressure drop, circulatory collapse, shock, low PaO₂, increased PaCO₂, low pH). The infant has **pale gray/white skin** and is limp; reflexes are absent, and respiratory efforts are absent.
 - i. **Cyanosis in stages of shock**
 - i. **Warm shock (early stage of shock).** **Extremities are warm**, with loss of vascular tone, peripheral vasodilation, tachycardia, bounding peripheral pulses, increase in systemic blood flow, and a decrease in blood pressure.
 - ii. **Cold shock (late stage of shock).** **Extremities are cold and mottled**, with a prolonged capillary refill time (>2 seconds), decreased peripheral pulses, increase in vascular tone, vasoconstriction, decrease in systemic blood flow, and decrease in blood pressure.
7. **Extensive bruising (ecchymoses) may be confused with cyanosis.** May be associated with a prolonged and difficult delivery and may result in early jaundice. Facial bruising can occur with a tight nuchal cord or difficult delivery. This can be confused with cyanosis. **Petechiae (pinpoint hemorrhages)** can be limited to 1 area and are usually of no concern. If they are

widespread and progressive, then they are of concern, and a workup for coagulopathy should be considered. Upper body petechiae can be seen in pertussis.

8. **“Blue on pink” or “pink on blue.”** Whereas some infants are pink and well perfused and others are clearly cyanotic, some do not fit in either of these categories. They may appear bluish with pink undertones or pink with bluish undertones. This coloration may be secondary to poor perfusion, inadequate oxygenation, inadequate ventilation, or polycythemia.
9. **Harlequin sign/coloration.** A clear line of demarcation between an area of redness and an area of normal coloration. This is a vascular phenomenon, and the cause is usually unknown, but it may be due to immaturity of the hypothalamic center that controls the dilation of peripheral blood vessels. The coloration can be benign and transient (a few seconds to <30 minutes) or can be indicative of shunting of blood (persistent pulmonary hypertension or coarctation of the aorta). There can be varying degrees of redness and perfusion. The demarcating line may run from the head to the belly, dividing the body into right and left halves, or it may develop in the dependent half of the body when the newborn is lying on one side. The dependent half is usually deep red, and the upper half is pale. This occurs most commonly in lower birthweight infants. It can also occur in 10% of full-term infants and usually occurs on the second to fifth day of life. It has been noted after an abdominal paracentesis in an infant with neonatal hemochromatosis. (*Note:* This is not **harlequin fetus**, see page 68).
10. **Cutis marmorata.** Reticular mottling, lacy red pattern of the skin, marbled, purplish skin discoloration.
 - a. **Physiologic cutis marmorata.** May be seen in healthy infants and in those with cold stress, hypovolemia, shock, or sepsis. It can be caused by an instability or immaturity of the nerve supply to the superficial capillary blood vessels in the skin. Physiologic dilatation of capillaries and venules occurs in response to cold stimulus. In hypovolemia, shock, and sepsis, it occurs because of insufficient perfusion of the skin, and mottling can occur. It is usually in a symmetric pattern and can be seen on the extremities but also on the trunk. It is most pronounced when the skin is cooled. It disappears with rewarming.
 - b. **Persistent cutis marmorata.** Occurs in infants with Down syndrome, Cornelia de Lange syndrome, homocystinuria, Menkes disease, familial dysautonomia, trisomy 13, trisomy 18, Divry-Van Bogaert syndrome, and in hypothyroidism, cardiovascular hypertension, and CNS dysfunction.
 - c. **Cutis marmorata telangiectatica congenita.** A rare congenital cutaneous vascular malformation. The marbling is persistent, and 20% to 80% have another congenital abnormality with skin atrophy and ulceration. Asymmetry of the lower extremities is the most common extracutaneous finding. The mottling does not disappear with warming. It can be associated with body asymmetry, glaucoma, retinal detachment, neurologic anomalies, and other vascular anomalies. (See Figure 7–2.)
- B. **Hair characteristics of the newborn** can vary and can indicate a serious condition, be part of a syndrome, or be normal and isolated. Look at not only the color of the hair but also the amount of hair. Does the infant have hair whorls, which are patches of hair growing in a circular direction with a center point (may indicate intellectual disability and abnormal brain growth)? Does the infant have dry, coarse brittle hair (hypothyroidism)? Does the infant have normal hair mixed with hypopigmented hair (oculocerebral syndrome with hypopigmentation, Cross syndrome)?
 1. **Lanugo.** Downy fine unpigmented hair that acts as a protectant in the womb that is seen in infants on surfaces such as the face, back, or ears; more common

FIGURE 7–2. Cutis marmorata telangiectatica congenita (CMTc). (Used with permission from Leslie Castelo-Soccio, MD, PhD, Children’s Hospital of Philadelphia Division of Dermatology.)

in premature infants but can be seen in term infants. By the time they are term and born, most infants have lost their lanugo.

2. **Neonatal alopecia (hair loss in the neonate).** Causes include telogen effluvium (hair loss in the first 6 months of life from hormone level drop, high fever, or stress), perinatal trauma causing pressure-induced alopecia (halo ring of hair loss associated with caput succedaneum), birth trauma causing occipital alopecia, pressure over the bony occipital prominence causing occipital hair loss, congenital nevi, aplasia cutis congenita, congenital triangular alopecia, underlying cystic/meningocele lesion, complex developmental disorders (Kabuki syndrome—circumscribed congenital alopecia with severe developmental delay and malformations), hypothyroidism, hypopituitarism, tinea capitis, and rare conditions of total or near total hair loss (atrachia with papular lesions and vitamin D-resistant rickets).
3. **Alopecia areata causes partial (patchy) or total nonscarring hair loss and is very rare in neonates.** Associated with an increased prevalence of human leukocyte antigen alleles DQB1 03 and DRB1 1104. It may be an autoimmune disease or an indicator of severe disease (alopecia totalis/alopecia universalis).
4. **White patch or forelock of hair on the scalp** can be seen in Waardenburg syndrome or tuberous sclerosis.
5. **Albinism** is autosomal recessive; is characterized by a generalized hypopigmentation of the eyes, skin, and hair (snow white hair, pink eyes, hypopigmented skin); and is seen in all races. Infants with fair skin can have PKU.
6. **Hypopigmented scalp hair can be seen in the following syndromes:** Prader-Willi syndrome, Chédiak-Higashi syndrome, ectrodactyly ectodermal dysplasia clefting syndrome, and piebaldism. Light-colored hair can be seen in

inborn errors of metabolism (PKU) and homocystinuria or can indicate a nutritional deficiency.

7. **Hypertrichosis** (“Werewolf syndrome”) is an excessive amount of hair growth for the age, sex, and race of the infant. It can be normal or associated with the following syndromes: trisomy 18, Cornelia de Lange, Coffin-Siris, Barber-Say, Cantu, Hurler, leprechaunism, and others. **Drug-induced hypertrichosis** is seen with fetal hydantoin syndrome and occasionally with fetal alcohol syndrome and postnatal use of diazoxide and corticosteroids. It can also be an indication of congenital adrenal hyperplasia.
8. **Hypotrichosis** can be seen with homocystinuria, ichthyoses, and ectodermal dysplasia.
9. **Hair collar sign** is a ring or collar of long coarser hair that surrounds a bald nodule of skin on the midline of the newborn’s scalp. It is a marker of cranial dysraphism, and one needs to rule out meningocele, encephalocele, dermoid cyst, Dandy-Walker malformation, heterotopic brain tissue, or agenesis of the corpus callosum.

C. Other skin conditions

1. **Vernix caseosa.** This greasy white substance covers the skin until the 38th week of gestation. Its purpose is to provide a moisture barrier and is completely normal.
2. **Collodion infant.** The skin is covered in a membrane that resembles parchment, and there can be some restriction in growth of the nose and ears. This is usually due to abnormal desquamation, and although sometimes normal, the condition is usually associated with congenital ichthyosis or other rare condition.
3. **Dry skin.** Infants can have a dry flaky skin, and postdate or postmature infants can exhibit excessive peeling and cracking of the skin. Congenital syphilis and candidiasis can present with peeling skin at birth.
4. **Harlequin fetus.** The most severe form of congenital ichthyosis. Affected infants have thickening of the keratin layer of skin that causes thick scales. Survival of these infants has improved with supportive care. (This condition is different than harlequin sign/coloration.)
5. **Aplasia cutis congenita.** Absence of some or all the layers of the skin. Most common is a solitary area on the scalp (70%). The prognosis is excellent, but if the area is large, surgical repair may be necessary (see Figure 80–1).
6. **Subcutaneous fat necrosis.** A reddish lesion with a firm nodule in the subcutaneous tissue that is freely mobile. It is more common in difficult deliveries, perinatal asphyxia, and cold stress. These lesions are usually benign unless there are extensive lesions, in which case calcium levels should be monitored (see Figure 80–7).
7. **Abnormal fat distribution.** Seen with congenital disorders of glycosylation.
8. **Constriction rings around digits, arms, legs.** Occurs in amniotic band syndrome (see Figure 93–1).
9. **Decreased pigmentation.** Seen in PKU.

D. Rashes (rashes are also discussed in Chapter 80)

1. **Milia.** A rash in which tiny sebaceous retention (of keratin) cysts are seen. The whitish yellow pinhead-size concretions are usually on the chin, nose, forehead, and cheeks without erythema (see Figure 80–4). These are seen in approximately 33% of infants, and these benign cysts disappear within a few weeks after birth. **Miliaria** occurs from sweat retention from incomplete closure of the eccrine structures. **Miliaria crystallina** lesions are usually are on the head, neck, and trunk and are from superficial eccrine duct closure. **Miliaria rubra** (heat rash) involves a deeper area of sweat gland obstruction. **Pearls** are large single milia or inclusion cysts that can occur on the newborn’s palate (**Epstein pearls**), on buccal or lingual mucosa (**Bohn nodules**), or

dental lamina cysts (on crests of alveolar ridges), genitalia (**penile pearls**), and areola.

2. **Sebaceous hyperplasia.** In contrast to milia, these raised lesions are more yellow and are sometimes referred to as “miniature puberty of the newborn.” The cause is maternal androgen exposure in utero; they are benign and resolve spontaneously within a couple of weeks.
 3. **Erythema toxicum (erythema neonatorum toxicum).** Consists of numerous small areas of red skin with a yellow-white papule in the center. Lesions are most noticeable 48 hours after birth but may appear as late as 7 to 10 days. Wright staining of the papule reveals eosinophils. This benign rash, which is the most common rash, resolves spontaneously. If suspected in an infant <34 weeks’ gestation, rule out other causes because this rash is more common in term infants (see Figure 80–2).
 4. **Candida albicans rash (“diaper rash”).** Appears as erythematous plaques with sharply demarcated edges. Satellite bodies (pustules on contiguous areas of skin) are also seen. Usually the skin folds are involved. Gram stain of a smear or 10% potassium hydroxide prep of the lesion reveals budding yeast spores, which are easily treated with nystatin ointment or cream applied to the rash 4 times daily for 7 to 10 days.
 5. **Transient neonatal pustular melanosis.** A benign, self-limiting condition that requires no specific therapy. The rash starts in utero and is characterized by 3 stages of lesions, which may appear over the entire body: pustules, ruptured vesicopustules with scaling/typical halo appearance, and hyperpigmented macules. These remain after the pustules have resolved (see Figure 80–3).
 6. **Infantile seborrheic dermatitis.** A common rash usually occurring on the scalp “cradle cap,” face, neck, and diaper area that is erythematous and with greasy scales. A self-limiting condition that is likely due to maternal hormones.
 7. **Acne neonatorum (neonatal acne).** Lesions are typically seen over the cheeks, chin, and forehead and consist of comedones and papules. The condition is usually benign and requires no therapy; however, severe cases may require treatment with mild keratolytic agents (see Figure 80–6).
 8. **Herpes simplex.** Seen as pustular vesicular rash, vesicles, bullae, or denuded skin. The rash is most commonly seen at the fetal scalp monitor site, occiput, or buttocks (presentation site at time of delivery) (see Figure 80–10).
 9. **Sucking blisters.** Solitary lesions that can be intact blisters or can appear as flat, scabbed areas on the hand or forearm. They are only in areas accessible by the mouth, are benign, and resolve spontaneously.
- E. **Nevi (moles)** can be pigmented, brown or black to bluish, or vascular and may be present at birth (see also Chapter 80).
1. **Nevus simplex (fading macular stain; “stork bites,” “angel kiss,” “salmon patch”).** A macular stain is a common capillary malformation normally seen on the occipital area, eyelids, and glabella. They are called “angel kisses” when located on the forehead or eyelids and “stork bites” when on the back of the neck. The lesions disappear spontaneously within the first year of life. Occasionally lesions on the nape of the neck may persist as a medial telangiectatic nevus.
 2. **Port-wine stain (nevus flammeus).** Usually seen at birth, does not blanch with pressure, and does not disappear with time. If the lesion appears over the forehead and upper lip, then **Sturge-Weber syndrome** (port-wine stain over the forehead and upper lip, glaucoma, and contralateral Jacksonian seizures) must be ruled out (see Figure 80–17).
 3. **Congenital dermal melanocytosis (previously called Mongolian spots) is the most common birthmark.** These are slate grey, dark blue, or purple

bruise-like macular spots usually located over the sacrum. Most common in babies of African, Indian, Asian and Hispanic descent, but can occur in <10% of fair-skinned infants. Usually disappear by 5 years of age. (See Figure 80–8.) May be associated with inborn errors of metabolism. Documentation is important because it can be confused with bruising after discharge (child abuse).

4. **Cavernous hemangioma.** Usually appears as a large, red, cyst-like, firm, ill-defined mass and may be found anywhere on the body. Most of these lesions regress with age, but some require corticosteroid therapy. In more severe cases, surgical resection may be necessary. If associated with thrombocytopenia, **Kasabach-Merritt syndrome** (thrombocytopenia associated with a rapidly expanding hemangioma) should be considered.
5. **Strawberry hemangioma (macular hemangioma).** Strawberry hemangiomas are flat, bright red, sharply demarcated lesions that are most commonly found on the face. Spontaneous regression usually occurs (70% disappearance by 7 years of age).

VI. Head. Note the general shape of the head. Some amount of molding is normal in all infants and may be more pronounced in infants who are delivered vaginally compared to cesarean section. Inspect for any cuts or bruises secondary to forceps or fetal monitor leads. Check for microcephaly or macrocephaly. Transillumination can be done for severe hydrocephalus and hydranencephaly. Bruising of the vertex of the head is common after birth. Look for unusual hair growth (**hair whorls** are patches of hair growing in a circular direction). Multiple hair whorls or hair whorls in unusual locations can signify abnormal brain growth. **Abnormal hair** can also be seen in some inborn errors of metabolism, including argininosuccinic acidemia, lysinuric protein intolerance, or Menkes kinky hair syndrome. Swelling may represent **caput succedaneum**, a **cephalohematoma**, or a **subgaleal hemorrhage**. Examine the occipital, parietal, and frontal bones and the suture lines. The fontanelles should be soft when palpated.

- A. **Macrocephaly.** Occipitofrontal circumference is >90th percentile. May be normal or secondary to hydrocephaly, hydranencephaly, or a neuroendocrine or chromosomal disorder.
- B. **Microcephaly.** Is a rare neonatal malformation where the infant's head is much smaller compared to babies of the same sex and age. Occipitofrontal circumference is <10th percentile, and brain atrophy or decreased brain size can occur. Causes include infections (rubella, chickenpox, toxoplasmosis, cytomegalovirus, Zika), genetic mutations, malnutrition, exposure to toxins or prescription medications, untreated PKU, or alcohol and substance abuse.
- C. **Anterior and posterior fontanelles.** The anterior fontanelle usually closes by 24 months (median age ~13 months) and the posterior fontanelle by 2 months. Normal size of anterior fontanelle is 0.6 to 3.6 cm (African American: 1.4–4.7 cm). Posterior fontanelle size is 0.5 cm (African American: 0.7 cm). A **large anterior fontanelle** can be a normal variation or can be seen in congenital hypothyroidism and may also be found in infants with skeletal disorders such as achondroplasia, osteogenesis imperfecta, or hypophosphatasia, and chromosomal abnormalities such as Down syndrome and in those with intrauterine growth restriction. A **bulging fontanelle** may be associated with increased intracranial pressure, meningitis, or hydrocephalus. **Depressed (sunken) fontanelles** are seen in newborns with dehydration. A **small anterior fontanelle** may be associated with hyperthyroidism, microcephaly, or craniosynostosis.
- D. **Cephalic molding.** A temporary asymmetry of the skull resulting from the birth process. Most often seen with prolonged labor and vaginal deliveries, it can be seen in cesarean deliveries if the mother had a prolonged course of labor before delivery. A normal head shape is usually regained within 1 week. Rarely it may be associated with other abnormalities. If it persists, intracranial hypertension can occur.

FIGURE 7-3. Types of extradural fluid collections seen in newborn infants. (Modified from Volpe JJ. *Neurology of the Newborn*. 4th ed. Philadelphia, PA: WB Saunders; 2001.)

- E. Caput succedaneum.** A diffuse edematous swelling of the soft tissues of the scalp that **may extend across the suture lines** but usually is unilateral. It does not increase after birth. It is secondary to the pressure of the uterus or vaginal wall on areas of the fetal head bordering the caput. Elicit the characteristic pitting edema by putting firm constant pressure in one area. Usually, it resolves within several days (Figure 7-3).
- F. Cephalhematoma.** A subperiosteal hemorrhage that **never extends across the suture line** and can be secondary to a traumatic delivery or forceps delivery. It increases after birth. Radiographs or computed tomography scans of the head should be obtained if an underlying skull fracture is suspected (<5% of all cephalhematomas). Hematocrit and bilirubin levels should be monitored. Most cephalhematomas resolve in 2 to 3 weeks. Aspiration of the hematoma is rarely necessary (see Figure 7-3).
- G. Subgaleal hematoma/hemorrhage.** The subgaleal area is the area between the scalp and the skull and is a very large space. Hemorrhage occurs between the epicranial aponeurosis and the periosteum, and when pressure is placed, a fluid wave can be seen. It can cross over the suture line and onto the neck or ear. It progresses after birth. It may be necessary to replace blood volume lost and correct coagulopathy if present, and hemorrhage can be life threatening. It can be caused by asphyxia, vacuum extraction, forceps delivery, or coagulopathy (see Figure 7-3).
- H. Increased intracranial pressure.** The increased pressure may be secondary to hydrocephalus, hypoxic-ischemic brain injury, intracranial hemorrhage, or subdural hematoma. The following signs are evident in an infant with increased intracranial pressure:
1. Bulging anterior fontanelle
 2. Separated sutures
 3. Paralysis of upward gaze (“setting-sun sign”)
 4. Prominent veins of the scalp
 5. Increasing macrocephaly

- I. **Craniosynostosis.** The premature closure of ≥ 1 sutures of the skull; must be considered in any infant with an asymmetric skull. On palpation of the skull, a bony ridge over the suture line may be felt, and inability to move the cranial bones freely may occur. Radiographs of the head should be performed, and surgical consultation may be necessary.
 - J. **Craniotabes.** A benign condition, craniotabes is a congenital softening or thinness of the skull that usually occurs around the suture lines (top and back of head) and disappears within days to a few weeks after birth. It can also be associated with rickets, osteogenesis imperfecta, syphilis, and subclinical vitamin D deficiency in utero.
 - K. **Plagiocephaly.** An oblique shape of a head, which is asymmetric and flattened. It can be seen in preemies and infants whose heads stay in the same position. Anterior plagiocephaly can be due to premature fusion of the coronal or lambdoidal sutures.
 - L. **Brachycephaly.** This is caused by premature closure of the coronal suture and causes the head to have a short broad appearance. It can be seen in trisomy 21 or Apert syndrome.
 - M. **Anencephaly.** The anterior neural tube does not close, and the brain is malformed. Most of these infants are stillborn or die shortly after birth; folate deficiency appears to play a significant role.
 - N. **Acrocephaly.** The coronal and sagittal sutures close early. The skull has a narrow appearance with a cone shape at the top. It can be seen in Crouzon and Apert syndromes.
 - O. **Dolichocephaly/scaphocephaly.** The sagittal suture closes prematurely, and there is a restriction of lateral growth of the skull, resulting in a long, narrow head.
 - P. **Skull fracture.** Most commonly occurs secondary to birth trauma from the pressure of the mother's pelvic bones against the skull during labor. Fracture typically involves either a linear (break but no displacement) or depressed ("ping pong" inner buckling of the calvarium) skull fracture. Linear skull fractures usually present with a subgaleal hematoma. Depressed skull fractures may be associated with intracranial bleeding or cephalhematoma and may need further workup.
- VII. **Neck.** Eliciting the rooting reflex (see page 90) causes the infant to turn the head and allows easier examination of the neck. Palpate the sternocleidomastoid for a hematoma and the thyroid for enlargement, and check for thyroglossal duct cysts.
- A. **Short neck.** Seen in Turner, Noonan, Down, and Klippel-Feil syndromes.
 - B. **Webbed neck (with redundant skin).** Seen in Turner, Noonan, Down, and Klippel-Feil syndromes.
 - C. **Brachial cleft cysts.** Firm, <1-cm cysts that can be on the lateral aspects of the neck, along the anterior margin of the sternomastoid muscle. If dimples are seen here, they are brachial cleft sinuses.
 - D. **Cystic hygroma.** The most common neck mass. It is a fluctuant mass that can be transilluminated and is usually found laterally or over the clavicles. Due to lymphatic blockage, it may be associated with chromosomal abnormalities.
 - E. **Goiter.** May be a result of maternal thyroid disorders or neonatal hyperthyroidism.
 - F. **Thyroglossal duct cyst.** Rarely seen in neonates. They are subcutaneous structures in the midline of the anterior neck at the level of the larynx.
 - G. **Torticollis ("wry neck").** A shortening of the sternocleidomastoid muscle that causes the head to go toward the affected side. Treated initially with physical therapy.
- VIII. **Face.** Observe for obvious facial abnormalities such as symmetry of the face. Is there asymmetry of the face with crying? Note the general shape of the nose, mouth, and chin. Look for unequal movement of the mouth and lips. **Coarse facies** (can be seen in acromegaly or inborn errors of metabolism) includes features such as large lips and tongue, saddle-like nose, and large bulging head with prominent scalp veins.

Flat facial profile can be seen in Down syndrome. The presence of **hypertelorism** (eyes widely separated) or **low-set ears** should be noted. If delivered by **forceps**, a **forceps mark** may be present. It is usually a semicircular mark on the cheek that will resolve spontaneously. **Micrognathia** is a small lower jaw that can interfere with feeding. It is most commonly seen in Pierre Robin sequence but can also be seen in other genetic syndromes.

A. Low-set ears (melotia). See Section IX below on ear disorders.

B. Micrognathia. A small lower jaw that can interfere with feeding. It is most commonly seen in Pierre Robin sequence but can also be seen in other genetic syndromes.

C. Hypertelorism (wide-set eyes with extra bone between the eyes). See page 75.

D. Asymmetric crying face (ACF), also called **congenital unilateral lower lip palsy (CULLP).** The face is symmetric at rest and asymmetric during crying, and the mouth is pulled down on one side and not moving on the other side. In ACF, all the other functions of the facial muscles are normal (eg, forehead wrinkling, closure of eyelids, normal sucking, no drooling). Incidence is 1 in 160 live births (usually term, less frequent in preterm) with a male predominance. Major and minor malformations and deformations can be associated with ACF (risk of anomalies is 3.5 times higher, and most common are cardiovascular system and cervicofacial region). It can be caused by nerve compression, agenesis or hypoplasia of the depressor anguli oris muscle (DAOM), or hypoplasia of the depressor labii inferioris muscle (DLIM).

- 1. Nerve compression of one of the branches of the facial nerve** during delivery (mandibular branch of the seventh cranial nerve that innervates the DAOM and DLIM is superficial and is easily compressed). Electromyography shows abnormal values of the mandibular branch of the facial nerve.

- 2. Agenesis or hypoplasia of the depressor anguli oris muscle (DAOM).** Usually on the left side. This muscle controls the downward motion of the lip. The eye and forehead muscles are unaffected with ACF. Ultrasound shows hypoplasia or agenesis of the DAOM.

- 3. Hypoplasia of the depressor labii inferioris muscle (DLIM)** may be associated with other malformations.

E. Congenital facial nerve paralysis. This is caused by either trauma (most common) or developmental deformities of the facial nerve (cranial nerve VII).

- 1. Trauma.** The most common cause is birth trauma. Risk factors include an injury from forceps, a large baby, and primiparity. On physical examination, there is facial asymmetry with crying, the corner of the mouth droops, there is drooling on the side of the paresis, the nasolabial fold is absent in the paralyzed side, and there is partial closing of the eye (ptosis). Most symptoms disappear within the first week of life, but sometimes it may take several months. If the palsy persists, absence of the nerve should be ruled out.

- 2. Agenesis of the facial nerve nucleus** (Moebius syndrome) is a rare congenital neurologic disorder that is due to the underdevelopment of cranial nerves VI (lateral eye movement) and VII (facial expression). Infants have facial paralysis, are unable to move their eyes from side to side, and have difficulty swallowing.

IX. Ears. Evaluate for an unusual shape or an abnormal position. Confirm that structures of the ear are all present: helix, antihelix, tragus, antitragus, scaphoid/triangular fossa, and external auditory canal. Genetic syndromes are frequently associated with abnormal ear shapes. Assess gross hearing with an infant blinking in response to loud noises. The normal position of ears is determined by drawing an imaginary horizontal line from the inner and outer canthi of the eye across the face, perpendicular to the vertical axis of the head. If the helix of the ear lies below this horizontal line, the ears are designated as **low set**. An otoscopic examination is usually not done on the first examination because the ear canal is usually full of amniotic debris.

- A. **Low-set ears (melotia).** Seen with many congenital anomalies, most commonly Treacher-Collins, Down, triploidy, and trisomy 9 and 18 syndromes, fetal aminopterin effects, and trisomy 13 and 21.
 - B. **Preauricular skin tags (papillomas).** Benign, fairly common, and usually inherited.
 - C. **Ear pits (preauricular pits).** May be unilateral or bilateral and are usually located at the superior attachment of the pinna. They are more common in the Asian population (~10%).
 - D. **Hairy ears.** Lanugo hair or can be more prominent in infants of diabetic mothers.
 - E. **Complete absence of the pinna of the ear (anotia)** is associated with thalidomide and retinoic acid embryopathy. Bilateral anotia is sometimes seen in infants of consanguineous parents.
 - F. **Small ears (microtia).** Used to describe small pinnae, it is a misshaped dysplastic ear that can be associated with other abnormalities such as middle ear abnormalities. Approximately 50% of infants with microtia will have an underlying congenital syndrome. Pediatric ear, nose, and throat (ENT) evaluation and hearing evaluation are required. A hypoplastic ear may be an indicator of internal ear abnormalities. Renal ultrasound is also recommended. Small ears are seen in trisomy 21, as well as trisomy 18 and 13 triploidy and thalidomide and retinoic acid embryopathy.
 - G. **Large ears (macrotia).** The auricle is large, and the scaphoid fossa is the most exaggerated part. It is usually bilateral and symmetric. It can be autosomal dominant and can also be associated with Marfan syndrome, fragile X syndrome, De Lange type 2 syndrome, and others.
 - H. **Lop ear (folded down superior edge of the helix) and cup ear or prominent ear (ear stands away from the head).** Plastic surgery consultation can be obtained.
 - I. **Satyr ear (“Spock ear”).** Characterized by a flattened scaphoid fossa and a flat helix at the superior pole and a third crus into the helix. This is only a cosmetic concern, and molding in the first week of life can be done. Plastic surgery consultation is recommended.
 - J. **Floppy ears with no cartilage** are associated with bilateral renal agenesis, which is uniformly fatal.
- X. **Eyes.** Most infants have some degree of eyelid edema after birth, which usually resolves after the first few days of life. The eyes can still be gently opened and examined. The sclera, which is normally white, can have a bluish tint if the infant is premature because the sclera is thinner in these infants than in term infants. Check for the following: **scleral hemorrhages, exudates** (suggest **conjunctivitis**), and **yellow sclera (icterus)**, which is indicative of hyperbilirubinemia. Check the pupil size bilaterally and verify pupil reactivity; if not the same size, rule out tumor or vascular abnormality. Evaluate eye movements. Is there a **cherry red spot** in the macula of the eye (lipidosis, or occlusion of the central retinal artery)? Check the red reflex with an ophthalmoscope. If a red reflex cannot be obtained or if the pupil is white or cloudy, immediate evaluation by a pediatric ophthalmologist is required. See also Chapter 96.
- A. **Leukocoria (opacification of the lens).** A white pupil with loss of a red light reflex. Opacity behind the pupil is sometimes seen without an ophthalmoscope. Evaluate further for:
 1. **Congenital cataracts.** If suspected, emergency referral of a pediatric ophthalmologist is necessary for early intervention and to preserve sight. Infants with congenital cataracts should be evaluated for an underlying metabolic, genetic, or infectious cause, and 20% will have an identifiable cause. This can be seen in galactosemia and Zellweger syndrome. An **oil drop cataract** can be seen with galactosemia, and on retinoscopy, one sees a classic “oil droplet” against a red reflex due to accumulation of dulcitol within the lens.
 2. **Congenital glaucoma** can present with corneal opacities.

3. **Retinoblastoma.** Tumor requires emergency ophthalmology consultation.
 4. **Retinal detachment** is most commonly due to retinopathy of prematurity.
 5. **Peters anomaly.** Abnormal cleavage of the anterior chamber occurs from anterior segment dysgenesis. There is a central, paracentral, or complete corneal opacity.
- B. **Osteogenesis imperfecta.** Sclera is deep blue.
 - C. **Small eye (microphthalmia)** is often associated with coloboma.
 - D. **Colobomas** are missing pieces of tissue in structures of the eye. A key-shaped defect in the iris, eyelid, or other eye structures can be seen, and numerous syndromic and chromosomal abnormalities are associated.
 - E. **Brushfield spots.** Salt-and-pepper speckling of the iris or white or yellow spots on the iris. Often seen with Down syndrome or may be normal.
 - F. **Subconjunctival hemorrhage.** Occurs in 5% of newborns as a result of rupture of small conjunctival capillaries and can occur normally but is more common after a traumatic delivery. Petechiae on the forehead may be associated. It is asymptomatic and resolves in a few days.
 - G. **Conjunctivitis.** Suspected with hyperemia and if a discharge is present. (See Chapter 58.)
 - H. **Epicanthal folds.** May be normal or may occur in infants with Down syndrome. This is a skin fold of the upper eyelid covering the inner corner of the eye.
 - I. **Dacryocystoceles.** Obstructions of both the superior and inferior ends of the nasolacrimal duct. Presents as bluish nodules inferior to the medial canthi of both eyes. If bilateral, ENT consult should be obtained to evaluate nasal obstruction.
 - J. **Dacryostenosis.** The nasolacrimal ducts are too narrow to drain tears properly. Tears may pool on the eyelids and eyelashes. Usually resolves within the first week of life in approximately 50% of infants. In others, it resolves in several weeks to a few months.
 - K. **Hypertelorism (widely spaced eyes).** The interorbital distance is greater than normal. Normal interorbital distance is 20 mm at birth. This can occur alone or with other congenital deformities.
 - L. **Nystagmus.** This is an involuntary usually rapid eye movement that can be horizontal, vertical, or mixed. Can be normal if occasional, but if persistent, it needs to be evaluated.
 - M. **Ptois.** A drooping of an upper eyelid caused by cranial nerve III paralysis or weakness in the levator muscle. Ptois and ophthalmoparesis can be seen in transient neonatal myasthenia gravis.
 - N. **Dysconjugate eye movements.** During the first months of life, infants will have dysconjugate eye movements, where eyes appear to move independently of each other. They may even appear crossed. Transient movements are normal, especially if this occurs when the infant falls asleep or awakes. If the movement is fixed, a consult with a pediatric ophthalmologist should be obtained.
- XI. **Nose.** Note the appearance of the nose. Sometimes due to a positional deformity, the nose will be asymmetric. If unilateral or bilateral **choanal atresia** is suspected, verify the patency of the nostrils with gentle passage of a nasogastric tube. **Infants are obligate nose breathers**; therefore, if they have **bilateral choanal atresia**, they will have cyanosis and severe respiratory distress at rest.
- A. **Nasal flaring.** Indicative of respiratory distress.
 - B. **Sniffling/snuffles and discharge.** Typical of congenital syphilis.
 - C. **Sneezing.** This can be a response to bright light or drug withdrawal.
 - D. **Dislocated nasal septum.** Incidence of around 4%. The vertical axis of the nose is deviated, and the septum is not straight. Immediate pediatric ENT evaluation is needed, as correction in the first few days of life can prevent a permanent deformity.
- XII. **Mouth.** Examine the hard and soft palates for evidence of a cleft palate including submucosal and partial clefts that can be easily missed.

- A. Cleft lip/palate.** Secondary to midline fusion failure. Unilateral clefts are usually an isolated finding; midline clefts are often associated with midline defects in the brain. May interfere with feeding, and ENT consultation is indicated.
- B. Bifid uvula.** The uvula is larger than normal and has 2 halves and may be associated with a submucous palatal cleft.
- C. Positional deformity of the jaw.** Causes asymmetry of the chin, and gums are not parallel to each other, usually due to utero molding. Resolution occurs without treatment.
- D. Epstein pearl.** A small white papule usually in the midline of the palate. Common and benign, it is secondary to epithelial tissue that is trapped during palatal fusion.
- E. Gingival cysts (dental lamina cysts).** Transient oral mucosal cysts located on the alveolar ridge.
- F. Teeth.** Primary teeth usually begin to erupt at 6 to 8 months of age. **Natal teeth** are teeth that are present at birth. **Neonatal teeth** are teeth that erupt during the first 30 days after birth. **Infancy teeth** are teeth that erupt after 30 days. Supernumerary teeth are teeth that are not part of the normal dentition and should be extracted. Teeth in newborns are uncommon (prevalence 1:1000 to 1:30,000). Etiology is unknown, but the most common accepted theory is based on hereditary factors. There is conflicting information on sex predilection. The most common area involved is the mandibular region of the central incisors in 85% of cases. Other causes include infection (congenital syphilis has varying effect because some erupt early and some erupt late), endocrine disturbances (excessive secretion by the pituitary, thyroid, or gonads), malnutrition (hypovitaminosis), maternal fever (accelerates eruption), hormonal stimulation, environmental factors (polychlorinated biphenyls [PCBs] and dibenzofuran both increase the occurrence of natal teeth), and position of the tooth germ. The most acceptable theory is hereditary factors causing the superficial localization of the dental follicles. Radiographs are sometimes needed to differentiate whether the teeth are supernumerary or part of the normal deciduous dentition. Clinically, teeth can be classified as mature or immature. Complications include aspiration of the tooth, difficulty in feeding, ulceration to the nipple of the mother, and ulceration to the ventral surface of the tongue (Riga-Fede disease). Pediatric dentistry consultation is recommended to decide treatment (early intervention or no treatment).
- 1. Natal teeth (more common).** Erupt most commonly in pairs and are usually poorly attached to the bony structure and can have a poorly developed root system. They are associated with Ellis-van Creveld syndrome, pachyonychia congenita, Rubinstein-Taybi syndrome, steatocystoma multiplex, cyclopia, Pallister-Hall syndrome, short rib polydactyly type II, Wiedemann-Rautenstrauch syndrome, cleft lip and palate, Pfeiffer syndrome, ectodermal dysplasia, craniofacial dysostosis, multiple osteocystomas, adrenogenital, epidermolysis bullosa simplex, Jadassohn-Lewandowski syndrome, Hallermann-Streiff syndrome, Sotos syndrome, and Pierre Robin syndrome. It is best to leave these teeth in the mouth to avoid future space management issues unless symptomatic (highly mobile (risk of aspiration), cause maternal pain during breast feeding, or cause irritation and injury to infant's tongue); then they can be extracted after birth. If loose, it is important to remove the teeth to decrease the risk of aspiration.
 - 2. Neonatal teeth (less common than natal teeth).** These often have a firm root structure and are typically more securely anchored. If mature and of normal dentition, the tooth should be preserved and maintained in a healthy condition. Pediatric dentistry should be involved with periodic follow-up.
 - 3. Supernumerary teeth** Evaluate the infant for risk of hemorrhage due to hypoprothrombinemia present in newborns prior to the extraction.
 - 4. Hutchinson teeth** are an abnormality seen with congenital syphilis. The teeth are smaller, more widely spaced, and have notches on their biting surface. Upper central incisors are the most affected.

- G. **Bohn nodules.** Appear as white bumps on the gum (may look like teeth) or periphery of the palate and are secondary from heterotrophic salivary glands or from remnants of the dental lamina. Benign and will resolve without treatment.
- H. **Ranula.** Cystic swelling in the floor of the mouth. Many resolve spontaneously, but excision may be indicated in some cases.
- I. **Mucocele.** This small lesion on the oral mucosa is secondary to trauma to the salivary gland ducts. Often are benign and resolve spontaneously, but excision may be indicated.
- J. **Macroglossia.** Enlargement of the tongue can be congenital or acquired. Localized macroglossia is usually secondary to congenital hemangiomas. Macroglossia can be seen in **Beckwith syndrome** (macroglossia, gigantism, omphalocele, and severe hypoglycemia), **Pompe disease** (type II glycogen storage disease), and **hypothyroidism**.
- K. **Glossoptosis.** Downward displacement or retraction of the tongue that is seen in Pierre Robin sequence and Down syndrome.
- L. **Ankyloglossia (short lingual frenulum, “tongue tied”).** Occurs in 4% to 10% of newborns. Often a frenotomy will be indicated if tongue mobility and feeding are an issue.
- M. **Frothy or copious saliva** is commonly seen in infants with an esophageal atresia with tracheoesophageal fistula.
- N. **Thrush.** Oral thrush, common in newborns, is a sign of overgrowth of *C albicans*.
- O. **Micrognathia (small jaw).** An underdeveloped jaw that is seen in **Pierre Robin syndrome**; other genetic syndromes should be considered.

XIII. Chest

- A. **Observation.** Note the shape and symmetry of the chest. An asymmetric chest may signify a space- or air-occupying lesion such as tension pneumothorax. Look for tachypnea (increased respiratory rate), retractions (upper and lower chest), xiphoid and sternal subcostal and intercostal retractions, nasal flaring and dilatation, and grunting on expiration. **Note: Grunting, nasal flaring, and intercostal or subcostal retractions indicate increased work of breathing.**
 1. **Grunting.** Occurs when the glottis is closed during expiration. This improves oxygenation by increasing the end expiratory pressure in the lungs. Occasional grunting is acceptable; grunting with every breath is abnormal. Grunting respirations usually occur in the first few hours of life. In one study, **prolonged or persistent grunting** (lasting >2 hours after birth) in term and near-term infants occurred in 1.2% of newborns. Causes included poor adaptation to extrauterine life (most common cause), transient tachypnea, respiratory distress syndrome, and infection (sepsis and pneumonia). Less common causes included birth trauma, pneumomediastinum, hypoxic ischemic encephalopathy, polycythemia, anemia, meconium aspiration, congenital heart defect, congenital diaphragmatic hernia, malformation of the nose, and immature teratoma of the thymus.
 2. **Nasal flaring.** Widening of the nostrils on inspiration; occurs with respiratory distress.
 3. **Retractions.** Can be subcostal or intercostal and represent muscles sucked in between the ribs to increase air flow. One sees a shadow at the lower margin of the rib cage with subcostal retractions (“rib shadows”). Mild retractions, usually subcostal, may be normal.
 4. **Phonatory abnormalities.** Depend on the level of abnormality or obstruction. Phonation is a primary function of the larynx, and an abnormality of this causes no cry or a weak cry. Laryngeal obstruction can be supraglottic, glottic, or subglottic. A **muffled cry and inspiratory stridor** occur with supraglottic obstruction; a **high-pitched or absent cry** is associated with glottic abnormalities (laryngeal web or atresia). Subglottic stenosis can present with **hoarse or weak cry, stridor**, and obstructive breathing.

- a. **Stridor.** A high-pitched sound on inspiration heard without a stethoscope. It can be normal if it occurs occasionally and there are no other signs of respiratory distress. If stridor is persistent, **laryngomalacia is the most common cause**. Other causes include congenital subglottic stenosis, vocal cord paresis, double aortic arch, and other congenital anomalies. **Inspiratory stridor with cyanotic attacks with feeding with aspiration** and pulmonary infections that reoccur can occur with laryngeal and laryngotracheoesophageal clefts.
 - b. **Intermittent hoarseness, dyspnea, weak cry, or aphonia** can be seen in saccular cysts (a mucus-filled dilatation of the laryngeal sacculle).
 - c. **High-pitched inspiratory stridor and inspiratory cry.** Bilateral vocal cord paralysis.
 - d. **Weak cry, usually no serious airway obstruction, occasional breathy, feeding problems.** Unilateral vocal cord paralysis.
 - e. **Mild hoarseness, little airway obstruction.** Thin anterior laryngeal web.
 - f. **Weaker voice, increased airway obstruction.** Thicker laryngeal webs (>75% glottic involvement) cause aphonia and severe airway obstruction.
 - g. **Muffled or absent cry.** Laryngeal web or pharyngeal obstruction.
 - h. **Weak cry, weak sucking, aphonia, and lethargy** can be seen from medications in pregnancy (selective serotonin reuptake inhibitor–induced neonatal abstinence syndrome).
 - i. **Weak but high-pitched cry resembling a cat.** Cri du chat (5p deletion) syndrome.
 - j. **Whistling noise** can occur with a blockage in the nostril.
 - k. **Weak cry.** Hypoglycemia.
 - l. **Weak cry, mild respiratory distress.** Transient neonatal myasthenia gravis.
 - m. **High-pitched cry.** Neonatal abstinence syndrome or hypoglycemia.
 - n. **Hiccups.** Nonketotic hyperglycinemia.
 - o. **Hoarse cry.** Hypothyroidism.
 - p. **Aphonia in a newborn.** Laryngeal web, vocal cord paralysis, tracheal agenesis (respiratory distress and impossible to intubate).
- B. Breath sounds.** Listen for the presence and equality of breath sounds. A good place to listen is in the right and left axillae. Absent or unequal sounds may indicate pneumothorax or atelectasis. Absent breath sounds with the presence of bowel sounds plus a scaphoid abdomen (flat abdomen relative to the chest) suggest diaphragmatic hernia; an immediate radiograph and emergency surgical consultation are recommended.
- C. Fractured clavicle.** Palpate both clavicles; if they cannot be palpated easily and crepitus is felt over the clavicle, the infant may have a fractured clavicle. No treatment is necessary. Note that a healed clavicle fracture will have a firm lump (as new bone develops) in the area.
- D. Rib fractures.** Posterior rib fractures are very rare and can result from birth trauma. Risk factors include high birth weight and shoulder dystocia. Other causes include osteogenesis imperfecta, rickets, or fragile bones secondary to prematurity.
- E. Pectus excavatum (funnel chest)** is a sternum that is depressed in shape. Usually, this condition is of no clinical concern but may be associated with Marfan and Noonan syndromes.
- F. Pectus carinatum (pigeon chest).** Caused by a protuberant sternum. May be associated with Marfan and Noonan syndromes.
- G. Prominence of the xiphoid process.** A firm lump at the end of the sternum; it is a benign finding.
- H. Barrel chest.** Occurs when there is an increased anteroposterior diameter of the chest. It can be secondary to mechanical ventilation, pneumothorax, pneumonia, or space-occupying lesions.

I. Breasts in a newborn. Usually 1 cm in diameter in term male and female infants and may be abnormally enlarged (3–4 cm) secondary to the effects of maternal estrogens. This maternal effect, which lasts <1 week, is of no clinical concern. A usually white discharge (galactorrhea of the newborn), commonly referred to as “neonatal milk” or “witch’s milk,” may be present and is normal and seen in approximately 5% of term or near-term neonates. It is often seen in infants with larger than average breast nodules and may continue for up to 2 months of age. It is caused by the effects of maternal hormones before birth. The term “witch’s milk” is from the ancient folklore that the milk leaking from a newborn’s nipple was nourishment for witches or familiar spirits. It is not recommended to remove the milk by massage, as this can cause a neonatal mastitis or breast abscess. **Supernumerary nipples (polythelia)** are extra nipples along the mammary line (“milk line”) and occur as a normal variant; their association with renal disorders is *controversial*. They can occur singularly or be multiple and be unilateral or bilateral. Skin tags on the nipple area are usually small and should not be confused with polythelia. **Bloody nipple discharge is rare** in an infant and can be seen in breast-fed and formula-fed infants. Causes can include benign mammary ductal ectasia (most common), ductal hyperplasia caused by maternal hormonal stimulation (usually not bloody), temporarily increased progesterone levels, mastitis (bacterial infection), possible herbal medication use by the mother, and pituitary tumor.

XIV. Heart. Observe for heart rate (normal 110–160 beats/min awake, may drop to 80 beats/min during sleep), rhythm, quality of heart sounds, precordium activity, and presence of a murmur. The position of the heart may be determined by auscultation. Physical examination alone can miss up to 50% of cyanotic CCHD, supporting the pulse oximetry screening. (See page 61.) Abnormal situs syndromes and other physical manifestations of congenital heart disease are discussed in Chapter 94.

A. Murmurs. May be associated with the following conditions:

- 1. Ventricular septal defect.** The most common heart defect, this accounts for approximately 25% of congenital heart disease. Typically, a loud, harsh, blowing, pansystolic murmur is heard (best heard over the lower left sternal border). It is not heard at birth but often on day 2 or day 3 of life. Symptoms such as congestive heart failure usually do not begin until after 2 weeks of age and typically are present from 6 weeks to 4 months. Most of these defects close spontaneously by the end of the first year of life.
- 2. Patent ductus arteriosus (PDA).** A harsh, continuous, machinery-type, “washing machine–like,” or “rolling thunder” murmur that usually presents on the second or third day of life, localized to the second left intercostal space. It may radiate to the left clavicle or down the left sternal border. It can be heard loudest along the left sternal border. A hyperactive precordium is also seen. Clinical signs include wide pulse pressure and bounding pulses.
- 3. Coarctation of the aorta.** A systolic ejection murmur that radiates down the sternum to the apex and to the interscapular area. It is often loudest in the back.
- 4. Peripheral pulmonic stenosis.** A systolic murmur is heard bilaterally in the anterior chest, in both axillae, and across the back. It is secondary to the turbulence caused by disturbed blood flow because the main pulmonary artery is larger than the peripheral pulmonary arteries. This usually benign murmur may persist up to 3 months of age. It may also be associated with rubella syndrome.
- 5. Hypoplastic left heart syndrome.** A short midsystolic murmur usually presents anywhere from day 1 to 21. A gallop is usually heard.
- 6. Tetralogy of Fallot.** Typically, a loud, harsh systolic or pansystolic murmur best heard at the left sternal border. The second heart sound is single.

7. **Pulmonary atresia**
 - a. **With ventricular septal defect.** An absent or soft systolic murmur with the first heart sound is followed by an ejection click. The second heart sound is loud and single.
 - b. **With intact intraventricular septum.** Most frequently, there is no murmur, and a single second heart sound is heard.
 8. **Tricuspid atresia.** A pansystolic murmur along the left sternal border with a single second heart sound is typically heard.
 9. **Transposition of the great vessels.** More common in males than females.
 - a. **Isolated (simple).** Cardiac examination is often normal, but cyanosis and tachypnea are present along with a normal chest radiograph and electrocardiogram.
 - b. **With ventricular septal defect.** The murmur is loud and pansystolic and is best heard at the lower left sternal border. The infant typically has congestive heart failure at 3 to 6 weeks of life.
 10. **Ebstein disease.** A long systolic murmur is heard over the anterior portion of the left chest. A diastolic murmur and gallop may be present.
 11. **Truncus arteriosus.** A systolic ejection murmur, often with a thrill, is heard at the left sternal border. The second heart sound is loud and single.
 12. **Single ventricle.** A loud systolic ejection murmur with a loud single second heart sound is heard.
 13. **Atrial septal defects**
 - a. **Ostium secundum defect.** Rarely presents with congestive heart failure in infancy. A soft systolic ejection murmur is best heard at the upper left sternal border.
 - b. **Ostium primum defect.** Rarely occurs in infancy. A pulmonary ejection murmur and early systolic murmur are heard at the lower left sternal border. A split second heart sound is heard.
 - c. **Common atrioventricular canal.** Presents with congestive heart failure in infancy. A harsh systolic murmur is heard all over the chest. The second heart sound is split if pulmonary flow is increased.
 14. **Anomalous pulmonary venous return**
 - a. **Partial anomalous pulmonary venous return.** Findings are similar to those for ostium secundum defect.
 - b. **Total anomalous pulmonary venous return.** With a severe obstruction, no murmur may be detected on examination. With a moderate degree of obstruction, a systolic murmur is heard along the left sternal border, and a gallop murmur is heard occasionally. A continuous murmur along the left upper sternal border over the pulmonary area may also be audible.
 15. **Congenital aortic stenosis.** A coarse systolic murmur with a thrill is heard at the upper right sternal border and can radiate to the neck and down the left sternal border. If left ventricular failure is severe, the murmur is of low intensity. Symptoms that occur in infants only when the stenosis is severe are pulmonary edema and congestive heart failure.
 16. **Pulmonary stenosis (with intact ventricular septum).** If the stenosis is severe, a loud systolic ejection murmur is audible over the pulmonary area and radiates over the entire precordium. Right ventricular failure and cyanosis may be present. If the stenosis is mild, a short pulmonary systolic ejection murmur is heard over the pulmonic area along with a split second heart sound.
- B. Palpate the pulses (femoral, pedal, radial, and brachial).** Bounding pulses can be seen with PDA. Absent or delayed femoral pulses are associated with coarctation of the aorta.
- C. Check for signs of congestive heart failure.** Signs may include hepatomegaly, gallop, tachypnea, wheezes and rales, tachycardia, and abnormal pulses.

XV. Abdomen. See also Chapters 122, 123, and 124.

A. Observation. Obvious birth defects may include an **omphalocele** (see **Figure 123-3**), in which organs (usually stomach, intestines, liver) covered by peritoneum protrude out of an opening in the center of the abdomen in the area of the umbilical cord; **gastroschisis** (see **Figure 123-1**), a **defect in the abdominal wall to the right of the umbilicus** in which typically the large and small intestines (or other organs) not covered by peritoneum protrude out; or **exstrophy of the bladder** (see **Figure 127-1**), in which the bladder protrudes outward through an absent abdominal wall segment.

B. Auscultation. Listen for bowel sounds.

C. Palpation. Check the abdomen for distention, tenderness, or masses. The abdomen is most easily palpated when the infant is quiet or during feeding. In normal circumstances, the liver can be palpated 1 to 2 cm below the costal margin and the spleen tip at the costal margin. Hepatomegaly can be seen with congestive heart failure, hepatitis, some inborn errors of metabolism (storage disorders, urea cycle defects), or sepsis. Splenomegaly is found with cytomegalovirus or rubella infections or sepsis. The lower pole of both kidneys can often be palpated. Kidney size may be increased with polycystic disease, renal vein thrombosis, or hydronephrosis. Abdominal masses are more commonly related to the urinary tract.

D. Abdominal circumference. See page 63.

E. Linea nigra. See page 64.

F. Diastasis rectus abdominis. A protrusion (vertical bulge) from the xiphoid to the umbilicus because of the weakness of the fascia between the 2 rectus abdominis muscles, which causes a separation of the muscles. It can be seen when intra-abdominal pressure increases and is typically a benign finding in newborns and will resolve with time.

G. Scaphoid abdomen. A sunken abdomen is associated with congenital diaphragmatic hernia. The abdomen looks flat relative to the chest.

H. Prune belly syndrome (Eagle-Barrett syndrome). Usually seen in males (97%) and of unknown genetic origin, it consists of a large, thin, wrinkled abdominal wall; genitourinary malformations; and cryptorchidism. Surgery may be required, and survival rate has improved.

XVI. Umbilicus. Normally, the umbilicus has 2 arteries and 1 vein. The absence of 1 artery occurs in 5 to 10 of 1000 singleton births and in 35 to 70 of 1000 twin births. The presence of **only 2 vessels** (1 artery and 1 vein) could indicate renal or genetic problems (commonly trisomy 18). If there is a **single umbilical artery**, there is an increased prevalence of congenital anomalies (40%) and intrauterine growth restriction and a higher rate of perinatal mortality. If it occurs without any other abnormalities, it is usually benign. **If the umbilicus is abnormal, ultrasonography of the abdomen is recommended.** In addition, inspect for any discharge, redness, or edema around the base of the cord that may signify a **patent urachus or omphalitis**. Some amount of periumbilical erythema is considered normal with separation of the cord. The cord should be translucent; a **greenish yellow color** suggests meconium staining, usually secondary to fetal distress. **Dark stripes** in the cord are intravascular clots and are a normal finding. A normal umbilical cord stump sloughs off at approximately 7 to 10 days of age. (See also Chapter 123, which discusses ophthalmoceles and gastroschisis.)

A. Omphalitis is an infection of the cord. This is a very serious condition, can be fatal, and requires immediate treatment. Therefore, any redness of the cord with or without purulent drainage should be promptly evaluated. (See Chapter 80.)

B. Patent urachus is a communication between the bladder and the umbilicus, resulting in urine coming from the umbilicus. Pediatric urology workup is needed to rule out lower urinary tract obstruction. Other urachal abnormalities include urachal cysts and sinuses.

- C. Umbilical hernias.** Result from a weakness in the muscle of the abdominal wall or umbilical ring and usually resolve during the first year of life without treatment. Can be seen in hypothyroidism.
- D. Umbilical hematomas.** From rupture of the umbilical vessels, usually the vein, from birth or trauma or a spontaneous occurrence. Risk factors include traction on the cord, chorioamnionitis, cord prolapse cord torsion, velamentous insertion, short cord, or thinning of the cord from a postdate delivery. They are rare (1:5000) and usually resolve with no treatment.
- E. Umbilical hemangiomas.** Rare benign tumor but can be very serious. Complementary studies are needed to evaluate associated anomalies, including cutaneous and systemic hemangiomas and other malformations.
- F. Wharton jelly cyst (umbilical cord pseudocyst).** This is a benign condition in which there is a single or multiple fluid-filled spaces within the umbilical cord where liquefaction of the jelly has occurred. The cord appears translucent and cystic, and 20% of infants will have other abnormalities.
- G. Patent omphalomesenteric (vitelline) duct** is a communication between the ileum and the umbilicus. It presents with drainage of enteric contents, often with a prolapse of the duct and adjacent ileum from the umbilicus.
- H. Umbilical polyp** is a bright red nodule representing intestinal or gastric mucosa remnant.
- XVII. Genitalia.** Any infant with a disorder of sex development (presence of genitalia that do not fit into a male or female classification; formerly called “ambiguous genitalia”) should not undergo gender assignment until a formal endocrinology and urologic evaluation has been performed (see Chapter 95). **Note: A male with any question of a penile abnormality should not be circumcised until he is evaluated by a pediatric urologist or pediatric surgeon.**
- A. Male genital examination.** Observe the color of the scrotum. Pigment in the scrotum varies depending on the ethnicity and hormonal influence. It can also be hyperpigmented from adrenogenital syndromes. A **bluish color** may suggest testicular torsion or trauma and requires immediate urologic/surgical consultation. Infants will have well-developed scrotal rugae at term; a smooth scrotum suggests prematurity. **Examine the penis;** newborn males always have a marked **phimosis** and the foreskin may not be easily retracted. Verify that the testicles are in the scrotum and examine for groin hernias and masses. If born breech by vaginal delivery, the infant can have bruised and swollen genitals from pressure on the cervix.
- 1. Determine the site of the meatus.** Hypospadias is abnormal location of the urethral meatus on the ventral surface of the penis, **epispadias** is abnormal location of the urethral meatus on the dorsal surface of the penis, **dorsal hood** (foreskin that is incompletely formed that covers the dorsal or top of the penis) is associated with hypospadias, and **chordee** is a dorsal or ventral curvature of the penis. **Megalourethra** is congenital dilation of the urethra usually caused by abnormal development of the corpus spongiosum and will require surgical correction.
 - 2. Check the size of the penis.** It is important to measure the penile size appropriately. In a supine position, using a rigid ruler pressed firmly against the pubic symphysis, grasp the penis with the other hand and carefully stretch it measuring from the tip of the glans to the base of the penis. The average range of stretched penile length is:
 - a. Newborn 30 weeks’ gestation: 2.1–2.9 cm**
 - b. Newborn 34 weeks’ gestation: 2.6–3.4 cm**
 - c. Term newborn: 3.1–3.9 cm**

A **micropenis** is defined as a penis that is 2.5 standard deviations below the mean for a given age, without any hypospadiac abnormalities. This corresponds to ≤ 1.5 cm at 30 weeks’ gestation, ≤ 2.0 cm at 34 weeks’ gestation, and ≤ 2.5 cm in a term newborn.

3. **Palpate and check the size of the testicles.** Normal testicles should be similar in size (normal testicular size at birth: width 1.0 cm, length 1.5 cm, volume $1.0 \pm 0.14 \text{ cm}^3$).
4. **Priapism.** Persistent erection of the penis is an abnormal finding and can be seen in polycythemia, but the most common neonatal reason is idiopathic.
5. **Webbed penis.** Penoscrotal web can occur and is a contraindication for circumcision.
6. **Buried penis.** Rare congenital penile deformity where the penis appears buried in the tissues surrounding it. Do not circumcise.
7. **Penile pearls.** Similar to Epstein pearls on palate; can be present on the tip of the foreskin and will resolve with time.
8. **Penile torsion.** Check to see position of the penis and if it is toward the midline. If it is facing the thigh, torsion may be present. Also check the position of the median raphe. It should start and end at the midline of the scrotum and the tip of the penis. Mild torsion of <60 degrees is normal. High degrees of torsion will need to be surgically corrected.
9. **Hypoplastic urethra.** Infants will have thinning of the foreskin on the ventral side and a penile raphe that is not straight. If a feeding tube through the urethra is visible through the skin, then a hypoplastic urethra is present and circumcision is contraindicated. A pediatric urology consult should be obtained.
10. **Undescended testicles.** More common in premature infants. Sometimes term infants will have 1 testicle that has not descended from the abdomen to the scrotum. Palpation of the inguinal canal will verify that the testicle is there. **Unilateral undescended testicle is common** and should be followed by routine physical examinations over time. **Bilateral undescended testicles are considered a disorder of sex development.** An ectopic testicle passes through the inguinal ring and then goes off in another location (perineum, femoral canal, superficial inguinal pouch, or the other hemiscrotum).
11. **Hydroceles.** Hydroceles are common, especially in premature infants, and are collections of fluid in the scrotum. They usually disappear by 1 year of age unless associated with an inguinal hernia. If there is a patent processus vaginalis, the fluid is coming from the peritoneal cavity and it is called a **communicating hydrocele**. Palpation or transillumination will assist in the diagnosis.
12. **Neonatal testicular torsion** accounts for 10% of all testicular torsions, and the majority are extravaginal. The testis twists around its vascular pedicle and compromises arterial, venous, and lymphatic flow, which can result in ischemia, infarction, and necrosis. Infants present with an acute scrotal color change (usually bluish) with no signs of pain (in contrast to older patients). The torseid testicle is smaller in size, and this is a surgical emergency to prevent loss of the organ.
13. **Antenatal testicular torsion.** Usually the scrotal appearance is normal. The torseid testicle can be larger in size and feel more mass-like in texture. A Doppler ultrasound should be done to verify blood flow. The torseid testicle must be removed and the opposite side fixed to prevent torsion since it is at an increased risk.
14. **Inguinal hernia** is common in males. The bowel enters the scrotal sac through the patent processus vaginalis. Presents as a fullness in the inguinal area. Premature infants have a higher risk for inguinal hernias ($\sim 3\%$ – 5% in term infants and 13% in infants born at <33 weeks of gestational age).
15. **Supernumerary testicle** is very rare and is the presence of >2 testes. The most common type is triorchidism, and it is most often left sided. It can be associated with cryptorchidism, indirect inguinal hernia, torsion, and malignancy.

16. **Scrotal hematoma** is a masslike area of the scrotum secondary to blood products from birth trauma, hypoxia, sepsis, or bleeding diathesis. Rule out hemorrhage from abdomen or retroperitoneum and traumatic testicular rupture.

B. Female genital examination

1. **Examine the labia majora and minora and clitoris.** Labia majora of term infants are enlarged and frequently reddish in color secondary to maternal hormones. If the labia are fused and the clitoris is enlarged, adrenal hyperplasia should be suspected. The labia minora decrease in size near term.
2. **Clitoromegaly (a large clitoris).** This can be normal in a premature infant or can be associated with maternal drug ingestion (excess androgens during fetal life) or a disorder of sex development such as congenital adrenal hyperplasia. Normal newborn clitoral length is <7 mm, and mean length is 4 mm. Suspect androgen excess if clitoromegaly and hyperpigmentation (ie, congenital adrenal hyperplasia) are present.
3. **Mucosal/vaginal tag.** Commonly attached to the wall of the vagina and is of no clinical significance.
4. **Discharge from the vagina.** Common and is often clear, thick, and whitish or blood tinged. It is secondary to maternal hormones and only lasts a few days. If bloody discharge (pseudo-menses), this can be normal and secondary to maternal estrogen withdrawal.
5. **Vaginal mass. Benign or malignant neoplasms of the vagina are not very common.** The vaginal mass often can be seen with crying or from increased abdominal pressure. Imaging studies are required. The differential of a vaginal mass in a newborn include: most common (hymenal cysts or paraurethral gland cysts); others are prolapsed urethra, vagina, or uterus; ectopic ureterocele; Gartner's duct cyst; Skene's gland cyst; hydrometrocolpos caused by an imperforate hymen; and rhabdomyosarcoma of the vagina.
6. **Paraurethral cyst (rare).** Interlabial spherical cystic mass that is yellowish in color and can cover both urethral meatus and orifice of the vagina. Surgery is usually not necessary because many resolve spontaneously.
7. **Perineal groove (failure of midline fusion).** Rare. This has 3 major features: moist perineal cleft between the anus and the posterior fourchette, hypertrophy of the labial tails, and normal vagina and urethra. Check anus, as some may have an ectopically placed anus. Conservative management is recommended.
8. **Prolapsed ureterocele.** This is a urologic emergency.

XVIII. Anus and rectum. Make sure the infant does not have a fistula. Meconium should pass within 48 hours of birth for term infants. Premature infants are usually delayed in passing meconium. Check for patency of the anus to rule out **imperforate anus** (absence of a normal anal opening). Insert a small feeding tube not >1 cm or observe for passage of meconium. Check the position of the anus using the anal position index (API), and if out of range, consult pediatric surgery.

A. Anal position index (API).

1. **API in females.** Measure the distance in centimeters from the posterior fourchette (thin fold of skin at the back of the vulva) to the center of the anus divided by the distance between the fourchette and the lowermost point of coccyx. The mean API in term females is 0.45 ± 0.08 . Mean ± 2 standard deviations is considered normal.
2. **API in males.** Measure ratio of the distance between the center of the anus and the first scrotal fold to the distance between the first scrotal fold and the lowermost point of the coccyx. Mean API in males is 0.54 ± 0.07 . Mean ± 2 standard deviations is considered normal.

XIX. Lymph nodes. Palpable lymph nodes, usually in the inguinal and cervical areas, are found in approximately 33% of normal neonates.

- XX. Extremities.** Examine the arms and legs, check for lack of movement or pain response upon palpation (fracture). Pay close attention to the digits and palmar creases. (See also Chapter 112.) Most infants have 2 major creases on the palm. A single transverse palmar crease is associated with Down syndrome. Edematous hands and feet can be associated with Turner syndrome. Was the infant born breech? If the infant was born frank breech (baby buttocks aimed at birth canal with legs sticking straight up in front with feet near the head), the legs may maintain this position for days after birth.
- A. Syndactyly.** Abnormal fusion of the digits; most commonly involves the third and fourth fingers and the second and third toes. A strong family history exists. Surgery is performed when the neonates are older. Severe syndactyly can involve all 4 digits being fused together.
 - B. Polydactyly.** Supernumerary digits on the hands or the feet. The most common is postaxial polydactyly. This condition is associated with a strong family history. Preaxial polydactyly is less common and may have an underlying medical condition. A radiograph of the extremity is usually obtained to verify whether any bony structures are present in the digit. If there are no bony structures, a suture can be tied around the digit until it falls off. If bony structures are present, surgical removal is necessary. Axial extra digits are associated with heart anomalies. **Polysyndactyly** involves more than a normal amount of digits with fusion of some of them.
 - C. Brachydactyly.** This is a shortening of ≥ 1 digits. It is usually benign if an isolated trait.
 - D. Camptodactyly.** This usually involves the little finger and is a flexion deformity that causes it to be bent.
 - E. Arachnodactyly.** This is spiderlike fingers that can be seen in Marfan syndrome and homocystinuria.
 - F. Clinodactyly.** This usually involves the little finger, is usually benign, and is usually a slight medial incurvation, a radial or ulnar deviation. Can be associated with Down syndrome and other genetic disorders.
 - G. Finger or toe hypoplasia.** Nail hypoplasia usually accompanies this. This can be seen in association with maternal teratogens, chorionic villus sampling, chromosome abnormalities, and malformation syndromes, or there can be no cause.
 - H. Digit or thumb aplasia.** Amniotic bands can cause missing digits. A workup for genetic and chromosomal causes should be done.
 - I. Overlapping toes.** Usually a positional deformity that has no significance if an isolated finding. If other abnormal physical findings are seen, a genetic workup may need to be done.
 - J. Nail deformities.** Hypoplastic nails can be seen in Turner syndrome, Edward syndrome (with overlapping digits), nail-patella syndrome, and fetal phenytoin exposure. Hyperconvex nails can be seen in Patau syndrome. The fingernails and toenails may be thickened and abnormally colored or shaped in pachyonychia congenita. It is associated with autosomal dominant inheritance related to an abnormal keratin gene.
 - K. Arthrogryposis multiplex congenita.** A persistent contracture of the joints of the fingers that can be associated with oligohydramnios.
 - L. Positional deformities of the feet.** Positional deformities of the foot are usually from in utero position, and there is resolution without treatment.
 - M. Simian crease.** A single transverse palmar crease is most commonly seen in Down syndrome but is occasionally a normal variant seen in 5% of newborns.
 - N. Clubfoot (talipes equinovarus).** More common in males, the foot is turned downward and inward, and the sole is directed medially. If this problem can be corrected with gentle force, it will resolve spontaneously. If not, orthopedic treatment and follow-up are necessary.

- O. **Metatarsus varus.** A defect in which the forefoot rotates inward (adduction). This condition usually corrects spontaneously.
- P. **Metatarsus valgus** is a defect in which the forefoot rotates outward.
- Q. **Rocker bottom feet.** Usually seen with trisomy 13 and 18, it involves an arch abnormality that causes a prominent calcaneus with a rounded bottom of the sole.
- R. **Tibial torsion.** This is an inward twisting of the tibia bone that causes the feet to turn in. It is most commonly caused by the position in the uterus and resolves spontaneously.
- S. **Genu recurvatum.** The knee is able to be bent backward. This abnormal hyperextensibility can be secondary to joint laxity or trauma and is found in Marfan and Ehlers-Danlos syndromes.
- T. **Congenital amputation of arms, legs, digits.** Think amniotic band syndrome or maternal substance use.
- U. **Extremity fractures.** Incidence is 0.23 to 0.67 in 1000 live births. The majority of are caused by birth trauma from vaginal and cesarean breech deliveries and are easily diagnosed by radiography or ultrasonography. Breech delivery remains the most common factor in long bone fractures. General symptoms include swelling around the broken bone, obvious pain, and constant crying. The **humerus** is the second most commonly fractured bone associated with birth trauma. Humerus fracture occurs from rotation or hyperextension of the upper extremity during delivery. Symptoms include decreased movement, pain with palpation and movement of the affected arm, swelling around the broken bone, and obvious constant crying. If the fracture is near the epiphysis, ultrasound or magnetic resonance imaging is better for diagnosis. **Femur fractures** from birth trauma are rare (0.13 in 1000 live births), are usually secondary to torsional injury leading to a spiral fracture, and usually occur in the proximal half of the femur. Infant may present with no symptoms.

XXI. Trunk and spine. Check for any gross defects of the spine. An increased amount of hair on the lower back can be normal in infants who have an increase in pigmentation. Any abnormal pigmentation, swelling, or hairy patches over the lower back should increase the suspicion that an underlying vertebral or spinal abnormality exists. A sacral or pilonidal dimple may indicate a small meningocele or other anomaly. Congenital midline vascular lesions may raise suspicion about occult spinal dysraphism (eg, spinal bifida occulta), and if the lesions appear with other abnormal findings, then imaging studies should be done.

- A. **Sacral dimples below the line of the natal cleft are benign** (within 2.5 cm of the anus) and have a visible base and no other abnormalities on physical examination. These require no further evaluation. If they are above the natal cleft, an ultrasound is indicated to check for a track to the spinal cord.
- B. **Coccygeal pits.** A simple dimple in which the base cannot be seen. These are benign.
- C. **Sacral skin tags.** Require spinal ultrasound examination to rule out spinal dysraphism. They may also represent a residual tail.
- D. **Meningomyelocele.** A neural tube defect in which there is incomplete closure of the posterior spine; the lumbar spine is the most common location.

XXII. Hips. (See also Chapter 112.) When examining the hips, the most important clinical aspect is to **screen for developmental dysplasia of the hip (DDH)**. This is a very controversial topic regarding definition, screening, and treatment. The majority of physicians agree that screening is important because the earlier DDH is detected, the simpler and more effective is the treatment. **The AAP published a policy statement in 2000 and an updated the clinical report in 2016.** The AAP indicates that screening is beneficial to prevent the late presentation after 6 months of age with hip dislocation or subluxation.

There is no uniform definition of DDH, as the exact definition is controversial. It includes a spectrum of hip disorders, including mild instability of the

femoral head, frank dislocation (head of femur is completely out of the acetabulum [hip socket]), partial dislocation, dysplastic hips (spectrum of femoral head or acetabulum dysgenesis that can often be seen radiologically that may or may not cause clinical instability), and subluxated (head of the femur is simply loose in the socket and moves to the edge but not out of the hip socket) or malformed acetabula.

It is difficult to differentiate what developmental variation is versus true disease. The majority of physicians agree it is a condition in which the femoral head has an abnormal relationship to the acetabulum.

A. Controversy regarding screening and treatment. Screening is *controversial*, as most mild cases of DDH (neonatal hip instability and dysplasia) resolve spontaneously. Note that no screening program has been shown to completely eliminate the risk of a late presentation of a dislocated hip. The following are the various screening guidelines from the US Preventive Services Task Force (USPSTF), Cochrane review, AAP, American Academy of Orthopedic Surgeons (AAOS), Pediatric Orthopedic Society of North America (POSNA), and Canadian Task Force on DDH:

1. **US Preventive Services Task Force.** “Based on insufficient evidence, the USPSTF does not recommend routine screening for developmental dysplasia of the hip (DDH) as a means to prevent adverse outcomes.” This statement only applies to infants who do not have obvious hip dislocations or other abnormalities evident without screening.
2. **Cochrane review.** “There is insufficient evidence to give clear recommendations for practice on screening programs for developmental dysplasia of the hip. There is evidence that delaying treatment for infants with unstable but not dislocated hips, or infants who on ultrasound have mild hip dysplasia by 2 to 8 weeks decreases the need for treatment without a huge increase in late diagnosed dysplasia or surgery.”
3. **AAP.** “The AAP recommends that all newborn infants be screened for DDH by physical examination. They also recommend frequent follow up at scheduled well infant visits up to 6 to 9 months of age. For preterm infants they feel that despite the medical urgencies the infant has, it is critical to do a complete physical examination as DDH may go unrecognized in premature infants.”
4. **AAOS, POSNA, and Canadian Task Force on DDH.** Each group recommends newborn and periodic screening for DDH.

B. Incidence. Clinical instability of the hips occurs in approximately 1% to 2% of full-term infants. The incidence of developmental dislocation of the hip is approximately 1 in 1000 live births. Up to 15% of infants have hip instability or hip immaturity seen on imaging.

1. **Risk factors for DDH.** The majority of infants with DDH do not have any risk factors. Risk factors are additive.
 - a. **Breech presentation in the third trimester for both males and females** is probably the **single most important risk factor**, with an incidence of 2% to 27% of boys and girls presenting in breech position. The highest risk is in a female presenting frank breech (sacral presentation, hips flexed, knees extended). Breech position near the end of pregnancy contributes to DDH more than just the breech delivery. Risk may be decreased with cesarean delivery. Breech-associated DDH is milder and has a more rapid spontaneous normalization.
 - b. **Female sex** with no other risk factors accounts for 75% of DDH. More common in white females (9:1), this condition is more likely to be unilateral and to involve the left hip. It may be increased in females because of the hormone relaxin, which males are protected from. It makes ligaments stretchier and bones more likely to move out of position.

- c. **Positive family history.** When a first-degree relative is affected, the infant has a 12-fold increased risk of DDH compared with controls. The left hip is more likely to be involved. **Genetics may play** a bigger role than previously thought. If a monozygotic twin has DDH, the risk is 40% to the other twin; if a dizygotic twin has DDH, the risk is 3%.
 - d. **Incorrect/improper lower extremity swaddling.** Traditional swaddling puts the hips in an extended and adducted position, which increases the risk of DDH. Traditional swaddling occurs in Navajo Indian, Turkish, and Japanese infants, in whom an increase in DDH is seen.
- C. Recommendations and best practices from the AAP, POSNA, AAOS, and Canadian DDH Task Force.** The goal for the physician is to be able to diagnose hip subluxation or dislocation by 6 months of age. This is done by periodic physical examination and selective ultrasound or radiography, with consultation by orthopedics or a pediatric radiologist.
1. **Screen all newborns (even premature infants) by physical examination for DDH.** This is the **most important primary screening tool**. Remember, most DDH occurs in infants without risk factors.
 - a. **Evaluate for asymmetric thigh or buttock gluteal creases.** Normal inguinal folds do not extend beyond the anus. This is better to observe when the infant is prone.
 - b. **Determine if there is limb length discrepancy.** Shortening of the affected leg is a warning sign.
 - c. **Test for limited or asymmetric abduction.** Restricted movement can be a significant sign. Normal findings include abduction to 75 degrees and adduction to 30 degrees in a supine infant with stable pelvis. Best to perform after 3 months of age when it is generally positive.
 2. **Perform the Ortolani test.** Perform the Ortolani test (preferred) with or without the Barlow test. Best to perform before 3 months of age, at which point the dislocated hip becomes fixed, making these tests not useful. The Barlow test can be performed but has no proven predictive value for hip dislocation.
 - i. **The Ortolani test for stability** (a reductive maneuver) is “where a subluxated or dislocated femoral head is reduced into the acetabulum with gentle hip abduction.” This is the most important clinical test for detecting newborn dysplasia. **Do this test gently.** Place the infant in the frog-leg position. Abduct the hips by using the middle finger to apply gentle inward and upward pressure over the greater trochanter. A “clunk sensation” is a palpable and sometimes audible sound that corresponds to the femoral head being dislocated or reduced on exam. It is a significant finding and denotes a true positive test. A hip click is a benign or palpable sound that is caused by benign soft tissue movement and is not associated with the movement of the femoral head, is not predictive of DDH, and, therefore, is clinically insignificant.
 - ii. **The Barlow maneuver can be performed but has less clinical significance when compared to the Ortolani maneuver. It has no proven predictive value for future hip dislocation.** It is a test with flexion, adduction, and posterior pressure that tests for laxity. It is “where a reduced femoral head is gently adducted until it becomes dislocated or subluxated.” The significance of the Barlow test has been questioned, and some feel there is no value in performing it. In addition, if performed too forcefully or too many times, it could cause instability by stretching the capsule unnecessarily. **AAP recommends that if it is performed that one should gently adduct the hip while palpating for the head falling out the back of the acetabulum.** There should be no posterior directed force applied. A palpable

“clunk” during the Barlow maneuver indicates positive instability with a positive test.

2. Imaging. Ultrasound or radiography can be used at any age between 4 and 6 months (“watershed period”). Most sources agree that universal ultrasound imaging is not recommended. The AAP **Choosing Wisely campaign** states “when an infant exhibits no risk factors or physical findings, a screening hip ultrasound to rule out developmental hip dysplasia or developmental hip location should not be ordered.” **Selective imaging** is recommended, which includes:

a. Hip ultrasonography should be performed and interpreted using the American College of Radiology and American Institute of Ultrasound in Medicine guidelines by experienced examiners.

i. AAP recommends that one can consider selective hip ultrasound from 6 weeks to 6 months of age in high-risk infants without positive findings. High-risk factors include male or female breech presentation, positive family history, concerned parents, suspicious but inconclusive periodic examination, history of a previous positive instability, and history of tight lower extremity swaddling.

ii. AAOS states that moderate evidence supports performing an imaging study on all infants <6 months old if they have 1 of the following risk factors: breech presentation, family history, or clinical instability.

b. Radiography (anteroposterior and frog pelvis plain radiographs). Historically used to diagnose an infant with DDH. Plain radiography is not recommended before 4 to 6 months of age since the femoral head is composed of cartilage and will not be readily seen. If used, it is recommended after 4 to 6 months of age when the ossification center develops in the femoral head. Because the position can affect the results, make sure the pelvis is not rotated or the gonadal shield is not covering the hip joint. Hip asymmetry, subluxation, and dislocation can be seen on a radiograph when the infant has dysplasia. There is controversy on whether minor variability on the radiograph constitutes actual disease.

i. AAP notes that radiography can be considered for diagnosis in any infant without physical findings >4 months old with risk factors or any infant with an abnormal examination (positive clinical findings).

ii. AAOS states there is limited evidence to use an anteroposterior pelvic radiograph instead of ultrasound at 4 months of age to assess DDH.

3. Orthopedic referral for suspected hip abnormalities

a. Obtain an orthopedic referral for a positive Ortolani test, a dislocated hip on a physical examination, or any infant >4 weeks of age who has limited or asymmetric hip abduction.

b. Possible indications for an orthopedic referral include any infant with risk factors for DDH, questionable physical examination, or concern of pediatrician or parents.

XXIII. Nervous system. Observe the infant for any abnormal movement (eg, seizure activity, bicycling, and jitteriness) or excessive irritability. **Jitteriness** can be stopped if the extremity is held (unlike **seizures**, which cannot be stopped) and can be normal or be secondary to hypoglycemia (most common), hypocalcemia, or drug withdrawal. Remember, neurologic symptoms of hypotonia, lethargy, poor sucking, seizures, and coma can be seen with some inborn errors of metabolism, which are discussed in Chapter 100. Then evaluate the following parameters:

A. Muscle tone

1. Hypotonia. Observe the posture and activity of the infant. Pick the infant up and see that the arms fall back and almost feel like a ragdoll. In ventral

suspension, the head drops very low, and there is an exaggerated convex curvature of the spine. Floppiness and head lag are seen.

2. **Hypertonia.** Increased resistance is apparent when the arms and legs are extended. Hyperextension of the back and tightly clenched fists are often seen.
- B. Reflexes.** The following reflexes are considered normal for a newborn infant. These primary reflexes reflect normal brainstem activity. CNS depression/injury should be suspected if these reflexes cannot be elicited, and their persistence beyond a certain age can suggest damage of cortical functioning.
1. **Protective reflex.** If the nose and eyes are covered with something, the infant will arch and make efforts to move the item away.
 2. **Rooting reflex.** Stroke the lip and the corner of the cheek with a finger and the infant will turn in that direction and open the mouth. This helps the infant find the breast to initiate breast feeding, and this reflex disappears at 4 months.
 3. **Babkin reflex.** If both thumbs are pressed equally against the palms, there is a reflex opening of the mouth and a twist of the head on the vertical axis until the median line, and at the same time, the head is bowed forward. This reflex is normal in the first 10 weeks of life; persistence after 12 weeks suggests spastic-motor development disorder.
 4. **Glabellar reflex (blink reflex).** Tap gently over the forehead and the eyes will blink.
 5. **Sucking reflex.** Touch roof of baby's mouth with finger, pacifier, breast, or bottle nipple and the infant begins to suck. This reflex begins after 32 weeks of pregnancy and is fully developed at 36 weeks. Preterm infants may have a weak sucking ability.
 6. **Grasp reflex (palmar grasp).** Place a finger or object in the palm of the infant's hand and the infant will grasp the finger (flexion of the fingers will occur). This reflex is also present in the feet of a newborn. Stroke up the middle of the foot and the toes will curl under as if to grasp the examiner. It is present until 2 to 3 months of age.
 7. **Galant reflex.** Suspend the infant in a prone position. Stroke the back in a cephalocaudal direction. The infant should respond by moving the hips toward the stimulated side.
 8. **Neck-righting reflex.** Turn the infant's head to the right or left, and movement of the contralateral shoulder should be obtained in the same direction.
 9. **Asymmetric tonic neck reflex (fencing reflex).** With the infant in a supine position, turn the infant's head to one side, and the arm and leg on the side of the head that is turned will extend outward, and there will be flexion of the limbs on the opposite side. This is the fencing position.
 10. **Moro reflex (startle reflex).** Support the infant behind the upper back with 1 hand, and then drop the infant back ≥ 1 cm to, but not on, the mattress. This should cause symmetrical abduction of both arms and extension of the fingers followed by flexion and adduction of the arms. Asymmetry may signify a fractured clavicle, hemiparesis, or brachial plexus injury. An absent Moro reflex is of concern and may signify CNS pathology. This reflex normally disappears at 4 to 5 months.
 11. **Plantar grasp.** When one strokes the ball of the foot, the toes will curl.
 12. **Placing reflex.** Hold the infant upright and place the dorsum of the foot by the edge of the bed; the infant places the foot on the surface. This reflex disappears by 5 months of age.
 13. **Stepping/walking reflex.** Hold the infant upright under his or her arms while supporting the infant's head and have the infant's feet touch a flat surface. The infant will appear to take a step and walk.

14. **Positive support reflex.** Hold the infant under the arms with head support, have the feet bounce on a flat surface, and the infant will extend the legs for 20 seconds and then flex the legs into a sitting position.
 15. **Swimming reflex.** Place an infant abdomen down in a pool of water and the infant will paddle and kick in a swimming motion up to 6 months of age.
- C. Cranial nerves.** Note the presence of gross nystagmus, the reaction of the pupils, and the ability of the infant to follow moving objects with his or her eyes.
- D. Movement.** Check for spontaneous movement of the limbs, trunk, face, and neck. A fine tremor is usually normal. Clonic movements are not normal and may be seen with seizures.
- E. Peripheral nerves**
1. **Brachial plexus injuries.** These involve damage to the spinal nerves that supply the arm, forearm, and hand. Etiology is multifactorial.
 - a. **Erb-Duchenne paralysis (upper arm paralysis).** Involves injury to the fifth and sixth cervical nerves and is the most common brachial plexus injury. There is adduction and internal rotation of the arm. The forearm is in pronation, the power of extension is retained, the wrist is flexed, and the Moro reflex is absent. This condition can be associated with diaphragm paralysis.
 - b. **Klumpke paralysis (lower arm paralysis).** Involves the seventh and eighth cervical nerves and the first thoracic nerve. The hand is flaccid with little or no control. If the sympathetic fibers of the first thoracic root are injured, ipsilateral ptosis, enophthalmos, and miosis (**Horner syndrome**) can rarely occur.
 - c. **Paralysis of the entire arm.** The entire arm is limp and cannot move. The reflexes are absent.
 2. **Facial nerve palsy.** Intrauterine position or forceps can cause compression of the seventh cranial nerve. This results in ptosis, unequal nasolabial folds, and asymmetry of facial movement. Differentiate it from **asymmetric crying facies**, which can be caused by nerve compression, or agenesis or hypoplasia of the depressor anguli oris muscle or hypoplasia of the depressor labii inferioris muscle, which controls the downward motion of the lip. The eye and forehead muscles are not affected in this condition. Asymmetric crying facies can be associated with major and minor deformations or 22q11 deletion.
 3. **Phrenic nerve injury.** This can occur secondary to a brachial plexus injury. It causes paralysis of the diaphragm, leading to respiratory distress.
- F. General signs associated with neurologic disorders**
1. **Symptoms of increased intracranial pressure.** Bulging anterior fontanelle, dilated scalp veins, separated sutures, and setting sun sign. (See page 71.)
 2. **Hypotonia or hypertonia.**
 3. **Irritability or hyperexcitability.**
 4. **Poor sucking and swallowing reflexes.**
 5. **Shallow, irregular respirations.**
 6. **Apnea.**
 7. **Apathy.**
 8. **Staring.**
 9. **Seizure activity.** Sucking or chewing of the tongue, blinking of the eyelids, eye rolling, and hiccups.
 10. **Absent, depressed, or exaggerated reflexes.**
 11. **Asymmetric reflexes.**

8 Temperature Regulation

The chance of survival of neonates is markedly enhanced by the successful prevention of excessive heat loss. The newborn infant must be kept under a **neutral thermal environment**. This is defined as the external temperature range within which metabolic rate and hence oxygen consumption are at a minimum while the infant maintains a normal body temperature (Figures 8-1 and 8-2 and Table 8-1). The **normal skin temperature** in the neonate is 36.0°C to 36.5°C (96.8–97.7°F), and the **normal core (rectal) temperature** is 36.5°C to 37.5°C (97.7–99.5°F). **Axillary temperature** may be 0.5°C to 1.0°C lower (95.9–98.6°F). A normal body temperature implies only a balance between heat production and heat loss and should not be interpreted as the equivalent of an optimal and minimal metabolic rate and oxygen consumption.

I. Hypothermia and excessive heat loss. Preterm infants are predisposed to heat loss because they have a high ratio of surface area to body weight (3–5 times more than the adult), little insulating subcutaneous fat, and reduced glycogen and brown fat stores. In addition, their hypotonic (“frog”) posture limits their ability to curl up to reduce the skin area exposed to the colder environment.

A. Mechanisms of heat loss in the newborn include the following:

1. **Radiation.** Heat loss from the infant (warm object) to a colder nearby (not in contact) object. It is the major source of daily heat loss (40% or more without clothing/blanket and low room air movement and room air temperature of 24–26°C).
2. **Conduction.** Direct heat loss from the infant to the surface with which he or she is in direct contact such as lying on a cold table or under an x-ray plate.
3. **Convection.** Heat loss from the infant to the surrounding air proportional to the surrounding air temperature and movement velocity.
4. **Evaporation.** Heat loss by water evaporation from the skin of the infant. Immediately after delivery, evaporative heat loss may contribute to >50% of all heat loss. Thereafter, its magnitude is inversely proportional to the degree of immaturity. The underdeveloped stratum corneum results in higher skin permeability for the extremely low birthweight infant (<1000 g body weight). Transepidermal water loss as high as 6 to 8 mL/kg/h may be seen in the most immature infants during the first weeks of life.

B. Consequences of excessive heat loss. In contrast to adults, the newborn is unable to compensate for heat loss by increasing production through shivering and increased muscular activity. Heat production is thus performed through a non-shivering process (nonshivering thermogenesis) that involves oxidation of fatty acids from brown fat. Brown adipocytes are found in a discrete location in the cervical-supraclavicular area (the most common) and in perirenal/adrenal and paravertebral regions around the major vessels. They contain a large number of mitochondria, hence their brown coloration. Temperature receptors sensing a low temperature stimulate increased sympathetic output from the central nervous system, resulting in norepinephrine release, which in turn stimulates β -adrenergic receptors in brown fat, increasing cyclic adenosine monophosphate production. The release of cytoplasmic stores of triglycerides and fatty acids increases metabolism, resulting in increased oxygen consumption and heat production. This compensatory augmentation in heat production through the increase in metabolic rate includes the following:

1. **Insufficient oxygen supply and hypoxia** from increased oxygen consumption that can be 2 or 3 times as high as the normal resting value.
2. **Hypoglycemia secondary** to depletion of glycogen stores.

FIGURE 8-1. Neutral thermal environment during the first week of life (in degrees Celsius), based on gestational age. (Reproduced with permission from Sauer PJ, Dane HJ, Visser HK: *New standards for neutral thermal environment of healthy very low birthweight infants in week one of life*, Arch Dis Child. 1984 Jan;59(1):18-22.)

3. **Metabolic acidosis** caused by hypoxia and peripheral vasoconstriction.
 4. **Decreased growth.**
 5. **Apnea.**
 6. **Pulmonary hypertension** as a result of acidosis and hypoxia.
- C. Consequences of hypothermia.** As the capacity to compensate for the excessive heat loss is overwhelmed, hypothermia will ensue.
1. **Clotting disorders** such as disseminated intravascular coagulation and pulmonary hemorrhage can accompany severe hypothermia.
 2. **Shock** with resulting decreases in systemic arterial pressure, plasma volume, and cardiac output.
 3. **Intraventricular hemorrhage.**
 4. **Severe sinus bradycardia.**
 5. **Increased neonatal mortality.**
- D. Treatment of hypothermia.** Rapid versus slow rewarming continues to be *controversial*, although the trend is toward more rapid rewarming. Rewarming may induce apnea, hypotension, and rapid electrolyte shifts (Ca^{2+} , K^{+}); therefore, the hypothermic infant should be continuously and closely monitored regardless of the rewarming method. One recommendation is to rewarm at a rate of $1^{\circ}\text{C}/\text{h}$ unless the infant weighs <1200 g, the gestational age is <28 weeks, or the temperature is $<32.0^{\circ}\text{C}$ (89.6°F) and the infant can be rewarmed more slowly (with a rate not to exceed $0.5^{\circ}\text{C}/\text{h}$). Another

FIGURE 8-2. Neutral thermal environment from days 7 to 35 (in degrees Celsius), based on body weight. (Reproduced with permission from Sauer PJ, Dane HJ, Visser HK: *New standards for neutral thermal environment of healthy very low birthweight infants in week one of life*, *Arch Dis Child*. 1984 Jan;59(1):18-22.)

recommendation is that, during rewarming, the skin temperature not be $>1^{\circ}\text{C}$ warmer than the coexisting rectal temperature.

1. Equipment and techniques

- a. **Closed incubators.** Usually used for infants who weigh <1800 g. Closed incubators are convectively heated (heated airflow); therefore, they do not prevent radiant heat loss unless they are provided with double-layered walls. Similarly,

Table 8-1. APPROXIMATE NEUTRAL THERMAL ENVIRONMENT IN INFANTS WHO WEIGH >2500 G OR ARE >36 WEEKS' GESTATION^a

Age	Temperature ($^{\circ}\text{C}$)
0–24 hours	31.0–33.8 ^b
24–48 hours	30.5–33.5
48–72 hours	30.1–33.2
72–96 hours	29.8–32.8
4–14 days	29.0–32.6
>2 weeks	Data not established ^b

^aFor infants <2500 g or <36 weeks, see Figures 8-1 and 8-2.

^bIn general, the smaller the infant, the higher the temperature.

Data from Scopes JW, Ahmed I: Range of critical temperatures in sick and premature newborn babies, *Arch Dis Child*. 1966 Aug;41(218):417-419.

evaporation loss is compensated for only when additional humidity is added to the incubator. One disadvantage of incubators is that they make it difficult to closely observe a sick infant or to perform any type of procedure. Body temperature changes associated with sepsis may be masked by the automatic temperature control system of closed incubators. Such changes will hence be expressed in the variations in the incubator's environmental temperature. An infant can be weaned from the incubator when his or her body temperature can be maintained at an environmental temperature of $<30.0^{\circ}\text{C}$ (usually when the body weight reaches 1600–1800 g). Enclosed incubators maintain a neutral thermal environment by using one of the following devices:

- i. Servo-controlled skin probe attached to the abdomen of the infant.** If the temperature falls, additional heat is delivered. As the target skin temperature ($36.0\text{--}36.5^{\circ}\text{C}$) is reached, the heating unit turns off automatically. A potential disadvantage is that overheating may occur if the skin sensor is detached from the skin or the reverse if the infant is lying on the probe-attached side.
 - ii. Air temperature control device.** The temperature of the air in the incubator is increased or decreased depending on the measured temperature of the infant. Use of this mode requires constant attention from a nurse, and it is usually used in older infants.
 - iii. Air temperature probe.** This probe hangs in the incubator near the infant and maintains a constant air temperature. There is less temperature fluctuation with this kind of probe.
- b. Radiant warmer.** Typically used for very unstable infants or during the performance of medical procedures. Heating is provided by radiation and therefore does not prevent convective and evaporative heat loss. The temperature can be maintained in the “servo mode” (ie, by means of a skin probe) or the “nonservo mode” (also called the “manual mode”), which maintains a constant radiant energy output regardless of the infant's temperature. Serious overheating can result from mechanical failure of the controls, from dislodgment of the sensor probe, or from manual operation without careful monitoring. Deaths are associated with hyperthermia-induced radiant warmers. On manual mode, such as in the delivery room, they should be used only for a limited period. Insensible water loss may be extremely large in the very low birthweight (VLBW) infant (up to 8 mL/kg/h). Covering of the skin with semipermeable dressing or the use of a water-based ointment (eg, Aquaphor) may help reduce insensible transepidermal water loss. Improved thermal stability can be provided by the addition of a heating mattress.
- c. Hybrid incubator.** More recent development of a hybrid incubator allows the intermittent use of a vertically adjustable radiant heater as well as drop-down incubator walls to improve access while allowing for better control of environmental humidity. Lesser incidence of bronchopulmonary dysplasia and better fluid balance and growth velocity have been reported with the use of these new types of incubators.
- d. Kangaroo mother care.** The infant is placed skin-to-skin in a vertical position between the mother's breasts and under her clothes. This technique was initially advocated as an effective way for mothers to keep their full-term babies warm while breastfeeding and as an alternative method of caring for low-birthweight babies in resource-limited countries. More recently, intermittent kangaroo care skin-to-skin contact (SSC), provided by the mother or father, has been introduced in resource-rich countries for babies requiring neonatal intensive care—even extremely premature infants and those on ventilators. Conduction of heat from parent to infant is sufficiently high to compensate for the increase in evaporative and convective heat loss seen during SSC. Enhanced parental bonding, facilitation of breast feeding, better sleep patterns, and procedural pain relief are some of its purported benefits.

2. **Temperature regulation in the healthy term infant (weight >2500 g).** Studies have shown that a healthy term infant can be wrapped in warm blankets and placed directly into the mother's arms without any significant heat loss.
 - a. **Place the infant** under a preheated radiant warmer immediately after delivery.
 - b. **Dry the infant** completely to prevent evaporative heat loss.
 - c. **Cover the infant's head with a cap.**
 - d. **Place the infant,** wrapped in blankets, in a crib.
3. **Temperature regulation in the sick term infant.** Follow the same procedure as that for the healthy term infant, except place the infant under a radiant or hybrid warmer with temperature servoregulation.
4. **Temperature regulation in the premature infant (weight 1000–2500 g).**
 - a. **For an infant who weighs 1800 to 2500 g** with no medical problems, use of a crib, cap, and blankets is usually sufficient.
 - b. **For an infant who weighs 1000 to 1800 g**
 - i. **A well infant** should be placed in a closed incubator with servo-control.
 - ii. **A sick infant** should be placed under a radiant or hybrid warmer with servo-control.
5. **Temperature regulation in the extremely low birthweight (ELBW) infant (weight <1000 g).** See Chapter 13.
 - a. **In the delivery room.** Considerable evaporative heat loss occurs immediately after birth. Consequently, speedy drying of the infant has been emphasized as a very important aspect of the management of the ELBW infant. A more efficient and different approach has been advocated whereby the infant is placed in a plastic bag from feet to shoulders, without drying, immediately at birth.
 - b. **In the nursery.** Either the radiant warmer or the incubator can be used, depending on the institutional preference. Hybrid devices offer the combined features of radiant warmer and closed incubator with controllable humidity in a single device, allowing for seamless conversion between modes as deemed clinically necessary.
 - i. **Radiant warmer**
 - (a) **Use servo-control with the temperature for abdominal skin** set at 36.0°C to 36.5°C.
 - (b) **Cover the infant's head with a cap.**
 - (c) **To reduce convective heat loss,** place plastic wrap (eg, Saran Wrap) loosely over the infant. Prevent this wrap from directly contacting the infant's skin. Avoid placing the warmer in a drafty area.
 - (d) **Maintain an inspired air temperature** of the hood or ventilator of $\geq 34.0^{\circ}\text{C}$ to 35.0°C.
 - (e) **Place under the infant a heating pad (K-pad)** that has an adjustable temperature between 35.0°C and 38.0°C. To maintain thermal protection, it can be set between 35.0°C and 36.0°C. If the infant is hypothermic, the temperature can be increased to 37.0°C to 38.0°C (*controversial*).
 - (f) **If the temperature cannot be stabilized,** move the infant to a closed incubator (in some institutions).
 - ii. **Closed incubator.** Excessive humidity and dampness of the clothing and incubator can lead to excessive heat loss or accumulation of fluid and possible infections.
 - (a) **Use servo-control,** with the temperature for abdominal skin set at 36.0°C to 36.5°C.
 - (b) **Use a double-walled incubator** if possible.
 - (c) **Cover the infant's head** with a cap.
 - (d) **Keep the humidity level** at $\geq 40\%$ to 50% (as high as 89% if needed).
 - (e) **Keep the temperature** of the ventilator at $\geq 34.0^{\circ}\text{C}$ to 35.0°C.
 - (f) **Place under the infant** a heated mattress (K-pad) that has an adjustable temperature between 35.0°C and 38.0°C. For thermal protection,

the temperature can be set between 35.0°C and 36.0°C. For warming a hypothermic infant, it can be set as high as 37.0°C to 38.0°C.

(g) **If the temperature is difficult to maintain**, try increasing the humidity level or use a radiant warmer (in some institutions).

II. Hyperthermia. Defined as a temperature that is greater than the normal core temperature of 37.5°C.

A. Differential diagnosis

1. **Environmental causes.** Some causes include excessive environmental temperature, overbundling of the infant, placement of the incubator in sunlight, a loose skin temperature probe with an incubator or radiant heater in servo-control mode, or a servo-controlled temperature set too high.

2. **Infection.** Bacterial or viral infections (eg, herpes).

3. **Dehydration.**

4. **Maternal fever in labor.**

5. **Maternal epidural analgesia during labor.**

6. **Drug withdrawal.**

7. **Unusual causes**

a. **Hyperthyroid crisis or storm**

b. **Drug effect** (eg, prostaglandin E₁)

c. **Riley-Day syndrome** (periodic high temperatures secondary to defective temperature regulation)

B. Consequences of hyperthermia. Hyperthermia, like cold stress, increases metabolic rate and oxygen consumption, resulting in tachycardia, tachypnea, irritability, apnea, and periodic breathing. If severe, it may lead to dehydration, acidosis, brain damage, and death. The risk of neurologic injury after asphyxia has been shown to be enhanced in the presence of elevated infant's body temperature.

C. Treatment

1. **Defining the cause of the elevated body temperature is the most important initial issue.** Determine whether the elevated temperature is the result of a hot environment or increased endogenous production, such as is seen with infections. In the former case, one may find a loose temperature probe, an elevated incubator air temperature, and the temperature of the extremities of the infant as high as the rest of the body. In the case of "true fever," one expects a low incubator air temperature as well as cold extremities secondary to peripheral vasoconstriction.

2. **Other measures.** Turn down any heat source and remove any excessive clothing.

3. **Additional measures for older infants with significant temperature elevation:**

a. **A tepid water sponge bath.**

b. **Acetaminophen** (5–10 mg/kg per dose, orally or rectally, every 4 hours).

c. **Water-filled cooling blanket such as the Kool-Kit Neonate and Blanketrol III** (Cincinnati Sub-Zero, Cincinnati, OH; see Figure 43–1).

9 Respiratory Management

The management of infants with respiratory distress has long been a basic function of neonatal intensive care. Today, death from acute respiratory failure is uncommon, even among the extremely premature, but significant morbidity from mechanical ventilation persists. Current trends in neonatal ventilation focus on reducing ventilator-induced lung injury, and noninvasive support is preferred. When mechanical ventilation is needed, new ventilators cede as much control as possible to the patient. Optimal treatment continues to be difficult to define, and considerable variability exists in assessing the risk–benefit ratio of various management

strategies. This chapter provides an overview of current techniques used for neonatal respiratory support.

I. Assessing and monitoring respiratory status

A. Physical examination. The presence of the following signs may be useful in recognizing respiratory distress and evaluating the response to treatment. The absence of signs may be secondary to neurologic depression rather than absence of pulmonary disease.

- 1. Nasal flaring.** One of the earliest signs of respiratory distress, nasal flaring may be present in intubated, ventilated patients as well.
- 2. Grunting.** Commonly seen early in respiratory distress syndrome (RDS) and transient tachypnea, grunting is a physiologic response (partial closure of the glottis during expiration) to prevent end-expiratory alveolar collapse. Grunting helps maintain functional residual capacity (FRC) and therefore oxygenation.
- 3. Retractions.** Intercostal, subcostal, and sternal retractions are present in conditions of decreased lung compliance or increased airway resistance and may persist during mechanical ventilation if support is inadequate.
- 4. Tachypnea.** A respiratory rate >60 breaths/min implies the inability to generate an adequate tidal volume and may persist during mechanical ventilation.
- 5. Cyanosis.** Central cyanosis indicates hypoxemia. Cyanosis is difficult to appreciate in the presence of anemia. Acrocyanosis is common shortly after birth and is not a reflection of hypoxemia.
- 6. Abnormal breath sounds.** Inspiratory stridor, expiratory wheezing, and rales should be appreciable. Unfortunately, unilateral pneumothorax may escape detection on auscultation.

B. Blood gases. Management of ventilation, oxygenation, and changes of acid-base status is most accurately determined by **arterial blood gas studies**.

- 1. Arterial blood gas studies.** The most standardized and accepted measure of respiratory status, especially for the oxygenation of low-birthweight infants. They are considered invasive monitoring and require arterial puncture or an indwelling arterial line. Access is now considered routine by the umbilical artery or peripherally in the radial or posterior tibial artery.
- 2. Normal arterial blood gas values.** May not be the same as target values for particular patients, nor acceptable values. Table 9–1 lists examples of normal values for infants.
- 3. Calculated arterial blood gas indexes.** For determining progression of respiratory distress and are as follows:
 - a. Alveolar-to-arterial oxygen gradient ($AaDO_2$).** Greater than 600 mm Hg for successive blood gases over 6 hours is associated with high mortality in most

Table 9–1. NORMAL RANGE OF ARTERIAL BLOOD GAS VALUES FOR TERM AND PRETERM INFANTS AT NORMAL BODY TEMPERATURE AND ASSUMING NORMAL BLOOD HEMOGLOBIN CONTENT^a

Gestational Age	PaO ₂ (mm Hg)	PaCO ₂ (mm Hg)	pH	HCO ₃ (mEq/L)	BE/BD
Term	80–95	35–45	7.32–7.38	24–26	±3.0
Preterm (30–36 weeks' gestation)	60–80	35–45	7.30–7.35	22–25	±3.0
Preterm (<30 weeks' gestation)	45–60	38–50	7.27–7.32	19–22	±4.0

HCO₃, bicarbonate; BE, base excess; BD, base deficit.

^aValues for PaO₂, PaCO₂, and pH are measured directly by electrodes. HCO₃ and BE/BD values are calculated from nomograms of measured values at normal (14.8–15.5 mg/dL) hemoglobin content and body temperature (37°C) and assuming hemoglobin saturation of $\geq 88\%$.

infants if treatment and ventilation do not become effective. The formula for $AaDO_2$ is

$$A - aDO_2 = \left[(FiO_2)(Pb - 47) - \frac{PaCO_2}{R} \right] - PaO_2$$

where Pb = barometric pressure (760 mm Hg at sea level), 47 = water vapor pressure, $PaCO_2$ is assumed to be equal to alveolar PCO_2 , and R = respiratory quotient (usually assumed to be 1 in neonates).

- b. Arterial-to-alveolar oxygen ratio (a/A ratio).** Also an index for effective respiration. The a/A ratio is the most often used index for evaluation of response to surfactant therapy and is used as an indicator for inhaled nitric oxide therapy for pulmonary hypertension. The formula for the a/A ratio is

$$a/A = \frac{PaO_2}{\left[(FiO_2)(Pb - 47) - \frac{PaCO_2}{R} \right]}$$

- 4. Venous blood gases.** Determination of values is the same as for arterial blood gases, but the interpretation is different. The pH values are slightly lower, and $PvCO_2$ values are slightly higher, whereas PvO_2 values are of no value in assessing oxygenation.
- 5. Capillary blood gases.** Arterializing of capillary blood is done by warming the infant's heel just before sampling. The pH value is usually slightly lower, and the PCO_2 is usually slightly higher than arterial values, but this may vary considerably depending on the sampling technique. PO_2 data are of no value.
- C. Noninvasive blood gas monitoring.** Use of these technologies is strongly encouraged. They allow for continuous monitoring and can dramatically reduce the frequency of blood gas sampling, reducing iatrogenic blood loss and decreasing cost. Blood gas sampling is still necessary for calibrating noninvasive measures, determining acid-base status, and detecting hyperoxia.
- 1. Pulse oximetry.** The pulse oximeter measures the relative absorption of light by saturated and unsaturated hemoglobin, which absorbs light at different frequencies. The ratio changes in response to the rapid influx of arterial blood during the upstroke of the pulse. Through the detection of the peak of the ratio, the oximeter is able to determine the pulse rate and the percentage of arterial oxygen saturation. SaO_2 is arterial oxygen saturation by direct measurement; SpO_2 is arterial oxygen saturation by pulse oximetry.
- a. Limitations.** Include poor correlation of SaO_2 to PaO_2 at upper and lower PaO_2 values. SaO_2 of 88% to 93% corresponds to PaO_2 of 40 to 80 mm Hg. For infants with high or low saturations, arterial blood gas correlation is needed.
- b. Advantages.** Include minimal damage to the skin and no required manual calibration. SaO_2 by pulse oximetry is less affected by skin temperature and perfusion than transcutaneous oxygen ($tcPO_2$).
- c. Disadvantages.** Include the tendency of patient movement and excessive external lighting to interfere with readings and the lack of correction for abnormal hemoglobin (eg, methemoglobin).
- 2. Transcutaneous oxygen ($tcPO_2$) monitoring.** Measures the partial pressure of oxygen from the skin surface by an electrochemical sensor. Contact is maintained through a conducting electrolyte solution and an oxygen-permeable membrane.
- a. Limitations.** Include the need for daily recalibration, relocation to different skin sites every 4 to 6 hours, and irritation or injury to a premature infant's skin secondary to adhesive rings and thermal burns. Poor skin perfusion caused by shock, acidosis, hypoxia, hypothermia, edema, or anemia may prevent accurate measurements.
- b. Advantages.** $tcPO_2$ is noninvasive and may provide indication of excessively high PaO_2 (>100 mm Hg).

3. **Near-infrared spectroscopy (NIRS).** The light-absorbing characteristics of oxygenated and deoxygenated hemoglobin are used for this technique. NIRS relies on this differential absorption of light and also on the relatively transparent nature of tissue to infrared light to give an estimation of tissue oxygenation. NIRS represents a weighted average of arterial and venous saturation, which varies from tissue to tissue and over time.
 4. **Transcutaneous carbon dioxide monitoring (tcPCO₂).** Usually accomplished simultaneously by a single lead enclosed with a tcPO₂ electrode.
 5. **End-tidal carbon dioxide (CO₂) monitoring (ETCO₂ or PetCO₂).** Expired breath analysis by infrared spectroscopy for CO₂ content gives close correlation to PaCO₂. This technique is increasingly available for neonates. It gives rapid information about changes in CO₂, unlike the slow response time of tcPCO₂.
 - a. **Limitations.** An adapter to the endotracheal tube is required, which may significantly increase the dead space of the patient's circuit. Accuracy is limited when the respiratory rate is >60 breaths/min or if the humidity of inspired air is excessive. Current devices are of limited use for premature infants.
 - b. **Advantages.** It is a noninvasive technique that may correlate well with arterial PaCO₂.
- D. Monitoring mechanical ventilation.** Modern mechanical ventilators measure and display many variables.
1. **Inspired oxygen.** Fraction of inspired oxygen (FiO₂) is a percentage of oxygen available for inspiration. It is expressed either as a percentage (21%–100%) or as a decimal (0.21–1.00).
 2. **Airway pressure.** Measured either at the endotracheal tube connector or within the ventilator, depending on the specific machine. The ventilator may display set and/or measured pressures for mechanical and/or spontaneous breaths. Pressures of common interest are:
 - a. **Peak inspiratory pressure (PIP).** The maximum pressure reached during inspiration. The need for high PIP reflects poor pulmonary compliance or the use of excessively large tidal volume.
 - b. **Positive end-expiratory pressure (PEEP).** The pressure maintained between breaths. A PEEP of 3 to 4 cm H₂O is considered physiologic. Lung compliance is often improved by increasing PEEP to 5 to 6 cm H₂O in RDS.
 - c. **Mean airway pressure (Paw).** Average of the proximal pressure applied to the airway throughout the entire respiratory cycle (Figure 9–1).

FIGURE 9–1. Graphic representation of ventilator airway pressure waveforms and other ventilator terminology. See Glossary (page 116) for explanations.

- i. \overline{Paw} correlates well with mean lung volume for a given mode and strategy of mechanical ventilation.
 - ii. $\overline{Paw} > 10$ to 15 cm H₂O during conventional ventilation is associated with an increased risk of air leaks (pneumothorax or pulmonary interstitial emphysema).
 - iii. \overline{Paw} of high-frequency ventilation is *not* strictly comparable with the \overline{Paw} of conventional mechanical ventilation.
3. **Tidal volume (V_T)**. A function of PIP during mechanical ventilation, V_T is integrated from flow (mL/s) and measured as milliliters per breath. By convention, V_T is expressed as breath volume adjusted to body weight as milliliters per kilogram. Newer infant ventilators allow setting desired V_T and will adjust PIP automatically in certain modes.
4. **Minute volume (MV)**. The respiratory rate and V_T combine to give MV as

$$MV = \text{Rate} \times V_T$$

Example: 40 breaths/min \times 6.5 mL/kg = 260 mL/kg/min.

5. **Pressure-volume (P-V) and flow-volume (F-V) loops**. A visualization of breath-to-breath dynamics. Flow, volume, and pressure signals combine to give P-V and F-V loops. Loops give inspiratory and expiratory limits of the breath cycle. F-V loops provide information regarding airway resistance, especially restricted expiratory breath flow. P-V loops illustrate changing lung dynamic compliance.
6. **Compliance (C_L)**. Values of <1.0 cm H₂O/mL are consistent with interstitial or alveolar lung disease such as RDS. Lung compliance of 1.0 to 2.0 mL/cm H₂O reflects recovery, as in after surfactant therapy.
7. **Resistance (R_L)**. Value of >100 cm H₂O/L/s is suggestive of airway disease with restricted airflow such as in bronchopulmonary dysplasia or the need for airway suctioning.
8. **Time constant (K_T)**. The product of C_L \times R_L (in seconds). Normal values are 0.12 to 0.15 seconds. K_T is a measure of how long it takes for alveolar and proximal airway pressures to equilibrate. At the end of 3 time constants, 95% of the V_T has entered (during inspiration) or left (during expiration) the alveoli. To avoid gas trapping, the measured expiratory time should be >3 times K_T (0.36–0.45 seconds).
- E. **Chest radiographs**. Chest radiographs (see Chapter 12) are essential to the diagnosis of lung disease, in the management of respiratory support, and in the investigation of any acute change in respiratory status.
- II. **Types of respiratory support**. Infants with respiratory distress may need only supplemental oxygen, whereas those with respiratory failure and apnea require mechanical ventilatory support. This section reviews the spectrum of available means for ventilatory support, with the exception of high-frequency ventilation (see Section V below). Mechanical ventilatory support offers great benefits but also incurs significant risks. There continues to be considerable *controversy* concerning the proper use of any mode or strategy of assisted ventilation. Current practice uses the capabilities of ventilators to automatically coordinate support with patient effort with the goal of maintaining consistent ventilation with minimal risk for mechanical lung injury.
- A. **Oxygen supplementation without mechanical ventilation**. Hypoxic infants able to maintain adequate minute ventilation are assisted with free-flow oxygen or air-oxygen mixtures. Continuous pulse oximetry is useful to monitor adequate oxygenation.
- 1. **Oxygen hoods**. Provide an enclosure for blended air-oxygen supply, humidification, and continuous oxygen concentration monitoring. Hoods are easy to use and provide access to and visibility of the infant.
 - 2. **Mask oxygen**. Usually not as well tolerated or controlled as nasal cannula oxygen delivery.

Table 9–2. NASAL CANNULA CONVERSION TABLE

Flow Rate (L/min)	FiO ₂			
	100%	80%	60%	40%
0.25	34%	31%	26%	22%
0.50	44%	37%	31%	24%
0.75	60%	42%	35%	25%
1.00	66%	49%	38%	27%

General guideline only; numbers are not exact.

3. Nasal cannulas. Well suited for infants needing low concentrations of oxygen. Delivery can be controlled by flow meters delivering as little as 0.025 L/min. Flow rates of >1 L/min impart distending airway pressure. Table 9–2 gives approximate percentages of nasal cannula oxygen based on flow rates of 0.25 to 1.0 L/min at blended FiO₂ settings of 40% to 100%.

B. Continuous positive airway pressure (CPAP). A nasal mask, nasal prongs, or an endotracheal tube can be used to apply CPAP to improve PaO₂ by stabilizing the airway and allowing alveolar recruitment. CO₂ retention may result from excessive distending airway pressure.

1. CPAP devices can be broadly divided into 2 types according to their use of flow for CPAP delivery: **continuous or variable flow.**

a. Continuous-flow CPAP devices

i. Bubble CPAP. A warmed humidified gas is continuously provided through the inspiratory limb using a blender and a flow meter. CPAP is created by submersing the expiratory limb of the respiratory tubing into a water chamber to the depth of the desired cm H₂O CPAP level. A sufficient flow of gas through the system creates continuous bubbling in the water chamber. Benefits to gas exchange and lung recruitment due to the high-frequency oscillatory content of the bubbling have been hypothesized and disputed. The bubbly bottle CPAP pressure-generating system has the advantage that the adequacy of flow can be seen and heard. However, the pressure at the nares is often higher than the predicted positive pressure based on the set immersion depth. The advantages of bubble CPAP lie mostly in its ease of application and its low cost. Few clinical data are available to infer its superiority over other CPAP devices. Its resurgence in popularity relates to the report of a remarkably low incidence of bronchopulmonary dysplasia (BPD) in a single medical center using this form of CPAP.

ii. Ventilator-derived CPAP. Infant ventilators are used to provide a continuous flow of a blended gas. CPAP is modulated by varying the ventilator's expiratory orifice size. The expiratory valve works in conjunction with other controls, such as flow control and pressure transducers, to maintain the CPAP at the desired level. It is thus less likely than bubble CPAP to be influenced by the presence of a variable leak from the intermittent opening of the oral cavity. It also allows for rapid and simple transition to noninvasive positive-pressure ventilation when required.

b. Variable flow CPAP. These devices (such as Infant Flow SiPAP System) use a dedicated driver and generator with unique fluidic mechanics that adjust and redirect gas flow throughout the respiratory cycle. The expiratory limb of the device is open to the atmosphere. Such devices may assist spontaneous

breathing and reduce the work of breathing by reducing expiratory resistance and maintaining a stable airway pressure throughout respiration. It requires specially designed nasal prongs.

2. CPAP modes of delivery

a. Nasal mask CPAP. Requires the proper size mask and a good seal on the face to be effective. Although more cumbersome than nasal prongs, a mask reduces risk of injury to the nasal septum.

b. Nasal CPAP (nCPAP). Because newborn are “obligatory” nose breathers, nasal prongs are the most commonly applied means of delivering CPAP and are used for respiratory assistance in an infant with mild RDS. The prongs are also used after extubation to maintain airway and alveolar expansion in the process of weaning from mechanical ventilation and recovery from respiratory diseases. This treatment maintains upper airway patency and, as such, is useful in infants with apnea of infancy. nCPAP may range from 2 to 8 cm H₂O, although 2 to 6 cm H₂O is most often used. Overdistention of the bronchioles and alveoli can lead to excessive CO₂ retention or air leak (pneumothorax). Gastric distention may be a complication of nCPAP, and an orogastric tube for decompression should be used. Infants can be fed by nasogastric tube during nasal CPAP therapy with close monitoring of abdominal girth.

c. Nasopharyngeal CPAP. An alternative to nasal prongs. An endotracheal tube or long binasal prongs are passed nasally and advanced to the nasopharynx. A ventilator or CPAP device is used to deliver continuous distending pressure as with nasal prongs. This approach is slightly more secure in active infants and may cause less trauma to the nasal septum.

d. Endotracheal tube CPAP. Rarely used or indicated in neonates.

C. Heated humidified high flow nasal cannula (HHHFNC). This recent development in neonatal noninvasive respiratory support is gaining popularity and is increasingly being used in clinical practice worldwide. A number of differently branded HHHFNC devices exist, including the Vapotherm 2000i (Vapotherm Inc. Stevensville, MD, USA) and the Fisher & Paykel Healthcare (Auckland, New Zealand, and Irvine, CA, USA) devices.

Three main features are common to the high flow (4-L min) delivery devices:

1. A respiratory circuit with a means to maintain the temperature and, by extension, the humidity of the continuously delivered gas (of variable FiO₂) until the distal end of the circuit.

2. A humidifier to effectively warm and humidify the respiratory gases

3. Short binasal prongs with adapter that connects to the delivery circuit and allow little or no excess tubing between the end of the delivery circuit and the actual nasal prongs, minimizing gas cooling and precipitation.

HHHFNC generates ends expiratory positive airway pressures that is not measured but “estimated” to vary generally between 2 and 10 cm H₂O. This level of pressure is influenced by flow rate (4–8 L/min), nasal cannula size (not to exceed 30%–50% of the nares width), mouth position (oral leak will decrease generated pressures by 50%), and infant size.

In addition to generating PEEP, HHHFNC may also reduce minute ventilation demand by overcoming increased airway resistance and flushing extrathoracic dead space, thereby reducing rebreathed exhaled CO₂.

Most meta-analysis suggest a statistically significant difference only for nasal trauma leading to a change of treatment, favoring HHHFNC over NCPAP. Supporting preterm infants on HHHFNC was equivalent in efficacy as any other form of NIV (NIPPV or nCPAP). This efficacy was mainly observed in the moderate to late preterm infants (>28 weeks' gestation at birth), and after extubation from IPPV. There were no statistically significant differences in the odds of death or air leaks or chronic lung disease.

The greater ease of use of HHHFNC devices compared with NCPAP allows both practitioners and family members to handle and care for infants (ELBWIs). Its efficacy compared to CPAP has not been established in particular among infants with a gestation at birth <26 weeks.

The same level of monitoring and nursing observations should be adopted as would be in place for a baby receiving nCPAP. Any patient with nasal trauma from nCPAP should be considered a candidate for rescue with HHHFNC.

- D. Noninvasive ventilation.** This refers to any technique that uses constant or variable pressure to provide ventilatory support, but without tracheal intubation. Sometimes this term includes CPAP techniques described previously. Common examples are **nasal intermittent positive-pressure ventilation (NIPPV)** that combines nCPAP with superimposed ventilator breaths, which may be **synchronized NIPPV (SNIPPV)** with patient breathing movements. (CPAP [PEEP] ranges from 3 to 6 cm H₂O, whereas PIP is set at 10 cm H₂O above CPAP. Inspiratory time ranges from 0.3 to 0.5 seconds and respiratory rate from 10 to 60 breaths/min.) It may be assumed that the pressure delivered is variable and frequently lower than the set PIP, mostly because of leakage at the nose and mouth. For SNIPPV, a technically unsolved problem is the reliable identification of spontaneous breathing efforts in preterm infants to synchronize the noninvasive ventilation. **NIPPV** may be used as a primary mode of respiratory support in preterm infants with RDS but is more often used as a method to decrease the risk of postextubation failure or need for reintubation. Nasal ventilation seems to be particularly helpful in managing apnea. NIPPV may lead to abdominal distension and possibly gastrointestinal perforation. Nasal trauma and leak around the prongs are commonly seen; therefore, careful selection of prong size and monitoring of position are important.
- E. Mechanical ventilation.** The decision to initiate mechanical ventilation is complex. The severity of respiratory distress, severity of blood gas abnormalities, natural history of the specific lung disease, and degree of cardiovascular and other physiologic instabilities are all factors to be considered. **Because mechanical ventilation may result in serious complications, the decision to intubate and ventilate should not be taken lightly.**
- 1. Bag-and-mask or bag-to-endotracheal tube handheld assemblies.** These allow for emergency ventilatory support. Portable manometers are always required for monitoring peak airway pressures during hand-bag ventilation. Bags may be self-inflating or flow-dependent, anesthesia-type bags. All handheld assemblies must have pop-off valves to avoid excessive pressures to the infant's airway (see Figure 3-2).
 - 2. Conventional infant ventilators.** Conventional mechanical ventilation delivers physiologic tidal volumes at physiologic rates via an endotracheal tube. Modern microprocessor-controlled ventilators provide numerous modes of ventilation, which vary in the degree to which patient effort controls the ventilator. These modes are critically dependent on the function of flow and/or pressure sensors for accurate performance.
 - a. Ventilator settings.** Various modes of mechanical ventilation are determined by the parameters that are set by the clinician to determine the characteristics of the mechanical breath and the circumstances under which it is delivered. Not all modes are available on every ventilator, and subtle differences between the same modes may exist between different manufacturers. The characteristics of each breath are as follows:
 - i. Length of breath (T_I).** Either set by the clinician and machine controlled or patient controlled.
 - (a) Time cycled.** Each mechanical breath lasts for a machine-controlled set time: 0.2 to 0.3 seconds for extremely low birthweight (ELBW), up to 0.5 to 0.6 seconds for term.

- (b) **Flow cycled.** Each mechanical breath lasts until inspiratory flow falls below a threshold (when the patient reaches end inspiration). The T_i will vary, usually in response to changes in patient effort.
- ii. **Size of breath (V_T)**
 - (a) **Volume limited.** Each mechanical breath is the same volume; the pressure used may vary in response to patient effort.
 - (b) **Pressure limited.** A set pressure is reached with each mechanical breath.
 - (c) **Volume assurance/guarantee.** The clinician sets both a maximum PIP and a desired V_T (target volume) for mechanical breaths. Once the target V_T is reached, the ventilator cuts the inspiration short. Some ventilators will decrease PIP for a breath if previous breaths have been cut short. If subsequent breaths are below target V_T , the ventilator increases PIP until the set maximum PIP is reached. Ideally, volume assurance/guarantee delivers consistent V_T , even with varying patient effort and/or variable lung pulmonary mechanical characteristics.
- iii. **Frequency of mechanical breaths**
 - (a) **Intermittent mandatory ventilation (IMV).** Breaths are delivered at set “mandatory” intervals without regard to patient spontaneous breathing effort.
 - (b) **SIMV (synchronized IMV).** Breaths are provided a preset number of times, as in standard IMV, but these are synchronized with the infant’s spontaneous respiratory effort. During expiration, there is a brief refractory period so that triggering of the mechanical breath can occur only within a trigger window to prevent a mandatory breath to be started during a spontaneous expiratory effort. If no spontaneous effort is detected during a trigger window, a mandatory inflation will be given. Spontaneous breaths in excess of the set ventilator rate are not supported. The minimum and maximum ventilator rates are equal.
 - (c) **A/C (assist/control).** Each patient initial respiratory effort triggers a ventilator breath. If no effort is sensed, a minimum set rate is delivered. Maximum rate may be much higher than minimum. Excessive trigger sensitivity may lead to auto cycling and much greater rates than needed.
 - (d) **Pressure support ventilation.** Each patient respiratory effort triggers a concomitant partial assisted mechanical inflation that results in a breath. There is no mandatory backup rate.
- iv. **Patient triggers.** The advanced patient-regulated ventilation modes available with modern microprocessor-controlled ventilators depend on reliable detection of patient initial respiratory effort. In the smallest premature infants, it is difficult to separate flow or pressure changes due to inspiratory effort from those due to measurement error or leaks.
 - (a) **Flow determinations by a pneumotachometer or mass airflow sensors.** Sensors at the patient airway are often more reliable.
 - (b) **Pressure.** Pressure triggers may be confused by ringing within the circuit, especially with rainout in the tubing.
 - (c) **Neural.** Using a bipolar esophageal lead placed at the level of the diaphragm, phrenic nerve impulses to the diaphragm can be detected and used to trigger mechanical breaths. Flow and pressure sensors trigger during a breath. Neural sensors potentially allow for the onset of a mechanical breath to match onset of the spontaneous effort. This promising technology has yet to be fully evaluated in neonates.
- v. **The preceding sets of parameters are often combined to yield the following modes.** *Note:* Volume assurance/guarantee may be added to pressure-limited modes.

- (a) **IMV.** Refers to nontriggered, usually pressure-limited, time-cycled ventilation. **Use:** In absence of reliable patient trigger.
- (b) **SIMV.** May be either volume or pressure limited, time cycled. Synchronized pressure-limited, time-cycled ventilation (**PLV**) has been the standard mode of ventilation. **Use:** Prevents the risk of ineffective ventilation and generation of excessive intrapulmonary pressure when a spontaneous exhalation occurs during a “mandatory” mechanical breath. Provides no support for patient breathing above the set rate.
 - (i) **SIMV + pressure support.** Patient breaths above the SIMV is provided by the ventilator and is called pressure support breath. The pressure of the triggered assisted breath is usually set well below the SIMV PIP and is called pressure support. **Use:** Decrease the work of breathing. May facilitate weaning.
 - (ii) **Volume-targeted SIMV.** Rapidly being adopted as the new standard mode. Expected benefits are decreased variability in delivered breath size resulting in more stable PCO_2 and less chance for intermittent overdilation. Limitations include poor sensor function from air leaks, condensation in the ventilator tubing, or extremely small flows/pressure in ELBW infants.
- (c) **Pressure control.** Pressure-limited (usually with a decreasing flow rate during inspiration), time-cycled, A/C. May be volume targeted. **Use:** Provides well-tolerated support in patients with easily sensed respiratory effort.
- (d) **Volume control.** Volume-limited, time-cycled, A/C. **Use:** As in pressure control, but may result in more consistent V_T .
- (e) **Pressure support.** Pressure-limited, flow-cycled support. May be volume targeted. **Use:** In addition to SIMV, especially during weaning.

III. Pharmacologic respiratory support and surfactant. Numerous medications are available for improvement of respiration. They represent a broad range of therapeutics, of which the bronchodilators and anti-inflammatory drugs are the oldest and most common. The use of mixtures of inhaled gases such as helium and nitric oxide is a recent form of treatment. Sedatives and paralyzing agents remain *controversial* in neonatal respiratory management. Finally, surfactant replacement therapy has rapidly become a major adjunct in the care of preterm infants, and its use has expanded to disease states other than RDS (hyaline membrane disease), for which it was originally intended. All medications are discussed with regard to dosage and side effects in Table 9–3, but they are briefly reviewed here for the purpose of incorporating their use into respiratory management strategies.

- A. Bronchodilators (inhaled agents).** Most of these drugs are sympathomimetic agents that stimulate β_1 -, β_2 -, or α -adrenergic receptors. They have both inotropic and chronotropic effects and provide bronchial smooth muscle and vascular relaxation. Albuterol is probably the most commonly used aerosolized bronchodilator. Other bronchodilators are presented in Table 9–3. Two anticholinergic agents (atropine and ipratropium) are also used as inhaled bronchodilators for inhibition of acetylcholine at lung receptor sites and bronchial smooth muscle relaxation. All are used to minimize airway resistance and allow decreased $\overline{\text{Paw}}$ needed for mechanical ventilation.
- B. Bronchodilators (systemic).** Aminophylline (parenteral) and theophylline (enteral) are methylxanthines with considerable bronchial dilating action. Neonatal use includes bronchodilation and, more often, stimulation of respiratory efforts.
- C. Anti-inflammatory agents**

- 1. Steroid therapy.** This has been used to treat or prevent chronic lung disease. Although steroid therapy results in significant short-term improvement in pulmonary function, long-term benefit remains unproved. The substantial adverse effects of steroid therapy with dexamethasone have led the **American Academy of Pediatrics (AAP) and the Canadian Pediatric Society to issue a joint recommendation against the routine use of steroid therapy.** Hydrocortisone may provide similar pulmonary benefits without the adverse neurodevelopmental effects of dexamethasone.

Table 9-3. AEROSOL THERAPY IN NEONATES

Drug	Receptors	Side Effects
Albuterol (Salbutamol, Ventolin): 1.25–2.5 mg per dose Dilute with NS to 3 mL Dose: every 4–6 hours	β_2 : Long lasting (duration, 3–8 hours) Fewer side effects than metaproterenol	Tachycardia (potentiated by methylxanthines) Hypertension Hyperglycemia Tremor
Atropine: 0.025–0.05 mg/kg per dose (maximum dose 2.5 mg) Dilute IV solution with NS to 2.5 mL Dose: every 6–8 hours	Vagolytic	Tachycardia Arrhythmia Hypotension Ileus, airway dryness If thick secretions, suggest use in combination with albuterol
Budesonide inhalation suspension (Pulmicort Respules): 0.25–0.5 mg per dose Dose: every 12–24 hours	Anti-inflammatory	Side effects: Oral candidiasis, stridor, respiratory infection, adrenocortical insufficiency, growth suppression
Epinephrine, racemic: Dose: 0.05–0.1 mL/kg diluted in 2–3 mL of NS. Maximum dose is 0.5 mL Epenephrine: 1 mg/mL injectable Dose: 0.5 mL/kg (Maximum dose 5 mL)	α -Receptor	Tachycardia Tremor Hypertension
Ipratropium (Atrovent): Neonates: 25 μ g/kg per dose Infants: 125–250 μ g per dose Dilute with NS to 3 mL Dose: every 8 hours	Antagonizes acetylcholine at parasympathetic sites	Dizziness Nausea, blurred vision Cough, palpitations Rash, urinary difficulties
Levalbuterol (Xopenex): 0.31–1.25 mg every 4–6 hours as needed for bronchospasm (NHLBI 2007 asthma guidelines)	β_2 : R(-)-enantiomer of racemic albuterol: little effect on heart rate	Nervousness, tremor, tachycardia, hypertension, hypokalemia. Paradoxical bronchospasm may occur, especially with first use.
Terbutaline (Brethine): 0.01–0.02 mg/kg per dose Dilute IV solution with NS to 3 mL Dose: every 4–6 hours Minimum dose: 0.1 mg	β_2 : Peripheral dilation	Hypertension Hyperglycemia Tachycardia

NHLBI, National Heart, Lung, and Blood Institute; NS, normal saline.

Neonate, birth to 28 days postnatal age; infant, >28 days to 1 year of age.

- 2. Cromolyn.** Prevents mast cells from releasing histamine and leukotriene-like substances. Its actions are slow but progressive over 2 to 4 weeks. Indications for its use in neonates have not been established.

D. Inhaled gas mixtures

- 1. Heliox (helium, 78%–80%; oxygen, 20%–22%).** Produces an inspired gas less dense than nitrogen-oxygen mixtures or oxygen alone. Use of heliox reduces the

increased resistive load of breathing, improves distribution of ventilation, and creates less turbulence in narrow airways. Limited neonatal use has indicated that heliox is associated with lower inspired oxygen requirements and shorter duration of mechanical ventilatory support.

2. Inhaled nitric oxide (iNO). A potent gaseous vasodilator produced by endothelial cells. Nitric oxide (NO) is rapidly bound by hemoglobin, limiting its action to the site of production or administration. Delivered in the ventilatory gas, iNO produces vasodilation only in the vascular bed of well-ventilated regions of the lung, thereby reducing intrapulmonary shunt as well as pulmonary vascular resistance. Furthermore, there is no systemic effect.

a. Actions. iNO diffuses rapidly across alveolar cells to vascular smooth muscle, where it causes an increase in cyclic guanosine monophosphate (GMP), resulting in smooth muscle relaxation.

b. Dosage. iNO is administered at low concentration, 2 to 20 parts per million (ppm). The dose is titrated to effect (improved oxygenation being the most common). Rarely do concentrations >20 to 40 ppm yield additional benefit.

c. Administration. iNO is blended into the ventilatory gases, preferably close to the patient connector to avoid excessive dwell time with high oxygen concentrations, which may result in excessive NO₂ concentrations. Inline sensors are used to measure delivered NO and NO₂ concentrations. Techniques for use with high-frequency ventilators have also been developed. **Co-oximetry measurement of methemoglobin is required.** The iNO dose should be decreased if methemoglobin is >4% or if the NO₂ concentration is >1 to 2 ppm.

d. Indications for use. iNO is indicated for hypoxic respiratory failure of term and near-term newborns. Recommendations have been made by the AAP for care and referral of these infants. It is currently under investigation for use in a variety of lung diseases in which inappropriate pulmonary vascular constriction adversely affects oxygenation. The resultant vasodilation may decrease pulmonary vascular resistance in general, thereby reducing right-to-left shunting, or may result in less intrapulmonary shunt, or both. Use in cases of severe respiratory failure suggests that iNO may reduce the need for extracorporeal membrane oxygenation (ECMO) in 30% to 45% of eligible patients. Use of inhaled NO in premature infants with RDS is controversial and is generally used when respiratory failure is associated with pulmonary hypertension associated to hypoplastic lungs.

e. Adverse effects. Systemic vascular effects are *not* seen with iNO use. NO₂ poisoning and methemoglobinemia are the most likely complications.

E. Other medications

1. Sildenafil. An oral phosphodiesterase-5 inhibitor, sildenafil reduces pulmonary vascular resistance and is approved in adults for pulmonary hypertension. Its use is attractive in patients with BPD, with further study required before use in newborns.

2. Prostaglandin (PGI₂). A potent pulmonary vasodilator given as an aerosol or intravenous drip. Hypotension may develop. Use with iNO has been reported.

3. Bosentan. An oral endothelin 1 receptor blocker, bosentan reduces pulmonary vascular resistance. Its use in neonates is undefined.

F. Sedatives and paralyzing agents. Agitation is a common problem for infant mechanical ventilation. Infants may have interrupted respiratory cycles and respond by “bucking” or “fighting” the ventilator breaths. The agitation that results is often associated with hypoxic episodes. Sedation or muscle relaxation by paralysis may be required. It should be noted, however, that with the use of ventilators with either flow-sensed or patient-triggered synchronized ventilation (SIMV), much less sedation is required, and paralysis is rarely needed. “Fighting” the respirator may indicate inadequate respiratory support because of changes in lung compliance/airway resistance. Careful assessment for possible remedial causes for those changes (eg, obstructed or

malpositioned endotracheal tube, pneumothorax) needs to be performed before any pharmacologic intervention.

1. **Sedatives.** Include lorazepam, phenobarbital, fentanyl, or morphine. Each agent has advantages and side effects. (See Chapter 81.)
 2. **Paralyzing agents.** Include rocuronium and vecuronium. Prolonged muscle relaxation by paralysis results in considerable body fluid accumulation with the development of pulmonary and skin edema.
- G. Surfactant replacement therapy.** The availability of surfactant treatment has dramatically changed the care of infants with RDS (formally known as hyaline membrane disease). Surfactant administration early in the course of RDS restores pulmonary function and prevents tissue injury that otherwise results from ventilation of surfactant-deficient lungs. As a result, mortality from RDS has decreased dramatically.
1. **Composition.** Currently available surfactants are all of animal origin. Beractant (Survanta) and calfactant (Infasurf) are derived from bovine lung and lung lavage, respectively. Poractant alfa (Curosurf) is derived from porcine lung. All contain the hydrophobic surfactant proteins, SpB and SpC, although at different concentrations. Calfactant and poractant alfa contain surfactant phospholipids. In beractant, additional phospholipid is added to the minced lung extract to increase the ratio of surfactant to membrane phospholipids. Synthetic surfactants that equal the *in vivo* actions of the natural surfactants have been on the horizon for several years.
 2. **Actions.** All surfactant preparations are intended to replace the missing or inactivated natural surfactant of the infant. Surface tension reduction and stabilization of the alveolar air–water interface are the basic functions of surfactant compounds. Air–water interface stability imparts lower alveolar surface tension and prevents atelectasis or alternating areas of atelectasis and hyperinflation.
 3. **Dosage and administration.** Each preparation has specific dosage and dosing procedures. Direct tracheal instillation is involved in all preparations. The possibility to effectively administer surfactant through noninvasive nebulization is presently being investigated. Surfactants are given both by continuous infusion via side port on the endotracheal tube adapter and mostly by aliquots via a catheter placed through the endotracheal tube. Changes in body position during dosing aid in more uniform delivery of surfactant. The relative advantages of these methods of administration are currently being studied (see Chapter 117 for detailed information on each medication).
 - a. **Prophylactic dosing at birth.** This form of treatment is used less often and only when resuscitation and surfactant administration can be safely pursued simultaneously. Current practice prefers use of CPAP in the delivery room.
 - b. **Administration of surfactant preparations after respiratory distress is established.** Currently, surfactant therapy occurs once the patient has been stabilized and the diagnosis of RDS has been established.
 - c. **Repeat dosing.** May follow at 6- to 12-hour intervals. Repeat doses should follow loss of response after initial improvement has been seen. Repeat dosing after the second dose is *controversial*.
 - d. **Airway obstruction.** May occur during surfactant administration because of the viscosity of the surfactant preparations. Increased mechanical support may be required until the surfactant is spread from the airways to the alveoli.
 - e. **Lesser invasive methods of pulmonary administration of surfactant** through methods such as **LISA** (surfactant via thin diameter tubes under direct vision using laryngoscopes) or **INSURE** (intubation and surfactant administration followed by immediate extubation) both in conjunction with CPAP have been described. (See Chapter 90.)
 4. **Efficacy.** Efficacy of surfactant treatment can be observed for both immediate and long-term clinical conditions.

- a. **Early effects.** Include a reduction of FiO_2 need and improved PaO_2 , PaCO_2 , and a/A ratio. Likewise, improved V_T and compliance should be noted with improved lung function and decreased ventilator PIPs.
- b. **Long-term effects.** Should result in decreased necessity for mechanical ventilation and less severe chronic lung disease of infancy. Complications of patent ductus arteriosus, necrotizing enterocolitis, and intraventricular hemorrhage have not been significantly influenced by surfactant therapy to date.

5. Side effects

- a. Small risk of pulmonary hemorrhage.
- b. Secondary pulmonary infections.
- c. Air leak (pneumothorax) following bolus administration of surfactant compounds. Rapid changes in V_T require immediate reduction of PIPs. Failure to do so while also decreasing FiO_2 may lead to air leaks.

- 6. **Surfactant therapy for diseases other than RDS.** Encouraging preliminary reports of surfactant therapy have been noted in cases of pneumonia, meconium aspiration syndrome, persistent pulmonary hypertension, pulmonary hemorrhage, and acute respiratory distress syndrome (ARDS), but no protocols for treatment are available at this time.

IV. Strategies of neonatal respiratory support

A. General approach. Although use of the tools and techniques discussed in this section are essential to neonatal intensive care, their use is not without peril. One general approach is to provide the minimal support necessary for adequate gas exchange, unless a more aggressive intervention may change the course of the pulmonary disease, such as early intubation for the delivery of surfactant in RDS. Noninvasive nasal CPAP or ventilation is preferable to intubation and mechanical ventilation. Patient-triggered ventilation modes are usually better tolerated by patients and may result in less need for support. Meta-analysis of volume-targeted ventilation in neonates reveals a decrease in death and BPD/chronic lung disease (CLD) as compared with classic PLV. The optimal use of the myriad modes of assisted ventilation has yet to be determined, but the trend is to use ventilator modes that allow the patient more control. The decision to initiate or escalate ventilatory support should always take into account the risk of ventilator-induced lung injury and systemic effects of poorly controlled ventilation.

1. Mechanisms of lung injury

- a. **Oxygen toxicity.** Risk factor for BPD/CLD and retinopathy of prematurity (ROP) and may be reduced by careful monitoring and the setting of gestational age-appropriate SpO_2 targets.
- b. **Inflammation and infection.** Result from intubation. Use of noninvasive ventilation and early extubation are desired.
- c. **Barotrauma/volutrauma.** Results from overinflation of the lung or stress from repeated reopening of collapsed lung units or from shear between adjacent lung units. Maintenance of FRC using appropriate PEEP and the use of small V_T to prevent overdistention help limit injury.

2. Adverse effects of poorly controlled ventilation

- a. **Hyperoxia (high PO_2)** is associated with an increased risk for ROP.
- b. **Hypoxemia (low PO_2)** has been recently associated with increased risk of mortality.
- c. **Overventilation (low PCO_2)** causes a decrease in cerebral blood flow that increases the risk for periventricular white matter injury and cerebral palsy.
- d. **Hypercapnia (high PCO_2)** may increase the risk for intraventricular hemorrhage and poor neurodevelopmental outcome.
- e. **Overinflation** may impair venous return and cardiac output to the point of systemic hypotension.

B. Initiation of mechanical ventilation for respiratory distress. See Chapter 51, Table 51-1, and below for more detail on management of ventilators.

1. Indications

- a. Failure to maintain adequate PO_2 and PCO_2 with supplemental oxygen and nasal CPAP or nasal ventilation.
- b. Worsening RDS is an indication for early intubation for surfactant administration with subsequent mechanical ventilation.

2. Ventilator settings. **Note:** Refer to the operating manual for your specific ventilator to understand the specific modes available.

a. Classic pressure-limited ventilation (PLV). Preferably with synchronization and V_T measurement.

- i. PEEP 4 to 5 cm H_2O .
- ii. T_i 0.3 seconds.
- iii. PIP to yield V_T of 4 to 5 mL/kg. If V_T measurement is unavailable, limit PIP so that chest rise is barely perceptible on breaths without patient effort.
- iv. Rate 30 to 40 per minute SIMV. Higher rates and/or A/C ventilation may result in initial hyperventilation.
- v. Trigger sensitivity setting requires specific machine knowledge. Refer to ventilator manual.
- vi. Evaluate response with clinical examination, noninvasive monitors, and blood gases and chest radiograph as necessary. Adjust PIP and rate as required. See later for managing ventilation.

b. Volume-targeted ventilation (VTV)

- i. PEEP 4 to 5 cm H_2O .
- ii. T_i 0.3 seconds.
- iii. Set volume target to 4 to 5 mL/kg. Set PIP limit high enough for ventilator to meet target.
- iv. Rate 30 to 40 per minute SIMV. Higher rates and/or A/C ventilation may result in initial hyperventilation.
- v. Evaluate response with clinical examination, noninvasive monitors, blood gases, and chest radiograph as necessary. Adjust PIP and rate as required. See later for managing ventilation.
- vi. Large air leaks around the endotracheal tube interfere with volume-targeted ventilator modes. In such cases, either switch to PLV or reintubate with a larger tube.

C. Fine-tuning mechanical ventilation. (See also Chapter 51.) Adequate gas exchange must be determined for each patient because goals vary depending on diagnosis, patient's gestational age, and level of support required.

1. Low PO_2 . Usually caused by poor matching of ventilation and perfusion (low V/Q ratio). Support beyond the use of supplemental oxygen is directed either at improving aeration in the lung or influencing the distribution of perfusion. To improve oxygenation:

- a. **Maintain lung expansion.** Maintain lung expansion at end expiration by the use of PEEP and the use of surfactant in RDS. Preventing collapse also reduces lung injury from reopening alveoli.
- b. **Recruit collapsed lung by the use of adequate V_T and PIP.**
- c. **iNO selectively decreases vascular resistance in well-ventilated regions of the lung, improving oxygenation.** Extrapulmonary shunt due to persistent pulmonary hypertension may respond to prostacyclin in addition to iNO.
- d. **Consider the use of high-frequency oscillation.** To maintain high mean lung volume in cases of severe, uniform alveolar disease (RDS, ARDS).

2. High PCO_2 . Results from inadequate minute volume.

- a. **$PaCO_2$ is decreased by increasing MV.** If V_T is adequate (5–6 mL/kg), an increase in rate is preferable. Special attention is required when adjusting patient-triggered ventilation modes to ensure that a real increase in rate results from an increase in the ventilator set rate.

b. Increasing V_T requires increasing PIP. Although a high PIP itself does not necessarily produce lung injury, high-frequency ventilation should be considered if a PIP >20 to 25 cm H_2O is required in a premature infant or >30 cm H_2O in a term infant.

c. When using patient-triggered ventilation modes, set the ventilator rate high enough to prevent hypoventilation should the patient become apneic.

3. Neonatal lung disease. Rarely static, necessitating frequent adjustments to ventilator parameters.

D. Weaning from mechanical ventilation and extubation. As lung function improves with disease resolution, mechanical support should be decreased as quickly as tolerated. Most patients do not need to be “weaned” from mechanical support; they need support decreased to match their need. Continuous monitoring with pulse oximetry and $tPCO_2$ aids in weaning and limits the need for blood gas sampling. A reduced oxygen requirement and improved compliance (decrease in PIP to maintain V_T) usually herald the weaning phase. **Pretreatment of infants with caffeine may enhance infant response to progressive weaning efforts.** Disease state, gestational age, and caloric support influence response to the weaning process.

1. PIP. Usually weaned first because overinflation injury is more deleterious than providing a greater rate than necessary. Volume-targeted ventilation modes may adequately decrease PIP as the lungs heal and provide a somewhat automatic wean.

2. FiO_2 . Weaned whenever possible as determined by pulse oximetry or blood gases. Decreases in PIP decrease $\bar{P}aw$ and may transiently increase oxygen requirements during weaning.

3. Progressive rate wean (does not apply to assist/control modes). Rate settings should be decreased frequently. Infants ready to be weaned tolerate the rate wean and do not require more FiO_2 . An infant should be able to maintain adequate minute ventilation without developing hypercarbia or apnea. When the ventilator rate is <15 to 20 breaths/min, the infant should be extubated. Some infants may require several hours to wean, whereas others need several days to a week or more.

4. Weaning A/C ventilation. Because all spontaneous breaths are mechanically supported by this mode of ventilation, reduction of the rate below the patient’s spontaneous rate has no effect on the level of support. Weaning is accomplished by successive decreases in PIP. When adequate ventilation is maintained with minimal PIP (12 – 16 cm H_2O), extubation may be attempted.

E. Care after extubation. Continued monitoring of blood gases, respiratory effort, and vital signs is required. Additional oxygen support is often needed in the immediate postextubation period.

1. Supplemental oxygen. May be given by hood or by nasal cannula. The oxygen concentration may be increased by $>5\%$ over the last oxygen level obtained while the infant was on the ventilator.

2. Nasal CPAP. May be especially helpful in preventing reintubation secondary to postextubation atelectasis.

3. Chest radiograph. If the infant has had an increasing oxygen requirement or has clinically deteriorated, a chest radiograph should be obtained at 6 hours postextubation to monitor for atelectasis.

V. Overview of high-frequency ventilation. High-frequency ventilation refers to a variety of ventilatory strategies and devices designed to provide ventilation at rapid rates and very low V_T s. The ability to provide adequate ventilation despite reduced V_T (equal to or less than dead space) may reduce the risk of barotrauma. Rates during high-frequency ventilation are often expressed in hertz (Hz). A rate of 1 Hz (1 cycle/s) is equivalent to 60 breaths/min. All methods of high-frequency ventilation should be administered with the assistance of well-trained respiratory therapists and after

comprehensive education of the nursing staff. Furthermore, because rapid changes in ventilation or oxygenation may occur, continuous monitoring is highly recommended. Optimal use of these ventilators is evolving, and different strategies may be indicated for a particular lung disease.

A. Definitive indications for high-frequency ventilation support

1. **Pulmonary interstitial emphysema (PIE).** A multicenter trial has demonstrated high-frequency jet ventilator (HFJV) to be superior to conventional ventilation in early PIE as well as in neonates who fail to respond to conventional ventilation.
2. **Severe bronchopleural fistula.** In severe bronchopleural fistula not responsive to thoracostomy tube evacuation and conventional ventilation, HFJV may provide adequate ventilation and decrease fistula flow.
3. **Respiratory distress syndrome (RDS).** High-frequency ventilation has been used with success. It is usually implemented at the point of severe respiratory failure with maximal conventional ventilation (a rescue treatment). Earlier treatment has been advocated. No advantages have yet been demonstrated for a very early intervention (in the first hours of life) when infants are pretreated with surfactant.
4. **Patients qualifying for ECLS (extracorporeal life support).** Pulmonary hypertension with or without associated parenchymal lung disease (eg, meconium aspiration, pneumonia, hypoplastic lung, or diaphragmatic hernia) can result in intractable respiratory failure and high mortality unless the patient is treated by ECLS. The prior use of high-frequency ventilation among ECLS candidates has been successful and eliminated the need for ECLS in 25% to 45% of cases.

B. Possible indications. High-frequency ventilation has been used with success in infants with other disease processes. Further study is needed to develop clear indications and appropriate ventilatory strategies before this treatment can be recommended for routine use in infants with these diseases.

1. **Pulmonary hypertension**
2. **Meconium aspiration syndrome**
3. **Diaphragmatic hernia with pulmonary hypoplasia**
4. **Postoperative Fontan procedures**

C. High-frequency ventilators, techniques, and equipment. Two types of high-frequency ventilators in the United States are the HFJV and the high-frequency oscillatory ventilator (HFOV).

1. **High-frequency jet ventilator.** The HFJV injects a high-velocity stream of gas into the endotracheal tube, usually at frequencies between 240 and 600 breaths/min and V_T s equal to or slightly greater than dead space. During HFJV, expiration is passive. The only HFJV approved by the US Food and Drug Administration is the Life Pulse (Bunnell, Inc., Salt Lake City, UT) ventilator, discussed here.

a. **Indications.** Mostly used for PIE, the Life Pulse HFJV has been used for the other indications described for all types of high-frequency ventilation.

b. Equipment

i. **Bunnell Life Pulse ventilator.** The inspiratory pressure (PIP), jet valve “on time,” and respiratory frequency are entered into a digital control panel on the jet. PIPs are servo-controlled by the Life Pulse from the pressure port. The ventilator has an elaborate alarm system to ensure safety and to help detect changes in pulmonary function. It also has a special humidification system.

ii. **Conventional ventilator.** A conventional ventilator is needed to generate PEEP and sigh breaths. PEEP and background ventilation are controlled with the conventional ventilator.

c. Procedure

i. Initiation. **Close observation** is required at all times, especially during initiation.

(a) **Replace the endotracheal tube adapter with a jet adapter**

(b) **Settings on the jet ventilator**

(i) **Default jet valve “on time.”** 0.020 seconds.

(ii) **Frequency of jet.** 420 per minute.

(iii) **PIP on the jet.** 2 to 3 cm H₂O below what was on the conventional ventilator. Frequently, infants require considerably less PIP during HFJV.

(c) **Settings on the conventional ventilator**

(i) **PEEP.** Maintain at 3 to 5 cm H₂O.

(ii) **Rate.** As the jet ventilator comes up to pressure, the rate is decreased to 5 to 10 breaths/min.

(iii) **PIP.** Once at pressure, the PIP is adjusted to a level at least 1 to 3 cm H₂O below that on the jet (low enough not to interrupt the jet ventilator).

d. Management. Management of HFJV is based on the clinical course and radiographic findings.

i. Elimination of CO₂. Alveolar ventilation is much more sensitive to changes in V_T than in respiratory frequency during high-frequency ventilation. As a result, the **delta pressure** (PIP minus PEEP) is adjusted to attain adequate elimination of CO₂, whereas jet valve “on time” and respiratory frequency are usually not readjusted during HFJV.

ii. Oxygenation. Oxygenation is often better during HFJV than during conventional mechanical ventilation in neonates with PIE. However, if oxygenation is inadequate and if the infant is already on 100% oxygen, an increase in P_a \bar{w} usually results in improved oxygenation. It can be accomplished by:

(a) **Increasing PEEP.**

(b) **Increasing PIP.**

(c) **Increasing jet valve “on time.”** 0.022 to 0.026 seconds.

(d) **Increasing background conventional ventilator** (either rates or pressure).

iii. Positioning of infants. Positioning infants with the affected side down may speed resolution of PIE. In bilateral air leak, alternating placement on dependent sides may be effective. Diligent observation and frequent radiographs are necessary to avoid hyperinflation of the nondependent side.

e. Weaning. When weaning, the following guidelines are used.

i. PIP is reduced as soon as possible (PaCO₂ <35–40 mm Hg). Because elimination of CO₂ is very sensitive to changes in V_T, PIP is weaned 1 cm H₂O at a time.

ii. Oxygen concentration. Weaned if oxygenation remains good (PaO₂ >70–80 mm Hg).

iii. Jet valve “on time” and frequency. Usually kept constant.

iv. Constant attention is paid to the infant’s clinical condition and radiographs to detect early atelectasis or hyperinflation.

v. Air leaks are resolved. Continuation of HFJV occurs until the air leak has been resolved for 24 to 48 hours, which often corresponds to a dramatic drop in ventilator pressures and oxygen requirement.

vi. In case of no improvement in the condition. A trial of conventional ventilation is used after 6 to 24 hours on jet ventilation.

f. Special considerations

i. Airway obstruction. This problem can usually be recognized quickly. Chest wall movement is decreased, although breath sounds may be adequate. The servo pressure (driving pressure) is usually very low.

ii. **Inadvertent PEEP (air trapping).** In larger infants, the flow of jet gases may result in inadvertent PEEP. Decreasing the background flow on the conventional ventilator may correct the problem, or it may be necessary to decrease the respiratory frequency to allow more time for expiration.

2. **High-frequency oscillatory ventilator.** The HFOV generates V_T less than or equal to dead space by means of an oscillating piston or diaphragm. This mechanism creates active exhalation as well as inspiration. The SensorMedics 3100B HFOV (CareFusion Corporation, San Diego, CA) is currently approved by the US Food and Drug Administration for use in neonates.

a. **Indications.** High-frequency oscillatory ventilation is indicated when conventional ventilation used for respiratory failure does not result in adequate oxygenation or ventilation or requires the use of very high airway pressures. Like other forms of high-frequency ventilation, success is more likely when increased airway resistance is not the dominant pulmonary pathophysiology. Best results are seen when parenchymal disease is homogeneous. Some clinicians advocate high-frequency oscillatory ventilation as the primary method of assisted ventilation in premature infants with RDS.

b. **Equipment.** HFOV is used without a conventional ventilator. The user-defined parameters are frequency, \overline{Paw} , and power applied for piston displacement.

c. **Procedure**

i. **Initiation**

(a) **Conventional ventilator is discontinued.**

(b) **Settings**

(i) **Frequency.** Usually set at 15 Hz for premature infants with RDS. Larger infants, or those with a significant component of increased airway resistance (meconium aspiration), should be started at 5 to 10 Hz.

(ii) **\overline{Paw} .** Set higher (2–5 cm H_2O) than on the previous conventional ventilation. If overdistention or air leaks were present before initiation of HFOV, a lower \overline{Paw} should be considered.

(iii) **Amplitude.** Analogous to PIP on conventional ventilation and is regulated by the power of displacement of the piston. This power is increased until there is visible chest wall vibration.

(c) **After high-frequency oscillatory ventilation has been initiated, careful and frequent assessment of lung expansion and adequate gas exchange are necessary.** Air trapping is a continuous potential threat in this form of treatment. Signs of overdistention, such as descended and flat diaphragms and small heart shadow, are monitored with frequent chest radiographs.

d. **Management**

i. **Low PaO_2 .** An increase in \overline{Paw} may be necessary. Chest radiographs may be helpful in determining the adequacy of lung expansion.

ii. **High $PaCO_2$**

(a) **Oxygenation is also poor.** The \overline{Paw} may be too high or too low, resulting in either hyperinflation or widespread collapse, respectively. Again, chest radiographs are necessary to differentiate between these 2 conditions.

(b) **Oxygenation is adequate.** The amplitude (power) should be increased. Decreasing the rate may be an alternative if hypercapnia is associated with evidence of lung hyperinflation.

e. **Weaning**

i. **In the absence of hyperinflation.** FiO_2 is weaned before \overline{Paw} for adequate PaO_2 . Below 40% FiO_2 , wean \overline{Paw} exclusively.

ii. **\overline{Paw} .** Should be weaned as the lung disease improves with the goal of maintaining optimal lung expansion. Excessively aggressive early weaning

of \overline{Paw} may result in widespread atelectasis and the need for significant increases in \overline{Paw} and FiO_2 .

- iii. **Amplitude.** Should be weaned for acceptable $PaCO_2$.
- iv. **Frequency.** Usually not adjusted during weaning. A decrease in frequency is necessary when signs of lung overdistention cannot be eliminated by a reduction in \overline{Paw} .
- v. **The neonate may be switched to conventional ventilation** at a low level of support or may be extubated directly from HFOV.
- f. **Complications.** Hyperinflation with compromise of cardiac output. Frequent evaluation with chest radiography is advised.

GLOSSARY OF TERMS USED IN RESPIRATORY MANAGEMENT

ARTERIAL-TO-ALVEOLAR RATIO (A/A RATIO). See Section I.B.3.b.

ASSIST. A setting at which the infant initiates the mechanical breath, triggering the ventilator to deliver a preset V_T or pressure.

ASSIST/CONTROL. The same as assist, except that if the infant becomes apneic, the ventilator delivers the number of mechanical breaths per minute set on the rate control.

CONTINUOUS POSITIVE AIRWAY PRESSURE (CPAP). A spontaneous mode in which the ambient intrapulmonary pressure that is maintained throughout the respiratory cycle is increased.

CONTROL. A setting at which a certain number of mechanical breaths per minute is delivered. The infant is unable to breathe spontaneously between mechanical breaths.

END-TIDAL CO_2 (ET CO_2 OR PET CO_2). A measure of the PCO_2 of end expiration.

EXPIRATORY TIME (ET). The amount of time set for the expiratory phase of each mechanical breath.

FLOW RATE. The amount of gas per minute passing through the ventilator. It must be sufficient to prevent rebreathing (ie, 3 times the minute volume) and to achieve the PIP during T_I . Changes in the flow rate may be necessary if changes in the airway waveform are desired. The normal range is 6 to 10 L/min; 8 L/min is commonly used.

FRACTION OF INSPIRED OXYGEN (FI O_2). The percentage of oxygen concentration of inspired gas expressed as decimals (room air = 0.21).

I:E RATIO. Ratio of inspiratory time to expiratory time. The normal values are 1:1, 1:1.5, or 1:2.

INSPIRATORY TIME (T $_I$). The amount of time set for the inspiratory phase of each mechanical breath.

INTERMITTENT MECHANICAL VENTILATION. Mechanical breaths are delivered at intervals. The infant breathes spontaneously between mechanical breaths.

MINUTE VENTILATION. V_T (proportional to PIP) multiplied by rate.

OXYGEN INDEX (OI). Mean airway pressure (MAP) \times $FiO_2 \times 100/PaO_2$.

OXYHEMOGLOBIN DISSOCIATION CURVE. A curve showing the amount of oxygen that combines with hemoglobin as a function of PaO_2 and $PaCO_2$. The curve shifts to the right when oxygen take-up by the blood is less than normal at a given PO_2 , and it shifts to the left when oxygen take-up is greater than normal.

PAO_2 . Partial pressure of arterial oxygen.

PAP. The total airway pressure. In the Siemens Servo 900-C, it is the PIP plus the PEEP.

Paw . The average proximal pressure applied to the airway throughout the entire respiratory cycle.

PCO_2 . Carbon dioxide partial pressure.

PEAK INSPIRATORY PRESSURE (PIP). The highest pressure reached within the proximal airway with each mechanical breath. **Note:** In the Siemens Servo 900-C, the PIP is defined as the inspiratory pressure above the PEEP.

PO_2 . Oxygen partial pressure.

POSITIVE END-EXPIRATORY PRESSURE (PEEP). The pressure in the airway above ambient pressure during the expiratory phase of mechanical ventilation.

RATE. Number of mechanical breaths per minute delivered by the ventilator.

SaO_2 . Oxygen saturation of arterial blood measured by direct measurement (arterial blood gas).

TIDAL VOLUME (V $_T$). The volume of gas inspired or expired during each respiratory cycle.

10 Fluid and Electrolytes

An assessment of body water metabolism and electrolyte balance plays an important role in the early medical management of preterm infants and sick term infants coming to neonatal intensive care. Intravenous or intra-arterial fluids given during the first several days of life are a major factor in the development, or prevention, of morbidities such as intraventricular hemorrhage, necrotizing enterocolitis (NEC), patent ductus arteriosus, and bronchopulmonary dysplasia. Clinicians must pay close attention to the details of maintaining and monitoring body water and serum electrolytes and the management of fluid infusion therapies.

Bodily fluid balance is a function of the distribution of water in the body, water intake, and water losses. Body water distribution gradually changes with increasing gestational age of the fetus. At birth, these gestational changes in body water are reflected in the developing maturity of renal function, transepidermal insensible water losses, and neuroendocrine adaptations. One must account for these variables when deciding the amount of infusion fluids to administer to an infant.

I. Body water

A. Total body water (TBW). Water accounts for nearly 75% of the body weight in term infants and as much as 85% to 90% of body weight of preterm infants. TBW is divided into 2 basic body water compartments: intracellular water (ICW) and extracellular water (ECW). ECW is composed of intravascular and interstitial water. For the fetus, there is a gradual decrease in ECW from two-thirds of TBW at 16 weeks' gestation to 53% of the TBW at 32 weeks' gestation. Thereafter, the proportions remain fairly constant until 38 weeks of gestation when increasing body mass of protein and fat stores reduces ECW further by approximately 5%.

At birth, there begins a further contraction of the ECW as a function of the normal transition from intrauterine to extrauterine life. A diuresis occurs that reduces body weight proportionally to gestational age. For the very low birthweight preterm infant body, weight losses of 10% to 15% can be expected, whereas full-term infants usually lose 5% to 10% of body weight. Intrauterine growth-restricted neonates have a smaller initial weight loss and more rapidly regain their birth weight than their normally grown counterparts.

B. TBW balance in the newborn

1. Renal. Fetal urine flow steadily increases from 2 to 5 mL/h to 10 to 20 mL/h at 30 weeks' gestation. At term, fetal urine flow reaches 25 to 50 mL/h and then drops to 8 to 16 mL/h (1–3 mL/kg/h). These volume changes illustrate the large exchange of body water during fetal life and the abrupt changes forcing physiologic adaptation at birth. Despite marked fetal urine flow in utero, glomerular filtration rates (GFRs) are low. At birth, GFR remains low but steadily increases in the newborn period under the influence of increasing systolic blood pressure, increasing renal blood flow, and increasing glomerular permeability. Infant kidneys are able to produce dilute urine within limits dependent on GFR. The low GFR of preterm infants is the result of low renal blood flow but increases considerably after 34 weeks' postconceptional age. Term infants can concentrate urine up to 800 mOsm/L, compared to the 1500 mOsm/L of older children and adults. The preterm infant kidney is less able to concentrate urine secondary to a relatively low interstitial urea concentration, an anatomically shorter loop of Henle, and a distal tubular and collecting system that is less responsive to antidiuretic hormone (ADH). In extreme prematurity, urine osmolality can be as low as 70 mOsm/L. Although limitations exist, healthy preterm infants with constant sodium intake but variable fluid infusion between 90 and 200 mL/kg/d are able to concentrate or dilute urine to maintain a balance of body water.

Against the backdrop of changing GFR and variable urine concentrating ability, all infants undergo a diuresis and a natriuresis in the days immediately following birth. Newborn diuresis is a contraction of the ECW and the initiation of body water conservation as the adaptation from an aquatic intrauterine existence to the less humidity and free water-dependent newborn state. The diuresis is facilitated by limited ADH responsiveness but is diminished by increasing serum osmolality (>285 mOsm/kg) and decreasing intravascular volume. Natriuresis is the result of increasing levels of atrial natriuretic peptide and decreased renal sodium absorption; infant kidneys also have decreased secretion of bicarbonate, potassium, and hydrogen ion.

2. **Insensible water loss (IWL).** Evaporation of body water occurs largely through the skin and mucous membranes (two-thirds) and the respiratory tract (one-third). A most important variable influencing IWL is the maturity of the infant's skin. The greater IWL in preterm infants results from body water evaporation through an immature epithelial layer. The stratum corneum is not well developed until 34 weeks' gestation. Throughout the third trimester, the stratum corneum and epidermis thicken. Keratinization of the stratum corneum forms the principal barrier to water loss. Keratinization begins early in the second trimester and continues throughout the third trimester. In addition, IWL is related to a larger skin surface area-to-body weight ratio in preterm infants and relatively greater skin vascularity.

IWL through the respiratory tract is related to the respiratory rate and the water content of the inspired air or air-oxygen mix (humidification). Table 10-1 lists other factors for IWL in newborn infants.

In general, for healthy premature infants weighing 800 to 2000 g cared for in double-walled incubators, IWL increases linearly as body weight decreases (Table 10-2).

However, for sick infants of similar weight cared for under a radiant warmer and undergoing ventilator respiratory support, IWL increases exponentially as body weight decreases.

Phototherapy may increase IWL by way of increasing body temperature and increasing peripheral blood flow. Generally, recommended fluid increases for preterm infants have been 10 to 20 mL/kg/d. This may not be necessary with newer phototherapy lights using light-emitting diodes (LEDs) because they generate very little heat. Moreover, term infants receiving adequate fluid intake and with no other

Table 10-1. FACTORS IN THE NICU ENVIRONMENT THAT AFFECT INSENSIBLE WATER LOSS

Body weight	Inversely proportional to maturity
Radiant warmer use during procedures	IWL increases by 50%–100% over incubator care (see also Chapter 13)
Phototherapy	IWL <i>controversial</i> ; may be minimal for term infants, but appreciable for preterm infants (up to 25%)
Ambient humidity and temperature in double-walled humidified incubators	High ambient humidity and a thermal neutral environment conserve TBW
High body temperature	May increase loss by 30%–50%
Tachypnea	Variable depending on respiratory support
Skin breakdown	Most often from removal of adhesives denuding skin
Congenital absence of normal skin covering	Large omphaloceles, neural tube defects, or skin losses as in epidermolysis bullosa

IWL, insensible water loss; NICU, neonatal intensive care unit; TBW, total body water.

Table 10–2. ESTIMATES OF INSENSIBLE WATER LOSS IN PRETERM INFANTS DURING FIRST WEEK OF LIFE IN A THERMAL NEUTRAL ENVIRONMENT

Birthweight (g)	Insensible Water Loss (mL/kg/d)
<750	100–200
750–1000	60–70
1001–1250	50–60
1251–1500	30–40
1501–2000	20–30
>2000	15–20

Adapted from Martin RJ, Fanaroff AA, Walsh MC: Fanaroff and Martin's Neonatal-Perinatal Medicine: *Diseases of the Fetus and Infant*, 8th ed. Philadelphia, PA: Mosby Elsevier; 2006.

increased body water loss may not need added fluid intake. Occasionally, phototherapy induces loose stools, and IWL would need to be reconsidered.

- 3. Neuroendocrine.** TBW balance is also influenced by hypothalamic osmoreceptors and carotid baroreceptors. Serum osmolarity >285 mOsm/kg stimulates the hypothalamus, and ADH is released to affect free water retention. In addition, volume diminution affects carotid bodies and baroreceptors to further stimulate ADH secretion to retain free water at the level of the collecting ducts of the distal nephrons. Collectively the osmoreceptors and the baroreceptors seek to maintain TBW with adequate intravascular volume at normal serum osmolarity. In the neonate, hypoxia with acidemia and hypercarbia are potent stimulators of ADH. An excessive secretion of ADH can follow 1 or more insults such as intracranial hemorrhage, sepsis, and/or hypotension. Conversely, excessive ADH secretion can occur in the absence of hyperosmolarity or volume depletion. Thus, a phenomenon known as the **syndrome of inappropriate ADH secretion (SIADH)** can occur. It is manifested as hyponatremia, hypo-osmolar serum, nondilute urine, and low blood urea nitrogen. Because ADH secretion begins early in fetal development, SIADH can occur as readily in preterm infants as in term infants.

C. Monitoring TBW balance

- 1. Body weight.** Using in-bed scales, body weight should be recorded daily for all infants undergoing intensive care and twice daily for very low birthweight and extremely low birthweight infants. **Expected weight loss** during the first 3 to 5 days of life is 5% to 10% of birthweight for term infants and 10% to 15% of birthweight for preterm infants. A loss of >15% of birthweight during the first week of life should be considered excessive and body water balance carefully reevaluated. If weight loss is <2% in the first week of life, maintenance infusion fluid administration may be excessive.
- 2. Physical examination.** Edema or loss of skin turgor, moist or dry mucous membranes, sunken or puffy periorbital tissues, and full or sunken anterior fontanel have been time-honored sites to examine for dehydration or overhydration. They may be helpful when observing newborn infants but are unreliable in low birthweight infants. They must be observed within the context of all other TBW points of monitoring.
- 3. Vital signs**
 - a. Blood pressure** can be an indicator of altered intravascular volume, but usually is a later sign rather than earlier sign. Pressure changes and trends are needed in the overall assessment of TBW balance.

- b. **Pulse volumes**, decreased in dehydration in association with tachycardia, are somewhat sensitive indicators of early intravascular volume loss.
 - c. **Tachypnea** can be an early sign of metabolic acidosis accompanying inadequate intravascular volume.
 - d. **Capillary refill time (CRT)** has been a reliable and time-honored observation. CRT of >3 seconds in term infants is suspect for decreased intravascular volume, whereas a CRT of barely 3 seconds in a preterm infant should be equally suspected.
4. **Hematocrit (Hct)**. Increases or decreases of central Hct (venous or arterial) from accepted normal values suggest changes in intravascular volume as it relates to TBW. Apart from obvious hemorrhage, changes in Hct may reflect overhydration or dehydration and must be considered in the assessment of TBW for fluid therapy in the first week of life.
5. **Serum chemistries**
- a. **Sodium values** of 135 to 140 mEq/L are indicative of TBW and sodium balance. Values above or below are suggestive of hyper- or hypo-osmolarity. A sodium value of ≤ 130 mEq/L frequently suggest overhydration in the first days of life. Excessive sodium deficit or SIADH needs to be considered in its differential diagnosis in conjunction with associated pathology such as gastroenteritis, NEC, renal failure, or preceding severe hypoxemic events. One needs to be aware that a measurement of Na^+ level from a hemolyzed blood sample may result in an inaccurate diagnosis of hyponatremia.
 - b. **Serum osmolarity** of 285 mOsm/L (± 3 mOsm) is the standard for TBW balance; values above or below must be considered indicative of over or underhydration.
6. **Acid-base status**
- a. **Hydrogen ion (pH)**. A less than normal pH (7.28–7.35) can be indicative of metabolic acidosis and will be accompanied by other factors, suggesting a contracted intravascular volume and hyperosmolarity.
 - b. **Base deficit**. An increasing base deficit (ie, metabolic acidosis with deficit >5.0) with decreased urine output, decreased blood pressure, and a prolonged CRT strongly suggests hypovolemia.
 - c. **Chloride ion, carbon dioxide (CO_2) content, and bicarbonate (HCO_3^-)**. These determinations are important for calculating anion gap and overall acid-base status.
 - d. **Anion gap**. The anion gap is a unifying determination for identifying metabolic acidosis in the face of dehydration. It is the sum of the serum sodium and potassium ions *minus* the sum of the serum chloride and bicarbonate ions. The normal range for anion gap is 8 to 16. Values for an anion gap >16 are indicative of an organic acidemia. In the face of dehydration with decreased intravascular volume, lactic acidemia follows poor tissue perfusion and is reflected as a widening anion gap. See Chapter 51.
7. **Urine**
- a. **Urine output should be 1 to 3 mL/kg/h by the third day of life in all newborn infants with normal kidneys**. Preterm infants have limited urine formation on day 1 of life but should begin to increase urine production throughout day 2.
 - b. **Urine specific gravity** of 1.005 to 1.012 is consistent with adequate with TBW balance.
 - c. **Urine electrolytes and urine osmolarity** offer additional information as to renal concentrating ability. Term infants can concentrate urine to 800 mOsm/kg, whereas preterm infants are limited to 600 mOsm/kg.
- D. **Maintenance of TBW**. Infusion fluid therapy for newborn infants (term and preterm) must be calculated to allow for normal ECW losses and body weight losses while avoiding dehydration from excessive IWL. The consequences of dehydration are hypotension, hyponatremia, and acidosis. Conversely, excessive infusion fluid therapy is

associated with clinically significant patent ductus arteriosus and may aggravate respiratory distress. Given careful monitoring for TBW as detailed earlier, the following infusion fluid therapy guidelines are offered for maintenance of TBW balance in term and preterm infants (with the exception of infusion fluid therapy for extremely low birthweight infants; see Chapter 13).

1. Term infants in need of infusion fluid therapy

- a. **Day 1.** Give dextrose 10% in water (D10W) at a rate of 60 to 80 mL/kg/d. This provides 6 to 7 mg/kg/min of glucose in support of energy needs while providing limited hydration during the immediate postnatal adaptation period. Neither sodium nor potassium supplementation are needed unless unusual body fluid losses are known.
- b. **Days 2 to 7.** Once tolerance of infusion fluid therapy has been established and confirmed by TBW monitoring (eg, urine output of 1–2 mL/kg/h), the rate and composition of fluid therapy can be modified. The goals of infusion fluid therapy include expected weight loss of 5% body weight, confirmed normal serum electrolyte values, and continued urine output of 2 to 3 mL/kg/h. Specifics of fluid therapy are as follows:
 - i. **Infusion fluid volume** 80 to 120 mL/kg/d. May increase to 120 to 160 mL/kg/d by week's end as tolerated or to meet needs per monitoring.
 - ii. **Glucose** to be provided to maintain serum glucose values >60 mg/dL; may increase to 8 to 9 mg/kg/min infusion as D10W or D12.5W.
 - iii. **Sodium requirement daily** is 2 to 4 mEq/kg/d per monitoring of serum (target values, 135–140 mEq/L).
 - iv. **Potassium daily requirements** are 1 to 2 mEq/kg/d per monitoring of serum (target values, 4.0–5.0 mEq/L). Potassium supplementation is not begun until the second or third day and only when normal renal function is confirmed by adequate urine output and normal serum electrolyte values have been established.
 - v. **Nutrition.** Infusion fluid glucose does not meet all energy needs for basal metabolism, growth, and activity. Enteral feeds must be started as soon as possible; however, if the infant is unable to take formula by mouth or only in limited amount, then total parenteral nutrition (TPN) becomes necessary. As enteral feeds increase, infusion fluids or TPN can be progressively decreased, but keeping total volume intake at 120 to 160 mL/kg/d.

2. Preterm infants

- a. **Day 1.** During the immediate postnatal period, critically ill premature infants may require volume resuscitation for shock or acidosis. Fluids administered during stabilization should be considered when planning subsequent fluid management.
- b. **Days 1 to 3.** Infusion fluid therapy is aimed at allowing a 10% to 15% body weight loss through the first week while maintaining TBW balance and electrolyte balance.
 - i. **Infusion fluid volumes.** Preterm low birthweight infants (>1500 g) require 60 to 80 mL/kg/d. Preterm very low birthweight infants (1000–1500 g) require 80 to 100 mL/kg/d. Preterm extremely low birthweight infants (<1000 g) require a range of fluid volumes from 50 to 80 mL/kg/d if cared for in double-walled humidified (80%) closed incubators or in a hybrid humidified incubators. If cared for under a radiant warmer or in incubators without humidity, fluid requirements may be 100 to 200 mL/kg/d (see Table 13–1 for breakdown into 100-g birthweight increments).
 - ii. **Glucose supplementation.** Best achieved by using D5W or D7.5W infusion fluids to avoid hyperglycemia. Because of the high fluid requirements in the smallest infants, glucose utilization may not be sufficient to prevent buildup of serum glucose and a hyperosmolar state secondary to hyperglycemia.

If allowable, reduced glucose maintenance is preferred, but extremes of hyperglycemia (>150 mg/dL) may require insulin therapy or intragastric sterile water supplementation (controversial).

- iii. **Sodium.** During the first week of life, fluid therapy should be managed by increments or decrements of 20 to 40/mL/kg/d depending on weight changes and serum sodium values, while attempting to keep serum sodium at 135 to 140 mEq/L. Sodium supplementation is not usually required in the first 2 to 3 days of life. Sodium supplementation is begun based on body weight losses (postnatal isotonic contraction of ECW compartment, a physiologic diuresis). Usually by day 3 to 5, weight loss and a slight serum sodium decrease from baseline dictate the need to start sodium supplementation by way of the infusion fluids. Judicious restriction of sodium intake during the first 3 to 5 days of life facilitates a trend for normal serum osmolarity throughout the first week of life for preterm infants.
 - iv. **Potassium.** Supplementation follows that of term infants, meaning that well-established renal function with good urine output is required before supplementation at 1 to 2 mEq/kg/d.
 - v. **Nutrition.** Caloric needs to provide for the relative hypermetabolic state of low birthweight infants can be met through TPN fluid therapy. Initiation of TPN after the first 24 hours of life is desirable (see Chapters 11 and 13).
- c. **Days 3 to 7.** Infusion fluid and electrolyte management is dictated by the monitoring parameters as already given. Infusion fluids should be advanced or decreased as the transition period progresses. Excessive weight loss suggests increased IWL losses and the threat of dehydration. Likewise, edema and minimal or no weight loss suggests excessive fluid administration or decreasing renal function and decreased urine output. All preterm infants should be cared for whenever possible in double-walled incubators for a more stable humidity control and less IWL.

3. Other infusion fluid calculations and considerations

a. Environmental

- i. **Radiant warmers.** Infusion fluid volume recommendations as outlined earlier are for assumed double-walled incubator care. If radiant warmer exposure is to be maintained, fluid therapy must be increased by 50% to 100%. Plastic sheeting limits increased needs to 30% to 50%.
 - ii. **Phototherapy.** If infant is full term, increased fluid therapy may not be needed. If infant is low birthweight, most likely 10 to 20 mL/kg/d will be needed to minimize IWL while phototherapy lights are in use.
- b. **Glucose.** The normal glucose requirement is 6 to 8 mg/kg/min, and intake can be slowly increased to 10 to 12 mg/kg/min as needed, but with careful monitoring for hyperglycemia and glycosuria to avoid an osmotic diuresis. Calculations for glucose supplementation are:

$$\begin{aligned} & \text{Glucose requirements (mg/kg/min)} \\ &= \frac{(\text{Percentage of glucose} \times \text{Rate [mL/h]} \times 0.167)}{\text{Weight (kg)}} \end{aligned}$$

An alternate method is

$$\begin{aligned} & \text{Glucose requirements (mg/kg/min)} \\ &= \frac{(\text{Amount of glucose/mL [from Table 10-3]} \times \text{Total fluids})}{\text{Weight (kg)}/(60 \text{ min})} \end{aligned}$$

Table 10–3. GLUCOSE CONCENTRATION IN COMMONLY USED INTRAVENOUS INFUSION FLUIDS

Solution	Glucose Concentration (mg/mL)
Dextrose 5% water	50
Dextrose 7.5% water	75
Dextrose 10% water	100
Dextrose 12.5% water	125
Dextrose 15% water	150

- c. **Sodium.** The normal sodium requirement for infants is 2 to 3 mEq/kg/d. The following calculations can be used to determine the amount of sodium (Na^+) per day that an infant will receive from a given saline infusion fluid:

$$\text{Amt of Na}^+/\text{mL (from Table 10–4)} \times \text{Total fluids/d} = \text{Amt of Na}^+/\text{d}$$

$$\frac{\text{Amt of Na}^+/\text{d}}{\text{Weight (kg)}} = \text{Amt of Na}^+ \text{ (kg/d)}$$

- d. **Potassium.** The normal potassium requirement for infants is 1 to 2 mEq/kg/d. Potassium supplementation should not begin until adequate urine output is established.

II. Electrolyte disturbances

- A. **Sodium.** Serum values of 135 to 145 mEq/L represent homeostatic sodium balance. The wide range of 131 to 149 mEq/L is the lower and upper limit for sodium (Na^+) balance. Values above or below are clinical indicators of either hyper- or hyponatremia.

1. Hypernatremia

a. Decreased ECW with Na^+ of ≥ 150 mEq/L

- i. **Causes.** Include increased renal free water losses and/or increased IWL, primarily through skin, especially very low birthweight and extremely low birthweight infants.
- ii. **Clinical findings.** Weight loss, low blood pressure, tachycardia, decreased or absent urine output, and increased urine specific gravity.
- iii. **Treatment.** Requires careful infusion fluid management. **Replacing free water is the first goal, and maintaining Na^+ balance is the second goal.** Both goals need to be accomplished without precipitating rapid ICW and ECW shifts of water or sodium, especially within the central nervous system (CNS). **Excessively rapid correction of hypernatremia can result in**

Table 10–4. SODIUM CONTENT OF COMMONLY USED INFUSION FLUIDS

Solution	Sodium Concentration (mEq/mL)
3% normal saline	0.500
Normal saline	0.154
0.50% normal saline	0.075
0.25% normal saline	0.037
0.125% normal saline	0.019

seizures. Hypernatremic dehydration does not represent a deficit of body sodium. Infusion therapy should be guided to reduce serum Na^+ by not more than 0.5 mEq/L/kg/h, or less, with a target of total correction time of 24 to 48 hours. Consider using D5W 0.25 normal saline (NS) as an initial infusion fluid for correction.

b. Increased ECW and hyponatremia

- i. Causes.** Include excessive administration of normal saline or sodium bicarbonate as in resuscitation efforts or postresuscitation treatment for perinatal asphyxia with metabolic acidosis and hypotension.
- ii. Clinical findings.** Increased weight gain and edema. If cardiac output has been compromised, findings of edema and weight gain increase. Depending on cardiac status, heart rate, blood pressure, and urine output will be within normal limits or decreased.
- iii. Treatment.** Involves identification of cardiac status. Identify infusion fluid excesses and establish maintenance infusion fluid limits; thereafter, restrict sodium until serum Na^+ values return to normal range.

2. Hyponatremia. See also Chapter 69.

a. Increased ECW as increased intravascular water and increased third space interstitial water

- i. Causes.** Increased ECW with serum $\text{Na}^+ < 130$ mEq/L, which most likely represents excessive infusion fluid administration, and increased third space (interstitial) water secondary to sepsis, shock, and capillary leakage. It may also be secondary to cardiac failure or pharmacologic neuromuscular paralysis during mechanical ventilation. It may occur with fluid retention associated to oliguric renal failure (such as acute tubular necrosis associated with perinatal asphyxia) or in newborn infants developing SIADH following CNS trauma, intracranial hemorrhage, meningitis, perinatal asphyxia, or pneumothorax.
- ii. Clinical findings.** Result from inadvertent excessive infusion fluid administration: body weight is increased with edema, serum Na^+ is decreased, and urine output is increased with decreased urine osmolarity and specific gravity. Conversely, if SIADH is the root cause of increased ECW and hyponatremia, the clinical findings reveal increased body weight, variable presence of edema, decreased serum Na^+ , decreased urine output, and increased urine specific gravity, whereas oliguric renal failure is associated with isosthenuria (neither concentrated nor diluted urine).
- iii. Treatment.** In both situations, treatment is free water restriction allowing serum Na^+ to concentrate to normal levels. If serum Na^+ is < 120 mEq/L and neurologic symptoms are present, consider titrating with infusion of 3% saline solution boluses. Consultation with a nephrologist is recommended.

b. Decreased ECW with hyponatremia

- i. Causes.** Include excessive diuretic therapy, glycosuria with an osmotic diuresis, vomiting, diarrhea, and third space fluid with NEC.
 - ii. Clinical findings.** Include decreased body weight, signs of dehydration with sunken fontanel, loss of skin turgor, dry mucous membranes, increased blood urea nitrogen, metabolic acidosis, decreased urine output, and increased urine specific gravity.
 - iii. Treatment.** Involves replacing sodium and water while minimizing any ongoing sodium losses (See Chapter 69 for management details.)
- c. Isotonic losses may occur and present as hyponatremia.** Such losses may be cerebrospinal fluid from drainage procedures, thoracic as in chylothorax, nasogastric drainage, or peritoneal fluid (ascites). Normal saline for fluid replacement usually suffices, or normal saline plus colloid as fresh-frozen plasma or human albumin may facilitate intravascular volume and restore serum saline.

B. Potassium

1. **Hyperkalemia.** Represented by serum K^+ values >5.5 mEq/L. Some infants do not manifest symptoms until serum levels reach 7 to 8 mEq/L. Hyperkalemia can be caused by or related to renal failure, hemolysis, massive blood transfusions, exchange transfusions, or inadvertent excessive administration of a potassium solution (eg, KCl). Cardiac conduction is the most immediate concern, and electrocardiographic monitoring is essential until treatment corrects serum K^+ levels. For a detailed discussion of hyperkalemia and treatment, see Chapter 65.
2. **Hypokalemia.** Potassium levels <4.0 mEq/L suggest impending hypokalemia, and values <3.5 mEq/L require treatment to correct. Meanwhile, cardiac conduction abnormalities may occur, and monitoring electrocardiographically, as in hyperkalemia, is essential until hypokalemia is corrected. For a detailed discussion of hypokalemia and treatment, see Chapter 68.

C. Chloride. See also Chapter 51, section on metabolic alkalosis.

1. **Hypochloremia.** Serum values of 97 to 110 mEq/L are taken as normal in most newborn infants. Serum values <97 mEq/L are indicative of low chloride and suggest either inadequate supplementation during infusion fluid therapy or, more commonly, chloride ion losses. Typically, chloride ion accompanies Na^+ and K^+ as NaCl or KCl solutions in maintenance infusion solutions. Chloride losses independent of Na^+ or K^+ occur usually from excessive gastrointestinal fluid losses, particularly gastric hydrochloric acid losses. Chloride losses lead to increased bicarbonate reabsorption and metabolic alkalosis.
2. **Hyperchloremia.** Uncommon in the newborn period but may be found when inadvertent concentrations of Cl^- ion are given in parenteral nutrition solutions. Occasionally increased Cl^- ion is reflective of excessive renal conservation of Cl^- during correction of alkalosis when forming alkaline urine.

11 Nutritional Management

GROWTH ASSESSMENT

- I. **Anthropometrics.** Serial measurements of weight, length, and head circumference allow for evaluation of growth patterns.
 - A. **Weight.** Birthweight (BW) is reflective of maternal, placental, and fetal environment. Both term and preterm neonates experience weight loss after birth (approximately 10%, or higher in preterm infants) due to loss of extracellular free water. Term infants regain birth weight by 7 to 10 days, whereas preterm infants may take 10 to 15 days to regain birth weight (or even longer in extremely low BW [ELBW] infants). Once BW is reached, average daily weight gain should be 14 to 20 g/kg/d for preterm infants and 20 to 30 g/d for term infants.
 - B. **Length.** Length is a better indicator of lean body mass and long-term growth and is not influenced by fluid status. Weekly assessment is recommended using a neonatal length board. Average length gain is 1.4 cm/wk in preterm infants and 0.7 cm/wk in term infants.
 - C. **Head circumference.** Occipitofrontal circumference (OFC) reflects brain growth and correlates with long-term neurodevelopment. Weekly assessment is recommended. Preterm infants grow at a rate of 0.9 cm/wk and term infants at 0.33 cm/wk. Premature infants exhibit catch-up growth in head circumference that may exceed normal growth rate, but an increase in head circumference >1.25 cm/wk

may be abnormal and should prompt evaluation for hydrocephalus or intraventricular hemorrhage. Poor head circumference growth may reflect underlying poor nutritional status or medical condition and may be associated with motor and cognitive delays.

- D. Weight for length.** This reflects symmetry of growth. Current weight expressed as a percentage of ideal weight for length can identify infants at risk for under- or overnutrition. Catch-up growth occurs faster if only weight is lagging compared with length and head circumference. Weight gain is slower in large for gestational age infants.
- E. Z-scores.** Z-scores express anthropometric data as a function of standard deviation from the mean or median value and can be used to compare weight for age, weight for height, and height for age across various ages; they are useful for comparing populations.
- F. Body composition.** Body mass index (BMI) for gestational age reference curves allow assessment of proportionality of weight and length growth. BMI and weight for length show high agreement. Body mass composition curves for healthy preterm infants at birth assess patterns of fetal body composition variation and can identify infants at risk for metabolic syndrome.
- G. Growth velocity.** Growth velocity is higher at earlier gestational age; at <27 weeks, it is approximately 20 g/kg/d; at 33 weeks, approximately 14 g/kg/d; and at term, approximately 10 g/kg/d. Fetal growth velocity approximates 1% to 3% of body weight per day.

II. Classification

- A. Measurements.** Weight, length, and head circumference are plotted on growth charts to facilitate comparison with established norms.
- B. Growth charts.** Growth can be monitored longitudinally on standard growth charts. For term infants, the World Health Organization (WHO) growth charts (2006) based on data from different ethnicities reflect *growth standards* of healthy breast-fed infants and should be used until 2 years of age. The Centers for Disease Control and Prevention (CDC) growth charts (2000) are a *reference* for anthropometric growth parameters at any given time and should be used to monitor growth after 2 years of age (https://www.cdc.gov/growthcharts/who_charts.htm). The two charts are now merged; the WHO centiles are used before 2 years and the CDC after 2 years (www.who.int/childgrowth/standards/en).

Growth patterns of term infants differ based on diet, with breast-fed infants experiencing rapid early weight gain in the first 6 months and slower weight gain thereafter compared to formula-fed infants, but linear growth remains similar. Breast-fed infants, compared to formula-fed infants, also drop down the centiles between 6 and 18 months with decreases in weight and weight for length.

Two types of **growth charts exist for very low birthweight (VLBW) infants**: those based on fetal (intrauterine growth) and those based on postnatal growth. Intrauterine growth charts provide **fetal reference standards**. Assessment of postnatal growth failure is better reflected on postnatal growth charts, but these are limited because they do not show the “catch-up growth” or the growth velocity relative to the fetus.

Normal growth customarily falls between the 10th and 90th percentiles when adjusted for gestational age. Population-specific customized growth charts have been developed to determine term optimal BW and to identify fetal growth restriction (www.gestation.net). Growth charts from different regions around the world allow monitoring postnatal growth of infants born preterm.

- 1. The INTERGROWTH-21st study** followed intrauterine, newborn, and postnatal growth in 8 diverse geographic regions (Brazil, China, India, Italy, Kenya, Oman, United Kingdom, and United States) and provide growth charts up to 64 weeks after birth (<https://intergrowth21.tghn.org>); these curves were published in late 2014 and are expected to be used more often in the future.

2. Two commonly used growth charts for preterm infants are the Olsen and Fenton growth charts. The **2010 Olsen growth charts** (<https://www.aap.org/en-us/Documents/GrowthCurves.pdf>) are based on intrauterine growth of 257,855 singleton infants who were born in the United States between 22 and 42 weeks' postmenstrual age (PMA) and survived. The charts incorporate data from the WHO charts for the period of 39 to 50 weeks' PMA. The **2013 Fenton growth charts** (www.ucalgary.ca/fenton/2013chart) are based on anthropometric measurements from 3 intrauterine growth datasets; BW for gestation data on approximately 676,000 Canadian infants from 22 to 40 weeks' gestation, and length and OFC data from 376,000 Swedish infants from 28 to 40 weeks' gestation and from approximately 27,000 Australian infants from 22 to 40 weeks' gestation. The curves include data to 50 weeks PMA based on the WHO 2006 data. The charts reflect the actual age instead of completed weeks. Both charts (Olsen and Fenton) are widely used and easily accessible and are reproduced in Chapter 6.

NUTRITIONAL REQUIREMENTS

- I. Calories.** The energy provided by dietary intake contributes to basal resting metabolism, thermoregulation, physical activity, and growth. In term infants, optimal weight gain is 20 to 30 g/d and usually achieved with a caloric intake between 100 and 120 kcal/kg/d. Preterm infants may require 120 to 140 kcal/kg/d for optimal weight gain that matches or exceeds the fetal growth rate of approximately 14 to 20 g/kg/d. Acutely ill infants become relatively insulin resistant with increased levels of stress hormones, leading to tissue catabolism, and may need higher caloric intake for adequate growth. Examples of states of altered nutritional needs include acute respiratory disease, chronic respiratory disease, sepsis, surgery, and congenital heart disease.
- II. Carbohydrates.** Approximately 10 g/kg/d (12–14 g/kg/d in preterm) are needed to provide 40% to 50% of total calories.
- III. Proteins.** In the term infant, adequate protein intake has been estimated at 1.5 to 2.2 g/kg/d (7%–16% of total calories). Preterm infants require 3.5 to 4.4 g/kg/d.
- IV. Lipids.** In the term infant, fat requirements are estimated at 3.3 to 6 g/kg/d (40%–55% of total calories). Preterm infants require 4 to 7 g/kg/d to account for decreased intestinal fat digestion and absorption.
- V. Long-chain polyunsaturated fatty acids (LCPUFA).** To meet essential fatty acid requirements, preterm infants should receive 385 to 1540 mg/kg/d of linoleic acid and >55 mg/kg/d of linolenic acid. Linoleic and linolenic acids are precursors for arachidonic acid (ARA) and docosahexaenoic acid (DHA), which are important in neural and retinal maturation. LCPUFAs are transferred predominantly through the placenta in the third trimester, which places preterm infants at risk of deficiency. Additionally, concentrations of LCPUFAs in human milk varies (0.1%–1.4%) across regions. Although human milk intake meets the LCPUFA requirements of term infants but not preterm infants, preterm neonates fed LCPUFA-enriched feeds have failed to show benefits in retinal sensitivity and visual acuity. It is not clear if maternal supplementation of DHA would be beneficial for their VLBW offspring.
- VI. Vitamins and minerals.** Guidelines for vitamin and mineral requirements for preterm infants, although not clearly established, are provided in Tables 11–1 and 11–2 for low BW infants. Caution is required with vitamin supplementation because toxicity may occur with both water- and fat-soluble vitamins as a result of immature renal and hepatic function. Vitamin supplementation may be needed with certain types of infant formulas and human milk fortifiers.
 - A. Vitamin A.** May be useful in attenuating chronic lung disease in VLBW infants at a dose of 5000 IU intramuscularly 3 times per week for 12 doses.
 - B. For infants with osteopenia of prematurity.** Various amounts of calcium, phosphorus, and vitamin D may need to be supplemented. See Chapter 113.

Table 11–1. DAILY ENTERAL VITAMIN AND MINERAL REQUIREMENTS FOR TERM AND STABLE PRETERM LOW BIRTHWEIGHT INFANTS

Nutrient	Term Infant (per day)	Stable Very Low Birthweight Infant (dose/kg)
Vitamins		
Vitamin A (with lung disease)	400 mcg	700–1500 IU
Vitamin D	400 IU	150–400 IU
Vitamin E	7 IU	6–12 IU
Vitamin K	200 mcg	8–10 mcg
Vitamin C	80 mg	18–24 mg
Thiamine	1.2 mg	180–240 mcg
Riboflavin	1.4 mg	250–360 mcg
Niacin	17 mg	3.6–4.8 mg
Pyridoxine	1.0 mg	150–210 mcg
Vitamin B12	1.0 mcg	0.3 mcg
Folic acid	140 mcg	25–50 mcg
Biotin	20 mcg	3.6–6.0 mcg
Pantothenate	5 mg	1.2–1.7 mg
Choline	125 mg	14.4–28 mg
Minerals		
Calcium	250 mg	150–220 mg
Phosphorus	150 mg	75–140 mg
Magnesium	20 mg	7.9–15 mg
Sodium	1–2 mEq/kg	69–115 mg
Potassium	2–3 mEq/kg	78–195 mg
Iron	1 mg/kg	2–3 mg
Copper	20 mcg/kg	100–230 mcg
Zinc	2.5–5.0 mg/d	1000 mcg
Manganese	5 mcg/100 kcal	0.75–7.5 mcg
Molybdenum	0.75–7.5 mcg	0.3 mcg
Selenium	2 mcg/kg	5–10 mcg
Chromium	0.20 mcg/kg	0.1–2.25 mcg
Iodine	1 mcg/kg	10–55 mcg
Linoleic acid	4.4 g	385–1540 mg
Linolenic acid	0.5 g	>55 mg
Docosahexaenoic acid (DHA)		>18 mg
Arachidonic acid (ARA)		>24 mg

Table 11–2. DAILY PARENTERAL REQUIREMENTS FOR VITAMINS AND MINERALS IN TERM, PRETERM, AND STABLE PRETERM INFANTS

Nutrient	Term Infant (per day)	Stable Very Low Birth Weight Infant (dose/kg)
Vitamins		
Vitamin A (with lung disease)	700 mcg	700–1500 IU
Vitamin D	400 IU	40–160 IU
Vitamin E	7 mg	2.8–3.5 mg
Vitamin K	200 mcg	10 mcg
Vitamin C	80 mg	15–25 mg
Thiamine	1.2 mg	200–350 mcg
Riboflavin	1.4 mg	150–200 mcg
Niacin	17 mg	4–6.8 mg
Pyridoxine	1.0 mg	150–200 mg
Vitamin B12	1.0 mcg	0.3 mcg
Folic acid	140 mcg	56 mcg
Biotin	20 mcg	5–8 mcg
Pantothenate	5 mg	1.2 mg
Minerals		
Calcium		60–80 mg
Phosphorus		45–60 mg
Magnesium		4.3–7.2 mg
Sodium	1–2 mEq/kg	69–115 mg
Potassium	2–3 mEq/kg	78–117 mg
Iron ^a		100–200 mcg
Copper ^b	20 mcg/kg	20 mcg
Zinc	250 mcg/kg	400 mcg
Manganese	1 mcg/kg	1 mcg
Molybdenum	0.25 mcg	0.25 mcg
Selenium ^c	2 mcg/kg	1.5–4.5 mcg
Chromium	0.20 mcg/kg	0.05–0.3 mcg
Iodine	1 mcg/kg	1 mcg

^aStart supplementation at 6 to 8 weeks.

^bOmit in cholestatic jaundice.

^cStart supplementation at 2 to 4 weeks. Omit in renal dysfunction.

C. Iron deficiency. Iron deficiency anemia is associated with short-term and long-term neurodevelopmental deficits, delayed maturation of the auditory brainstem responses, and abnormalities of memory and behavior. Iron supplementation of term infants at risk of iron deficiency is associated with improved neurodevelopmental

outcomes. Preterm infants are more susceptible to iron deficiency due to small iron stores at birth, high growth velocity, and phlebotomy losses. Furthermore, anemia may be associated with increased rates of necrotizing enterocolitis (NEC) in this population. Blood transfusions provide a rich source of iron; 1 mL of packed red blood cells provides 0.5 to 1.0 mg of iron, and iron overload may be a risk with multiple transfusions. Delayed cord clamping improves iron stores in both term and preterm infants. **Stable preterm infants without recent blood transfusions** should receive iron supplementation (2–4 mg/kg/d; maximum 15 mg/d) starting at 2 to 4 weeks of age and continued until 12 months. **Formula-fed infants** require less iron supplementation than human milk–fed infants, although iron is more bioavailable in human milk. A rising reticulocyte count may indicate the need for starting iron supplementation. **Term breast-fed infants (but not formula-fed infants)** should receive iron supplementation at 1 mg/kg starting at 4 months until age-appropriate diet is established.

D. Recombinant human erythropoietin therapy (rhEPO). Additional iron supplementation is necessary for infants receiving rhEPO. Recommended dose is 6 mg/kg/d added to enteral feedings or 3 mg/kg/wk (iron dextran) added to parenteral nutrition. For infants receiving high doses of iron, monitoring for hemolytic anemia is important, and vitamin E supplementation (15–25 IU/d) may be required. Administration of rhEPO reduces the number of transfusions in VLBW infants but may have limited efficacy in decreasing the number of blood donors to which the infant is exposed. rhEPO is being currently investigated as a neuroprotective agent. Its use is variable among neonatal intensive care units (NICUs), and it is controversial whether early rhEPO is associated with increased risk of retinopathy of prematurity (ROP).

VII. Fluids. See Chapter 10 for fluid requirements.

VIII. Parenteral nutrition. (See section on parenteral nutrition, page 155.)

PRINCIPLES OF ENTERAL FEEDING

I. Term infants. Term healthy infants should be breast fed within the first hour after birth or as soon as medically stable. Once tolerated, feeding should be advanced to ad libitum. In sick infants, gavage feeds should be started as soon as the infant is clinically stable and milk is available.

II. Preterm infants. Enteral feedings with human milk should be initiated as soon as clinically possible, ideally within 24 to 48 hours (see also discussion of trophic feeds later in this chapter). Preterm infants are at risk of postnatal growth and nutritional failure as they are deprived of in utero transfer of nutrients, particularly proteins, fats, and minerals. Early enteral feedings are associated with better endocrine adaptation, enhanced immune functions and gut maturation, decreased time to attain full feeds, and earlier discharge without an increase in risk of NEC. Although the intake of proteins (both enteral and parenteral) and a shorter time to regain BW positively influence neurodevelopmental outcomes, aggressive feeding and rapid weight gain predominantly as fat deposition increase the risks of subsequent metabolic syndrome. In preterm infants, parenteral nutrition should be initiated to provide adequate protein and caloric intake and improve weight gain (see further discussion in section on parenteral nutrition).

III. Feeding guidelines

A. Type of feeds. Breast feeding and human milk intake are the biological norm for infant feeding in both the term and preterm infant. Pasteurized donor human milk and commercial formulas are available if maternal milk is unavailable.

B. Mode of feeding. Feeds can be provided orally or via gavage. Oral feeds are the preferred method of delivery if the infant is clinically stable and has a mature feeding pattern; otherwise, gavage feeds can be used. Oromotor coordination (sucking, swallowing, and breathing) is not mature in preterm infants and usually precludes

oral feeds. Limited studies suggest that preterm neonates on noninvasive support (continuous positive airway pressure or high flow) are capable of maintaining airway during feeds, but caution should be exercised with oral feeds. Some institutions allow the infant to attempt nuzzling at breast while on noninvasive respiratory support. This may increase the mother's milk supply and encourage bonding of the mother–infant dyad. Preterm and sick neonates are also at risk for oral aversion.

- C. Contraindications to enteral feeds** Oral feeds are a contraindication in neonates with: a risk for aspiration, such as in intubated patients, and tachypnea (respiratory rate >70 breaths/min); neurologic injury; and in infants with bilious emesis, abdominal distension, or excessive oral secretions. Gavage feeds may be used instead.

Feeding caution should be exercised in the presence of perinatal asphyxia, hemodynamic instability, sepsis, absent or reversed end-diastolic (A/REDF) umbilical arterial flow in utero, severe intrauterine growth restriction (IUGR), indomethacin or ibuprofen therapy, hemodynamically significant patent ductus arteriosus (PDA), polycythemia, severe anemia, and packed red cell transfusion. This caution stems from concerns, in many institutions, for NEC in ELBW and VLBW infants. However, there is increasing evidence that it is safe to provide feeding (at least trophic) for infants exposed to absent or reversed end-diastolic umbilical arterial flow, indomethacin or ibuprofen therapy, and PDA.

- D. Oral care.** Oropharyngeal administration of maternal colostrum or milk exposes infants to the benefits of the mother's own milk. Administration of colostrum directly to the buccal mucosa may mimic the protective effects of amniotic fluid, accelerate intestinal maturation, and improve time to oral feeding.
- E. Minimal enteral feedings.** Minimal enteral or trophic feeds are subnutritional quantities of milk feeds (maternal or donor milk) given during the first few days of life to stimulate the development of the immature gastrointestinal (GI) tract of the preterm infant. This practice, also called hypocaloric, trophic, trickle feedings, low-volume enteral substrate, or GI priming, is characterized by a small-volume feeding to supplement parenteral nutrition. Most institutions consider approximately up to 24 mL/kg/d as trophic feeds. Trophic feeds are usually given for 3 to 7 days prior to advancing feeding volume. Potential benefits include improved feeding tolerance, improved gastric emptying, prevention of GI atrophy, and facilitation of GI tract maturation leading to faster attainment of full enteral feedings. Other benefits may include decreased incidence of cholestasis, nosocomial infections, and metabolic bone disease and decreased hospital stay without an increase in the incidence of NEC.
- F. Feeding advancement.** While advancement protocols vary among institutions, a standardized approach (agreed upon among various NICU providers and implemented consistently) in preterm infants can lead to improved feeding-related outcomes, including less time to full feeds, better weight gain, decreased costs, and decreased incidence of NEC. For stable VLBW infants (between 1000 and 1500 g), rapid advancement (35 mL/kg/d) of enteral feeds versus slower advancement (15–20 mL/kg/d) does not increase the risk of NEC or death and decreases the risk of invasive infection. Most institutions would provide trophic feeds for a period of 5 to 7 days in ELBW infants at 10 to 15 mL/kg/d divided every 2 to 3 hours. At our institution, for example, for infants <1000 g, we start feeds at 15 mL/kg/d divided every 3 hours and advance by 15 mL/kg/d daily as tolerated. For infants >1000 g, we start feeds at 25 to 35 mL/kg/d divided every 3 hours and advance by 25 to 35 mL/kg/d daily as tolerated. Caution should be exercised in infants at high risk of NEC, particularly growth restricted infants with absent or reversed end-diastolic flow and on formula feeds.
- G. Feeding intolerance.** If feeding is initiated but not tolerated, a complete abdominal examination should be performed. Preterm infants <32 weeks may not establish

antegrade peristalsis. In the absence of other clinical signs, bilious aspirate by itself is not a contraindication for feedings in VLBW infants. It is questionable whether checking gastric residuals prior to feeds, although routine in most NICUs, can improve feeding intolerance or prevent NEC. When studied, the color and volume of aspirates have not been shown to predict NEC. In addition, aspiration can damage friable gastric mucosa, lead to discarding of nutrients and enzymes that help mature the GI system, and delay time to full feeds. Some institutions have shown that abandoning the practice of checking residuals is safe and allows reaching full feeds early with less exposure to central venous access. In clinically stable infants, increasing feeding volume or continuing feeding (in the face of residuals) may be helpful in improving feeding tolerance due to possible increase in gastric emptying and stimulation of the gastrocolic reflex. Presence of bilious or bloody emesis, blood in stool, abdominal distension, or other systemic signs such as apnea and bradycardia should prompt evaluation for infections and NEC (see Chapter 54 on bloody stool and Chapter 109 on NEC).

- H. Continuous feeds.** Infants with short gut syndromes, feeding intolerance, or gastroesophageal reflux may tolerate continuous feeds better than bolus feeds. However, there is no clear evidence that continuous feeding is better than bolus feeding. Of importance when on continuous feeds, substantial amounts of fat and nutrients from human milk can adhere to the feeding bag, syringe, and tubing and may not be delivered to the infant, resulting in suboptimal growth. The infusion syringe should be placed upward at a 45-degree angle to promote even distribution of human milk fat and fortifier.

FORMS OF ENTERAL NUTRITION: HUMAN MILK (TABLE 11–3)

Breast feeding and human milk are the biological standard for feeding term, preterm, and sick infants. Breast feeding is recommended as the sole source of nutrition for the first 4 to 6 months of age and then as complementary feeds thereafter as long as desired.

I. Effectiveness of breast feeding and human milk

- A. Infants.** Breastfeeding provides immunologic protection against bacterial and viral infections (particularly upper respiratory tract infections, otitis media, and GI infections). Risk of sudden infant death is decreased by 36% for infants with any amount of breast feeding >1 month. Breast-fed infants have lower risks of obesity, type 1 diabetes mellitus, celiac and inflammatory bowel disease, and acute lymphocytic leukemia. Breast feeding may improve neurodevelopmental outcomes.

B. Human milk in the preterm infant

- 1. Effectiveness of human milk in the NICU.** Human milk feeding in preterm infants is associated with less feeding intolerance, less time to reach full feeds, decreased risk of NEC (formula-fed infants have a 6- to 10-fold higher risk), and higher intelligence quotient (IQ) at the age of 8 years. Breast milk may protect against NEC by lowering gastric pH, decreasing intestinal epithelial permeability, improving motility, and altering bacterial flora. Maternal milk feedings are associated with decreased rates of ROP and larger white matter and total brain volumes and have beneficial effects on visual, cognitive, psychomotor, and neurodevelopmental outcomes that persist into childhood. A dose-response relationship between amount of human milk and decreased incidences of feeding intolerance, nosocomial infection, NEC, bronchopulmonary dysplasia (BPD), and ROP has been demonstrated, with benefits seen even with partial human milk feeds (>50 mL/kg) in preterm infants. The volume of human milk intake during an infant's stay in the NICU may directly impact later neurodevelopmental scores.
- 2. Postdischarge.** Postdischarge rates of hospital readmission are lower in infants who have ever received human milk even if not receiving human milk at the

Table 11–3. ENTERAL FEEDINGS INDICATIONS AND USES

Formula	Indications	Vitamin and Mineral Supplement ^a
Human milk	All infants	Vitamin D 400 IU/d; iron at 4 months
Breast milk fortifiers	Preterm infant (<1800 g and <34 weeks)	Vitamin D 400 IU/d; iron; MV
Cow milk–based formulas		
Enfamil Infant Similac Advance Similac Organic	Full-term infants: as supplement to breast milk	MV if <32 oz./d (~1 L/d)
Enfamil Gentlease/Similac Sensitive	Term infants: to reduce fussiness or gas	
Gerber Good Start	Term infants: whey protein; moderate mineral content; may be more palatable	
Enfamil Added Rice	Rice starch added for thickening after ingestion (pH sensitive). Used for simple reflux. Not indicated for preterm infants	
Preterm formulas		
Enfamil Premature 20, 24, and 30 Similac Special Care 20, 24, and 30	Preterm infants: for infants on fluid restriction or who cannot handle required volumes of 20-calorie formula to grow. Calcium and phosphorus content to mimic intrauterine accretion rates	
Enfamil Premature 24 High Protein Similac Special Care 24 High Protein	Approximately 10% more protein than above formulas at same caloric density	
Enfamil EnfaCare Similac NeoSure	Preterm infants preparing for discharge; increased protein, calcium, phosphorous, vitamins A and D; promotes better mineralization. Use up to 6–9 months corrected age	
Soy formulas (<i>Note:</i> Soy formulas not recommended in infants <1800 g)		
Enfamil ProSobee (lactose and sucrose free) Gerber Good Start Soy Similac Soy Isomil (lactose free)	Term infants: milk sensitivity, galactosemia, carbohydrate intolerance, desire for vegetarian diet. Term infants; hydrolyzed soy proteins <i>Do not use soy formulas in preterm infants. Phytates can bind calcium and cause rickets</i>	MV if <32 oz./d (~1 L/d)

(Continued)

Table 11–3. ENTERAL FEEDINGS INDICATIONS AND USES (CONTINUED)

Formula	Indications	Vitamin and Mineral Supplement ^a
Protein hydrolysate formulas (casein predominant)		
Nutramigen with Enflora LGG (Probiotic LGG)	Term infants: hypoallergenic, hydrolyzed casein with lactose, galactose, and sucrose free for gut sensitivity to proteins, galactosemia, multiple food allergies, persistent diarrhea, colic due to cow milk allergy	MV if <32 oz./d (~1 L/d)
Pregestimil	Preterm and term infants: disaccharides deficiency, fat malabsorption, diarrhea, GI defects, cystic fibrosis, food allergy, celiac disease, transition from TPN to oral feeding	
Similac Alimentum	Term infants: lactose-free formula; protein sensitivity, pancreatic insufficiency, diarrhea, severe food allergies, colic, carbohydrate, and fat malabsorption	
Free amino acid elemental formulas		
Neocate	Term infants: severe cow milk protein allergies; contains 100% free amino acids (elemental formula)	
EleCare for infants	Elemental formula containing amino acids indicated for malabsorption, protein malabsorption, short bowel syndromes	
Special formulas		
Similac PM 60/40	Preterm and term infants: problem feeders on standard formula; infants with renal, cardiovascular, or digestive diseases that require decreased protein and mineral levels; breast-feeding supplement; initial feeding	MV and Fe if standard formula weight >1500 g
Enfaport	For infants with chylothorax and LCHAD deficiency	
Metabolic formulas	Special metabolic formulas are available for infants with inherited metabolic disorders www.meadjohnson.com www.abottnutrition.com	

Fe, iron; GI, gastrointestinal; LCHAD, long-chain 3-hydroxyacyl-CoA dehydrogenase; MV, multivitamin; TPN, total parenteral nutrition.

^aSuch as Poly-Vi-Sol (Mead Johnson).

time of discharge. In adolescents who were former preterm infants, lower rates of metabolic syndrome including lower blood pressure and better insulin metabolism have been observed.

- C. **Maternal outcomes.** Breast feeding improves maternal and infant bonding and is associated with decreased rates of maternal blood loss, breast cancer, ovarian cancer, postpartum depression, type 2 diabetes, cardiovascular disease, hypertension, and rheumatoid arthritis. Breast feeding also leads to faster return to prepregnancy weight and can help optimize pregnancy spacing.
 - D. **Immunologic benefits.** Breast milk contains several bioactive factors that protect against bacteria and viruses. Extracellular vesicles deliver proteins, lipids, and long noncoding RNA to affect immune functions. Exosomes in breast milk regulate cellular communication, and microRNA may alter gene expression. Other immunologic benefits of breast milk include:
 1. **Anti-infectious and immune properties.** Lactoferrin, lysozyme, lactadherin, defensins, maternal leukocytes, and immunoglobulins are a few of the immune components of human milk that provide protection for the infant. The dose-dependent protection of human milk against NEC and sepsis may be secondary to a decrease in intestinal permeability and bacterial translocation as well as the maturational effects of breast milk on the intestine.
 2. **Cytokines and chemokines.** Cytokines in human milk promote maturation of the infant immune and GI systems and decrease excessive inflammatory responses. Chemokines aid infants by providing immune protection, promoting host defense against infection, and decreasing inflammation. Human milk contains the enzyme acetylhydrolase, which antagonizes platelet-activating factor, a major trigger for NEC in premature infants.
 3. **Growth factors and oligosaccharides.** Growth factors such as epidermal growth factor and insulin-like growth factor promote GI and immune system maturation. Oligosaccharides act as prebiotics, have antiadhesive activity to deter pathogens from sticking to host mucosa, and modulate cell responses to promote normal gut development.
 4. **Hormones.** Breast feeding promotes oxytocin release in both members of the breast-feeding dyad, which encourages bonding and provides maternal empowerment to participate in her infant's care.
 - E. **Economics.** Breast feeding can reduce costs and improve productivity and morale in the workplace.
- II. **Contraindications to breast milk feeding.** Temporary problems in the mother, such as sore or cracked nipples, mastitis, and the presence of “discolored milk” do not preclude nursing. The following are true contraindications to breast feeding.
- A. **Infections**
 1. **Active tuberculosis.** Breast feeding can resume after 2 weeks of treatment and documentation that the mother is no longer infectious.
 2. **Human T-cell lymphotropic virus (HTLV).**
 3. **Human immunodeficiency virus (HIV).** This only applies to developed countries with safe alternative forms of infant nutrition. For specific recommendations, see Appendix F. Issues in HIV-infected mothers are discussed in Chapter 138.
 4. **Untreated brucellosis.**
 5. **Active herpes simplex lesions on the breast.** No direct breast feeding until the lesions have resolved but appropriate to give expressed maternal milk.
 6. **Varicella.** Mothers with active varicella that develops 5 days before and 2 days after delivery should be separated from their infants but can provide expressed maternal milk safely.
 - B. **Metabolic. Galactosemia** is a contraindication to breast feeding. With other inborn errors of metabolism, often a combination of human milk and other metabolic formulas can be used.

- C. Medications, anesthesia, and radiologic studies.** Breast feeding is safe with most medications and after most surgical and most radiologic procedures. Maternal medications should be evaluated for their effect on lactation and milk supply (see Chapter 156).
- D. Breast feeding in mothers with substance use disorders.** Breast feeding can be considered in infants with in utero exposure to illicit substances if mothers are enrolled and compliant in treatment programs, abstinent from illicit drug use for 90 days before delivery, and have negative toxicology screen at delivery. Methadone treatment alone is not a contraindication for breast feeding. The effect of buprenorphine treatment on breast feeding is not clear but appears to be safe.
- III. Support for breast feeding mothers in the NICU.** The benefits of breast feeding or expressed milk feeding should be reviewed with mothers during pregnancy and after birth. Expression and storage of colostrum, skin-to-skin contact, lactation support, rooming in, and nonnutritive feeding should be encouraged. Transition to direct breast feeding should be encouraged when developmentally appropriate.
- IV. Storage.** Human milk can be stored at room temperature for 3 to 4 hours and likely up to 6 hours, in the refrigerator for 72 hours (up to 8 days may be acceptable), frozen at -18°C for up to 6 months, and frozen in a deep freezer at -20°C for up to 12 months.
- V. Donor human milk (DHM).** Maternal milk is the preferred nutritional substrate in infants. However, DHM should be pasteurized (pDHM) and is an acceptable alternative or supplement until maternal milk is available.
- A. Indications for use.** pDHM can be used as a bridge until the mother's own milk is available, and its use can be prioritized for VLBW infants ($<1500\text{ g}$) to decrease the risks of NEC and in medically complex infants (eg, gastroschisis, cyanotic heart disease) who do not tolerate specialized formula. In babies $<1500\text{ g}$, pDHM is used until approximately 34 weeks' gestation to reduce the risks of NEC. Recent trends are showing pDHM being used in term infants delivered directly to families outside of hospital settings. In preterm and low BW infants, formula-fed infants, compared to pDHM-fed infants, have better short-term growth but an almost 3-fold higher risk of NEC.
- B. Safety.** pDHM is available currently in the United States from 3 sources: the Human Milk Banking Association of North America (HMBANA), Medolac (Portland, OR), and Prolacta Biosciences (Minerva, CA); the latter 2 sources are commercial companies. Each source uses a unique method of recruitment of lactating, donating mothers and varied operational processes. Concerns for infections have been addressed; pDHM is considered safe and effective with formalized donor screening and serologic testing, collection and handling protocols, and pasteurization of the milk. Parental counseling should still be carried out prior to use. There have been no reported cases of HIV or hepatitis transmission via pDHM in the United States to date. Short-term heat activation eliminates cytomegalovirus (CMV) effectively.
- C. Limitations**
- 1. Growth.** As most donated milk is more mature, the protein and caloric content is lower than that of preterm milk. Since donor milk is pooled, fat content, LCPUFA, DHA, and AHA vary from batch to batch. Early use of pDHM was associated with poor growth, but more recent data suggest that infant growth is not significantly lagging when **fortification** (see later discussion) is added to pDHM.
 - 2. Cost.** Reimbursement for pDHM by insurance is variable from state to state with no clear guidelines regarding billing procedures.
 - 3. Effects of heat treatment, storage, and handling.** Heat treatment with either Holder pasteurization or high-temperature short-time pasteurization is used to reduce the risk of bacterial and viral diseases to the milk recipients (see previous discussion). Heat treatment also results in loss of beneficial probiotic bacteria; decreased fat, caloric, and protein content; and decreased lactoferrin

and immunoglobulins but has little effect on micronutrients and vitamins A, D, and E. Human milk oligosaccharides and LCPUFAs remain intact with pasteurization.

4. **Supply.** The supply of pDHM is currently limited. There are 26 milk banks in the United States and Canada that form HMBANA. As noted earlier, there are at least 2 commercial (for-profit) companies that sell human milk or products derived from human milk. The practice of selling human milk openly on the Internet and through social media outlets is increasing, which may further limit the human milk available for donation (see later discussion). The scarcity of this precious resource raises questions about how to increase the supply and equitably allocate it to infants who need it most. On a positive note, the California Perinatal Quality Care Collaborative has shown recently that the availability of pDHM has increased over time (2007–2013) and has been associated with positive changes, including increased breast milk feeding at NICU discharge and decreased NEC rates.

D. Nonpasteurized DHM. Nonpasteurized DHM increases the risks of transmission of viral diseases (eg, CMV, hepatitis, HIV) and bacterial contamination to the recipients and, as such, is not recommended. Donor exposure to medications, herbal supplements, and drugs may contaminate donated milk. However, programs are available in some countries (eg, Sweden) where donors are carefully screened for infectious diseases and live unpasteurized milk is used for feeding. There has been a rapid, virtual explosion of milk sharing through groups on the Internet and Facebook; this prompted the US Food and Drug Administration (FDA) to issue a warning against feeding babies breast milk acquired directly from individuals due to potential risks associated with the practice.

VI. Human milk fortifiers. Human milk is the preferred substrate for preterm nutrition. However, fortification of the milk is necessary to meet the demands of rapidly growing premature infants despite being higher in protein and energy content compared to mature milk. Use of human milk beyond the second week in preterm infants provides insufficient amounts of protein, calcium, phosphorus, and possibly copper, zinc, and sodium, especially in VLBW infants. Previous older formulations when added to preterm mother's milk resulted in nitrogen retention and increased blood urea levels but with increased somatic and linear growth. One study in low BW infants comparing unfortified human milk versus fortified human milk up to 4 months after discharge noted no differences in growth parameters at 1 year of age. Table 11–4 shows nutrient composition of some of the fortifiers currently available in the United States.

A. Indications. The addition of multinutrient fortifiers to either a mother's own milk or DHM increases nutrient content by 10% to 20% and decreases rates of in-hospital postnatal growth failure, metabolic bone disease, and vitamin deficiencies. Fortification of human milk can also help keep feeding volumes lower for infants who are fluid sensitive. Criteria for use of human milk fortifiers include <34 weeks' gestation and/or <1800 g at birth. Fortification (usually with cow milk-based fortifiers after 34 weeks' PMA) is recommended until infants reach approximately 3600 g or at hospital discharge. Postdischarge fortification of human milk is usually not recommended.

Both human milk-based and bovine milk-based fortifiers are available in powder and liquid forms in the United States. Sterile liquid fortifiers are recommended due to the risks of bacterial contamination with powdered fortifiers. A recent analysis of available fortifiers and preterm formula found that, although most fortifiers provide macronutrients within the recommended range, significant variations exist in micronutrient contents. Both excesses and deficiencies of some micronutrients were seen, most notably in the human milk-based fortifier (see following sections), where even additional vitamin supplementation may not be adequate. Fortification of fresh expressed breast milk is not associated with an increase in bacterial growth for up to 6 hours.

^aRepresents mature preterm human milk.

^bProlacta+4 H²MF: 20 mL fortifier to 80 mL preterm milk provides 100 mL of 24 kcal/oz. Other Prolacta H²MF products available.

^cSimilac HMF Hydrolyzed Protein Concentrated Liquid and Similac HMF Concentrated Liquid: 4 packets per 100 mL human milk provide 24 kcal/oz. with 120 mL of total volume.

^dEnfamil HMF Acidified Liquid: 4 vials (5 mL each) per 100 mL human milk provides 24 kcal/oz. with 120 mL of total volume. Table includes nutrition information for fortifier alone.

The use of fortifiers is associated with in-hospital growth including weight gain, length, and head circumference without increasing morbidities such as NEC or BPD. No significant differences in outcomes have been found with early or late fortification (at 40 mL/kg/d vs 100 mL/kg/d) with regard to feeding tolerance and weight gain. At our institution, we fortify human milk at enteral volumes of 60 mL/kg/d. The details of some of the fortifiers are discussed below.

1. Similac Human Milk Fortifier Hydrolyzed Protein Concentrated Liquid (commercially sterile)

a. Composition. The protein is hydrolyzed casein hydrolysate. The carbohydrate is maltodextrin and modified cornstarch. The fat is medium-chain triglycerides (MCTs) from soy and coconut oil. Additional iron and vitamin supplementation is recommended while using this product.

b. Calories. The fortifier provides 24 kcal/fl oz., when added in the ratio of 1 packet/25 mL of human milk. Each packet (5 mL) provides 7 calories, 0.5 g protein, 0.75 g carbohydrate, and 0.21 g fat. Each packet provides 30 mg calcium and 17 mg phosphorus.

2. Similac Human Milk Fortifier Concentrated Liquid (commercially sterile)

a. Composition. The protein is from whey protein concentrate. The carbohydrate is corn syrup solids. The fat is predominantly MCTs. Additional iron and vitamin supplementation is recommended while using this product.

- b. **Calories.** The fortifier provides 24 kcal/fl oz., when added in the ratio of 1 packet/25 mL of human milk. Each packet (5 mL) provides 7 calories, 0.35 g protein, 0.81 g carbohydrate, and 0.27 g fat. Each packet provides 35 mg calcium and 20 mg phosphorus.
 - c. **Not intended for use in preterm infants** once they reach a weight of 3600 g.
 - 3. **Enfamil Human Milk Fortifier–Acidified Liquid (commercially sterile)**
 - a. **Composition.** Whey protein hydrolysate, MCT oil, soy oil, ARA, and DHA. The carbohydrate is from citrates and pectin. Additional iron and vitamin supplementation is recommended while using this product.
 - b. **Calories.** The fortifier provides 24 kcal/fl oz., when added in the ratio of 1 packet/25 mL of human milk. Each packet (5 mL) provides 7.5 calories, 0.55 g protein, 0.3 g carbohydrate, and 0.58 g fat. Each packet provides 29 mg calcium and 15.8 mg phosphorus.
 - c. **Use of >20 vials/d** can result in hypervitaminosis A and D.
 - 4. **Prolacta H²MF products**
 - a. **Composition.** Commercial human milk–based human milk fortifier made from pasteurized/processed DHM. Additional iron and vitamin supplementation is recommended with its use, and it is available in different calories per ounce.
 - b. **Calories.** The fortifier (Prolact+4 H²MF) provides 24 kcal/fl oz., when added in the ratio of 20 mL fortifier/80 mL of human milk. Each bottle of fortifier provides an additional 28 calories, 1.2 g protein, 1.8 g carbohydrate, and 1.8 g fat. Each bottle of Prolact+4 H²MF provides 103 mg calcium and 53.8 mg phosphorus.
 - c. **Additional products.** Prolacta products are available to add an additional 6, 8, and 10 calories per ounce. Prolacta cream is available as a supplement once goal protein is reached with the addition of Prolacta fortifier to human milk. It adds an additional 2.5 calories per milliliter using mostly fat.
 - d. **Limitation.** With increasing fortification, the volume of maternal (or donor) human milk delivered to the infant is decreased. Additionally, the product is expensive; cost-effective analysis may not justify using it except for the most immature infants. In our institution (Washington University), we use Prolacta for infants with BW <1000 g and continue until 34 weeks' PMA.
 - B. **Human milk analyzers.** There is a trend toward increased use of human milk analyzers for bedside analysis of macronutrient content of human milk in order to customize human milk fortification. However, data are limited to show that customized fortification provides any additional growth or long-term advantage.
 - C. **Inpatient transition.** Transition from fortified human milk feeds to unfortified human milk or to preterm formula varies between institutions; the decision could be based on a specific length of time the patient has received fortification, IUGR status, target weight achieved, or PMA reached. In infants transitioning from donor milk to preterm formula, transition may be considered by 32 to 34 weeks' PMA or approximately 1500 to 1800 g. In infants receiving fortified maternal milk feeds, fortifier should be discontinued and adequate weight gain ensured a few days prior to discharge. In our institution, we transition infants 3 to 5 days before anticipated discharge date (when nipping 75% of their feeds) or at 36 to 38 weeks' PMA.
- VII. **Other supplements.** Previously, the use of supplements or single modulators such as MCT oil, corn oil or corn starch, or protein powders was routine for infants with growth faltering in the NICU. Because these modulators alter the ratio of macronutrients and osmolality of the milk, they are no longer routinely recommended for use.
- VIII. **Probiotics and prebiotics.** Meta-analyses of probiotics show benefits of supplementing milk with probiotics in decreasing the risk of NEC, nosocomial infections, and mortality in VLBW infants. Other benefits reported include decreasing intestinal permeability, improvements in growth and head circumference, and improved feeding tolerance. However, the optimal doses, organisms, and timing of supplementation and

the long-term benefits remain unclear. Concerns exist regarding probiotic use and risks of sepsis due to probiotic translocation. (See Chapter 109 on NEC.)

Prebiotics and human milk oligosaccharides such as inulin, galactose, and fructose enhance the growth of beneficial bacteria in the intestinal microbiome such as *Bifidobacterium* and potentially decrease risks of NEC and nosocomial infections. Despite formula supplemented with nonhuman milk oligosaccharides showing improved enteral feed tolerance, these formulas do not affect intestinal permeability. Long-term benefits are not yet known.

- IX. Postnatal growth failure.** Postnatal extrauterine growth restriction (EUGR) occurs in 28% to 75% of preterm births globally. EUGR is defined as growth values <10th percentile or <2 standard deviations (SD) from the mean expected intrauterine growth. Some define EUGR as a change in Z-score >1 SD or >2 SD from birth to discharge. The latter is more predictive of neurodevelopmental outcomes. Better nutritional support is associated with improved growth and neurodevelopmental outcome and EUGR.
- X. Discharge.** Routine fortification is not recommended at discharge of preterm infants, and human milk fortifiers are not available outside the hospital setting. Some have attempted to fortify human milk with preterm powder formula, but there is a risk of infection (*Cronobacter* spp.). Moreover, healthy preterm infants fed fortified maternal milk and unfortified milk after discharge show no significant differences in growth parameters, lean body mass, bone mineral density, or neurodevelopmental outcomes at 18 months of corrected age. In some high-risk neonates, breast feeding can be supplemented with 2 to 3 bottles of a transitional formula to improve protein accretion and bone mineralization.

Formula-fed preterm infants (BW <1500 g or birth gestational age <32 weeks) should continue on a transitional formula (see following section on commercial formula) until 6 to 9 months after term to improve bone mineralization.

FORMS OF ENTERAL NUTRITION: COMMERCIAL FORMULA

When human milk is unavailable, commercial formula may be used for feeding term and preterm infants. Approximately 80% of infants are fed infant formula by the time they reach the age of 1 year old. No special considerations regarding the type of formula apply to healthy, full-term newborn infants for routine feeding. Preterm infants may require more careful planning. Many different, highly specialized formulas are available. Table 11–3 outlines indications for various formulas. The compositions of commonly used infant formulas and breast milk can be found in Table 11–5. Because the nutritional composition of formula changes frequently, the most up-to-date information can be found on the manufacturer's website.

I. Types of formula

- A. Intact cow milk protein-based formulas.** This is the most common human milk substitute. Macronutrient sources and ratios vary widely among brands and different formulations. Iron-fortified formulas reduce the risk of iron deficiency anemia. Some formulas are now fortified with oligosaccharides and nucleotides and with probiotics. Formulas are available as ready-to-feed liquids or as powders that can be reconstituted before feeding, although the latter has been associated with risk of infection.
- B. Preterm formulas.** Preterm formulas were developed to meet the rapid growth of preterm infants and are fortified with extra calories, protein, minerals, and vitamins. Additionally, fat blends of oils have been optimized to account for the poor absorption in the preterm neonate. The majority of infant formulas (preterm and term) are iso-osmolar or mildly hypoosmolar to improve tolerance and decrease risk of NEC in preterm infants. Only sterile products should be used in the preterm population.
- C. Soy formulas.** Soy formulas are used in infants who have primary or secondary lactose intolerance or *galactosemia*, or desire for vegetarian diet. Some infants with

Table 11–5. COMPOSITION OF SELECTED INFANT FORMULAS (CONTINUED)

Characteristics	Similac Alimentum	Enfamil A.R.	Gerber Good Start 20 cal/oz.	Enfamil Nutramigen with AA/Enflora LGG 20 cal/oz.	Pregestimil 20 cal/oz.	Pregestimil 24 cal/oz.
Choline (mg)	8.1	16.0	16.0	16	16	19.0
Inositol (mg)	3.4	4.0	4.0	11.3	11.3	13.4
Potential renal solute load (mOsm/L)	171.3	153		169	169	200
Probiotic			<i>Bifidobacterium lactis</i>	<i>Lactobacillus rhamnosus GG</i>		
Nucleotides ^b			++			

ARA, arachidonic acid; DHA, docosahexaenoic acid; FOS, fructo-oligosaccharide; MCT, medium-chain triglyceride.

^aSimilac and Enfamil products: *C. coli* oil, source of DHA; *M. alpina* oil, source of ARA.

^bNucleotides: Adenosine 5'-monophosphate, cytidine 5'-monophosphate, disodium guanosine 5'-monophosphate, disodium uridine 5'-monophosphate.

^cConcentration of some nutrients vary depending on powder or liquid concentrate.

^dContains molybdenum and chromium.

^eCorn oil.

milk protein allergy (up to 60%) have a cross reactivity with soy. **Soy formulas increase risk of osteopenia in preterm infants and should be avoided.** Protein concentrations are slightly higher in soy than in cow milk-based formula. The American Academy of Pediatrics does not recommend routine use of soy formula for colic.

- D. Protein hydrolysate.** Formulas with extensively hydrolyzed proteins are used in infants who are severely intolerant (allergic) to cow milk and soy protein. They are also useful in infants at risk for malnutrition including those with cystic fibrosis, short gut syndrome, biliary atresia, and protracted diarrhea. However, these formulas are usually hyperosmolar and more expensive.
 - E. Free amino acid formulas.** Amino acid-based formulas are designed for infants with extreme protein hypersensitivity who do not tolerate hydrolyzed formulas. They are expensive, less palatable than hydrolyzed formulas, and difficult to obtain. Additionally, hypophosphatemia and osteopenia have been reported recently as significant complications of their use.
 - F. Other formulas.** Other formulas exist made for specific metabolic disease states. Please see manufacturers' websites.
 - G. Transitional formulas.** Preterm infants continue to need nutritional supplementation after discharge. Transitional formulas have higher caloric, protein, and mineral content than term formulas. Infants discharged on special formulas (eg, NeoSure, EnfaCare; see Table 11–5) have better somatic growth, weight gain, and bone mineralization.
 - H. Organic formulas.** Several organic milk formulas, including soy based, are available that are produced without the use of pesticides, antibiotics, or growth hormones. Concerns have been raised about the presence of high sugar content in some of these formulas and the risk for later childhood obesity and for injury to developing tooth enamel. The increased costs of organic formulas are also considerable. There are no randomized controlled trials comparing the benefits, or lack of benefits, of organic formulas versus proprietary infant formulas.
- II. Preparation, storage, and handling**
- A. Preparation.** There are 3 preparations of formula: ready to feed or use (RTU), concentrated liquid, and powder with comparable nutritional content. RTU can be fed as-is from the container. Concentrated liquid formula must be diluted with equal amounts of water. Powdered formula must be mixed with potable water from a safe source according to manufacturer's instructions. Powdered formula is not sterile and has recently been associated with *Cronobacter sakazakii* contamination. The CDC provides guidelines for preparation of powder formula and recommends the water temperature be greater than 158°F to mix the powder and then be allowed to cool prior to feeding to the infant.
 - B. Storage and handling.** RTU and powder-prepared formula should be discarded 1 hour after serving it to an infant. Twenty-four-hour batches are acceptable to make if that particular aliquot has not been exposed to the infant. It should be discarded after 48 hours of refrigeration even when unused. Open cans of powder are good for use for 4 weeks.

TOTAL PARENTERAL NUTRITION

Total parenteral nutrition (TPN) is the intravenous administration of all nutrients (fats, carbohydrates, proteins, vitamins, and minerals) necessary for metabolic requirements and growth. Parenteral nutrition (PN) is supplemental intravenous administration of nutrients. Enteral nutrition (EN) refers to oral or gavage feedings.

- I. Indications.** PN is used as a supplement to enteral feedings or as a complete substitution (TPN) when adequate nourishment cannot be achieved by the enteral route. Common indications in infants include extreme prematurity, congenital malformation of the GI tract such as gastroschisis and omphalocele, short bowel syndrome

following NEC, congenital heart disease, sepsis, and malabsorption. Most institutions initiate PN while establishing full enteral feeds for infants <34 weeks' gestational age and/or <1800 g. PN should be started on the first day of life and as soon as possible in preterm or sick infants to decrease catabolism and to optimize postnatal growth. Early PN is associated with better weight gain and neurodevelopmental outcomes in the VLBW population.

II. Methods of PN administration

A. Central PN. Central PN is used when infants have central access such as umbilical lines or for those infants requiring long-term parenteral support. PN involves infusion of a hypertonic nutrient solution (12.5%–25% dextrose, 5%–6% amino acids) into a suitable vessel with rapid flow through an indwelling catheter. Two methods are commonly used for long-term infusion of PN.

1. Percutaneously inserted central catheter. Positioned in the antecubital, temporal, external jugular, or saphenous vein and advanced into a large vessel outside the heart (eg, superior or inferior vena cava; see Chapter 46).

2. Tunneled central catheter (Browiac). Placed surgically in the internal or external jugular, subclavian, or femoral vein.

B. Peripheral PN (PPN). PPN can be infused via peripheral veins, but the concentrations of the amino acids and dextrose solution that can be infused are limited by the fragility of veins. The mOsm/L limit for PPN is <900 to 1100 mOsm/L, which limits dextrose to 12.5% and amino acid concentration to 3%; mOsm/L can be calculated with the following equation:

$$\text{mOsm/L} = [\text{amino acids (g/L)} \times 8] + [\text{glucose (g/L)} \times 7] \\ + [\text{Na (mEq/L)} \times 2] + [\text{phosphorus (mg/L)} \times 0.2] - 50$$

Peripheral infusion of PN carries higher risks of infiltration and phlebitis.

C. Umbilical catheters. PN can be given through an **umbilical venous catheter** (and occasionally through an **umbilical artery catheter** in some institutions) after ensuring the catheter is central and not in the liver. Hyperosmolar infusion in the hepatic vessels is associated with portal venous thrombosis and portal hypertension. Low-lying umbilical venous catheters should be used only temporarily and treated as peripheral vessels and, therefore, limited to concentrations similar to PPN.

III. Caloric requirements and densities. Goal caloric intake (including protein calories) for PN remains around 80 to 90 kcal/kg/d. The optimal amount of energy intake differs for each infant and may be higher for sick and ELBW infants. Caloric densities of various energy sources are as follows:

A. Dextrose (anhydrous). 3.4 kcal/g.

B. Protein. 4 kcal/g.

C. Fat. 9 kcal/g.

IV. Composition of PN solutions

A. Fluids. Goal fluid parenteral requirements after the first few days of life range from 120 to 150 mL/kg/d for term infants and from 130 to 160 mL/kg/d for preterm infants. These can vary based on clinical status. See Chapter 10 for fluid requirements.

B. Carbohydrates. Dextrose is the only commercially available form of glucose, with concentrations of 5.0% to 12.5% dextrose used in peripheral PN and up to 25% dextrose in central PN. **Glucose infusion rates (GIR)** should be calculated as milligrams per kilograms per minute (see Table 11–8 for calculations). Infants should be started on a GIR of 5 to 8 mg/kg/min to allow for appropriate response of endogenous insulin. Infusion rates can then be increased by 0.5 to 2 mg/kg/min each day as tolerated with the goal of maintaining blood glucose concentrations between 50 and 150 mg/dL. For most infants, GIR of 12 to 13 mg/kg/min will provide adequate caloric intake in the presence of stable blood glucose levels.

Excess glucose can lead to glucosuria and osmotic diuresis. Excess glucose is also converted into lipid via lipogenesis, which is an inefficient process that increases energy expenditure.

Endogenous gluconeogenesis in preterm ELBW infants may be independent of glucose infusion, and therefore, this population frequently experiences hyperglycemia. Other factors contributing to hyperglycemia include elevated birth-related catecholamines, use of inotropic drugs, and decreased production of and sensitivity to insulin. In the presence of hyperglycemia, glucose infusion rate should not be reduced below a basal rate of 4 mg/kg/min. Insulin may be required to maintain adequate blood glucose concentrations but is not recommended for routine use. Hyperglycemia in preterm infants is associated with worse outcomes.

Peripheral uptake and utilization of glucose are improved with simultaneous amino acid infusion because it increases endogenous insulin production. Providing glucose alone in the absence of proteins results in negative nitrogen balance that can be reversed by providing 1.1 to 2.5 g/kg/d of protein with energy intake as low as 30 kcal/kg/d. Providing 25 to 30 kcal of nonprotein energy per gram of protein optimizes protein deposition.

- C. Proteins.** In preterm ELBW and VLBW infants, amino acids should be started on day 1 and is associated with better linear growth and neurodevelopmental outcomes. Term infants who are likely to have delayed initiation of EN should also be started as early as possible. Inadequate protein intake may result in failure to thrive, hypoalbuminemia, and edema. Excessive protein can cause hyperammonemia, serum amino acid imbalance, metabolic acidosis, and cholestatic jaundice. Early addition of amino acids to PN may also stimulate endogenous insulin secretion. Postnatal protein loss is inversely proportional to gestational age. Low BW infants lose 1% of endogenous protein daily unless supplemented.

- 1. Crystalline amino acid solutions.** The standard solutions originally designed for adults are not ideal because they contain high concentrations of amino acids (eg, glycine, methionine, and phenylalanine) that are potentially neurotoxic in premature infants. Pediatric crystalline amino acid solutions (eg, TrophAmine, Aminosyn PF) contain less of those potentially neurotoxic amino acids as well as additional tyrosine, cystine, and taurine. The lower pH also allows for the addition of sufficient quantities of calcium (2 mEq/dL) and phosphorus (1–2 mg/dL) to meet daily requirements. Furthermore, newer crystalline amino acid solutions are associated with less azotemia, hyperammonemia, and metabolic acidosis than previous formulations. Conditionally essential amino acids are arginine, tyrosine, cysteine, glutamine, glycine, and proline.
- 2. Amino acids.** Early protein intake of up to 3 g/kg/d within the first 24 hours is safely tolerated in VLBW infants and improves nitrogen balance, increases ability to synthesize protein, and decreases protein catabolism. Early amino acid supplementation may decrease hyperglycemia and hyperkalemia in ELBW infants by promoting insulin secretion. In term infants, the starting rate should be at least 1 to 2 g/kg/d, with increases of 1 g/kg/d to a goal of 3 g/kg/d. For preterm infants, begin at 3 g/kg/d and advance by 0.5 to 1 g/kg/d to a goal of 3.5 to 4 g/kg/d.
- 3. Cysteine hydrochloride.** Cysteine is often added separately to TPN solutions because it is unstable over time and is omitted from preformulated amino acid solutions. The premature infant lacks the ability to convert methionine to cysteine; thus, it is conditionally essential. Cysteine is also converted to cystine and to glutathione, an antioxidant that is important in maintaining calcium homeostasis. Addition of cysteine to TPN lowers the pH of the solution, thereby improving the solubility of calcium and phosphorus. Cysteine may also decrease hepatic cholestasis. The recommended dose is 30 to 40 mg of cysteine per gram of protein (72–85 mg/kg/d). It should be held or used cautiously in infants with metabolic acidosis.

- 4. Glutamine.** Glutamine has been identified as a key amino acid, as respiratory fuel for rapidly proliferating cells such as enterocytes and lymphocytes, as a factor in acid-base balance, and as a nucleotide precursor. Glutamine may play a role in maintaining gut integrity and may decrease the incidence of sepsis. Despite all these theoretical benefits, randomized trials show that glutamine supplementation does not have significant effect on mortality or neonatal morbidities including invasive infection, NEC, time to achieve full EN, or duration of hospital stay. There is no commercially available amino acid solution that contains glutamine.
- D. Fats.** Fats are essential for normal body growth and development, in cell structure and function, and in retinal and brain development. Because of their high caloric density, intravenous lipids provide a significant portion of daily caloric needs. Most lipid solutions are derived from soybean, but newer combination oils with olive oil, MCT, and fish oil are now available (eg, Intralipid, Liposyn II, Nutrilipid, Soyacal, Omegavan, Lipoplus, and SMOF lipid). Omegavan is made exclusively from fish oil and is rich in omega-3 fatty acids. SMOF (a third-generation emulsion containing soybean oil, MCT, and fish and olive oil) has an altered ratio of omega-6 to omega-3 fatty acids that may decrease the risks of PN-associated liver disease (PNALD; see discussion of PNALD later in this chapter). Most intravenous fat solutions are isotonic (270–300 mOsm/L). Lipid emulsions contain linoleic and α -linolenic acid; the latter can be converted into DHA. DHA is accumulated in the third trimester, and preterm infants have limited capacity to convert α -linolenic acid to DHA, which plays a critical role in brain development. Delay in initiating lipids can result in biochemical and clinical evidence of essential fatty acid deficiency within 3 days and increase susceptibility to oxidant injury. Intravenous lipids at 0.5 to 1 g/kg/d are needed to prevent essential fatty acid deficiency.
- 1. Concentrations.** Lipid emulsions are usually supplied as 20% solutions providing 20 g of triglyceride per 100 mL. Starting lipids at 1 to 2 g/kg/d within 24 hours of birth is well tolerated. Advance by 0.5 to 1.0 g/kg/d as tolerated up to 3.0 g/kg/d. The infusion is given continuously over 20 to 24 hours, and the rate should not exceed 0.12 to 0.15 g/kg/h. To maintain calcium and phosphorous solubility, lipids should be administered separately from proteins because amino acid solutions are acidic. Adding lipids to protein solutions increases the pH and precipitates calcium and phosphorus (see discussion of photoprotection later in this chapter).
- 2. Carnitine supplementation.** Carnitine synthesis and storage are not well developed in infants <34 weeks' gestation. Carnitine is a carrier molecule necessary for oxidation of long-chain fatty acids. An exogenous source of carnitine is available from human milk and infant formulas; however, studies have shown that preterm infants on TPN become deficient in 6 to 10 days. Carnitine supplementation of 2 to 10 mg/kg/d is recommended for infants on TPN for >4 weeks. Some institutions use carnitine whenever lipid emulsions are used. Carnitine-deficient infants may experience hypotonic, nonketotic hypoglycemia, cardiomyopathy, encephalopathy, and recurrent infections. Newborn screening programs now test for carnitine deficiency.
- E. Minerals.** More than 80% of bone mineralization occurs in the third trimester. Therefore, preterm infants are at increased risk of metabolic bone disease and require supplementation of calcium and phosphorus. Delays in reaching full enteral feeds, medications such as diuretics and steroids, and risks of precipitation can limit calcium and phosphorus intake and increase risk of osteopenia of prematurity.
- 1. Calcium.** Calcium supplementation is typically provided in PN as calcium gluconate. Start at 2 mEq/kg and keep ratio of calcium to phosphorus at 2:1 to help prevent precipitation. Consider an increase if hypocalcemia or development of metabolic bone disease occurs.

- 2. Phosphorus.** Phosphorus is typically supplemented in PN as sodium phosphate in the United States. It can be contaminated with aluminum. Start at 1 mEq/kg and keep ratio of calcium to phosphorus at 2:1 to help prevent precipitation. Additional supplements may be needed with hypophosphatemia or metabolic bone disease.
- F. Vitamins.** Multivitamins are added to intravenous solutions in the form of a pediatric multivitamin suspension (MVI Pediatric). Preterm infants are especially prone to vitamin deficiencies due to their compromised stores and rapid growth. The dose of parenteral vitamins for preterm infants with normal organ function should be 1.5 to 5 mL (1.5 mL when patient weight is <1000 g, 3.25 mL when patient weight is 1000–3000 g, and 5 mL when patient weight is >3000 g). The 5-mL reconstituted MVI Pediatric sterile lyophilized powder contains: 2300 IU vitamin A; 400 IU vitamin D; 7 IU vitamin E; 200 µg vitamin K; 80 mg ascorbic acid; 1.2 mg thiamine; 1.4 mg riboflavin; 17 mg niacin; 5 mg pantothenic acid; 1 mg pyridoxine; 1 µg cyanocobalamin; 20 µg biotin; and 140 µg folic acid. Vitamin A delivery can be hampered by binding to plastic tubing.
- G. Trace elements.** Supplementation with zinc, copper, manganese, chromium, selenium, and molybdenum is currently recommended in neonatal PN, and deficiencies may occur if these elements are not added when infants are on long-term PN. Trace elements are added to the solution based on weight and total volume, with both single-agent and combination products commercially available. Increased amounts of zinc (1–2 mg/d) are often given to help promote healing in patients who require GI surgery. For recommended doses of trace elements, see Table 11–6.
- H. Electrolytes.** Electrolytes can be added according to specific needs (see Chapter 10).
- I. Heparin.** Heparin should be added to PN (unfractionated heparin 0.5 U/mL TPN) to maintain catheter patency. In addition, there is a decreased risk for phlebitis and an increase in lipid clearance as a result of release of lipoprotein lipase with use of heparin.
- V. Monitoring of PN.** Hyperalimentation can cause many alterations in biochemical function. Thus, frequent and consistent anthropometric and laboratory monitoring is

Table 11–6. RECOMMENDATIONS FOR TRACE ELEMENT SUPPLEMENTATION IN TOTAL PARENTERAL NUTRITION (TPN) SOLUTIONS FOR INFANTS

Element (mcg/kg/d)	Full Term	Premature
Zinc	100–250	400
Copper ^a	20	20
Chromium ^{b, c}	0.2	0.2
Manganese ^{a, b}	1	1
Iodide	1	1
Molybdenum ^{b, c}	0.25	0.25–1
Selenium ^c	2	2–3

^aShould not be given to infants with cholestasis.

^bFor TPN >4 weeks.

^cShould not be given to infants with chronic renal failure.

Table 11–7. SUGGESTED MONITORING SCHEDULE FOR INFANTS RECEIVING PARENTERAL NUTRITION

Measurement	Baseline Study	Frequency of Measurement
Anthropometric		
Weight	Yes	Daily
Length	Yes	Weekly
Head circumference	Yes	Weekly
Intake and output		
	Daily	Daily
Metabolic		
Glucose	Yes	2–3 times per day initially; then as needed
Calcium, phosphorus, and magnesium	Yes	2–3 times per week initially; then every 1–2 weeks
Electrolytes (Na, Cl, K, CO ₂)	Yes	Daily initially, then 2–3 times per week. More frequently in ELBW infants <1000 g
Hematocrit ^a	Yes	Every other day for 1 week; then weekly
BUN and creatinine	Yes	2–3 per week; then every 1–2 weeks
Bilirubin (direct/total)	Yes	Weekly
Total protein and albumin	Yes	Every 2–3 weeks
AST/ALT	Yes	Every 2–3 weeks
Triglycerides	Yes	When at 2 g/kg, monitor until stable (<200 mg/dL) and PRN
Vitamins and trace minerals		As indicated
Urine		
Specific gravity and glucose	Yes	1–3 times per day initially; then as needed (<i>controversial</i>)

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; ELBW, extremely low birthweight; PRN, as needed.

^aDue to frequent phlebotomy losses.

recommended for all patients, especially ELBW infants. Recommendations are given in Table 11–7.

- VI. Complications of PN.** Approximately 70% of infants admitted to the NICU receive some form of PN, with catheter infiltration and infections as the most common complications. Early initiation and rapid advancement of enteral feeds can limit the complications associated with PN.

A. Metabolic

- 1. Hyperglycemia.** Hyperglycemia can result from excessive glucose intake or change in metabolic rate, such as with infection or glucocorticoid administration. Routine insulin infusion to prevent hyperglycemia is not recommended and is associated with increased risks of mortality, hypoglycemia, and ROP. Insulin drip may be considered if blood glucose is >200 to 250 mg/dL despite GIR of <5 mg/kg/min.

2. **Hypoglycemia.** Hypoglycemia can result from sudden cessation of infusion, likely secondary to mechanical issues such as intravenous infiltration. Hypoglycemia may occur with insulin administration.
3. **Azotemia.** Azotemia can result from excessive protein (nitrogen) uptake; however, aggressive protein intake is safe (see earlier discussion), and this issue is less likely with current amino acid formulations. Elevated blood urea nitrogen may actually indicate better amino acid utilization rather than excessive protein intake.
4. **Hyperammonemia.** Currently available amino acid mixtures contain adequate arginine (>0.05 mmol/kg/d). Therefore, if there is an increase in blood ammonia secondary to PN, symptomatic hyperammonemia does not occur.
5. **Abnormal serum and tissue amino acid pattern.** Infants on TPN may have falsely abnormal newborn metabolic screening results due to multiple minor amino acid abnormalities; a protocol of interrupting TPN for 3 hours and replacing the infusion with dextrose 10% in water before newborn screening collection can result in a 74% reduction in false-positive results.
6. **Mild metabolic acidosis.** Metabolic acidosis in preterm infants is more likely a result of lack of urinary acidification and severity of illness leading to hypotension and poor perfusion than a result of PN itself (low pH). Acidosis can be buffered by titrating acetate concentrations in daily PN.

B. Systemic

1. **Parenteral Nutrition Associated Liver Disease (PNALD).** With prolonged administration of intravenous lipids, dextrose, and protein in the absence of enteral feeding, cholestasis usually occurs as evidenced by a direct hyperbilirubinemia. Even in the presence of normal bilirubin levels, evidence of liver disease such as fibrosis may be apparent by histopathologic examination after administration of PN. The incidence ranges from as high as 80% in VLBW infants receiving TPN for >30 days (with no enteral feeding) to $\leq 15\%$ in infants weighing >1500 g receiving TPN for >14 days. Monitoring for abnormalities in liver function and the development of direct hyperbilirubinemia is important in long-term TPN. IUGR infants and those with congenital GI diagnoses are at high risk of developing cholestasis. Fish oil-based lipid emulsions (Omegavan) and combination emulsions (SMOFLipid) have been used in prevention and treatment of TPN-induced cholestasis. Omegavan is available in Europe but can be used in the United States in research settings or in situations of compassionate use. SMOFLipid is an FDA-approved product in adults that has been occasionally used in the NICU; however, there is limited research on its use in neonates. Fish oil-based lipid emulsions may also decrease the risk of ROP. Starting with even minimal amounts of enteral feeds, decreasing lipid dose to 1 g/kg, and cycling lipid infusions (over 12–18 hours) help to decrease PNALD. Copper and manganese should be withheld in the presence of hepatic dysfunction. See Chapters 62 and 98.
2. **Complications of fat administration.** Hypertriglyceridemia may occur; periodic determination of blood triglyceride levels is recommended to maintain plasma triglyceride levels <200 mg/dL. Lipid infusion should be decreased or stopped when these levels are exceeded. Lipid infusion can be associated with platelet dysfunction, acute allergic reactions, deposition of pigment in the liver, and lipid deposition in the blood vessels of the lung. Most metabolic problems apparently occur with rapid rates of infusion and are not seen at infusion rates of <0.12 g/kg/h. Exposure of lipids to light, especially phototherapy, may cause increased production of toxic hydroperoxides. The addition of multivitamins and use of protective or dark delivery tubing decrease peroxide formation and limit vitamins loss. Steroids cause elevated triglyceride levels, whereas sepsis decreases peripheral utilization of lipids, resulting in

hypertriglyceridemia. Free fatty acids (FFA) produced from lipid breakdown compete with bilirubin for binding with albumin, resulting in elevated free bilirubin. The FFA-to-albumin ratio should be kept at <6 ; lipid infusion should not exceed 1 g/kg/d with plasma bilirubin >10 mg/dL and albumin levels of 2.5 to 3.0 g/dL. Additional complications include thrombocytopenia, increased risk of sepsis, alteration in pulmonary functions, hypoxemia, and increased pulmonary vascular resistance.

3. **Deficiency of essential fatty acids (EFAs).** EFA deficiency can occur within 72 hours in preterm infants if exogenous fatty acids are not supplemented. EFA deficiency is associated with decreased platelet aggregation (thromboxane A_2 deficiency), poor weight gain, scaling rash, sparse hair growth, and thrombocytopenia. Use of only safflower oil to provide lipid emulsions may result in deficiency of omega-3 LCPUFAs. EFAs are essential to the developing eyes and brain of infants.
4. **Photoprotection of parenteral nutrition.** Photoprotection helps decrease vitamin loss and oxidative damage to amino acids and decreases generation of hydrogen peroxides and free radicals. Photoprotection limits alterations in vasomotor tone via generation of lipid peroxides, decreases nitric oxide production, and improves tolerance to minimal EN. Additionally, it has been found to decrease risk of death and chronic lung disease due to lower triglyceride levels. Vitamins, trace elements, and iron should *not* be added together in the parenteral solution to decrease the risks of lipid peroxidation. Increased lipid peroxidation products may adversely influence neurodevelopment.
5. **Mineral deficiency.** Most minerals are transferred to the fetus during the last trimester of pregnancy. The following problems may occur if not adequately supplemented.
 - a. **Osteopenia, metabolic bone disease, and pathologic fractures.** See Chapter 113 and the earlier section in this chapter on PN minerals.
 - b. **Zinc deficiency.** Zinc deficiency can occur if zinc is not added to TPN after 4 weeks. Cysteine and histidine in PN solution increase urinary losses. Zinc deficiency results in poor growth, diarrhea, alopecia, increased susceptibility to infection, and skin desquamation surrounding the mouth and anus (acrodermatitis enteropathica). Zinc losses are increased in patients with an ileostomy or colostomy.
 - c. **Copper deficiency.** Long-term PN puts infants for copper deficiency, which can result in osteoporosis, hemolytic anemia, neutropenia, and depigmentation of the skin.
 - d. **Manganese, selenium, molybdenum, and iodine deficiency.** Trace element deficiency may occur if not supplemented after 4 weeks.
 - e. **Iron.** Adding iron to PN should be considered for infants on long-term PN who have not received recent blood transfusions, with rhEPO administration, and if ferritin levels fall below 100 ng/mL. Dose is 3 mg/kg/wk given once per week, preferably without vitamins and other trace elements for that day.
- C. **Mechanical.** Complications associated with placement of central catheters occur in approximately 4% to 9% of patients and include pneumothorax, pneumomediastinum, hemorrhage, and chylothorax (caused by injury to the thoracic duct). Thrombosis of the vein adjacent to the catheter tip, resulting in superior vena cava syndrome (edema of the face, neck, and eyes), may be seen. Pulmonary thromboembolism may occur. Malpositioned catheters can result in pleural or pericardial effusion and ascites as well cardiac arrhythmias and tamponade. Initial x-ray should show the tip outside the heart, and periodic x-rays may be required to identify catheters at risk of migration. Additionally, infiltration and phlebitis can occur more easily and frequently in infants due to the size and fragility of their vessels.

Table 11–8. TOTAL PARENTERAL NUTRITION (TPN) CALCULATIONS

Amino acids: % Amino acid =	$\frac{\text{Wt (kg)} \times (\text{g/kg/d}) \times 100}{\text{Vol in 24 h}}$
Dextrose: glucose utilization rate (mg/kg/min):	$\frac{\text{Rate (mL/h)} \times \% \text{ Dextrose}}{\text{Wt (kg)} \times 6}$
Lipids: Rate (mL/h):	$\frac{\text{g/kg/d} \times 5 \times \text{Wt (kg)}}{24}$

D. Infectious. Sepsis can occur in infants receiving central PN. The most common organisms include coagulase-positive and coagulase-negative *Staphylococcus*, *Streptococcus viridans*, *Escherichia coli*, *Pseudomonas* spp., *Klebsiella* spp., and *Candida albicans*. Infection may exacerbate cholestatic liver disease, leading to further morbidities. Standardizing procedures and bundled care of central lines can decrease catheter-related bloodstream infections (ie, central line–associated bloodstream infection [CLABSI]).

E. Cost. The costs of PN should be weighed against its risks, particularly when the anticipated need for PN is short term (<5 days). Complications such as CLABSI greatly increase the morbidity, mortality, and length of stay for infants in the NICU. Feeding protocols that encourage initiation and advancement of enteral feeds can help limit the morbidities associated with PN.

VII. Transitioning to enteral feeds. As enteral feeding volumes are increasing and volume of PN is decreasing, PN may need to be concentrated to prevent a decrease in caloric intake at the same fluid intake. Condensing PN to 80 to 90 mL/kg/d when enteral feeds reach 60 mL/kg/d helps maintain appropriate caloric intake at goal fluid volumes of 140 to 150 mL/kg/d. This can be accomplished by decreasing lipids to 1 g/kg/d, continuing full goal protein, and leaving dextrose concentrations the same. PN can be discontinued when enteral feeds reach 100 to 120 mL/kg/d.

CALORIC CALCULATIONS

Enterally fed healthy term infants should receive 100 to 120 kcal/kg/d for growth (70–90 kcal/kg/d if receiving TPN only). Some hypermetabolic infants may require >120 kcal/kg/d, and preterm infants can require up to 140 to 150 kcal/kg/d. Approximately 80 to 90 kcal/kg/d of nonprotein calories are required to maintain a positive nitrogen balance (nonprotein calories of 25–30 kcal/1 g of protein). Equations for calculating the caloric intake for EN and TPN follow (Table 11–8).

I. Enteral nutrition. Human milk (HM) caloric values can range from 14 to 26 kcal/oz. However, most standard calculations use 20 kcal/oz. Most standard infant formulas are 20 kcal/oz. (Similac uses 19 kcal/oz.) and contain 0.67 kcal/mL. Specific caloric concentrations of formulas are given in Table 11–4. To calculate total daily calories, use the following equation:

$$\text{kcal/kg/d} = \frac{\text{Total mL of HM or formula} \times \text{kcal/mL}}{\text{Wt (kg)}}$$

II. Carbohydrates. If only dextrose infusion is given, the total daily caloric intake is calculated as follows. (For caloric concentration of common solutions, see Table 11–9.)

$$\text{kcal/kg/d} = \frac{\text{mL of solution/h} \times 24\text{h} \times \text{kcal in solution}}{\text{Wt (kg)}}$$

Table 11–9. CALORIC CONCENTRATIONS OF VARIOUS PARENTERAL SOLUTIONS

	% Concentration	Caloric Concentration (kcal/mL)
Dextrose Solutions (anhydrous)		
D ₅	5	0.17
D _{7.5}	7.5	0.255
D ₁₀	10	0.34
D _{12.5}	12.5	0.425
D ₁₅	15	0.51
D ₂₀	20	0.68
D ₂₅	25	0.85
Protein Solutions (g/d)		
0.5	0.5	0.02
1.0	1	0.04
1.5	1.5	0.06
2.0	2.0	0.08
2.5	2.5	0.10
3.0	3.0	0.12

A 0.5% solution, if given at 100 mL/d = 0.5 g of protein/d.

- III. Proteins.** Use the prior formula given for carbohydrates and the caloric concentrations given in Table 11–9.
- IV. Fat emulsions.** A 20% fat emulsion (Intralipid) contains 2 kcal/mL. Use the following formula to calculate daily caloric intake supplied by Intralipid 20%.

$$\text{kcal/kg/d} = \frac{\text{Total mL/d of solution} \times 2 \text{ kcal/mL}}{\text{Wt (kg)}}$$

MATERNAL NUTRITIONAL STATUS AND FETAL AND POSTNATAL GROWTH

Maternal nutritional status affects fetal and postnatal growth. Maternal BMI and prepregnancy weight, as well as excessive weight gain during pregnancy, increase the risk of fetal adiposity and subsequent obesity. Conversely, increased weight loss in the prepregnancy period in healthy mothers (normal BMI) increases the risk of small for gestational age infants.

Maternal diet supplemented with LCPUFAs, particularly omega-3 fatty acids, may improve BW, length, and length of gestation. Antenatal maternal micronutrient (eg, iron, folic acid) supplementation may influence fetal growth, fetal weight, and length of gestation and decrease infant morbidity. Cord blood vitamin D status is inversely correlated with respiratory infections and childhood wheezing.

Rapid weight gain in neonates starting as early as 6 weeks of age may increase risk of obesity. Accelerated weight gain in IUGR infants increases the risks of “adiposity rebound” and risk of subsequent cardiovascular and metabolic diseases.

GUT MICROBIOTA

Microbial colonization of the neonatal gut is necessary for intestinal development and homeostasis and has increasingly been identified as a key determinant of later health. Gut microbiota colonization and diversity are influenced by maternal diet, gestational age, mode of delivery, use of antibiotics, and type of neonatal feeds. Microbiome colonization patterns over time show strong association with weight Z-scores. For example, predominant staphylococci and *Enterococcus* spp. compared to *Lactobacillus* spp. were associated with poor weight gain in preterm infants. Enterobacteriaceae, streptococci, and *Bacteroides fragilis* have been associated with higher weight gain and BMI Z-scores. Oligosaccharides present in human milk may influence gut microbiome-dependent increase in body mass.

12 Imaging Studies

Imaging a neonate requires the coordination of several medical professionals including nurses, respiratory therapists, radiology technologists, neonatologists, and radiologists. Effective and ongoing communication among all members of the team is required to ensure the appropriate modality is chosen according to the ALARA principle (as low as reasonably achievable) and to allow correct diagnosis. Imaging in the absence of clinical context is fraught with many complications including misdiagnosis. This chapter is a general outline of imaging studies that are commonly used to evaluate the neonate. Your choice in any clinical situation will depend on your institution and available resources.

I. Common radiologic studies. The need for radiographs must always be weighed against the risks of exposure of the neonate to radiation (eg, 3–5 mrem per chest radiographic view). The infant's gonads should be shielded as much as possible, and any person holding the infant during the x-ray procedure should also wear a protective shield. For the usual radiographic exposure, personnel need to be only 1 ft outside the zone of exposure.

A. Chest radiographs

- 1. Anteroposterior (AP) view (supine position).** The single best view for identification of heart or lung disease, verification of endotracheal tube and other line positions, and identification of air leak complications of mechanical ventilation, such as pneumothorax.
- 2. Cross-table lateral view (side view of infant lying on the back).** Of limited diagnostic value except to determine whether a chest tube is positioned anteriorly (best for drainage of a pneumothorax) or posteriorly (best for drainage of a pleural fluid collection). Also may visualize the tip of a high umbilical vein catheter and its relationship to the right atrium.
- 3. Lateral decubitus view (left lateral decubitus is infant lying on left side down against the film, right lateral decubitus is infant lying on right side down against the film).** Referred to as the “problem-solving film” since it can be used to differentiate a pneumothorax from a pneumomediastinum, or to detect a pleural effusion. Best to visualize a small pneumothorax or a small pleural fluid collection, as either can be difficult to identify on the AP view. **If a pneumothorax is suspected,** a contralateral decubitus view (with the side of interest up) of the chest should be obtained. An air collection between lung and chest wall will be visible on the side on which the pneumothorax is present. For pleural fluid identification, the ipsilateral decubitus view (side of interest should be down). The lateral decubitus view may not be safely obtainable in unstable infants.

B. Abdominal radiographs

- 1. AP view.** The single best view for diagnosing abdominal disorders such as intestinal obstruction and checking placement of support lines such as umbilical arterial and venous catheters and intestinal tubes. Small bowel cannot be differentiated from large bowel on a plain radiograph because of nondeveloped haustrae in large bowel. It is recommended as the initial radiographic study to determine further workup in a neonate with bilious vomiting up to 1 week of age.
- 2. Left lateral decubitus abdominal view (infant placed left side down).** Best for the diagnosis of intestinal perforation. Free intra-abdominal air resulting from bowel perforation will be visible as an air collection between the liver and right lateral abdominal wall.

C. **Chest and abdomen AP view** (“babygram” is a colloquial term). A radiograph that includes the whole body or just the chest and abdomen on a single image. It is most commonly ordered for line placement.

II. Common radiologic studies with contrast

A. **Enteric contrast.** Enteric contrast are contrast agents that are used in the GI tract and may be given orally or rectally. Barium sulfate and low-osmolality water-soluble agents are essentially interchangeable with a few exceptions outlined below.

1. **Barium.** Barium sulfate, an inert compound, coats the lining of the gastrointestinal (GI) tract after it is swallowed or introduced per rectum. It is not absorbed from the GI tract and results in no fluid shift. This is the contrast agent of choice in most routine upper GI (UGI) and contrast enema examinations without a suspicion of bowel perforation. **Barium contrast studies are not recommended** in infants with **suspected abdominal perforation or if the destination of the administered contrast is unknown** because barium is irritating to the peritoneum and can result in “barium peritonitis.”

2. **Low-osmolality water-soluble contrast agents.** These agents are interchangeable with barium and have replaced high-osmolality contrast agents in neonatal imaging. **Iohexol (Omnipaque)** is the only agent in this category with US Food and Drug Administration (FDA) approval for enteral administration in adults and children. **Omnipaque 180** (180 denotes amount of mg of organic iodine per mL) and **Omnipaque 240** may be used in premature and newborn infants. The off-label use of other contrast agents such as **iodixanol (Visipaque)** is common. **Omnipaque 180, Omnipaque 240, and Visipaque** do not require dilution prior to administration.

a. Advantages

i. **If bowel perforation is present**, these substances are nontoxic to the peritoneal cavity. In addition, they do not damage the bowel mucosa.

ii. **If aspirated**, there is limited irritation (if any) to the lungs.

iii. **They have limited absorption from the normal intestinal tract** and thus maintain good opacification throughout the intestinal tract on delayed imaging.

b. **Disadvantages.** None other than a higher cost than barium.

3. Indications:

a. **Any UGI or contrast enema in neonate.**

b. **Suspected H-type tracheoesophageal fistula.**

c. **Suspected esophageal or bowel perforation.**

d. **Unexplained pneumoperitoneum.**

e. **Evaluation of “gasless abdomen” in a neonate >12 hours old.**

B. **Neonatal fluoroscopy.** Fluoroscopy is an imaging technique that uses real time x-ray to capture a moving image of an organ usually with contrast. Rapid pulsed fluoroscopy is used to decrease radiation dose. It is most commonly used in neonates to image the gastrointestinal and genitourinary tracts.

1. **Contrast enema.** Used to investigate causes of lower intestinal obstruction such as meconium ileus, small left colon syndrome, ileal atresia, colonic atresia, Hirschsprung disease, anorectal malformation, and colonic stricture following necrotizing enterocolitis (NEC). It can be not only diagnostic but also therapeutic for certain conditions, such as small left colon syndrome and meconium ileus.

2. **Upper gastrointestinal imaging (UGI) imaging.** Diagnose intestinal malrotation, midgut volvulus, gastric outlet obstruction.

a. **Bilious vomiting.** An emergent UGI series is indicated in the workup of a neonate with bilious vomiting. Direct communication with the radiologist is suggested to ensure visualization of ligament of Treitz. Full small bowel study is not required.

b. **Nonbilious vomiting.** Consider delayed gastric emptying, gastroesophageal reflux (GER), and hypertrophic pyloric stenosis. Nonemergent UGI is

used in a neonate with nonbilious vomiting and infant <3 months of age with new-onset nonbilious vomiting if targeted ultrasound of the pylorus is not available.

c. **Suspected gastroesophageal reflux (GER).** The pH probe examination and the reflux nuclear scan more reliably identify and quantitate GER than the UGI series.

3. **Esophagram.** Infant is fed contrast material or administered contrast by nasogastric tube, and imaging is done. Used for tracheoesophageal fistula, esophageal stenosis or obstruction, perforation, unexplained pneumomediastinum, to investigate causes of stridor and dysphagia, and for great vessel anomalies.

4. **Small bowel follow-through.** High dose of radiation with combination of pulsed fluoroscopy and x-rays of abdomen. Used to diagnose stricture in a premature infant with feeding intolerance following NEC.

5. **Voiding cystourethrography (VCUG).** A fluoroscopic study of the lower urinary tract with contrast done in the neonate for congenital anomalies of the urinary tract, postoperative evaluation of the urinary tract, bladder outlet obstruction, hematuria, trauma, hydronephrosis/hydroureter, neurogenic bladder, or febrile urinary tract infection.

III. **Radionuclide studies.** Radionuclide studies provide more physiologic than anatomic information and usually involve a lower radiation dose to the patient compared with radiographic examinations.

A. **Reflux scintiscan.** Used for documenting and quantitating GER and is comparable to the pH probe examination and superior to the UGI series. Technetium-99m-sulfur colloid is a radioactive diagnostic agent that is instilled into the stomach with formula, and the tracer is not absorbed. The patient is then scanned in the supine position for 1 to 2 hours with a gamma camera.

B. **Radionuclide cystogram.** Used for documenting and quantitating vesicoureteral reflux. Advantages over the radiographic VCUG include a much lower radiation dose (reduced by 50- to 100-fold) and a longer monitoring period (1–2 hours). A disadvantage is much poorer anatomic detail; bladder diverticula, posterior urethral valves, or mild reflux cannot be reliably identified. This technique should not be the initial examination for evaluation of the lower urinary tract, especially in boys.

C. **Radionuclide bone scan.** Used for evaluation of possible osteomyelitis. This procedure involves a 3-phase study (blood flow, blood pool, and bone uptake) after intravenous injection of technetium-99m-labeled methylene diphosphonate.

1. **Advantages.** Sensitivity to bony changes earlier than with the radiograph.

2. **Disadvantages.** Magnetic resonance imaging (MRI) is preferred if available due to its lack of radiation. A bone scan may not identify the acute phase of osteomyelitis (ie, the first 24–48 hours). Bone scan and MRI require absence of patient motion by immobilization or sedation.

D. **Hepatoinodiacetic acid (HIDA; hepatobiliary) scan.** Used in certain types of neonatal jaundice to assist in differentiating biliary atresia (surgical disorder) from neonatal hepatitis (medical disorder). Oral phenobarbital (5 mg/kg/d) is given for 5 days prior to the examination (enhances bile flow in the liver).

IV. **Ultrasonography.** Ultrasound should be considered for the first line imaging modality for many indications in a neonate. Common ultrasounds obtained in the neonate include imaging the head, heart (echocardiography), hips for dysplasia, and abdomen/kidneys/bladder. Advantages include that it is noninvasive, it involves no ionizing radiation, imaging can be done in the NICU, and it is a real-time dynamic imaging modality. Disadvantages include the need for specific training, imaging is highly operator dependent, and inability to image through bowel gas and ossified bone.

A. **Ultrasonography of the head.** This is the first imaging study in a full-term infant with seizures. It is also performed in preterm infants to rule out intraventricular hemorrhage (IVH), ischemic change (periventricular leukomalacia [PVL]), hydrocephalus, and developmental anomalies. It can also be used to predict

long-term neurodevelopmental outcome (eg, grade III and IV IVH, periventricular cystic lesions, and moderate and severe ventriculomegaly are associated with adverse outcome). It can be performed in the NICU with a portable ultrasound unit. No special preparation is needed. The American Academy of Pediatrics (AAP) recommends that routine screening cranial ultrasound be performed on all infants <30 weeks' gestation once between 7 and 14 days of age and be repeated between 36 and 40 weeks' postmenstrual age. The classification of IVH based on ultrasonographic findings is demonstrated in Figures 12-1 through 12-4.

A

B

FIGURE 12-1. Ultrasonogram of the brain. Coronal (A) and left sagittal (B) views show a left germinal matrix hemorrhage (grade I or subependymal) at arrow.

FIGURE 12–2. Ultrasonogram of the brain. Coronal (A) and left sagittal (B) views show a limited intraventricular hemorrhage (IVH) without ventricular enlargement at arrows (grade II IVH).

Figure 12–5 shows a posterior fossa hemorrhage, and Figure 12–6 demonstrates ischemic changes of PVL.

1. **Grading of IVH** in the neonate by sonography is as follows (based on Papile et al., 1978):
 - a. **Grade I.** Subependymal, germinal matrix hemorrhage.
 - b. **Grade II.** IVH without ventricular dilatation.
 - c. **Grade III.** IVH with ventricular dilatation.
 - d. **Grade IV.** IVH with intraparenchymal hemorrhage.

A

B

FIGURE 12-3. Ultrasonogram of the brain. Coronal (A) and right parasagittal (B) views demonstrate severe dilatation of both lateral (small arrows) as well as the third (large arrows) ventricles, which are filled with clots (grade III intraventricular hemorrhage).

B. Abdominal ultrasonography. Useful in the evaluation of intraabdominal pathology such as abdominal distention, gallbladder disease, biliary obstruction, intraperitoneal fluid, abdominal masses, abscesses, pyloric stenosis, malrotation, and possible causes of renal failure. Ultrasound may be used to diagnose malrotation, but UGI is still the gold standard according to the Society for Pediatric Radiology. The addition of duplex and color Doppler evaluation of vessels can identify portal hypertension and complications of catheter placement such as renal vein thrombosis. In premature infants with NEC who develop a gasless abdomen, ultrasound

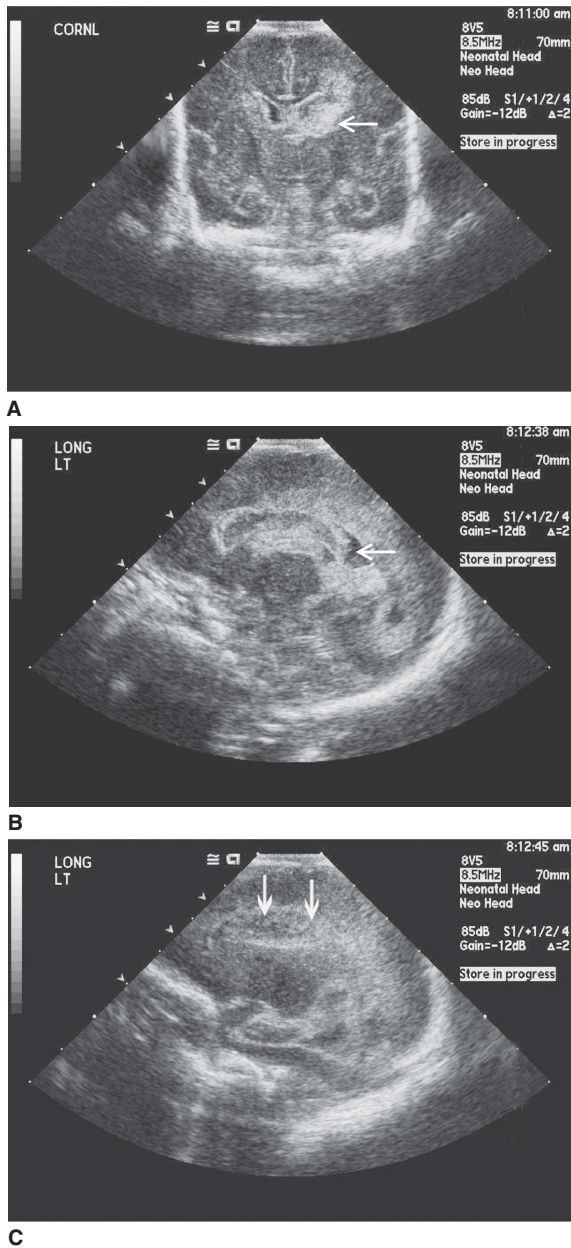

FIGURE 12–4. Ultrasonogram of the brain. Coronal (A) and left sagittal (B and C) views demonstrate left intraventricular hemorrhage (IVH) with ventricular dilatation and localized left intraparenchymal hemorrhage (grade IV IVH) (arrows). Follow-up sonogram 3 months later (coronal view [D] and left sagittal [E and F] views) shows resolution of clot, residual mild ventriculomegaly, and focal porencephaly (arrow) at the site of previous parenchymal hemorrhage.

D

E

F

can evaluate bowel peristalsis, wall thickness, vascularity, and bowel ischemia and may visualize abscess formation and bowel perforation.

- C. Ultrasound of the kidneys and bladder.** First line imaging for urinary tract pathology. Used for any infant with the first febrile urinary tract infection, with decreased urinary output/suspected bladder outlet obstruction, and in the initial evaluation of congenital anomalies of the genitourinary system.
- D. Ultrasound of the hips** is the preferred procedure for ruling out developmental dysplasia of the hip. It is best to do this between 4 and 6 weeks of age because of the high risk of false-positive results. AAP recommends ultrasound of hip to clarify suspicious or equivocal findings on physical examination or to detect a clinically silent developmental dysplasia of the hip (DDH) in a high-risk infant with a normal exam. Risk factors include breech in third trimester, family history of DDH, history

of improper swaddling, and history of abnormal hip physical examination in the neonatal period that normalizes.

- E. **Ultrasonography of the spinal cord** visualizes the entire spinal cord prior to ossification of the posterior elements without radiation or sedation. It is useful when there are cutaneous manifestations associated with spinal dysraphism including

A

B

FIGURE 12-6. Ultrasonogram of the brain. Periventricular leukomalacia (PVL). Coronal (A) and right sagittal (B) views demonstrate increased periventricular echogenicity, suggesting ischemic white matter disease (arrows). Follow-up sonography of the brain 1 month later (coronal [C] and sagittal [D] views) shows extensive periventricular cystic change reflecting PVL.

C

D

FIGURE 12-6. (Continued)

midline mass hair tuft, skin discoloration, skin tags, or deep sacral dimple located 2.5 cm above anus. Ultrasound of simple coccygeal dimples without cutaneous findings of spinal dysraphism and <2.5 cm above the anus is of extremely low diagnostic yield and not recommended.

- F. Point-of-care ultrasound (POCUS)** in neonatology is the use of a portable ultrasound by a nonradiologist (eg, a neonatologist) and is performed at the bedside of an infant in the NICU or newborn nursery. See Chapter 44.

V. Computed tomography (CT) scanning

- A. CT scan of the head.** The use of CT must balance the risk of radiation to the newborn. CT scanning provides more global information than ultrasonography of

FIGURE 12-7. Noncontrast computed tomography of the brain. Abnormal low density (white arrows) in basal ganglia, subcortical white matter, and cortex consistent with hypoxic ischemic injury. (Used with permission from Karuna Shekdar, MD, The Children's Hospital of Philadelphia.)

the head, particularly the periphery of the brain, extra-axial space, and cranium. It allows diagnosis of parenchymal hematoma and subdural and subarachnoid hemorrhage, which can be missed on head ultrasound. **Noncontrast CT scan of brain** is used in term infants with birth trauma, seizures, low hematocrit, or coagulopathy to rule out hemorrhage. CT may be used in patients with encephalopathy following a hypoxic or ischemic event. See Figure 12-7 for an example of hypoxic ischemic encephalopathy (HIE). **Contrast-enhanced CT of the brain** may help in the detection of intracranial vascular anomalies or evaluation of central nervous system (CNS) tumors. Other modalities without radiation, such as cranial ultrasound with Doppler and MRI, are preferred.

B. CT imaging of the neck, chest, abdomen, pelvis, and extremities in the neonate is infrequently performed. Radiography, ultrasound, and MRI are used more commonly.

VI. Magnetic resonance imaging (MRI)

A. Magnetic resonance imaging without contrast. MRI without contrast is an exceptional mode of imaging in the neonate due to its superb anatomic detail and lack of ionizing radiation. It is better than CT to evaluate CNS white matter changes and infarction.

B. MRI with gadolinium-based contrast agents (GBCAs). MRI with GBCAs and their use in the neonatal, pediatric, and adult population are evolving. The deposition of gadolinium utilizing GBCAs has been detected in the bones and brains of adult patients. Gadolinium deposition is dose dependent and increases with renal insufficiency. Neonates are more susceptible to gadolinium deposition due to low glomerular filtration rate and have the potential for numerous contrast-enhanced MRIs over their lifetime. Long-term effects and their clinical significance are not known. According to the most recent FDA drug safety announcement issued May 22, 2017, “[The] FDA identifies no harmful effects to date with brain retention of gadolinium-based contrast agents for MRIs; and will continue to review.” The FDA recommends that “health care professionals should consider limiting GBCA use to clinical circumstances in which the additional information provided by the contrast is necessary.” Direct communication with the radiologist is required to determine if nonenhanced MRI will answer the clinical question.

C. Common indications for MRI

1. MRI of the brain. Indications include determination of etiology of seizures; determination of hypoxic ischemic injury, congenital malformations, focal

cerebral injury (arterial or venous stroke), intracerebral hemorrhage, bilirubin encephalopathy, significant birth trauma, metabolic disorders, history of encephalopathy, or acute encephalopathy; and evaluation of neonatal meningitis. It may have a role in the following: predicting neurodevelopmental outcomes, pre- and postoperative evaluation in neonates with congenital heart disease, and detection of brain insult in extracorporeal membrane oxygenation infants with neurologic signs. See Figure 12–8. MRI of brain is used in preterm infants with profound HIE.

2. **MRI of the body.** Indications include evaluation of masses/neoplasms, hemangiomas/vascular malformations, congenital cystic masses of the head and neck, mediastinal vascular anomalies, and congenital pelvic GI/genitourinary anomalies.
3. **MRI of the spine.** Used to further characterize anomalies depicted on ultrasound and can give anatomic details of the malformations of the spine. See Figure 12–9.
4. **Specific MRI modalities**
 - a. **Magnetic resonance arteriography and magnetic resonance venography** are used to define vascular anatomy and flow. The need for intravenous contrast-enhanced magnetic resonance arteriography and venography should be discussed with the radiologist.

Diffusion

ADC maps

FIGURE 12–8. Magnetic resonance imaging of the brain in preterm infant. Bilateral symmetric restricted diffusion (white arrows) in thalamus, basal ganglia, midbrain, and pons consistent with profound hypoxic ischemic encephalopathy. (Used with permission from Karuna Shekdar, MD, *The Children's Hospital of Philadelphia*.)

FIGURE 12-9. Magnetic resonance imaging of spine. Low-lying conus at L3. Thickened filum with T1 hyperintense, T2 hypointense signal (white arrows) consistent with tethered cord and fatty filum. (Used with permission from Karuna Shekdar, MD, The Children's Hospital of Philadelphia.)

b. MRI spectroscopy and diffusion-weighted imaging (DWI)/diffusion tensor imaging (DTI) can help with disease prognostication. MRI spectroscopy provides information about biochemical composition of imaged tissue such as in HIE or inherited metabolic diseases. DWI provides an image based on differences in the magnitude of diffusion of water molecules in the brain, and DTI analyzes the 3-dimensional shape of the diffusion. Diseases can be identified earlier (cerebral ischemia), allowing one to monitor treatment and predict outcome.

D. Disadvantages of MRI include the potential need for sedation. Usually, infants are fed immediately prior to MRI and placed in an MRI-compatible infant immobilizer to avoid sedation; some neonatal units try swaddling with an optional pacifier with or without oral sucrose (feed and wrap/feed and bundle). Transportation of ill neonates outside of the NICU is a second disadvantage. An MRI compatible incubator is now available that can be used to provide safe transport of the infant and allows thermal regulation during transport and the MRI exam. A few centers have infant-sized MRI units in the NICU. In 2017, the FDA approved an infant-sized MRI unit for imaging the neonatal head that can be housed in the NICU (Embrace Neonatal MRI System). Researchers hope to provide advanced imaging to critically ill neonates with minimal disruption in care.

COMMON RADIOLOGIC PREPARATIONS

See Table 12-1 for guidelines for common radiographic studies. Institutional guidelines may vary from these.

NEONATAL RADIOGRAPHIC EXAMPLES

Invasive life support and monitoring techniques depend on proper positioning of the device being used. **Caution is necessary when identifying ribs and correlating vertebrae** in the newborn as a means for determining the proper position of a catheter or tube. Infants often have a noncalcified 12th rib; thus, the 11th rib is mistaken for the 12th rib, and an incorrect

Table 12–1. PREPARATORY PROCEDURES FOR PREMATURE AND NEWBORN INFANT RADIOLOGIC STUDIES^a

Neonatal Study	Preparation
Upper GI series	NPO for 2 hours for newborns and infants up to 4 months of age
Contrast enema	No preparation needed for evaluation of bowel obstruction or to rule out Hirschsprung disease
Renal sonography	No preparation
Abdominal sonography	NPO for 1 hour for filling of gallbladder
HIDA (hepatobiliary) scan	Oral phenobarbital (5 mg/kg/d) for 5 days prior to the examination
CT of abdomen/pelvis	Oral contrast beginning 2 hours prior to scanning
Voiding cystourethrogram	No preparation required

CT, computed tomography; GI, gastrointestinal; HIDA, hepatoinodiodiacetic acid; NPO, nothing by mouth.

^aReview institution-specific recommendations before ordering.

vertebral count may occur. Infants can also have an abnormal number of ribs. In 5% to 8% of normal individuals, there are only 11 ribs. Eleven ribs also occur in approximately 33% of infants with trisomy 21 syndrome and in campomelic dysplasia and cleidocranial dysplasia. An increased number of ribs can occur in VATER (vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia)/VACTERL (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and radial abnormalities, and limb abnormalities) association.

I. Endotracheal intubation

A. The preferred location of the endotracheal tube (ETT) tip is halfway between the thoracic inlet (the medial ends of the clavicles) and the carina. Ideally, it should be 1 cm above the carina, but this may not be possible in infants with severe intra-uterine growth restriction and premature infants weighing <1000 g. Correct tube placement is shown in Figure 12–10.

B. If the ETT is placed too low, the tip usually enters the right main bronchus, because it is easier to enter since it is not only a shallower angle but a straighter line than with the left main bronchus. If the ETT is in the right mainstem bronchus, one can see overdistention/hyperinflation of the right middle and lower lungs and underventilation and/or atelectasis of the remaining lungs. The chest film may show asymmetric aeration with both hyperinflation and atelectasis. If the tube extends below the carina or does not match the tracheal air column in position, suspect esophageal intubation. Dilatation of the esophagus and stomach with air and increased proximal intestinal air may also reflect esophageal intubation.

C. An ETT placed too high has the tip above the clavicle, and the x-ray film may show diffuse atelectasis.

II. Nasogastric/orogastric tube. The nasogastric/orogastric tube tip should be in the mid-stomach. It should not be at or above the gastroesophageal junction. Correct placement is shown in Figure 12–11.

III. Transpyloric tube. The weighted feeding tube is ideally placed in the mid to distal duodenum. Correct placement is shown in Figure 12–12.

IV. Umbilical vein catheterization (UVC). The catheter tip should be at the junction of the inferior vena cava and right atrium, projecting just above the diaphragm on the AP chest radiograph. Degree and direction of patient rotation affect how the UVC appears positioned on the radiograph. Due to its more anterior location, the UVC deviates more

FIGURE 12–10. Chest radiograph showing proper placement of an endotracheal tube.

FIGURE 12–11. Chest abdomen film showing the nasogastric tube tip in the mid-stomach (arrow at distal tube).

FIGURE 12-12. Chest abdomen film showing the transpyloric tube (weighted feeding tube tip) in the mid to distal duodenum (arrow at distal tube).

from the midline with patient rotation than will the UAC. Figure 12-13 shows correct UVC tip placement.

- V. Umbilical artery catheterization (UAC).** Cochrane review indicates that high catheters should be used exclusively. In certain instances, a catheter may have to be placed in the low position. The use of high versus low UAC placement used to depend on institutional preference. High catheters were once thought to be associated with a higher risk of vascular complications, but a recent analysis showed a decreased risk of vascular complications and no increased risk of hypertension, NEC, IVH, or hematuria. Low catheters are associated with an increased risk of vasospasms.

A. If high UAC placement is desired, the tip should be between thoracic vertebrae 6 and 9 (above the diaphragm, which is above the celiac axis at T12, the superior mesenteric artery at T12–L1, and the renal arteries [L1]) (Figure 12-14).

B. For low UAC placement, the tip should be below the third lumbar vertebra, optimally between L3 and L4 (above the aortic bifurcation, which is at L4–5) (Figure 12-15). A catheter placed below L5 usually does not function well and carries a risk of severe vasospasm in small arteries. Note that the catheter turns downward and then upward on an abdominal x-ray film. The upward turn is the point at which the catheter passes through the internal iliac artery (hypogastric artery).

Note: If both a UAC and a UVC are positioned and an x-ray study is performed, it is necessary to differentiate the 2 so that line placement can be properly assessed. The UAC turns downward and then upward on the x-ray film, whereas the UVC takes only an upward or cephalad direction.

FIGURE 12–13. Radiograph showing correct placement of an umbilical venous catheter (arrow). The tip of the nasogastric tube is properly positioned in the stomach.

- VI. Extracorporeal life support.** ECLS external life support using a membrane oxygenator is described in detail in Chapter 20. See the veno-arterial ECLS cannulae placement and veno-venous ECLS cannulae placement radiographs (Figures 20–3 and 20–4, respectively).

RADIOGRAPHIC PEARLS

- I. Pulmonary diseases.** The neonatal chest radiograph is one of the first and most frequently performed diagnostic examinations performed in the NICU. It plays a significant role in helping the clinician with the etiology and diagnosis of respiratory distress in the newborn.
- A. Respiratory distress syndrome (RDS).** A fine, diffuse reticulogranular pattern is seen secondary to microatelectasis of the alveoli. The chest radiograph reveals radiolucent areas known as air bronchograms, produced by air in the major airways and contrasted with the opacified, collapsed alveoli (Figure 12–16).
- B. Meconium aspiration syndrome.** Bilateral, patchy, coarse infiltrates and hyperinflation of the lungs are present (Figure 12–17). There is an increased incidence of pneumothorax.
- C. Pneumonia.** Diffuse alveolar or interstitial disease that is usually asymmetric and localized. Group B streptococcal pneumonia can appear similar to RDS. Pneumatoceles (air-filled lung cysts) can occur with staphylococcal pneumonia. Pleural effusions or empyema may occur with any bacterial pneumonia (Figure 12–18).

FIGURE 12-14. Radiograph showing correct positioning of a high umbilical artery catheter.

- D. Transient tachypnea of the newborn (TTN).** Hyperaeration with symmetric perihilar and interstitial streaky infiltrates are typical. Heart may be normal or mildly enlarged. Pleural fluid may occur as well, appearing as widening of the pleural space or as prominence of the minor fissure (Figure 12-19). Radiographs cannot reliably differentiate TTN from neonatal pneumonia. TTN is a diagnosis of exclusion; radiographic findings completely resolve in 24 to 48 hours. Radiographs of neonatal pneumonia may normalize in 1 to 2 weeks.
- E. Bronchopulmonary dysplasia, now referred to as chronic lung disease (CLD).** The radiographic appearance is highly variable, from a fine, hazy appearance of the lungs to mildly coarsened lung markings to a coarse, cystic lung pattern (Figure 12-20). Typically occurring in ventilated premature neonates, CLD usually requires a minimum of 7 to 10 days to develop. Many centers no longer rely on the following grading system for this condition, but it is included for historical purposes.
1. **Grade I.** X-ray findings are similar to those of severe RDS.
 2. **Grade II.** Dense parenchymal opacification is seen.
 3. **Grade III.** A bubbly, fibrocystic pattern is evident.
 4. **Grade IV.** Hyperinflation is present with multiple fine, lacy densities spreading to the periphery and with areas of lucency similar to bullae of the lung.
- F. Air leak syndromes**
1. **Pneumopericardium.** Air surrounds the heart, including the inferior border (Figure 12-21). Cardiac tamponade may result.

FIGURE 12-15. Radiograph showing correct positioning of a low umbilical artery catheter.

2. Pneumomediastinum

- a. **AP view.** A hyperlucent rim of air is present lateral to the cardiac border and beneath the thymus, displacing the thymus superiorly away from the cardiac silhouette (“angel wing sign”) (Figure 12-22, left panel).
 - b. **Lateral view.** An air collection is seen either substernally (anterior pneumomediastinum) or in the retrocardiac area (posterior pneumomediastinum) (Figure 12-22, right panel).
3. **Pneumothorax.** The lung is typically displaced away from the lateral chest wall by a radiolucent zone of air. The adjacent lung may be collapsed with larger pneumothoraces (as in Figure 12-23). The small pneumothorax may be very difficult to identify, with only a subtle zone of air peripherally, a diffusely hyperlucent hemithorax, unusually sharply defined cardiothymic margins, or a combination of these.
 4. **Tension pneumothorax.** The diaphragm on the affected side is depressed, the mediastinum is shifted to the contralateral hemithorax, and collapse of the ipsilateral lobes is evident (Figure 12-23).
 5. **Pulmonary interstitial emphysema (PIE).** Single or multiple circular radiolucencies with well-demarcated walls are seen in a localized or diffuse pattern. The volume of the involved portion of the lung is usually increased, often markedly so (Figure 12-24). PIE usually occurs in ventilated preemies with RDS within the initial few days of life.

FIGURE 12-16. Chest radiograph showing diffuse granular opacification of the lungs with air bronchograms. In the premature neonate, this would almost always represent respiratory distress syndrome.

FIGURE 12-17. Chest radiograph showing diffuse coarse increase in lung markings accompanied by hyperinflation, typical for meconium aspiration syndrome.

FIGURE 12–18. Diffuse increase in interstitial lung markings is typical with neonatal pneumonia but could also be produced by transient tachypnea of newborn.

- G. Atelectasis.** A decrease in lung volume or collapse of part or all of a lung is apparent, appearing as areas of increased opacity. The mediastinum may be shifted toward the side of collapse. Compensatory hyperinflation of the opposite lung may be present.
- 1. Microatelectasis.** Nonobstructive atelectasis associated with RDS.
 - 2. Generalized atelectasis.** Diffuse increase in opacity (“whiteout”) of the lungs is visible on the chest film. It may be seen in severe RDS, in airway obstruction, if the ETT is not in the trachea, and in hypoventilation.
 - 3. Lobar atelectasis.** Lobar atelectasis is atelectasis of one lobe. The most common site is the right upper lobe, which appears as an area of dense opacity (“whiteout”) on the chest film. In addition, the right minor fissure is usually elevated. This pattern of atelectasis commonly occurs after extubation.
- H. Pulmonary hypoplasia.** Small lung volumes and a bell-shaped thorax are seen. The lungs usually appear radiolucent. In unilateral hypoplasia, there is small lung, decreased vascularity, and heart is displaced to hypoplastic side. In bilateral hypoplasia, there is a bell-shaped thorax, low lung volumes, and possible pneumothorax/pneumomediastinum.
- I. Pulmonary edema.** The lungs appear diffusely hazy with an area of greatest density around the hilum of each lung. Heart size is usually increased.
- J. Pulmonary hemorrhage.** Variable appearance with symmetric homogenous to patchy heterogenous shadowing or “whiteout.” Quick resolution of airspace disease, often within hours, helps to differentiate this from neonatal pneumonia.
- K. Developmental abnormalities**
- 1. Esophageal atresia.** Dilated upper esophageal pouch. Nasogastric tube coiled in proximal esophagus. Air in the stomach consistent with distal tracheoesophageal fistula (TEF).
 - 2. Congenital diaphragmatic hernia (CDH).** Visible aerated lung on ipsilateral side to hernia indicates good prognosis; pneumothorax on contralateral side indicates poor prognosis. In left-sided CDH, stomach and bowel enter the thorax. Early on, opaque fluid-filled bowel displaces the mediastinum. Eventually, cystic radiolucencies deviate the mediastinum. In right-sided CDH, the liver herniates into thorax.
 - 3. Congenital pulmonary airway malformation, CPAM, formerly known as cystic adenomatoid malformation.** Appearance on x-ray depends upon the

A

B

FIGURE 12-19. Chest radiograph (A) showing diffuse, mild increase in interstitial lung markings, consistent with transient tachypnea of newborn. The findings had typically resolved by the following day (B).

subtype of CPAM. Can see a variety of lesions (multicystic air filled, solid, or with air-fluid levels) or large lesions causing a mediastinal shift. Small lesions may have a normal x-ray.

4. **Pulmonary sequestration.** Normal or increased basal opacity, mediastinal shift if segment is large. If basal opacity fails to clear over 1 or several months, consider sequestration.
5. **Upper airway obstruction.** Severe overinflation of lungs.
6. **Congenital lobar emphysema.** Initially the lobe is fluid filled and opaque on chest radiograph. Affected lobe becomes overaerated, and there is marked decreased in vascularity. Normal lung is compressed.

FIGURE 12–20. Chest radiograph showing a diffuse, moderately coarse increase in lung density, which in a 2-month-old ventilated ex-preemie is most consistent with bronchopulmonary dysplasia/chronic lung disease.

- II. Cardiac diseases.** Evaluate the cardiac size and shape, the aorta size, the pulmonary artery size, the presence of increased or decreased pulmonary vasculature, evidence of pulmonary edema (obstruction of blood flow), the position of the heart, and abdominal viscera. The cardiothoracic ratio, which normally should be <0.6 , is the width of the base of the heart divided by the width of the lower thorax. An index >0.6 suggests **cardiomegaly**. Lateral chest radiograph will show deviation of the posterior heart border toward the spine with cardiomegaly. The pulmonary vascularity is increased if the diameter of the descending branch of the right pulmonary artery exceeds that of the trachea.
- A. Cardiac dextroversion.** The cardiac apex is on the right, and the aortic arch and stomach bubble are on the left. The incidence of congenital heart disease associated with this finding is high ($>90\%$).

FIGURE 12–21. Chest radiograph showing pneumopericardium in a 2-day-old infant.

FIGURE 12-22. Pneumomediastinum on anteroposterior (left panel) and cross-table lateral (right panel) radiographs, demonstrating central chest air and elevation of the lobes of the thymus.

- B. Congestive heart failure.** Cardiomegaly, pulmonary venous congestion (engorgement and increased diameter of the pulmonary veins), diffuse opacification in the perihilar regions, and pleural effusions (sometimes) are seen.
- C. Patent ductus arteriosus.** Diagnosis is made on clinical basis. Cardiomegaly, pulmonary edema, ductal haze (pulmonary edema with a patent ductus arteriosus), and increased pulmonary vascular markings are evident usually after auscultation of heart murmur.
- D. Ventricular septal defect.** Findings include cardiomegaly, an increase in pulmonary vascular density, enlargement of the left ventricle and left atrium, and enlargement of the main pulmonary artery.
- E. Coarctation of the aorta**
 - 1. Preductal coarctation.** Generalized cardiomegaly, with normal pulmonary vascularity, is seen.
 - 2. Postductal coarctation.** An enlarged left ventricle and left atrium and a dilated ascending aorta are present.
- F. Tetralogy of Fallot.** The heart is boot shaped. A normal left atrium and left ventricle is associated with an enlarged, hypertrophied right ventricle and small or absent main pulmonary artery. There is decreased pulmonary vascularity. A right aortic arch occurs in 25% of patients.
- G. Transposition of the great arteries.** The chest film may show cardiomegaly, with an enlarged right atrium and right ventricle, narrow mediastinum, and increased pulmonary vascular markings, but in most cases, the chest film appears normal.
- H. Total anomalous pulmonary venous return (TAPVR).** Pulmonary venous markings are increased. Cardiomegaly is minimal or absent. Congestive heart failure and pulmonary edema may be present, especially with type 3 (subdiaphragmatic) TAPVR.
- I. Hypoplastic left heart syndrome.** The chest film can be normal at first but then may show cardiomegaly and pulmonary vascular congestion, with an enlarged right atrium and ventricle.

FIGURE 12-23. Left tension pneumothorax as shown on an anteroposterior chest radiograph in a ventilated infant on day 2 of life. Note the accompanying collapse of the left lung, depression of the left diaphragm, and contralateral shift of mediastinal structures, all signs of increased pressure within a pneumothorax.

- J. Tricuspid atresia.** Heart size is usually normal or small, the main pulmonary artery is concave, and pulmonary vascularity is decreased.
 - K. Truncus arteriosus.** Characteristic findings include cardiomegaly, increased pulmonary vascularity, and enlargement of the left atrium. A right aortic arch occurs in 30% of patients.
 - L. Atrial septal defect.** Varying degrees of enlargement of the right atrium and ventricle are seen. The aorta and the left ventricle are small, and the pulmonary artery is large. Increased pulmonary vascularity is also evident.
 - M. Ebstein anomaly.** Gross cardiomegaly and decreased pulmonary vascularity are apparent. The right heart border is prominent as a result of right atrial enlargement.
 - N. Valvular pulmonic stenosis.** Heart size and pulmonary blood flow are usually normal unless the stenosis is severe. Dilatation of the main pulmonary artery is the typical chest film finding.
- III. Abdominal disorders.** An abdominal film is usually obtained in a neonate with abdominal distension, unexplained emesis or feeding intolerance, suspected obstruction, or acute abdomen. It is important to look for the normal progression of air in the bowel, any dilatation, number of dilated bowel loops, pneumatosis intestinalis, air in the rectum,

FIGURE 12-24. Chest radiograph showing bilateral pulmonary interstitial emphysema in a 7-day-old ventilated infant.

free air, and ascites. Abdominal and retroperitoneal masses may also require evaluation with imaging.

A. Normal neonatal bowel gas pattern

1. **Normal mosaic bowel gas pattern.** All gas-filled loops are similar in caliber, fitting together like a puzzle.
2. **Normal progression of air in bowel**
 - a. **Air in the stomach.** Should occur within 30 minutes after delivery.
 - b. **Air in proximal bowel loops.** Should be seen by 3 to 4 hours of age.
 - c. **Air in distal bowel loops and rectum.** Should be seen in distal bowel by 6 to 8 hours of age and in rectum by 12 hours. Air in the rectum may not be seen on a radiograph obtained in the supine position because of its dependent location.
3. **Neonatal colon does not have developed haustra.** As a result, it is not possible to differentiate small bowel and colon on abdominal radiograph.

B. Abnormal abdominal findings that deviate from the mosaic pattern

1. **Dilated loops of bowel.** It is usually evident when bowel is dilated since the normal mosaic pattern is lost. As a general guideline, if the loop measures more than the interpedicular width of L2, it is considered dilated. Dilated loops can be seen with continuous positive airway pressure, ileus, ischemia, NEC, and obstruction.
 - a. **Neonatal obstruction** is classified as **proximal or distal** according to the number of dilated loops. The presence of ≤ 3 loops is considered a proximal obstruction; the presence of ≥ 4 is a distal obstruction. The differential diagnosis for **proximal obstruction** includes gastric atresia, duodenal atresia, duodenal stenosis with annular pancreas, malrotation with Ladd band, proximal jejunal stenosis, and atresia. **Distal obstruction** includes distal jejunal atresia, ileal atresia, meconium ileus, functional immaturity of the colon or small left colon syndrome, Hirschsprung disease, colonic atresia, anal atresia, and anorectal malformations.
 - b. **Malrotation with midgut volvulus** is a great masquerader. In an infant with bilious vomiting and this condition, the radiograph may be normal or look like a proximal or distal obstruction.

2. **Calcifications in the neonatal abdomen** is most often seen secondary to in utero bowel perforation. Meconium peritonitis may cause calcifications in the abdomen and in the scrotum in males. Calcifications can occur secondary to enterolithiasis from rectourinary fistula, small bowel obstruction (jejunoileal atresia), total colonic Hirschsprung disease, or rarely, secondary to hepatic calcifications. Calcifications in the infant abdomen may be seen with neuroblastoma, hepatoblastoma, teratoma, calcification of the adrenals after adrenal hemorrhage, and very rarely neonatal Wilms tumor.
3. **Ascites.** Gas-filled loops of bowel, if present, are located in the central portion of the abdomen. The abdomen may be distended, with relatively small amounts of gas (“ground-glass” appearance). A uniform increase in the density of the abdomen, particularly in the flank areas, may be evident.
4. **Air-fluid bowel gas levels.** Seen only on horizontal beam radiographs such as left lateral decubitus or upright abdominal films. Intraluminal fluid becomes dependent and air rises, creating an interface or line. Their presence implies either an abnormal bowel peristalsis such as ileus or bowel obstruction. Air-fluid levels occur proximal to the site of obstruction.
5. **Pneumoperitoneum**
 - a. **Supine view.** Free air is seen as a central lucency, usually in the upper abdomen (Figure 12–25).
 - b. **Upright view.** Free air is present in a subdiaphragmatic location.
 - c. **Left lateral decubitus view.** Air collects over the lateral border of the liver, separating it from the adjacent abdominal wall.
6. **Pneumatosis intestinalis.** Intraluminal gas in the bowel wall (produced by bacteria that have invaded the bowel wall) may appear as a string or cluster of bubbles (submucosal) or a curvilinear lucency (subserosal). It is most

FIGURE 12–25. Radiograph showing pneumoperitoneum in a 3-day-old infant.

FIGURE 12–26. Abdominal radiograph showing pneumatosis intestinalis.

frequently seen in infants with NEC (Figure 12–26) but can be seen in intestinal obstruction with ischemia (malrotation with midgut volvulus and ischemia).

7. **“Soap bubble” appearance of bowel loops** is present in meconium ileus because of air mixed with meconium. A clue to the diagnosis of meconium ileus is the lack or paucity of air-fluid levels in comparison to the number of dilated bowel loops. The soap bubble appearance, or **Neuhauser sign**, can also be seen in ileal atresia, NEC, and Hirschsprung disease.
8. **Situs inversus (complete)**. The stomach, aortic arch, and cardiac apex all are right sided. There is only a limited increased incidence of congenital heart disease.
9. **Ileus**. Distended loops of bowel are present. Air-fluid levels may be seen on the upright or cross-table lateral abdominal film.
10. **Absence of gas in the abdomen**. Absence of gas in the abdomen may be seen in neonates on sedative or muscle-paralyzing medications (eg, pancuronium) because they do not swallow air. It may also be evident in infants with esophageal atresia without tracheoesophageal fistula and in cases of severe cerebral anoxia resulting in CNS depression and absence of swallowing. It has also been seen in long-term persistent nasogastric suction, giant cystic meconium peritonitis, massive gangrene of the small bowel, massive ascites, massive intraabdominal tumors, massive duplication cyst, and omental cyst. The bubble sign in a gasless abdomen is a clue to the diagnosis of UGI obstruction. **Single bubble sign** suggests gastric outlet obstruction (ie, pyloric atresia). **Double bubble sign** suggests duodenal atresia. **Triple bubble sign** suggests proximal jejunal atresia.

FIGURE 12-27. Cross-table lateral radiograph of abdomen showing portal venous gas at arrow.

- 11. Portal venous air (Figure 12-27).** Air is demonstrated in the portal veins (right upper quadrant on supine AP radiograph), often best seen on lateral view. This finding may indicate bowel necrosis (advanced degree of NEC) or intestinal infarction secondary to mesenteric vessel occlusion or iatrogenically introduced gas into the portal vein, which can occur during UVC or exchange transfusion.

13 Management of the Extremely Low Birthweight Infant During the First Week of Life

This chapter addresses the initial care of premature infants of <1000 g birthweight. Many aspects of the care of extremely low birthweight (ELBW) infants are *controversial*, and each institution must develop its own philosophy and techniques for management. It is of utmost importance to follow the practices of your own institution. This chapter offers guidelines that the authors have found useful for stabilizing and caring for extremely small infants.

I. Delivery room management

A. Ethics/consult. The neonatologist and other healthcare team members should make every effort to meet with the family before delivery to discuss treatment options for the ELBW infant. Counseling should include discussions with the parents regarding survival rate and both short- and long-term complications based on institutional statistics and the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network calculator. Communication regarding treatment options for the 22- to 24-week gestation infant is crucial. Neonatal bioethics are discussed in detail in Chapter 23. The consult should also include recommendations to the obstetrician (OB) for antenatal steroids (Chapter 117) and magnesium for neuroprotection.

B. Resuscitation

- 1. Delayed cord clamping.** Ask the OB for 30 to 60 seconds of delayed cord clamping unless there are maternal or neonatal contraindications, or cord milking may be considered (American Academy of Pediatrics and American College of Obstetricians and Gynecologists recommendations).
- 2. Thermoregulation.** Consider increasing the ambient temperature of the room to 25°C to 26°C. A polyethylene wrap or bag used immediately after birth prevents heat loss at delivery. In addition, an underlying thermal mattress placed under warmed blankets and a hat provide extra warmth and help stabilize the infant for transport. The wrap is removed and the infant is dried after being placed in a neutral thermal environment in the neonatal intensive care unit (NICU) with stabilization of the infant's temperature.
- 3. Respiratory support.** Oxygen (O₂) use in resuscitation has been challenged in recent years. It takes 7 to 10 minutes for oxyhemoglobin saturations to rise to 90% after delivery. The Neonatal Resuscitation Program recommends availability of pulse oximetry and blended O₂ for resuscitation, starting at 30% fraction of inspired O₂ (FiO₂), and low saturation protocol. For infants who require intubation, surfactant is recommended; however, for infants breathing spontaneously, it remains **controversial**. If the infant is breathing spontaneously and has a heart rate >100 beats/min, continuous positive airway pressure (CPAP) of 4 to 6 cm H₂O should be initiated to prevent atelectasis. CPAP cannot be delivered with a self-inflating bag.
- 4. Transport.** As soon as possible, the infant should be transported to the NICU. Transport must be in a prewarmed portable incubator equipped with blended O₂ and CPAP availability. Infants transported from referring hospitals should be handled in a similar manner.

II. Temperature and humidity control. Because the tiny infant has a relatively large skin surface area and minimal energy reserves, a constant **neutral thermal environment** (environmental temperature that minimizes heat loss without increasing O₂ consumption or incurring metabolic stress) is essential. To maintain minimal evaporative heat loss, it is best if the environmental humidity is 80%. Lower ambient humidity requires higher ambient temperatures to maintain infant skin temperature.

A. Incubators and hybrid incubators. ELBW infants should be admitted into prewarmed **double-walled incubators**. Previously, only **radiant warmers** allowed accessibility to the infant; however, they caused large evaporative heat with water losses and somewhat higher basal metabolic rates. As a result, the development and exclusive use of hybrid humidified incubators have become the standard.

B. Humidification. ELBW infants have increased insensible water loss secondary to large body surface area and a greater proportion of body water to body mass. Transcutaneous water loss is enhanced by their thin epidermis and underdeveloped stratum corneum. Increased environmental humidity can minimize these losses. **Warm humidification within the incubator is recommended.** Double-walled incubators provide the best control for monitoring humidity levels.

- 1. Use a respiratory care humidification unit.** Humidification and warming of administered ventilator gases are important to minimize insensible fluid losses

and hypothermia. Infants receiving mechanical ventilation as well as noninvasive respiratory assistance require humidification. In-line warming of ventilator gas circuits minimizes “rainout” of the humidified air and O₂ and maintains airway temperature as close as possible to 35°C. The fluids used for humidification in these systems should be changed every 24 hours.

2. **Minimize nosocomial infection in humidified environments.** Do not allow nonmedical items inside the incubator and change linens regularly if the infant’s condition is stable. Change bed every 7 to 10 days per manufacturer’s recommendation.
- C. **Monitoring and maintenance of body temperature.** Infants weighing <1000 g have poor mechanisms for regulation of temperature and depend on environmental support.
1. **Maintain axillary skin temperature of 36.0°C to 36.5°C.** If skin temperature is outside the range, you may need to change from servo-control to manual control for warming the smallest infants. Use extreme caution while in the manual temperature mode because of the danger of hyperthermia. Rectal thermometers are not to be used for tiny infants; electronic thermometers have become standard.
 2. **Record skin temperature.** Using a servo-control skin probe, record skin temperature and environmental temperature every hour until the skin temperature is stable (36.0–36.5°C) and thereafter with recordings at 2-hour intervals.
 3. **Record the incubator humidity.** Record every hour until it is stable and then every 2 hours for maintenance.
 4. **Weigh low birthweight infants for management of fluids and electrolytes after the third day of life.** The incubator should be equipped with an in-bed scale for continuous weighing of the infant to minimize handling and loss of the thermal-controlled environment.
 5. **Other heat-conserving practices.** These include the use of knit hats, fetal positioning, and air boost curtains on incubators.
 6. **Accessory items for infant care must be prewarmed.** These items include intravenous (IV) fluids, stethoscope, saline lavages, and any other items that come in direct contact with the infant. Placement of these items in the infant’s incubator 30 minutes before use warms them to avoid heat loss by conduction from the infant.
- D. **Slow warming or cooling of infants.** Infants who become hypothermic must be gradually rewarmed.
1. **Warming.** If the infant’s temperature is <36.0°C, set the warmer temperature 0.4°C higher than the infant’s temperature. Continue this procedure until the desired temperature is achieved. Frequent observations of environmental and skin temperatures are essential to evaluate warming efforts. **Do not rewarm faster than 1°C/h.** When skin temperature of 36.5°C is achieved, rewarming efforts should be gradually discontinued, and temperature maintenance by servo-control should be monitored. Rapid rewarming of ELBW infants must be avoided because core body temperatures >37.5°C cause increased insensible water losses, increased O₂ consumption, apneic episodes, increased incidence of intraventricular hemorrhage (IVH), deviations in vital signs, and a detrimental effect on neurodevelopment.
 2. **Hyperthermia (skin temperature >37.0°C).** In case of hyperthermia, set the warmer temperature control to 0.4°C lower than the infant’s skin temperature. Continue to reduce the warmer temperature until desired temperature is achieved. If increased temperature persists, consider evaluation for pathologic conditions such as sepsis, IVH, or mechanical overheating by exterior lamps. Do not turn off the warmer, as this may cause a sudden decrease in the infant’s temperature.

III. Fluids and electrolytes. Because of increased insensible water loss and immature renal function, these infants have greater fluid requirements, necessitating IV fluid therapy (see Chapter 10).

A. Intravenous fluid therapy

1. **Insensible water loss.** Insensible water loss increases with the use of radiant warmers and low ambient humidity. Under these circumstances in which increased insensible fluid loss can occur, additional fluid supplementation is required. However, excessive fluid intake may contribute to the development of a hemodynamically significant patent ductus arteriosus (PDA).
 2. **First day of life.** Table 13–1 gives suggested guidelines for total fluids per kilogram of body weight for the first day of life for infants in humidified incubators/omnibeds and on radiant warmers.
 3. **Second and subsequent days of life.** Fluid management on the second and subsequent days depends on changes in renal function (blood urea nitrogen, creatinine, urine output), serum electrolyte concentrations (see Chapter 10), and body weight (measured after third day of life).
 4. **Additional fluid may be required if phototherapy is used.** The fluid volume should be increased by 10 to 20 mL/kg/d.
 - a. **Incubators/omnibeds.** Fluid rates are based on 80% or higher humidity; fluids should be increased incrementally with decreasing environmental humidity.
- B. Infusion of fluids.** Confirm appropriate line placement and document before infusion (see specific procedure chapter).
1. **Umbilical artery catheter.** Use only for laboratory and hemodynamic monitoring if other IV access is available. Infuse 0.5 normal saline (NS) + 0.5 U heparin/mL or 0.5 sodium acetate + 0.5 U heparin/mL (sodium acetate aids in acid-base balance).
 2. **Umbilical venous catheter.** Fluids containing glucose and amino acids add 0.5 U heparin/mL to maintenance fluids. Consider use of double-lumen catheters for additional fluid and drug administration.
 3. **Broviac, Hickman, or percutaneous central venous catheters.** Add 0.5 U heparin/mL to maintenance fluids. Avoid placement in first 3 days of life, if possible, to minimize stress.
 4. **Radial arterial line/posterior tibial arterial line.** Add 2 U heparin/mL to 0.5 NS.
- C. For catheter flushes, use the same fluids as those infused as IV fluids.** Avoid NS as a flush solution because of excessive sodium. In addition, avoid hypotonic solutions (<0.45 NS or <5% dextrose) as these solutions may cause red blood cell hemolysis.

Table 13–1. ADMINISTRATION RATES FOR THE FIRST DAY OF LIFE FOR INFANTS IN HUMIDIFIED INCUBATORS/OMNIBEDS AND RADIANT WARMERS

Birthweight (g)	Gestational Age (wks)	Fluid Rate (mL/kg/d)	
		Incubators ^a	Radiant Warmers ^b
500–600	23	60–80	140–200
601–800	24	60–80	120–150
801–1000	25–27	50–70	100–120

^aFluid rates based on 80% or higher humidity; fluids should be increased incrementally with decreasing environmental humidity.

^bFluid rates may be decreased with the addition of a humidity tent.

D. Monitoring of fluid therapy. The infant's fluid status should be evaluated at least twice daily during the first few days of life and the fluid intake adjusted accordingly. Fluid status is monitored via measurement of body weight, urine output, blood pressure measurements, serum sodium, hematocrit, and physical examination.

1. Body weight. This is the most important method of monitoring fluid therapy.

If an in-bed scale is used, weigh the infant daily after the first 3 days of life (to minimize stress). If unavailable, weighing may be delayed to every 48 hours, depending on the stability of the tiny infant, to prevent excessive handling and cold stress. A weight loss of up to 15% of birthweight may be experienced by the end of the first week of life. If weight loss is excessive, environmental controls for insensible fluid losses and fluid management must be carefully reviewed.

2. Urine output. This is the second most important method of monitoring fluid therapy. For greatest accuracy, diapers should be weighed before use and immediately after urination.

a. First 12 hours. Any amount of urine output is acceptable.

b. 12–24 hours. The minimum acceptable urine output is 0.5 mL/kg/h.

c. Day 2 and beyond. Normal urine output for the second day is 1 to 2 mL/kg/h. After the second day of life and during a diuretic phase, urine output may increase to 3.0 to 5.0 mL/kg/h; values outside this range warrant reevaluation of fluid management.

3. Hemodynamic monitoring. This is a valuable tool in assessing fluid status in the infant.

a. Heart rate. The accelerated heart rate of the tiny infant averages 140 to 160 beats/min and is generally considered within normal limits. Tachycardia, with a heart rate >160 beats/min, may be a sign of hypovolemia, pain, inadequate ventilation, anemia, sepsis, or hyperthermia. Low heart rate (<100 beats/min) may be related to hypoxia or medication.

b. Arterial blood pressure. This is most accurately measured via an indwelling arterial catheter and transducer. Cuff pressures are difficult to obtain because of the infant's small size and lower systemic pressures. A recognized standard is to maintain the infant's mean arterial pressure at or equal to the gestational age during the first 48 hours. Thereafter, mean blood pressure increases with chronological age. It is important to evaluate the infant's perfusion, urine output, and acid-base balance in conjunction with blood pressure monitoring.

4. Electrolyte values. Serum electrolyte levels should be monitored at least twice daily or every 8 hours for the most immature infants. Sodium and potassium are added as diuresis begins.

a. Sodium. Initially, tiny infants have a sufficient sodium level (132–138 mEq/L), and if there are no ongoing fluid losses, they will not require additional sodium. Serum sodium level may begin to decrease in the postdiuretic phase (usually third to fifth days of life). Subsequently, sodium chloride should be added to the IV fluids (3–8 mEq/kg/d of sodium). **Hyponatremia in the prediuretic phase usually indicates fluid overload, and hypernatremia during the same period usually indicates dehydration, often due to excessive insensible water loss.** For subsequent monitoring of the serum sodium levels:

i. Hypernatremia: $\text{Na}^+ >150 \text{ mEq/L}$. Differential diagnosis is (a) premature addition of sodium in the pre-diuretic phase, or (b) dehydration, or (c) excessive Na^+ intake.

ii. Hyponatremia: $\text{Na}^+ <130 \text{ mEq/L}$. Differential diagnosis is (a) fluid overload, or (b) inadequate Na^+ intake, or (c) excessive Na^+ loss.

b. Potassium

i. During the first 48 hours after birth. During this time, tiny infants are prone to increased serum potassium levels of $\geq 5 \text{ mEq/L}$ (range,

4.0–8.0 mEq/L). Most clinicians recommend that no potassium be given during the prediuretic phase. The increase is mostly a result of the following:

- (a) Relative hypoaldosteronism
- (b) Shift of intracellular potassium to the extracellular space due to an immature Na^+/K^+ -ATPase pump
- (c) Immature renal tubular function
- (d) Lack of arginine, a precursor to insulin

ii. **$\text{K}^+ > 6$ mEq/L mandates close electrocardiogram (ECG) monitoring of T-wave changes and rhythm disturbances along with electrolyte trends, acid-base status, and urine output.** Acidosis should be aggressively treated because this tends to cause intracellular potassium to leak out. Use of Kayexalate enemas is *controversial* in this age group and best avoided if possible. Albuterol metered-dose inhaler (4 puffs every 2 hours; 1 puff = 90 μg) can reduce high levels. Serum $\text{K}^+ > 7$ mEq/L can also be treated with insulin, sodium bicarbonate, and calcium gluconate (see Chapter 65).

iii. **3–6 days after birth.** Usually by this time, the initially elevated K^+ level begins to decrease. When K^+ levels approach 4 mEq/L, add supplemental K^+ to IV fluids. Begin with 1 to 2 mEq/kg/d. Measure serum K^+ every 6 to 12 hours until the level is stabilized.

IV. **Blood glucose.** ELBW infants should be supported with 4 to 6 mg/kg/min glucose infusion; start with a 5% to 10% dextrose solution, depending on glucose needs. Amino acid used immediately after birth along with glucose solutions achieves better glucose homeostasis. Bedside glucose levels should be monitored frequently until a blood glucose level of 50 to 90 mg/dL has been established. Abnormal values should be confirmed with serum glucose.

A. **Hypoglycemia is < 40 mg/dL for first 48 hours; thereafter < 50 mg/dL.** It may occur because of an inadequate glucose infusion rate or a physiologic lack of glycogen stores. In addition, pathologic states such as sepsis, cold stress, or hyperinsulinemia need to be considered.

B. **Hyperglycemia > 150 mg/dL.** This can cause osmotic glycosuria, resulting in excessive fluid loss. Hyperglycemia may be secondary to increased glucose infusion rate or pathologic causes such as sepsis, necrotizing enterocolitis (NEC), IVH, or a stress response. Determine the underlying etiology and recalculate glucose administration. Treatment with insulin infusion is *controversial*. An alternative is to decrease the glucose infusion rate (GIR); maintaining glucose infusion as low as 3 mg/kg/min has been demonstrated to provide adequate glucose for cerebral metabolism while not affecting proteolysis and protein turnover.

V. **Calcium.** Serum calcium should be monitored daily. Hypocalcemia in preterm infants is a serum calcium < 6 mg/dL. Some institutions also evaluate ionized calcium. In our institution, we provide daily maintenance calcium along with total parenteral nutrition soon after birth (eg, 2 mg of calcium gluconate/mL IV solution). Asymptomatic hypocalcemia is not treated with additional calcium because it resolves with time. Symptomatic hypocalcemia is treated with calcium salts (for dosage, see Chapter 155). This decrease usually happens on the second day of life.

VI. **Nutrition for the metabolically stable infant**

A. **Parenteral nutrition** can be started on admission and continued until the infant is receiving sufficient enteral feeding to promote growth. Along with an adequate GIR of 4 to 6 mg/kg/min, amino acids are started at 2.5 g/kg/d and increased by 0.5 g/kg/d to a maximum of 3.5 to 4 g/kg/d.

B. **Intravenous lipids (20%)** should be started by 24 hours of age; start with 1 to 2 g/kg/d and increase to 3 g/kg/d in 24 hours if triglyceride level is < 200 mg/dL. Septic and thrombocytopenic infants require caution before advancing lipids. A generally acceptable safe triglyceride level is < 200 mg/dL.

- C. **Early feeds of small amounts of breast milk (10–20 mL/kg/d)** can promote gut development, characterized by increased gut growth, villous hypertrophy, digestive enzyme secretion, and enhanced motility. This approach is called **trophic feedings**. The decision to either advance or maintain trophic feedings at a constant level should take into account the clinical status of the infant. Initial swabs of colostrum 0.1 mL to each cheek every 6 hours for the first 3 days, as available, should be considered. Trophic feeds should be started with maternal or donor breast milk. The incidence of infection, NEC, and retinopathy of prematurity is decreased when breast milk is used. Mothers should be provided information regarding the benefits of breast milk and should be encouraged to pump their breasts regularly. Once feedings are established, the breast milk can be fortified with supplements. If breast milk is not available, donor breast milk should be used. Use of probiotics is a consideration but **controversial**.
- D. **Controversy** exists with regard to feeding infants while undergoing pharmacologic treatment for PDA closure and during blood transfusions.

VII. **Respiratory support.** ELBW infants have underdeveloped muscles of ventilation. Many of these infants initially require support by mechanical ventilation; however, others, if vigorous, may be supported with CPAP or noninvasive positive pressure ventilation (NIPPV).

A. **Endotracheal intubation**

1. **Type of endotracheal tube (ETT).** When possible, use an ETT with 1-cm markings on the side. The internal diameter (ID) of the tube should routinely be 2.5 or 3.0 mm, according to body weight:

- a. **<500 to 1000 g.** 2.5 mm ID.
- b. **1000 to 1250 g.** 3.0-mm ID.

2. **ETT placement.** Described in detail in Chapter 33. Confirm proper placement by a chest radiograph study, performed with the infant's head in the midline position, noting the marking at the gum. **Note:** In ELBW infants, the carina tends to be slightly higher than T4. As a means of subsequently checking proper tube position, on every shift, the nurse responsible for the infant should check and record the numbers or letters at the gum line.

B. **Mechanical ventilation.** With the advancement of ventilation technology, various modes are available, including volume ventilation, pressure support, and high-frequency ventilation. Ventilation applied appropriately assists the clinician in avoiding overexpansion of the lung or atelectasis.

1. **Conventional ventilation.** Tiny infants respond to a wide range of ventilator settings. Some do relatively well on 20 to 30 cycles/min; others require 50 to 60 cycles/min with inspiratory times ranging from 0.25 to 0.35 seconds. The goal is to use minimal pressure and tidal volume for optimal expansion of the lung, avoiding volutrauma and atelectasis. Seek to maintain mechanical breath tidal volumes of 4 to 6 mL/kg; this often may be achieved with as little as 8 to 12 cm of inspiratory pressure and 3 to 5 cm of positive end-expiratory pressure. Pressures can be kept to a minimum by allowing permissive hypercapnia (pH 7.25–7.32, PCO₂ 45–60 mm Hg). The following conventional ventilator support guidelines are offered for the initiation of respiratory care. Each tiny infant requires frequent reassessment and revision of settings and parameters. Recommended initial settings for pressure-limited time-cycled ventilators in tiny infants are as follows (see also Chapter 9):

- a. **Rate.** 20 to 60 (usually 30) breaths/min.
- b. **Inspiratory time.** 0.25 to 0.35 seconds.
- c. **Peak inspiratory pressure (PIP).** Select PIP allowing optimal expansion of lungs.
- d. **FiO₂.** As required to maintain O₂ saturation of 88% to 92%.
- e. **Flow rate.** 6 to 8 L/min.

f. Synchronized intermittent mandatory ventilation and volume/pressure control ventilators. These have internal controls that adjust flow delivery.

Current ventilators have incorporated enhancements for pressure support, resulting in increased triggering sensitivity, shortened response times, reduced flow acceleration, and improved breath termination parameters.

- 2. High-frequency ventilation.** Uses small (less than dead space) tidal volumes and extremely rapid rates. The advantage of delivering small tidal volumes is that it can be done at relatively low pressures, reducing the risk of barotrauma. A slight disadvantage is that infant positioning is restricted.

- 3. Nasal CPAP (nCPAP).** Some ELBW infants may not require mechanical ventilation, whereas others may require ventilation for a short period of time for surfactant replacement. nCPAP has become a mainstay of respiratory management in these infants, initiating soon after birth. Infants requiring intubation and mechanical ventilation should be transitioned to nCPAP as clinical condition allows. nCPAP helps maintain lung expansion and improves oxygenation without significant barotrauma. Care should be taken to use nasal prongs appropriately to prevent nasal injuries and septal breakdown. A gel form of normal saline can help keep nasal passages moist and prevent such injuries.

- 4. High-flow nasal cannula.** Nasal flows >1 L using blended gases are used as an alternative to nCPAP in the management of respiratory distress and apnea of prematurity. There are insufficient data to establish its safety and efficacy; thus, caution should be used for this population, and it should be reserved for stable infants. Use has become more *controversial*.

C. Monitoring respiratory status

1. Oxygenation

- a. Blood gas sampling.** Arterial catheterization (see Chapter 27 for percutaneous arterial catheterization or Chapter 28 for umbilical arterial catheterization) should be performed for frequent blood gas sampling. As the infant becomes clinically stable, frequency of laboratory testing should be decreased to minimize blood loss and the need for blood transfusions.

i. Desirable arterial blood gas values in the extremely low birthweight infant:

- (a) PaO_2 , 45 to 60 mm Hg.
- (b) PaCO_2 , 45 to 60 mm Hg.
- (c) pH, 7.25 to 7.32 is acceptable.

- ii. Abnormal blood gas values.** Indicate the need for assessment including ETT placement, chest wall movement, effectiveness of ventilation, ventilator malfunction, assessment for pneumothorax, and need for suction. Actions may include immediate chest radiographs, chest wall transillumination (see Chapters 12 and 44), and repeat blood gas determinations.

- b. Continuous O_2 monitoring.** Should also be performed, preferably by pulse oximetry. To prevent skin breakdown, pulse oximetry sites should be changed every 8 hours and a protective barrier placed under the probe site. The O_2 mixture should be adjusted to maintain the pulse oximeter reading between 88% and 92% hemoglobin O_2 saturation. Excess oxygenation must be avoided in this group of infants. Failure to closely regulate the administration of O_2 can contribute to the development of retinopathy of prematurity and bronchopulmonary dysplasia.

2. Chest radiograph

a. Indications

- i. Abnormal change in blood gas values
- ii. Adjustment of the ETT (to confirm proper positioning)
- iii. Sudden change in the infant's status
- iv. Significant increase in O_2 requirement or frequent desaturations

- VIII. Surfactant.** Some literature supports early administration of surfactant during the first 4 hours of life to decrease chronic lung disease. Recent research supports early CPAP in the delivery room over prophylactic surfactant. Several preparations of surfactant are available; some have the advantage of smaller volume and dosing intervals. It should be administered according to the manufacturer's recommendations. Administration criteria for surfactant include absence of antenatal steroids, increased oxygen demand >30%, and a radiograph consistent with surfactant deficiency (see Figure 12–16).
- IX. PDA.** Incidence of persistent PDA is inversely proportional to gestational age. Infants should be monitored clinically for signs and symptoms of PDA. An echocardiogram is recommended to rule out other structural heart defects and for confirmation of PDA when concerned. Efforts should be made to minimize the risk of PDA. **Overhydration must be avoided.** Up to 30% of PDAs spontaneously close. Currently it is unclear whether a conservative, pharmacologic, or surgical approach is advantageous. If the decision is made to treat a hemodynamically significant PDA, indomethacin or ibuprofen is generally accepted (see Chapter 114). Acetaminophen may also be considered. Renal and gastrointestinal adverse effects are less common with administration of ibuprofen or with slower infusion rates of indomethacin. Indomethacin can also be considered for IVH prophylaxis, especially in high-risk populations, although its safety and benefit remain **controversial**. Concurrent administration of indomethacin and steroids should be avoided because of the associated risk for spontaneous intestinal perforation.
- X. Transfusion.** ELBW infants usually have low red blood cell volume, with a hematocrit <40%, and they are subjected to frequent phlebotomies. Most centers keep the hematocrit between 35% and 40%. Lower values may be acceptable if the infant is asymptomatic. Each institution should have transfusion guidelines established to minimize donor exposure and the number of transfusions.
- XI. Skin care.** Maintenance of intact skin is the tiny infant's most effective barrier against infection, insensible fluid loss, protein loss, and blood loss and provides for more effective body temperature control. Minimal use of tape is recommended because the infant's skin is fragile, and tears often result with removal. **Zinc-based tape** can be used. Alternatives to tape include the use of a **hydrogel adhesive**, which removes easily with water. Hydrogel adhesive products also include electrodes, temperature probe covers, and masks. In addition, the very thin skin of the tiny infant allows absorption of many substances. Skin care must focus on maintaining skin integrity and minimizing exposure to topical agents. Transparent adhesive dressings can be used over areas of bone prominence, such as the knees or elbows, to prevent skin friction breakdown and breakdown under adhesive monitoring devices that are frequently moved. Use of humidity helps maintain skin integrity until skin is mature (2–3 weeks). Humidity can be weaned as tolerated after 2 weeks. **Note: When the skin appears dry, thickened, and no longer shiny or translucent (usually in 10–14 days), these skin care recommendations and procedures may be modified or discontinued.**
- A. Use a hydrogel skin probe, or cut servo-control skin probe covers to the smallest size possible (try a 2-cm diameter circle).** This will help to reduce skin damage resulting from the adhesive.
- B. Monitoring of O₂ therapy is best accomplished by use of a pulse oximeter.** The probe must be placed carefully to prevent pressure sores. The site should be rotated a minimum of every 8 hours. Alternative means of O₂ monitoring include umbilical catheter blood sampling.
- C. Urine bags and blood pressure cuffs.** These **should not be used routinely** because of adhesives and sharp plastic edge cuts. Bladder aspirations should be avoided.
- D. Eye ointment for gonococcal prophylaxis.** Should be applied per routine admission plan. If the eyelids are fused, apply along the lash line.

- E. **Cleansing for required procedures (eg, umbilical artery or chest tube).** Use minimal povidone-iodine solution to cleanse the area. After the procedure is completed, the solution should be sponged off immediately with warm sterile water. The use of chlorhexidine in the ELBW infant is *controversial* and should be used per institution guidelines.
 - F. **Attach ECG electrodes using as little adhesive as possible.** Options include the following:
 - 1. Consider using limb electrodes.
 - 2. Consider water-activated gel electrodes.
 - 3. Use electrodes that have been trimmed down and secured with a flexible dressing material.
 - G. **An initial bath is not necessary,** but if HIV is a consideration, those infants should receive a mild soap bath when the infant's temperature has stabilized. Warm sterile water baths are given only when needed during the next 2 weeks of life.
 - H. **Avoid the use of anything that dries out the skin (eg, soaps and alcohol).** Bonding agents should be avoided.
 - I. **Sterile water-soaked cotton balls.** Helpful for removing adhesive tape, probe covers, and electrode covers.
 - J. **Environmental.** Use of mattress covers or blankets in humidified environments helps prevent skin breakdown.
 - K. **Treatment of skin breakdown**
 - 1. Clean skin breakdown/excoriated area with warm sterile water, leaving open to air.
 - 2. Apply topical antibiotic over broken-down infected areas, leaving open to air.
 - 3. Apply transparent dressings over excoriated areas.
 - 4. Administer IV antibiotics if necessary.
- XII. Other special considerations for the ELBW infant**
- A. **Infection**
 - 1. **Cultures.** If the infant is delivered from an infected environment, blood and cerebrospinal fluid should be cultured. Spinal fluid may be deferred if unstable. Surveillance skin cultures may be necessary on admission if methicillin-resistant *Staphylococcus aureus* strains are a threat.
 - 2. **Antibiotics.** If the infant has a septic risk after obtaining cultures, consider starting empiric **ampicillin** and **gentamicin**. Drug levels must be monitored if using aminoglycosides and the dose adjusted accordingly (see Chapter 155).
 - 3. **Nosocomial infection.** The ELBW infant is at higher risk for nosocomial infection because of immature immune system, poor skin integrity, and extended hospitalization. Hand hygiene is extremely important in the prevention and containment of infection. All caregivers/visitors should be instructed in appropriate hand hygiene. Consider removal of all jewelry, use of short sleeves, no use of lab coats, and no cell phone use in the NICU. Nosocomial infections should be contained by a cohort of infants and the use of dedicated equipment and staff.
 - 4. **Chemoprophylaxis with fluconazole.** ELBW infants in NICUs with moderate (5%–10%) or high (>10%) rates of invasive candidiasis should receive prophylaxis with **fluconazole**. Dosage: Start 48 to 72 hours after birth and give 3 mg/kg IV twice a week for 4 to 6 weeks or until IV access is no longer necessary.
 - B. **Central nervous system hemorrhage.** Cranial ultrasonography may be indicated during the first 7 days for possible intracranial hemorrhage.
 - C. **Hyperbilirubinemia**
 - 1. **Risk.** Efforts should be made to keep the serum bilirubin <10 mg/dL. Serum bilirubin may need to be monitored twice daily. An exchange transfusion should be considered when the bilirubin approaches or exceeds 12 mg/dL (see Chapter 34).

2. **Phototherapy.** To reduce the serum bilirubin level, phototherapy may be needed and can be used to minimize the need for exchange transfusion. Some centers start phototherapy immediately after birth; others when approaching 5 mg/dL. If the infant is treated with phototherapy, reassess fluid needs.
- D. **Pain.** Even the smallest of infants have shown response to painful stimuli. Several multidimensional pain assessment tools are available that include both physiologic (heart rate, O₂ saturation, respiratory rate, and blood pressure) and behavioral indicators (facial expression, vocalization, and motor activity). ELBW pain assessment is very difficult, and none of these tools have been standardized. Our unit uses a pain assessment tool that allows for gestational age adjustment. Pain should be assessed as the fifth vital sign and more often as indicated by pain scores (see Chapter 15).
- E. **Social problems.** Many families have great difficulty in coping with the issues related to their infant's extreme prematurity. Parents should be invited to participate in the infant's care from the beginning. Parent–infant bonding should be promoted, and parents should be encouraged to assist in caring for their child. A social service consultation should be mandatory. Participation in a parent-to-parent support group appears to improve maternal–infant relationships. Experienced nurses and the use of a **primary nurse** together with ongoing communication from the medical team can decrease the parents' stress and keep them up to date on their infant's medical problems. Parent conferences involving the physician, social worker, and primary nurse help the family understand the complex extended care of their infant. Additional discussions may include quality of life, death, dying, withholding and withdrawal of support, and parental religious or spiritual beliefs.
- F. **Developmental issues**
 1. **Minimal stimulation.** These infants do not tolerate handling and medically necessary procedures well. Other stressors include noise, light, and activity such as moving the incubator. Routine tasks should be clustered to allow the infant undisturbed and prolonged periods of rest; each task should have a time limit as well. Consider minimizing hands-on care to every 6 hours, avoiding heel sticks, and limiting ultrasounds/x-rays for the first 3 days of life.
 2. **Positioning.** The fetus is maintained in a flexed position with head midline. Care should be taken to simulate this positioning in the extremely premature infant. For the initial 3 to 7 days, consider keeping the head elevated and midline and body supine, and avoid lifting legs above the head to minimize IVH. A flexed side-lying or prone posture with supportive boundaries is preferred. A change in position is recommended every 4 hours or at the infant's cue after the third day of life. Many positioning aids are available and should be used per institution guidelines.
 3. **Kangaroo care.** This has been defined as “intra-hospital maternal–infant skin-to-skin contact” (see Chapters 15 and 22). It promotes behavioral state organization, increased parental attachment/confidence, and nurturing behaviors that support growth and development. Temperature, heart rate, respiratory rate, and O₂ saturation remain within normal limits during kangaroo care. It can be a safe practice for infants with ETs and central catheters in place if experienced NICU nurses participate closely with cooperative and well-informed parents.
 4. **Environmental issues.** Infants are unable to control their own environment, so efforts must be made to decrease ambient noise to <50 dB and provide cyclic lighting to support their circadian rhythms.
 5. **Parental education.** Family-centered care should be encouraged on admission. Parents should be educated about behavioral cues that invite interaction or signal overstimulation. Parents should be instructed on containment techniques and calming interactions.

14 Management of the Late Preterm Infant

I. Introduction. The most commonly agreed upon definition of a late preterm infant is an infant born between 34 0/7 and 36 6/7 weeks' gestation. Older literature refers to these infants as *near term*, suggesting that they are equivalent to term infants. Approximately 10 years ago, the term *late preterm* was introduced into the medical literature to convey an appropriate sense of these infants' vulnerability and increased risk for both short- and long-term complications. Since 2007, >500 articles about late preterm infants have been published, underscoring the increased risk of morbidity and mortality compared to term infants.

Late preterm births represent approximately 74% of all preterm births. Between 1992 and 2007, the incidence of late preterm births increased from 7.3% to 10.4% of all births. More recently, the rate of late preterm births has decreased to 9.6% in 2014, representing an 8% drop from 2007. This is likely related to an improved understanding of the increased risk of poor neonatal outcomes in this population.

II. Potential etiologies. Improvements in obstetrical surveillance over time may contribute to an increased incidence of medically indicated premature deliveries. Recent recommendations from the American College of Obstetricians and Gynecologists that discourage induction or scheduled repeat cesarean deliveries before 39 weeks, as well as specific guidelines for criteria for elective preterm delivery, likely contributed to the decreased rate of late preterm births seen over the past several years. However, not all late preterm deliveries are preventable, and potential etiologies include the following:

A. Preeclampsia

B. Spontaneous preterm labor and preterm premature rupture of membranes

C. Multifetal gestations

D. Antepartum bleeding

E. Fetal growth restriction

III. Complications of late preterm birth

A. Mortality. A systematic review investigating the outcomes of >2 million late preterm infants found that these infants were 5.9 times more likely to die within the first 28 days of life as compared to term infants. While the absolute number of deaths of late preterm infants is low, the relative risk is high.

B. Respiratory morbidity. A large systematic review showed that late preterm infants are 17.3 times more likely to develop respiratory distress syndrome than term neonates. This is secondary to immature lung architecture, surfactant deficiency, and deprivation of normal hormonal changes occurring at term that promote the clearance of lung fluid. The risk of respiratory distress increases with decreasing gestational age (relative risk [RR] of 10.9 in 36-week infants, 28.6 in 35-week infants, and 48.4 in 34-week infants). Late preterm infants are also 4.9 times more likely to require intubation and mechanical ventilation, 9.8 times more likely to need CPAP, and 24.4 times more likely to require nasal oxygen compared to term infants. In one review, 11% of late preterm infants with respiratory failure developed chronic lung disease and 5% died, emphasizing the serious long-term consequences of respiratory complications in this population.

C. Length of stay. Studies show that late preterm infants have a similar median length of initial hospital stay as term infants but with wider variability. The most common causes of delayed discharge are jaundice and poor feeding. Late preterm delivery triples the cost of the infant's initial hospital stay.

D. Jaundice. Late preterm infants are at increased risk of hyperbilirubinemia secondary to hepatic immaturity as well as difficulty establishing feeding. A large systematic review showed that late preterm infants are 5 times more likely to have prolonged jaundice requiring treatment compared to term infants. Late preterm

infants also may have an increased risk of bilirubin-induced neurologic dysfunction due to immaturity of the blood–brain barrier and decreased bilirubin binding, as evidenced by the 25% of babies in the Kernicterus Registry who were born late preterm. Hyperbilirubinemia is the most common reason for hospital readmission of late preterm infants.

- E. Poor feeding.** Late preterm infants are 6.5 times more likely to have feeding difficulties as compared to term infants. Many late preterm infants with poor feeding require a prolonged initial hospitalization and may require gavage feeds. Suck-swallow coordination and intestinal motility remain immature, which impacts their feeding ability. Late preterm infants may also lack the feeding skills to latch properly and the stamina to take sufficient volumes of breastmilk, resulting in delayed milk production and increased risk of lactation failure. At times, spoon feeding or formula supplementation may be necessary. Breast-feeding protocols for this population that are evidence based have been developed by the California Perinatal Quality Care Collaborative (<https://www.cpqcc.org/content/care-and-management-late-preterm-infant-0>) and the Academy of Breastfeeding Medicine (<https://www.bfmed.org/protocols>). Problems with adequacy of breast feeding may persist until these babies reach term equivalent age. Even babies being formula fed may require a nutrient-enriched approach in order to ensure adequate caloric intake.
- F. Temperature instability.** Hypothermia is 10.8 times more common in late preterm infants compared to term infants due to an immature epidermal barrier, higher surface area–to–body weight ratios, decreased amount of brown adipose tissue, and more frequent delivery room interventions.
- G. Hypoglycemia.** Late preterm infants are 7.4 times more likely to experience hypoglycemia compared to term infants. This is secondary to delay in the activity of hepatic glucose phosphate, which is needed in the final step of gluconeogenesis. Hypoglycemia in late preterm infants is further exacerbated by poor feeding, decreased body weight, and low glycogen stores at birth.
- H. Infectious morbidity.** According to a large systematic review, late preterm infants have an increased risk of culture-proven sepsis (RR, 5.6), pneumonia (RR, 3.5), meningitis (RR, 21), and necrotizing enterocolitis (RR, 7.5) compared to term infants.
- I. Sudden infant death syndrome (SIDS) and apnea.** Immaturity of the autonomic nervous system in late preterm infants increases the risk of apnea and bradycardia of prematurity. Infants born between 33 and 36 weeks are twice as likely to die from SIDS as those born ≥ 37 weeks.
- J. Readmission.** Late preterm infants are almost twice as likely to require readmission after initial hospital discharge. Several studies have demonstrated that early follow-up visits after hospital discharge or home nursing visits were effective at reducing rates of readmission.
- K. Respiratory syncytial virus (RSV) infection.** Late preterm infants have an increased susceptibility to RSV infection due to incomplete lung development, immature immune function, and the relative lack of passively acquired maternal antibodies. The risk of RSV bronchiolitis in infants born between 32 and 36 weeks is similar to those born before 32 weeks. The risk of hospitalization due to RSV infection is twice as high in late preterm infants compared to term infants. According to current American Academy of Pediatrics (AAP) guidelines, late preterm infants do not qualify for palivizumab prophylaxis unless they have additional risk factors such as hemodynamically significant congenital heart disease. Precautions such as decreased contact with sick individuals and good hand hygiene by those handling these infants may be effective risk reduction strategies.
- L. Long-term outcomes.** Multiple studies have shown that late preterm infants are at increased risk for long-term adverse neurodevelopmental and psychosocial outcomes. A systematic review showed that late preterm infants are 3 times more likely to develop cerebral palsy and 1.5 times more likely to develop mental retardation compared to term infants. Late preterm infants are also more likely to have poor

school performance, a learning disability, or attention deficit hyperactivity disorder and have a lower likelihood of completing high school. Late preterm infants have increased healthcare utilization during the first year of life and are more likely to have special healthcare needs or a chronic medical condition as compared to term infants.

IV. Recommendations for management. Iatrogenic prematurity should be prevented by prolonging pregnancy whenever medically feasible. Specific guidelines from the American College of Obstetricians and Gynecologists regarding indications for preterm delivery can help prevent unnecessary late preterm births. There is recent evidence to suggest that antenatal betamethasone administered to women at risk for late preterm delivery may decrease short-term respiratory morbidities in this population. Additional evidence is necessary before this intervention can be recommended for all women with threatened late preterm delivery due to the unknown long-term risks of fetal exposure to corticosteroids, a large number needed to treat to prevent a negative outcome, and a higher rate of neonatal hypoglycemia in the steroid-treated group.

Because late preterm infants are at risk for neonatal complications, as discussed earlier, specific management strategies should be developed for both their initial management after birth as well as their care after discharge home. Early monitoring of respiratory status, temperature, feeding ability, and bilirubin and glucose levels is critical. The AAP has published guidelines for screening and management of hypoglycemia in the late preterm infant. The AAP has also provided specific recommendations for discharge criteria for late preterm infants. In addition to fulfilling discharge criteria for term infants, the late preterm infant requires:

A. Accurate gestational age assessment

B. Absence of medical condition requiring further hospitalization (ie, hyperbilirubinemia, respiratory distress).

C. Demonstration of physiologic stability

1. **Maintaining normal cardiorespiratory control** with stable vital signs for at least 12 hours prior to discharge.
2. **Maintaining thermoregulation** with axillary temperature of 36.5°C to 37.4°C (97.7–99.3°F) in an open crib.
3. **At least 24 hours of successful feeding** in the absence of excessive weight loss.
4. **Formalized evaluation of breast feeding** when applicable.
5. **Passing at least 1 stool spontaneously.**
6. **Successful completion of a car seat safety study** to observe for apnea, bradycardia, and oxygen desaturation.

D. Screening for hyperbilirubinemia with arrangement of appropriate follow-up

E. Assessment of family and home environment risk factors

F. Individualized timing of discharge based on the infant's condition

G. Follow-up visit with an identified primary care provider 24 to 48 hours after discharge

In summary, late preterm infants represent a unique patient population with increased risk for both short- and long-term adverse health outcomes. Close monitoring of health status after birth as well as specialized management strategies in the first several days to weeks of life are needed to ensure optimal outcomes for these vulnerable infants.

V. Late and moderately preterm (LMPT) infants. There is emerging literature investigating the differences in long-term outcomes of infants born late and moderately preterm (32 0/7–36 6/7 weeks' gestation) compared to both infants born at term as well as infants born very preterm (<32 weeks' gestation). Risk of adverse neurodevelopmental outcomes is well documented in the very preterm population, but the risk for LMPT infants is just beginning to be understood. One study showed that LMPT infants were 3.6 times more likely to have a positive Modified Checklist for Autism in Toddlers (M-CHAT) autism screen compared to term infants. Another study demonstrated that LMPT infants are more likely than term infants to have oral motor problems and picky eating, particularly in those LMPT infants requiring prolonged nasogastric feedings or with behavioral

problems. A recent survey of parents in the United Kingdom whose children were 6, 12, and 24 months old found that parents with LMPT children were more likely to report overall poorer health, increased minor respiratory symptoms and need for prescribed inhalers, increased incidence of mild neurosensory impairment, increased frequency of cognitive difficulties, and increased incidence of socioemotional developmental delay compared to parents of children born at term. The pattern of abnormal development and cognitive impairment seen in children born LMPT appears to be milder and of unclear clinical significance compared to that observed in children born very preterm. These recent studies indicate that close monitoring of the long-term health and neurodevelopmental progress of former LMPT infants is imperative, and continued research may lead to better long-term outcomes in this population.

15 Pain in the Neonate

Before the 1980s, it was a common belief that preterm infants lacked the neurodevelopmental capacity to feel pain. This resulted in severe undertreatment of pain in the neonate during hospitalization. It is now known that infants have the required neuroanatomical connections to feel pain, and actually experience a higher degree of sensitivity to pain as compared to children and adults. Neonates are subject to many painful procedures, especially the most immature infant. Although neonatology has made strides in the past 20 years to understand pain, it remains a challenge to effectively assess and treat the various types of pain experienced in the neonatal intensive care unit (NICU). A recent study revealed that there is a worldwide trend of undertreatment of neonatal pain and that more attention should be given to pain prevention, assessment, and treatment. Countries with nationally accepted guidelines for pain management (such as France, Sweden, and the Netherlands) do a better job in treating neonatal pain than those countries without guidelines. The American Academy of Pediatrics (AAP) recently updated the recommendations for managing procedural pain in neonates. These recommendations include the following:

1. Every institution caring for neonates should implement a pain prevention program that includes written guidelines for a stepwise pain prevention and a treatment plan.
2. Validated neonatal pain assessment tools should be used consistently before, during, and after painful procedures.
3. Nonpharmacologic strategies decrease pain scores during short-term mild to moderately painful procedures and should be used. These include facilitated tucking, breast feeding or providing expressed human milk, nonnutritive sucking, sensorial stimulation, and others.
4. Oral sucrose/glucose solutions are effective with mild to moderately painful procedures, either alone or combined with other pain-relief strategies. If used, these solutions need to be tracked as medications.
5. Healthcare providers need to weigh actual benefits and burdens when using pharmacologic treatment methods. It is important to remember that some of the medications can potentiate the hypotension and respiratory depression that can occur with opioid use. Use caution when using newer medications that do not have data in neonates.
6. All providers should receive continuing education on the recognition, assessment, and management of pain.
7. More research needs to be done in this area.

Some have suggested that pain assessment should be considered the fifth vital sign, so with each vital sign determination, pain assessment should be done and recorded.

I. Physiology of pain in the neonate

- A. Definition.** Pain has been defined by the International Association for the Study of Pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in such terms of such damage.” An infant’s response to pain involves a collection of biochemical, physiologic, and behavioral reactions. There are many different layers of an infant’s response that can be understood by gestational age and development. Noxious stimuli lead to tissue damage, causing the release of sensitizing substances such as prostaglandins, bradykinin, serotonin, substance P, and histamine. These chemicals produce an impulse that is then transmitted to the nociceptive pathways. Nociception refers to the reflex movement occurring with exposure to noxious stimuli that does not require cortical involvement or the ability to perceive pain.
- B. Developmental considerations.** Development of sensory nerve endings begins very early in the process of nociception. Cutaneous sensory receptors and spinal reflexes that respond to noxious stimuli develop as early as 7.5 and 8 weeks, respectively. Conscious perception of pain can be felt as early as 25 weeks’ gestation.
- C. Repeated exposure to noxious stimuli.** This can cause physiologic and behavioral disorganization, leading to changes in the neurodevelopmental system of the infant and may change the pain pathway system. This may cause the infant to develop an inability to respond to pain or an exaggerated physiologic response to painful stimuli in the future.

II. Types of pain in the neonate

- A. Birth trauma.** Neonatal pain associated with birth trauma is typically a result of vacuum-assisted births. Some babies may show signs of bruising on the face or head simply as a result of the trauma of passing through the birth canal. Forceps deliveries can leave temporary marks or bruises on the baby’s face and head. Cephalohematomas are more common with forceps delivery or vacuum extraction. Acetaminophen may be used for the treatment of associated pain. Clavicular fractures are the most common birth-related fracture. If the fracture is painful, limiting movement of the arm or shoulder may be helpful.
- B. Acute procedural pain.** The frequency of painful procedures in the NICU can range from 5 to 15 per day. The most optimal method of pain control is to minimize the amount of painful procedures. Painful procedures performed in the NICU include endotracheal tube (ETT) suctioning, intubation, mechanical ventilation, chest tube insertion, retinopathy of prematurity (ROP) examinations, central line placement, intravenous (IV) placement, heel sticks, lumbar puncture, circumcision, patent ductus arteriosus (PDA) ligation, and peritoneal drain placement. (See each procedure chapter for specific recommendations for pain management.)
- C. Acute postoperative pain.** Postsurgical pain remains an issue in the NICU. The largest risk with postsurgical pain is undertreating. Postoperative pain protocols help standardize practice between healthcare professionals. Routine pain assessment should be performed using scales specific to postoperative or prolonged pain. It is important to alternate pain medications for maximum pain control with minimal toxicity. Opioids are the medications of choice and can be given by continuous infusion or bolus.
- D. Chronic pain.** Chronic pain remains to be well defined within neonatology. Some view chronic pain as the extension of uncontrolled acute pain. Pain assessment tools should include validated measurement for chronic pain. Research needs to continue in this critical area of study.

- III. Assessment of pain in the neonate.** One of the most challenging aspects of neonatal pain is recognition of the signs, of which people are becoming more aware. Careful assessment is critical when evaluating preterm infants for signs of pain. Assessment must include physiologic as well as behavioral changes since the infant is unable to report his or her own pain.

- A. **Common signs of pain in the neonate.** Commonly assessed signs of pain include increased heart rate, changes in respiratory rate, and fluctuations in blood pressure, as well as changes in facial expression such as brow bulge, eyes squeezed shut, nasolabial furrow, crying, palmar sweating, and increased movement.
 - B. **Physiologic changes due to pain.** These include increased oxygen consumption, ventilation-perfusion mismatch, increased gastric acidity, and disturbance of sleep-wake cycle. Infants experiencing prolonged pain may exhibit decreased heart rate, decreased respiratory rate, decreased oxygen consumption, lethargy, decreased perfusion, and cool extremities.
 - C. **Metabolic and hormonal changes related to pain.** Reported studies include increased plasma renin (after venipuncture in term infants); increased plasma epinephrine and norepinephrine (after chest physiotherapy (PT) and ETT suctioning in preterm infants); increased plasma cortisol levels (after circumcision without anesthesia); release of growth hormone, glucagon, cortisol, and aldosterone; and decreased insulin secretion (preterm and term infants undergoing surgery with minimal anesthesia).
 - D. **Perception of pain.** Compared to adults, the neonatal stress responses are 3 to 5 times greater. Functional magnetic resonance imaging (MRI) and near-infrared spectroscopy studies have shown that babies respond to weaker stimuli than adults. Preterm neonates are more sensitive to pain, showing increased excitability to sensory pathways and delayed maturation of descending inhibitory pathways and the endogenous opioid system.
 - E. **Pain versus discomfort.** Differentiating between infant pain and discomfort can be challenging for healthcare professionals. Premature infants can exhibit minimal response to pain, especially if they are septic or physiologically stressed. Older infants who have experienced multiple incidents or prolonged pain may over- or underreact to pain. Lack of pain response can also be observed in infants with neurologic impairment or those who have been chemically paralyzed.
 - F. **Pain assessment scales.** There are many pain scales that exist in neonatology. They can be broadly divided into the type of pain they are assessing (acute, prolonged, or postoperative) and by whether they are used for term or preterm infants. There is not one single pain assessment scale that can be applied to all infants. Early neonatal pain scales were designed for healthy babies. Newer scales have been designed for sick infants in the NICU setting. Gestational age and behavioral state have been added to some assessment tools as they may play a major role in pain assessment. The 4 most commonly used pain scales are the **Premature Infant Pain Profile-Revised (PIPP-R)**, **CRIBS Neonatal Pain Assessment Tool**, **Neonatal Infant Pain Scale (NIPS)**, and **Neonatal Pain, Agitation, and Sedation Scale (N-PASS)**. There are only 5 scales out of all the pain scales that have undergone rigorous psychometric testing and these include the **Neonatal Facial Coding System**, **Premature Infant Pain Profile**, **Neonatal Pain and Sedation Scale**, **Behavioral Infant Pain Profile**, and **Douleur Aiguë du Nouveau-né**. These and the other commonly used pain scales are compared in Table 15-1.
- IV. **Short- and long-term effects of pain. Pain can worsen hypoxia, acidosis, hypercarbia, respiratory distress, and hyperglycemia.** Untreated pain in the neonate can cause increased catabolism and hypermetabolism. This can also increase susceptibility to infection and increase morbidity and suboptimal outcomes. Eventually, untreated neonatal pain can lead to altered pain sensitivity (either an inability to respond to pain or an exaggerated physiologic response to pain) with permanent neuroanatomic and behavior outcomes. Long-term effects include emotional and behavioral abnormalities, along with learning disabilities. Studies have shown hyperalgesic responses and reduction in pain thresholds, increased incidence of intraventricular hemorrhage and periventricular leukomalacia, and increased somatization.
- V. **Pain intervention.** Pain management for neonates is ideally approached from multiple levels as described from a foundation of simply avoiding painful procedures to a top tier

Table 15–1. COMPARISON OF COMMONLY USED PAIN SCALES

Pain Scale	Facial Expression	Cry	Extremities	Vocal Expression	Oxygen Saturation	Vital Signs	Behavioral State	Term Infants	Preterm Infants	Type of Pain
PIPP-R	X				X	X	X	X	X	Acute
CRIES		X		X	X	X	X	X	X	Prolonged postop
NIPS	X	X	X		X	X	X	X	X	Acute postop
N-PASS	X	X	X		X	X	X	X	X	Acute prolonged level of sedation Postop, ventilated
NFCS	X								X	Acute prolonged postop
COMFORTtheo	X	X	X			X	X	X	X	Persistent prolonged, developed for sedation, level of sedation Postoperative pain
EDIN	X		X				X		X	Prolonged
DAN	X		X	X			X	X	X	Procedural
BPSN	X	X				X	X	X	X	Acute
BIIP	X		X				X		X	Acute
FANS			X	X	X	X			X	Acute
COVERS	X	X	X		X	X	X	X	X	Acute

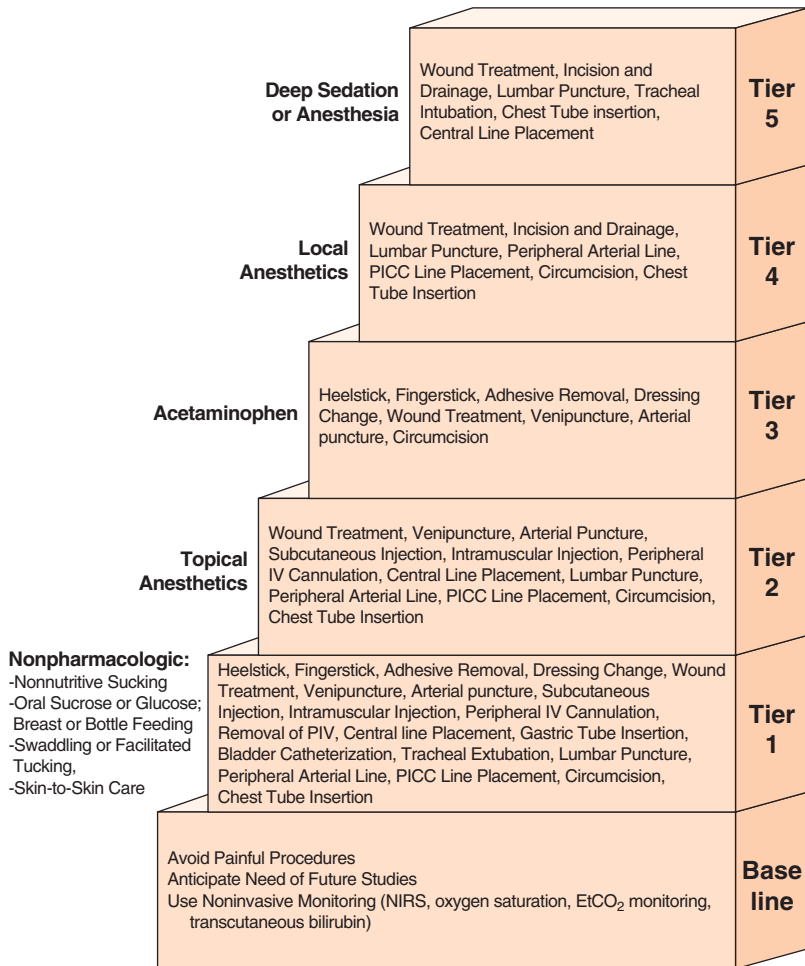

FIGURE 15–1. Tiered approach to analgesia in the neonate. EtCO₂, end-tidal carbon dioxide; NIRS, near-infrared spectroscopy; IV, intravenous; PICC, percutaneous inserted central catheter; PIV, peripheral intravenous line. (Reproduced with permission from Witt N, Coynor S, Edwards C: *A Guide to Pain Assessment and Management in the Neonate*, Curr Emerg Hosp Med Rep. 2016;4:1-10.)

of providing deep sedation or anesthesia. There are multiple recommendations for pain relief in the neonate. Witt and colleagues (Figure 15–1) proposed a “tiered” approach to analgesia in the neonate. Hall and Anand have provided guidance on specific procedures summarized in Table 15–2.

A. Nonpharmacologic. This approach is preferable for mild procedural pain due to the short-term efficacy and absence of side effects. It is most effective when combined with a reduction in lighting and sound. It is not to be used in place of pharmacologic therapy with severe and chronic pain. Cochrane review indicates the following: “There is evidence that different nonpharmacological interventions can be used

Table 15–2. COMMON PROCEDURES AND PAIN RELIEF RECOMMENDATIONS

Procedures	Proposed Pain Management	Notes
Arterial or venous cutdown	Nonpharmacologic interventions ^a and topical local anesthetic, lidocaine infiltration, intravenous (IV) fentanyl (1–2 mcg/kg), consider deep sedation	
Arterial puncture	Nonpharmacologic interventions, ^a use topical and subcutaneous local anesthetics	More painful than venipuncture
Central line	Nonpharmacologic interventions, ^a topical local anesthetics, consider low-dose opioids or deep sedation if needed	
Chest physiotherapy	Gentle positioning, fentanyl (1 mcg/kg) if a chest tube is present	Avoid areas of injured or inflamed skin and areas with indwelling drains or catheters
Circumcision	Nonpharmacologic interventions ^a and topical local anesthetic, lidocaine infiltration, IV/oral (PO) acetaminophen before and after procedure	Lidocaine infiltration for distal, ring, or dorsal penile nerve blocks (DPNB); liposomal lidocaine is more effective than DPNB; <i>never use with epinephrine</i>
Dressing change	Nonpharmacologic interventions ^a and topical local anesthetic, consider deep sedation if extensive	
Extracorporeal membrane oxygenation cannulation	Propofol 2–4 mg/kg, ketamine 1–2 mg/kg, fentanyl 1–3 mcg/kg, muscle relaxant as needed	
Endotracheal intubation	Give fentanyl (1 mcg/kg) or morphine (10–30 mcg/kg), with midazolam (50–100 mcg/kg) or ketamine (1 mg/kg), use muscle relaxant only if experienced clinician, consider atropine	Superiority of one drug regimen over another has not been investigated
Gastric tube insertion	Nonpharmacologic interventions, ^a consider local anesthetic gel	Perform rapidly, use lubricant, avoid injury
Heel stick	Use nonpharmacologic interventions ^a and automated lance; squeezing the heel is the most painful phase	Venipuncture is more efficient, less painful; local anesthetics, acetaminophen, heel warming will not reduce heel stick pain
Intramuscular injection	Avoid if possible, use nonpharmacologic interventions ^a and topical local anesthetics if procedure cannot be avoided	

(Continued)

Table 15–2. COMMON PROCEDURES AND PAIN RELIEF RECOMMENDATIONS (CONTINUED)

Procedures	Proposed Pain Management	Notes
Lumbar puncture	Nonpharmacologic interventions ^a and topical local anesthetic, lidocaine infiltration, careful positioning	Use IV analgesia/sedation, if patient is intubated and ventilated
Peripheral arterial line	Nonpharmacologic interventions ^a and topical local anesthetic, lidocaine infiltration, consider IV opioids	
Peripheral IV catheterization	Nonpharmacologic interventions, ^a topical local anesthetics	
Peripherally inserted central catheter	Nonpharmacologic interventions ^a and topical local anesthetic, lidocaine infiltration, consider IV fentanyl (1 mcg/kg) or IV ketamine (1 mg/kg)	Some centers prefer using deep sedation or general anesthesia
Subcutaneous injection	Avoid if possible, use nonpharmacologic interventions ^a and topical local anesthetics if procedure cannot be avoided	
Suprapubic bladder aspiration	Nonpharmacologic interventions and topical local anesthetic, lidocaine infiltration, consider IV fentanyl (0.5–1 mcg/kg)	
Tracheal extubation	Solvent swab for tape, consider nonpharmacologic interventions	
Umbilical vein catheterization	Nonpharmacologic interventions, ^a IV acetaminophen (10 mg/kg), avoid sutures to the skin	Cord tissue is not innervated; skin injury
Venipuncture	Nonpharmacologic interventions, ^a use topical local anesthetics	Less time, less repeat sampling, and less painful than heel stick

^aNonpharmacologic interventions include pacifier, oral sucrose, swaddling, and skin-to-skin contact with mother.

Adapted with permission from Hall RW, Anand KJ: Pain management in newborns, *Clin Perinatol*. 2014 Dec;41(4):895-924.

with preterms and neonates to significantly manage pain behaviors associated with acutely painful procedures.”

- 1. Kangaroo care or skin-to-skin care.** Kangaroo mother care is a method of skin-to-skin care whereby the mother, father, or caregiver holds the infant upright, flexed, and prone wearing only a diaper next to the caregiver’s chest (similar to how kangaroo mothers carry their young in their pouch) (Figure 15–2). Research supports its use to decrease the pain response in both preterm and term infants. It is effective for use in decreasing pain (reduced grimacing, reduced heart rate, improved pain scores, decreased stress and crying time) with heel sticks. A Cochrane review (2017) indicates that kangaroo care appears

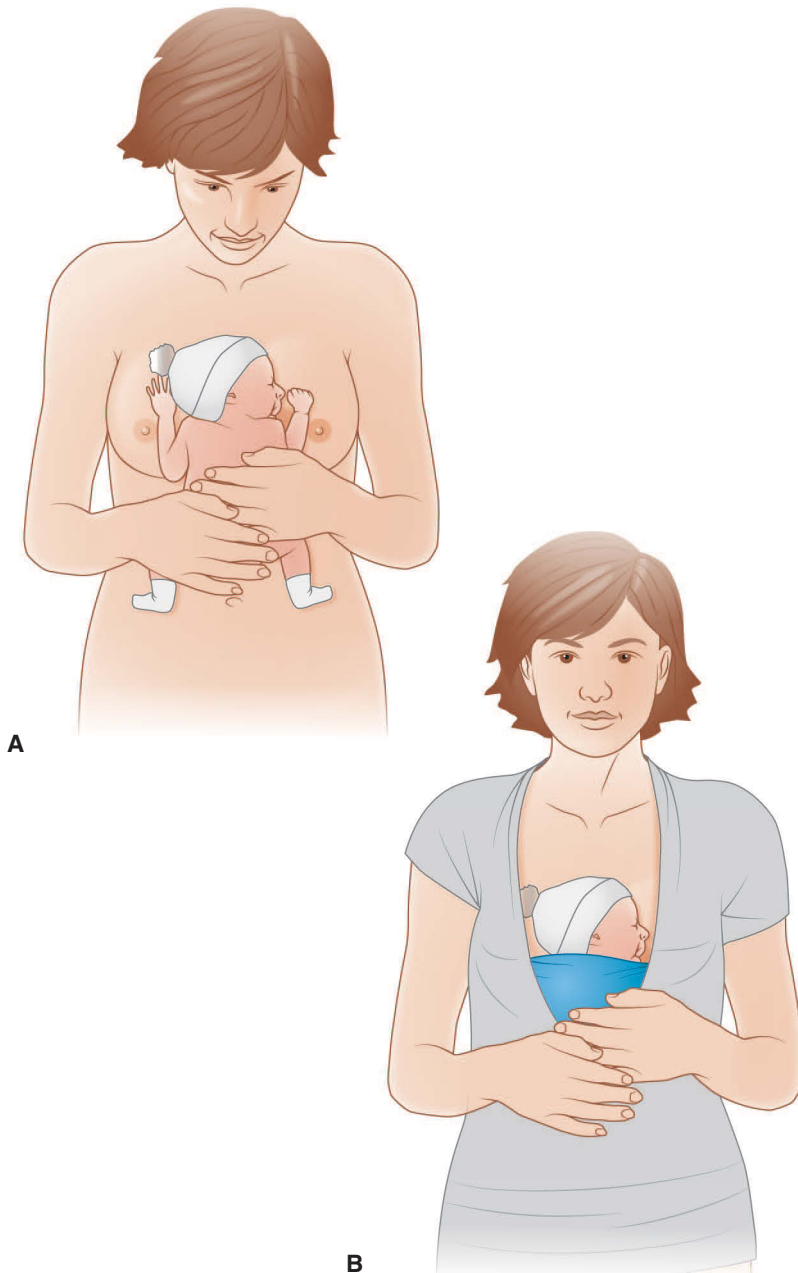

FIGURE 15-2. (A) Positioning the baby for kangaroo care. (B) Baby in Kangaroo care binder position. (Reproduced with permission from *Kangaroo Mother Care: A Practical Guide*. World Health Organization, Dept. of Reproductive Health and Research, Geneva Switzerland. [http://www.who.int/maternal_child_adolescent/documents/9241590351/en. Accessed January 31, 2019.])

to be safe and to reduce the pain response to and improve recovery from a single painful procedure (eg, heel stick, venous puncture, intramuscular injections, tape removal).

2. **Breast feeding and breast milk.** These can be used to alleviate procedural pain in neonates undergoing a single painful procedure or ROP examination. Cochrane review states that breast feeding or breast milk should be used to alleviate procedural pain in neonates undergoing a single painful procedure rather than placebo, positioning, or no intervention. Giving glucose/sucrose had similar effectiveness as breast feeding. Supplemental human milk (via a syringe or pacifier) is just as effective as giving sucrose or glucose for treating pain in term infants.
3. **Nonnutritive suck (NNS).** The type of suck associated with a pacifier without breast milk or formula. It seems to increase endogenous endorphins. When used in combination with oral sucrose (24%), it is effective in reducing the pain associated with heel sticks and peripheral IV catheter (PIV) placement. Cochrane review supports that NNS can be used to decrease pain immediately after a procedure and pain 30 seconds after a procedure in preterm and term infants (with low-quality evidence).
4. **Swaddling.** This involves wrapping an infant securely in a blanket. The arms are immobilized to prevent the Moro reflex. Swaddling can cause a decrease in heart rate, an increase in oxygen saturation, and an increase in ability to organize behaviors. It is good to use with heel sticks, PIV starts, ROP examinations, and ETT suctioning. It can also be recommended as a complementary therapy during painful procedures. A Cochrane review states that swaddling in a preterm infant can reduce both pain immediately after a procedure and 30 seconds after; in a neonate, swaddling can reduce pain immediately after a procedure (low-quality evidence).
5. **Facilitated tuck position.** This position brings the body to the middle and is achieved by holding the infant's arms flexed and close to the trunk and legs gently in a flexed position close to the midline of the torso and can be done in the supine, lateral, or prone position. The caregiver uses his or her hands on both the head and lower limbs to maintain the position. It is effective with PIV starts, heel sticks, ROP examinations, and ETT suctioning in decreasing heart rate and recovery time. A Cochrane review states that facilitated tucking in a preterm infant can reduce pain both immediately and 30 seconds after a procedure. In a neonate, facilitated tucking can reduce pain immediately after a procedure.
6. **Positioning.** A prone position can improve breathing effort and decrease the infant's oxygen requirement.
7. **Music.** Music is effective in infants >31 weeks' gestation. It assists with the regulation and reduction of heart rate as well as increase in oxygen saturation. In mature stable infants, music with sucrose was better than music or sucrose alone for heel stick.
8. **Massage.** Massage therapy involves skin manipulation of the soft tissue that includes brushing of the skin, light compression, and gliding and kneading strokes. It enhances vagal activity and modulates insulin and insulin-like growth factor-1. It also decreases cortisol and epinephrine levels. It has been shown to decrease NIPS scores, increase weight gain, and improve neurodevelopmental outcomes in very low birthweight infants. Some small studies suggest that massage therapy had positive effects on the immune system, decreased stress behavior, improved tolerance to pain, improved developmental scores, and resulted in earlier discharge of infants. A Cochrane review states that touch or massage is effective for decreasing pain immediately after a painful procedure in a preterm infant (low-quality evidence).
9. **Acupuncture.** Acupuncture works by stimulating the endorphin system via mechanical or electrical means at acupuncture points, but data are limited in

neonates. A pilot study using magnetic noninvasive acupuncture showed that auricular noninvasive magnetic acupuncture is feasible in neonates and may decrease PIPP-R scores when performing heel sticks.

10. **Applied mechanical vibration.** Infants had lower pain scores and more stable heart rates during heel stick and 2 minutes after heel lance in a pilot randomized controlled trial.
 11. **Sensorial stimulation (SS).** SS gently stimulates the tactile, gustatory, auditory, and visual systems. It has been shown to decrease pain during minor procedures. SS includes looking at and gently talking to the neonate, while simultaneously stroking or massaging the face or back as well as administering an oral sucrose or glucose solution prior to a procedure. Using all elements of SS was found to be more effective than sucrose alone in a review of multiple studies.
 12. **Familiar odor.** Maternal milk odor has been found to have an analgesic effect on preterm neonates. A Cochrane review indicates that a familiar odor was found to decrease pain during the regulatory phase after needle stick in neonates.
 13. **Rocking/holding.** This has not been found to decrease pain after a painful procedure, but helps an infant recover from painful stimuli. Sucking related and rocking/holding were beneficial for term infants during heel lance and IV catheter insertion.
- B. Pharmacologic treatment.** Most often, light pain and moderate pain of short duration are best dealt with using nonpharmacologic pain measures. However, when pain assessment scores indicate moderate to severe pain, pairing pharmacologic pain measures with comfort measures is strongly suggested. Procedures that require the use of pharmacologic pain intervention include nonemergency intubations, mechanical ventilation (with the selective use of opioids), chest tube insertion, central line placement, lumbar puncture, circumcision, PDA ligation, and placement of peritoneal drains and ROP examinations. The most common pharmacologic medication used in newborns with persistent pain is opioids, specifically morphine and fentanyl.
1. **Sucrose.** Oral sucrose is an effective and safe analgesic for decreasing procedural pain from a single event in infants from 25 to 44 weeks' gestational age. The mechanism of action is unknown in neonates, but it is believed the sweet taste may activate the opiate, endorphin, dopamine, or adrenocorticotrophic hormone pathway, as it does in animal studies. When combined with NNS, it is shown to be very efficacious with heel sticks. Facilities should adopt a specific protocol to standardize the use of oral sucrose. The optimal dose is not known, but the range is 0.012 to 0.12 g or 0.05 to 0.5 mL of a 24% solution. Recommended dosage is 0.1 to 1 mL (0.2 to 0.5 mL/kg) of 24% sucrose 2 minutes before the procedure. It lasts approximately 4 minutes. Sucrose is effective in infants >27 weeks' gestation; however, it is not approved by the US Food and Drug Administration. Infants who received sucrose were shown to have decreased behavioral pain scores, but there was no difference in their electroencephalograms. Caution should be taken when administering multiple doses of sucrose (worse neurodevelopmental scores in preterm infants getting >10 doses over 24 hours), and administration should be limited to the management of acute procedural pain. It is best if sucrose is treated as a medication, whereby doses are recorded and tracked. A Cochrane review (2016) concluded that sucrose is effective for reducing procedural pain from single events such as heel lance, venipuncture, and intramuscular injection in both preterm and term infants. Optimal dose could not be identified. It was not effective for circumcision, and the effects were inconclusive for arterial puncture, subcutaneous injection, insertion of nasogastric or orogastric tubes, bladder catheterization, eye examinations, and echocardiography exams.
 2. **Glucose.** Can be used as an alternative to sucrose. It was found that 20% to 30% glucose solutions decreased pain scores and crying times during

venipuncture and heel sticks. There is no recommendation for dose or timing of administration.

3. **Commonly used pain relief medications in neonates are as follows** (see Chapter 155 for specific dosing information):
 - a. **Topical anesthetic agents.** Topical anesthetics include EMLA (eutectic mixture of 2.5% lidocaine and 2.5% prilocaine) cream (most commonly used and studied), 4% tetracaine gel, 4% liposomal lidocaine (shorter onset of action), and S-Caine Peel (7% lidocaine and 7% tetracaine cream). These topical agents decrease pain during venipuncture, percutaneous central venous catheter insertion, and peripheral arterial puncture. EMLA does not work for heel sticks but may work for lumbar punctures when combined with oral sucrose/glucose. Topical agents can cause methemoglobinemia, transient skin rashes, and toxicity in premature infants. A Cochrane review states the following: “The evidence regarding the effectiveness or safety of topical anesthesia for needle-related pain in preterm and term newborns is inadequate to support clinical recommendations.”
 - b. **Subcutaneous infiltration with lidocaine (0.5–1% lidocaine).** Lidocaine blocks voltage-dependent sodium channels, which blocks low- and high-threshold axons that contribute to painful sensations. It has been used for penile blocks for circumcision (ring block) and for certain skin-breaking procedures (lumbar punctures, chest tube insertion). Buffered lidocaine (lidocaine is acidic and by adding 8.4% sodium bicarbonate solution it decreases the acidity and thereby decreases the pain) can be used.
 - c. **Systemic medications for pain in the neonate** are recommended for most invasive procedures. The AAP states that they are recommended for procedures such as circumcision, chest tube insertion and removal, and nonemergency intubations. Pain relief for mechanical ventilation is controversial. The AAP does not routinely recommend routine opioids for all mechanically ventilated infants and a Cochrane review states that opioids should be used selectively in term and preterm infants on mechanical ventilation.
 - i. **Medications that provide systemic analgesia include the following:**
 - (a) **Opioids.** Opioids are the most common pharmacologic agent used for pain relief in newborns. These provide potent pain relief but are associated with respiratory depression. Careful monitoring is recommended.
 - (i) **Morphine sulfate is the most commonly used opioid in neonates.** Side effects include respiratory and CNS depression, arterial hypotension, urinary retention, tolerance, dependence, and constipation.
 - (ii) **Fentanyl** is also commonly used and is faster acting than morphine. It has less hypotension, less sedation, and decreased effects on gastrointestinal motility and urinary retention when compared to morphine. It causes chest wall rigidity, and tolerance occurs more rapidly than with morphine. It is the most effective option for ROP exams and intubation.
 - (iii) **Alfentanil, sufentanil, and remifentanil** are short-acting medications and are being used for shorter procedures. Remifentanil may be preferred since it is not metabolized by the liver, but there are no studies on long-term use.
 - (b) **Acetaminophen** is known for its analgesic effects. It is typically used for mild or moderate pain relief. It has commonly been used for post-operative pain control. IV formulation (Ofirmev) has been approved by the US Food and Drug Administration (FDA) and has decreased the amount of opioids needed after surgery.

- (c) **Nonsteroidal anti-inflammatory drugs (NSAIDs)**. These have commonly been used for closure of the PDA in infants. The use of NSAIDs for pain control in newborns has not been recommended because of too many side effects (pulmonary hypertension and renal insufficiency and platelet dysfunction).
- (d) **Medications that have been suggested and used but not well studied in neonates** include the following:
- (i) **Methadone** has satisfactory analgesic effects, but dosing recommendations have not been developed.
 - (ii) **Propofol** is a nonbarbiturate anesthetic used for short-term procedural sedation and anesthesia. Side effects in neonates include prolonged hypotension, bradycardia, desaturations and significant variability in pharmacokinetics.
 - (iii) **Gabapentin** has been used for refractory pain and agitation and was associated with decreases in pain scores.
 - (iv) **Dexmedetomidine** is a selective α_2 -adrenergic agonist that produces sedation and analgesia with minimal respiratory depression. It has been used in neonates with congenital heart disease. It is not FDA approved in children but has been used in preterm and full-term neonates with a favorable safety profile over 24 hours.
 - (v) **Ketamine** is an *N*-methyl-D-aspartate receptor antagonist that provides potent sedation, analgesia, and amnesia and is used for anesthesia and analgesia in neonates. There is concern about possible neurotoxicity.

ii. **Medications that do not provide systemic analgesia but provide sedation** can be used for pain-related agitation and are used along with pain medication. Remember that sedative agents do not have an analgesic effect and should not be used alone to relieve pain. Sedative-hypnotics (most commonly benzodiazepines) are the most widely used because they provide sedation, muscle relaxation, and anxiolysis. Benzodiazepines can also potentiate respiratory depression and hypotension when used with opioids.

(a) **Benzodiazepines**

- (i) **Midazolam** is the most common benzodiazepine used in the NICU. It has a rapid onset of action. It has been used for computed tomography (CT) scans and procedural sedation. Caution should be exercised as its use has been associated with neurotoxicity (abnormal hippocampal growth and neurodevelopmental outcomes) and adverse short-term effects in the NOPAIN trial.
- (ii) **Lorazepam** has a longer duration of action.
- (b) **Chloral hydrate is not available in the United States** but is used elsewhere for short-term sedation, such as for CT and MRI.

iii. **Medications that are recommended for nonemergency intubation.**

Premedication can decrease pain and discomfort of a nonemergent intubation. See Chapter 33 and Table 33–2 for a list of recommended medications.

VI. **Potentially improved pain management practices**, as identified by the Vermont Oxford Network Neonatal Intensive Care Quality Improvement Collaborative, include the following (A to F):

- A. **Reduce the frequency of avoidable painful procedures.**
- B. **Develop a protocol for standardization of sucrose administration.**
- C. **Perform frequent pain assessment.**
- D. **Implement strategies to manage pain during the following:** heel sticks, peripheral vascular procedures, circumcision, nonemergent intubation, and mechanical ventilation.

- E. **Implement strategies to manage pain during the postoperative period.**
 - F. **Implement strategies to wean neonates effectively and safely from opiates.**
 - G. **Other approaches.** Put peripheral arterial or central venous catheters in infants who require multiple blood drawings or heel sticks and cluster care (try to limit disruptions by performing many tasks at once; eg, physical exam, diaper change, suctioning). If possible, use handheld devices that can analyze multiple tests with one blood sample. Try to use noninvasive monitoring as much as possible.
- VII. **Conclusion.** Pain continues to be an emerging field of study within the discipline of neonatology. More research is needed regarding the ongoing assessment and treatment of neonatal pain. Healthcare professionals need to diligently document pain assessment and follow-up scores after intervention to ensure proper pain management. Clinical practice guidelines need to be developed for the neonatal community at large for standardization of this practice. Research is evolving to support accurate assessment of pain in the neonate. Monitoring skin conduction scores during painful procedures and measuring the impact of pain on the infant's brain are areas of active investigation. Measurements would include values during the experience of noxious stimuli and the long-term impact on the neurodevelopment of the infant. Other technologies to measure pain response that are being studied include near infrared spectroscopy, amplitude integrated EEG, functional MRI, and heart rate variability. It is through continuous research and commitment to reducing the experience of pain for the neonate that we will fully understand and effectively treat the neonate while supporting their viability.

16 Newborn Screening

- I. **Definition.** Newborn screening is the **testing of all newborns in the first few days of life for certain congenital disorders or diseases** that can cause severe lifelong intellectual and physical disabilities, chronic disease, and possibly death if not detected early and treated as soon as possible. The purpose of newborn screening is to identify these conditions and provide treatment as early as possible. **It involves a blood test that screens for multiple congenital conditions, a pulse oximetry test to rule out critical congenital heart disease, and a hearing test to rule out congenital deafness.** This is a population-based system that is mandated in every state. The American Academy of Pediatrics (AAP) and American College of Medical Genetics and Genomics (ACMG) support offering newborn screening to all children. They recommend education and counseling about its benefits, its risks, and what to do if there is a positive result.
- II. **Components of newborn screening.** Once thought of as just a newborn screening test, the AAP states it is now a complex system that encompasses 5 very important components:
- A. **Testing of all newborns.** involves the following:
 - 1. **A blood test** that screens for certain metabolic or genetic conditions.
 - 2. **A pulse oximetry test** to test for a critical congenital heart defect that requires either a catheter-based intervention or heart surgery.
 - 3. **A routine hearing test** to rule out congenital deafness. Treatment needs to begin before 6 months of age so communication skills can develop.
 - B. **Timely follow-up** of abnormal screening results. Some disorders can cause severe disabilities and some are fatal if not treated early.
 - C. **Diagnostic testing** to verify results of the initial screening blood test. The initial blood test does not provide a definitive result to diagnose the infant; it only identifies newborns who need further diagnostic testing.

- D. **Management of the disease** which usually involves a multidisciplinary approach.
- E. **Ongoing evaluation** of the newborn screening system.

III. What congenital disorders or diseases should be screened for?

- A. **Recommended Uniform Screening Panel (RUSP)** is a standardized list of disorders **recommended** by the secretary of the Department of Health and Human Services and supported by the Advisory Committee on Heritable Disorders in newborns and children from which states select conditions to screen for as part of their universal newborn screening program. Most states screen for the majority of the disorders on RUSP, and some even screen for additional disorders.
- B. **Core and secondary conditions of RUSP**
 - 1. **Core conditions** are disorders that are recommended in every US newborn screening program. There are 35 core conditions on the newborn screening panel. See Table 16–1. **Criteria for conditions to be added to RUSP include:**
 - a. **It is a clearly defined disorder.**
 - b. **States are able to screen for the disorder.**
 - c. **There is a diagnostic confirmatory test to detect the disorder.**
 - d. **There is available treatment** that is effective and evidence to support improved outcome in the presymptomatic or early symptomatic period.
 - e. **It is beneficial to screen in neonates** because it can affect future reproductive decisions of the family.
 - 2. **Secondary conditions** are conditions that do not meet all the inclusion criteria but are believed to be clinically significant and are identified when screening for the core conditions. There are 26 secondary conditions. See Table 16–2.
- C. **Non-RUSP conditions** are additional newborn screening tests that are not on the RUSP list. They have been nominated but, after formal review, are found to be deficient in 1 or more of the criteria to be added to RUSP. This does not mean they should not be screened for. Each state makes choices on what conditions they recommend for screening. Non-RUSP conditions include 5-oxoprolinuria (pyroglutamic aciduria), ethylmalonic encephalopathy, HIV, nonketotic hyperglycinemia, glucose-6-phosphate dehydrogenase deficiency, prolinemia, carbamoylphosphate synthetase deficiency, hyperammonemia/ornithinemia/citrullinemia (ornithine transporter defect), mucopolysaccharidosis type II, toxoplasmosis, Krabbe disease, and Niemann-Pick disease.
- D. **State-mandated testing.** In the United States, this screening is mandated in every state, but the disorders on the screening panels vary. Screening is done for approximately 4.1 million infants each year, with >12,500 newborns being diagnosed with a detectable and treatable disorder. A list of the screening tests provided by each state can be found on the National Newborn Screening and Genetics Resource Center website at <http://genes-r-us.uthsca.edu>.
- E. **Genomic testing for newborn screening.** The majority of newborn screening is done by tandem mass spectrometry in addition to other forms of testing. Applying genomic technology can help with diagnosing metabolic or nonmetabolic genetic disorders in an infant. This is a useful tool for diagnosing infants with potentially treatable conditions that result from genetic mutations including early-onset seizure disorders, cardiomyopathies, liver and kidney diseases, and others. Difficulties in implementing genetic testing, besides the obvious ethical, legal, and social implications, involve the high cost of testing and cost effectiveness, clinical utility, question of parental consent, the time it takes to get the results (weeks), interpretation of the results, what to do with incidental findings, and ownership and appropriate storage of data. Recommendations in using genomic testing include the following: consider as an add on to current newborn screening, use targeted panels, and limit genomic testing to diseases that manifest and can be treated in the newborn period. Genetic and genomic testing is discussed in detail in Chapter 17.

IV. Newborn screening test

- A. **Blood test**

Table 16–1. RECOMMENDED UNIFORM SCREENING PANEL OF THE 35 CORE CONDITIONS AND ESTIMATED INCIDENCE (RECOMMENDED BY THE US SECRETARY OF THE DEPARTMENT OF HEALTH AND HUMAN SERVICES)

Condition or Disorder	Estimated Incidence
Amino acid disorders	
Classic phenylketonuria (PKU)	1:19,000–1:13,500
Argininosuccinic aciduria (ASA)	1:70,000
Tyrosinemia type 1 (TYR 1)	1:12,000–1:100,000
Citrullinemia (CIT) type 1	1:157,000
Maple syrup urine disease (MSUD)	1:185,000
Homocystinuria (HCY)	1:300,000
Organic acid condition	
Glutaric acidemia type I (GA I)	1:30,000–1:40,000
Methylmalonic acidemia (methylmalonyl-CoA mutase)	1:5000–1:100,000
3-Methylcrotonyl-CoA carboxylase (3MCC) deficiency	1:36,000
Propionic (PROP) acidemia	1:100,000
β -Ketothiolase (BKT) deficiency	<1:1,000,000
3-Hydroxy-3-methylglutaric (HMG) aciduria	<1:100,000
Isovaleric acidemia (IVA)	<1:250,000
Methylmalonic acidemia (cobalamin disorders)	<1:50,000–1:100,000
Holocarboxylase synthase deficiency	<1:87,000
Fatty acid oxidation disorders	
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	1:6400–1:46,000
Long-chain L-3 hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency	1:60,000
Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency	1:4000–1:20,000
Trifunctional protein (TFP) deficiency	Unknown
Carnitine uptake defect (CUD)/carnitine transport defect	1:40,000
Hemoglobin disorders	
Sickle cell disease (sickle cell anemia) (Hb SS)	1:200,000
Hb S/C disease	>1:25,000
Hb S/ β -thalassemia (Hbs/ β Th)	>1:50,000
Endocrine disorders	
Primary congenital hypothyroidism (CH)	1:3000–1:4000
Congenital adrenal hyperplasia (CAH)	1:15,981
Other disorders	
Hearing loss (HEAR)	1:1000
Cystic fibrosis (CF)	1:3500

(Continued)

Table 16–1. RECOMMENDED UNIFORM SCREENING PANEL OF THE 35 CORE CONDITIONS AND ESTIMATED INCIDENCE (RECOMMENDED BY THE US SECRETARY OF THE DEPARTMENT OF HEALTH AND HUMAN SERVICES) (CONTINUED)

Condition or Disorder	Estimated Incidence
Classical galactosemia (GALT)	1:47,000
Biotinidase (BIOT) deficiency	1:112,000–1:129,000
Critical congenital heart disease (CCHD)	1:8000–1:10,000
Severe combined immunodeficiencies (SCID)	1:58,000
Glycogen storage disease type II (Pompe)	1:40,000
Mucopolysaccharidosis type I (MPS I) (Hurler)	1:100,000
X-linked adrenoleukodystrophy (X-ALD)	1:20,000
Spinal muscular atrophy due to homozygous deletion of exon 7 in <i>SMN1</i>	1:6000–1:10,000

Data from Newborn screening: toward a uniform screening panel and system, *Genet Med.* 2006 May; 8 Suppl 1:1S-252S and Sweetman L, Millington DS, Therrell BL, et al: Naming and counting disorders (conditions) included in newborn screening panels, *Pediatrics.* 2006 May;117(5 Pt 2): S308-S314.

1. **Initial blood specimen.** A heel stick is done between 24 and 72 hours after birth (close to discharge). The blood from the heel is put onto a filter paper card, completely filling each circle, which is sent to the laboratory at the newborn screening and molecular biology branch of the Centers for Disease Control and Prevention, (CDC) ideally within 24 hours of collection, and screened for certain core conditions.
2. **Factors that can influence the results of the blood test.** Factors that can influence the results of the screening blood test include sample timing, diet, gestational age, preterm birth, transfusions (platelets, fresh-frozen plasma [FFP], whole/packed, exchange transfusions), total parenteral nutrition (TPN), antibiotics, and certain nipple creams.
 - a. **Sample timing**
 - i. **Increase in false positives** if test is done in the first 24 hours: cystic fibrosis and congenital adrenal hyperplasia.
 - ii. **Increase in false positives** if test is done in the first 48 hours: thyrotropin method of testing for congenital hypothyroidism.
 - iii. **Homocystinuria.** Must test at >24 hours and advisable to repeat at 2 to 4 weeks of age.
 - iv. **Medium chain acyl-CoA dehydrogenase (MCAD) deficiency.** Test before 8 days of age.
 - b. **Diet.** There needs to be adequate protein intake for the test to be valid for tyrosinemia, phenylketonuria (PKU), and homocystinuria. For galactosemia screening, the infant needs to be on a galactose-containing formula.
 - c. **Gestational age**
 - i. **Extreme preterm birth.** Increase in false negatives in sickle cell disease and other hemoglobinopathies.
 - ii. **Preterm birth**
 - (a) **Increase in false positives.** Congenital adrenal hyperplasia (due to normal increase in 17-hydroxyprogesterone); severe combined immunodeficiency screening using the T-cell receptor excision circles (TREC) assay.

Table 16–2. SECONDARY CONDITIONS THAT ARE IDENTIFIABLE WHEN SCREENING FOR THE CORE CONDITIONS LISTED IN TABLE 16–1

Secondary Condition	Metabolic Disorder				
	Organic Acid Condition	Fatty Acid Oxidation Disorders	Amino Acid Disorders	Hemoglobin Disorder	Other Disorder
Methylmalonic acidemia with homocystinuria	X				
Malonic acidemia	X				
Isobutyrylglycinuria	X				
2-Methylbutyrylglycinuria	X				
3-Methylglutaconic aciduria	X				
2-Methyl-3-hydroxybutyric aciduria	X				
Short-chain acyl-CoA dehydrogenase deficiency		X			
Medium/short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency		X			
Glutaric acidemia type II		X			
Medium-chain ketoacyl-CoA thiolase deficiency		X			
2,4 Dienoyl-CoA reductase deficiency		X			
Carnitine palmitoyltransferase type I deficiency		X			
Carnitine palmitoyltransferase type II deficiency		X			
Carnitine acylcarnitine translocase deficiency		X			
Argininemia			X		
Citrullinemia, type II			X		
Hypermethioninemia			X		
Benign hyperphenylalaninemia			X		
Biopterin defect in cofactor biosynthesis			X		
Biopterin defect in cofactor regeneration			X		
Tyrosinemia, type II			X		

(Continued)

Table 16–2. SECONDARY CONDITIONS THAT ARE IDENTIFIABLE WHEN SCREENING FOR THE CORE CONDITIONS LISTED IN TABLE 16–1 (CONTINUED)

Secondary Condition	Metabolic Disorder				
	Organic Acid Condition	Fatty Acid Oxidation Disorders	Amino Acid Disorders	Hemoglobin Disorder	Other Disorder
Tyrosinemia, type III			X		
Various other hemoglobinopathies				X	
Galactosepimerase deficiency (GALE)					X
Galactokinase deficiency (GALK)					X
T-cell related lymphocyte deficiencies					X

Reproduced with permission from Recommended Uniform Screening Panel. U.S. Department of Health and Human Services. (<https://www.hrsa.gov/advisory-committees/heritable-disorders/rusp/index.html>. Accessed January 31, 2019.)

- (b) **Increase in false positives and false negatives.** Thyroxine method of testing for congenital hypothyroidism.
- (c) **Increased likelihood** of neonatal tyrosinemia.
- d. **Transfusion** (includes blood [whole or packed], platelets, FFP, exchange transfusions)
 - i. **Do the test a few hours after transfusion:** Congenital adrenal hyperplasia.
 - ii. **Do the test >90 days after transfusion.** Sickle cell diseases and other hemoglobinopathies, galactose-1-phosphate uridylyltransferase (GALT) deficiency galactosemia, and biotinidase deficiency.
 - iii. **Do the test 3 to 6 weeks after transfusion.** Cystic fibrosis.
- e. **Total parenteral nutrition. If the infant is on TPN:**
 - i. **False positive:** Homocystinuria, maple syrup urine disease, MCAD deficiency, PKU, tyrosinemia.
 - ii. **False negative:** Galactose method of testing for galactosemia.
- f. **Antibiotics.** Use of pivalate-containing antibiotics (pivampicillin, cefditoren) during pregnancy may cause false-positive results when screening for isovaleric acidemia.
- g. **Use of nipple creams containing neopentanoate by nursing mothers** can cause false-positive results when screening for isovaleric acidemia.
- 3. **Follow-up** is of utmost importance because certain conditions can be fatal (galactosemia, maple syrup urine disease, congenital adrenal hyperplasia), whereas others can cause severe disabilities if not treated as early as possible. Early detection facilitates timely treatment to prevent lifelong health problems.
 - a. **Positive results for time-critical conditions** need to be communicated to healthcare provider within the first 5 days of life.
 - b. **Positive results for non-time-critical conditions** need to be communicated to healthcare provider within 7 days of life.
 - c. **Invalid, equivocal, or positive results** need to be repeated as soon as possible.

- B. Screening for critical congenital heart disease by pulse oximetry** is done at 24 to 48 hours of age or as late as possible for early discharge. See Chapter 7.
- C. Screening for hearing loss** is done before discharge from the hospital. See Chapter 71.
- V. Selected disorders included in the newborn screening panels** that specifically have AAP fact sheets. The AAP Committee on Genetics has published newborn screening fact sheets that address appropriate testing methods, diagnostic testing if the screen is positive, and follow-up for 12 disorders.
- A. Amino acid metabolism disorders**
- 1. PKU.** A high level of the amino acid **phenylalanine (Phe)** (>20 mg/dL) causes an accumulation of phenylketones. Incidence is 1 in 9000 to 13,500 and higher in those with northern European ancestry and American Indians/Alaska natives.
 - a. Manifestations** include developmental delay, intellectual disability, microcephaly, seizures, eczema, and delayed speech.
 - b. Screening.** Make sure infant is on adequate protein intake before screening. If on TPN, there can be false positives. Three screening methods are Guthrie bacterial inhibition assay (BIA; more false positives), fluorometric analysis, and tandem mass spectrometry (MS/MS). Cutoff values are 2 to 6 mg/dL. Repeat test if screened within the first 24 hours.
 - c. Follow-up.** If positive, check plasma Phe and tyrosine levels; if Phe increased, perform additional studies to see if the infant has a synthesis or recycling abnormality of tetrahydrobiopterin.
 - d. Lifelong dietary treatment** with special medical diets low in Phe. No consensus on optimal level of Phe. Breast feeding is allowed with the addition of Phe-free formula with guidance of metabolic dietician. Tetrahydrobiopterin treatment may also be recommended in some cases.
 - 2. Maple syrup urine disease (branched-chain ketoaciduria).** Deficiency of the branched-chain α -keto acid dehydrogenase complex, which causes an increase in branched-chain amino acids (BCAAs). There are 5 phenotypes of disease; classic is most common and most severe. Incidence is 1 in 185,000. Incidence is 1 in 176 in Mennonites in certain counties in Pennsylvania (founder effect).
 - a. Manifestations.** Occur between 4 to 7 days and 2 weeks: lethargy, poor sucking, weight loss, abnormal neurologic signs, characteristic odor of urine (maple syrup), seizures, coma, and death.
 - b. Screening.** If the infant is on TPN, a false-positive result may occur. Screening done by MS/MS and a diagnostic peak of leucine, isoleucine, and alloisoleucine.
 - c. Follow-up.** Check blood leucine level. If >3 to 4 mg/dL in the first 24 hours of life or >4 mg/dL at >24 hours, do a plasma amino acid analysis. Concern for disease if increased BCAA and low alanine and alloisoleucine are present. Molecular genetic testing is recommended to confirm the diagnosis. Metabolic team (physician, nutritionist) recommended to follow the infant.
 - d. Long-term treatment** consists of a strict regulated diet for life, BCAA-free supplementation, and trial of thiamine supplementation (50–300 mg/d for 3 weeks). **Treatment during crisis** includes dialysis (peritoneal, continuous venovenous hemofiltration), TPN, and high glucose with insulin.
 - 3. Homocystinuria.** A biochemical abnormality (of enzymatic defect) resulting in an elevated level of serum homocysteine and methionine.
 - a. Manifestations.** Recurrent thromboemboli, arterial/venous thromboses, developmental delay, intellectual disability, seizures, marfanoid habitus, ocular abnormalities (lens dislocation and progressive myopia), and death. Incidence is 1 in 300,000.
 - b. Screening.** Make sure the infant is on adequate protein before screening. If the infant is on TPN, a false-positive result may occur. Test should be done after 24 hours, with repeat recommended in 2 to 4 weeks. Screen using BIA test (increased blood methionine) or MS/MS (direct methionine assay).

- c. **Follow-up.** Do quantitative serum or plasma amino acid determination: increased methionine and homocysteine levels and decreased cysteine levels. Perform urine organic acid profile with MS/MS and gas chromatography: presence or absence methylmalonic acid.
 - d. **Treatment.** Pyridoxine supplementation (if found to be pyridoxine responsive), methionine-restricted cysteine-supplemented diet (if found to be non-responsive), folic acid, betaine therapy, aspirin, and dipyridamole (decrease thromboembolism).
4. **Tyrosinemia.** Increased serum tyrosine caused by deficiency of enzyme fumarylacetoacetate hydrolase (FAH; type I) or caused by deficiency of tyrosine aminotransferase (type II) or neonatal tyrosinemia (more common in preterm infants; most common cause of abnormal PKU and tyrosinemia results). Incidence only known for type I (1 in 12,000 to 100,000).
- a. **Manifestations.** Type I: failure to thrive (FTT), vomiting, diarrhea, cabbage odor, fever, hepatomegaly, jaundice, edema, liver disease, death from liver failure. Type II: oculocutaneous syndrome. Neonatal: nonspecific, prolonged jaundice, lethargic, impaired motor activity.
 - b. **Screening.** Make sure infant is on adequate protein before screening. In preterm births, there is an increased likelihood of neonatal tyrosinemia (transient). If the infant is on TPN, there is a risk of a false-positive test. It is best to do the test 48 to 72 hours after milk feeding. Use BIA test (abnormal level of tyrosine) or MS/MS (direct measurement).
 - c. **Follow-up.** An increased tyrosine level can be seen with other diseases (eg, infections, hemochromatosis, giant cell hepatitis, fructose/galactose enzyme deficiencies), and additional testing is required. Type I: increased urine succinylacetone, nonspecific aminoaciduria, tissue analysis for FAH activity. Type II: increased tyrosine in blood and urine. Neonatal: increased tyrosine and Phe.
 - d. **Treatment.** Type I: dietary, liver transplantation, nitisinone. Type II: diet low in tyrosine and Phe. Neonatal: usually transient, decrease protein intake and breast feeding. Possible ascorbic acid supplements.
- B. Fatty acid oxidation disorders**
1. **Medium chain acyl-CoA dehydrogenase (MCAD) deficiency.** Disorder of fatty acid oxidation. Previously implicated in some cases of sudden infant death syndrome (SIDS). Incidence in United States is 1 in 17,000.
- a. **Manifestations.** Vomiting, lethargy, coma, seizures, or death in some cases after 8 to 16 hours of fasting, during illness, or after surgery. Some infants who die are misdiagnosed as having SIDS.
 - b. **Screening.** Best to perform test in the first 8 days of life. Best test is MS/MS measuring octanoylcarnitine on filter blood spot.
 - c. **Follow-up.** Octanoylcarnitine $>1.0 \mu\text{mol/L}$ needs further testing (plasma acylcarnitine analysis and urinary organic acid analysis to confirm diagnosis, molecular testing).
 - d. **Treatment.** Avoid fasting, decrease intake of dietary fat, and provide carnitine supplementation in proven deficiency. If the infant is ill, admit for intravenous glucose and carnitine.
- C. Hemoglobinopathies**
1. **Sickle cell disease.** Group of genetic disorders caused by abnormal hemoglobin, resulting in distorted cells, hemolysis, vascular occlusion, and severe pain. Incidence is 1 in 200,000 in the United States and highest in African Americans (1 in 365 births) and Hispanic Americans (1 in 16,300 births).
- a. **Manifestations.** Later in infancy: painful crises involving the abdominal and musculoskeletal systems, splenic sequestration, priapism, bacterial sepsis/meningitis, stroke, pulmonary hypertension.
 - b. **Screening.** Increase in false negatives in extreme preterm birth. Screen before blood transfusion; if the infant had a blood transfusion, do the test >90 days

after the transfusion. Screen with isoelectric focusing, high-performance liquid chromatography (HPLC), or cellulose acetate electrophoresis. For retesting, use hemoglobin electrophoresis, HPLC, immunologic tests, and molecular genetic testing.

- c. **Follow-up.** For abnormal screen, do a second blood sample at <2 months of age. Do isoelectric focusing, HPLC, hemoglobin electrophoresis, and/or DNA analysis.
- d. **Treatment.** Specialized multidisciplinary care. Prophylactic penicillin (started at 2 months of age), immunizations (pneumococcal), urgent care of acute illness. Some may benefit from hydroxyurea therapy or stem cell therapy.

D. Other newborn screening tests

1. **Congenital hypothyroidism.** Inadequate production of thyroid hormone. Incidence is 1 in 2000 to 4000 newborns. It is more common in Asian, Native American, and Hispanic infants. It is 28 times more common among infants with Down syndrome (1 in 100) than in the general population (see also Chapter 129).
 - a. **Manifestations.** Normal at birth (maternal thyroid hormone protective); large fontanels, macroglossia, distended abdomen, umbilical hernia, mottling of skin, wide sutures, constipated, lethargic, increased sleepiness, cool to touch, prolonged jaundice (immature hepatic glucuronyl transferase), deafness, and others.
 - b. **Screening. Blood spot thyroid-stimulating hormone (TSH) or thyroxine (T_4) or both used.** If screening with the T_4 test in a preterm infant, it can be false positive; if screening with the TSH test in a preterm infant, it can be false negative. If testing at <48 hours with the thyrotropin method, false positives can occur. Screen by measuring T_4 first; if low (<10%), then measure thyrotropin. Some measure thyrotropin first.
 - c. **Follow-up.** If screening is abnormal, measure serum T_4 ; some measure free T_4 , TSH, and thyroid-binding proteins. Once diagnosis is made, additional testing may be done to determine etiology (optional), including thyroid ultrasound, thyroid uptake, and scan. If maternal autoimmune thyroid disease is present, measure thyrotropin-binding inhibitor immunoglobulin in mom and baby (to rule out transient hypothyroidism).
 - d. **Treatment.** Levothyroxine (tablet form; 10–15 $\mu\text{g}/\text{kg}/\text{d}$) is started as soon as possible after initial blood tests confirm the diagnosis. Pediatric endocrinologist should be involved, and close monitoring is recommended the first 2 to 3 years.
2. **Cystic fibrosis (CF).** An autosomal recessive genetic disorder caused by the defect in the *CFTR* gene that affects the secretory glands that make mucus. Incidence is 1 in 3500.
 - a. **Manifestations.** Meconium ileus occurs in 17% of infants with CF. Other manifestations include progressive lung disease with multiple chronic endobronchial infections, nutritional deficits (protein malnutrition) leading to edema, dysfunction of the pancreas, liver disease, and others.
 - b. **Screening.** Do the immunoreactive trypsinogen (IRT) test after the first 24 hours, due to false positives in the first 24 hours. Repeat the test if the infant had a blood transfusion in 3 to 6 weeks. IRT concentration on the initial blood test is the first-tier test. If high, either do a CF mutation analysis from the blood or repeat the test in 2 to 3 weeks to see if there is a persistent elevation of IRT.
 - c. **Follow-up.** Sweat chloride testing (>40 mmol/L to diagnose CF) is recommended after repeat IRT testing and after mutation analysis if 2 disease-causing variants are identified. Sweat chloride testing can be done in term infants at 1 week of age. Mutation analysis is recommended in preterm infants due to poor test validity.
 - d. **Treatment.** Nutrition is of utmost importance. Testing for fecal elastase may help to determine the need for pancreatic enzyme supplements. Fat-soluble

- vitamins, salt supplements, and pancreatic enzymes are recommended as soon as possible. Respiratory management includes inhalers, chest physiotherapy, and hospitalizations for pulmonary exacerbations.
3. **Biotinidase deficiency** is a condition where the infant is unable to process (reuse and recycle) the vitamin biotin, which is essential for breaking down fats, proteins, and carbohydrates.
 - a. **Manifestations.** Seizures, hypotonia, conjunctivitis, apnea, eczematoid rash, developmental delay, sensorineural deafness, optic atrophy. Incidence of profound deficiency is 1 in 112,000; incidence of partial deficiency is 1 in 129,000.
 - b. **Screening.** Screen before blood transfusion; otherwise, do the test >90 days after transfusion. Filter paper spotted with whole blood is assessed for biotinidase activity by a semiquantitative colorimetric method. Up to 20% of patients with symptomatic biotinidase deficiency can be missed if screened with MS/MS, so this method should not be used.
 - c. **Follow-up.** A serum specimen for quantitative measurement of biotinidase activity should be obtained if the screening results were positive.
 - d. **Treatment.** Many symptoms are reversible with treatment; others, such as optic atrophy and deafness, are not. **Profound deficiency:** High-dose biotin therapy (only free form; 5–20 mg/d). **Partial deficiency:** Lower doses of biotin (1–5 mg/d) daily or during stress.
 4. **Galactosemia.** An accumulation of galactose in the blood caused by 1 of 3 enzyme deficiencies (GALT deficiency [classic and most common], galactokinase [GALK] deficiency, or galactose epimerase [GALE] deficiency). It can be fatal if not treated early. Incidence is 1 in 47,000 for GALT deficiency and 1 in 40,000 for GALK deficiency; GALE deficiency is extremely rare.
 - a. **Manifestations.** Classical GALT deficiency presents within the first few weeks after birth with vomiting, diarrhea, lethargy, hypotonia, prolonged bleeding after venipuncture, hepatomegaly, feeding intolerance, jaundice, and cataracts. GALK deficiency usually presents in a more subtle manner, and bilateral cataracts is the often the only feature seen.
 - b. **Screening.** If using the GALT method of testing, screen before blood transfusion; otherwise, do the test >90 days after the transfusion. False negatives can be seen for infants on TPN. If using the galactose method, the infant needs to be on a galactose-containing formula. Screening tests vary by state and measure galactose, galactose-1-phosphate plus galactose, and/or GALT enzyme levels, which can be done using MS/MS. The GALT enzyme test is performed using red blood cells and is diagnostic only for classic galactosemia.
 - c. **Follow-up.** All infants with a positive screening result should be seen by a physician as soon as possible and placed on a galactose-restricted diet pending definitive diagnostic testing. Testing for classic galactosemia includes quantitative analysis of GALT and red blood cell galactose-1-phosphate. If normal, quantitative analysis for GALK and GALE is done to rule out these disorders.
 - d. **Treatment.** Lifelong galactose restriction is indicated for GALT deficiency, GALK deficiency, and the generalized form of GALE deficiency. Breast feeding is not allowed in these infants. Some suggest that an elemental galactose-free formula is preferred over a soy formula.
 5. **Congenital adrenal hyperplasia (CAH).** Group of disorders of the adrenal cortex that affect production of 1 or more of the following: cortisol, aldosterone, or mineralocorticoids. Screening focuses on the most common **21-hydroxylase deficiency** (>90%), which results in impaired conversion of 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol. Variants in the *CYP21A2* gene result in decreased production of cortisol and aldosterone, causing excess adrenocorticotrophic hormone (ACTH) secretion. Incidence is 1 in 15,981 in North America.
 - a. **Manifestations.** Depend on subtype. Salt-wasting form (70% of infants affected) can present with adrenal crisis from 1 to 4 weeks of age with vomiting,

diarrhea, FTT, lethargy, dehydration, and poor feeding. Circulatory shock and death can occur. Females with the disease may have ambiguous genitalia. The mild form of the disease usually manifests no symptoms as a newborn but later on can present with excessive acne, hirsutism, infertility, and premature axillary and pubic hair.

- b. **Screening benefits.** May prevent a life-threatening acute adrenal crisis, male sex assignment in virilized female newborns, and excess adrenal androgens that affect both males and females. Do the test at >24 hours of age to prevent false positives, before 5 to 7 days, and a few hours after a transfusion. False-positive results are increased in preterm infants. Screening is nonspecific and is done by measuring 17-OHP concentration on the dried blood sample with either radioimmunoassay or dissociation-enhanced lanthanide fluorescence immunoassay.
 - c. **Follow-up.** With an abnormal screen, check serum 17-OHP and electrolytes as soon as possible. Other indication for these tests include any newborn with a disorder of sex development. An ACTH stimulation test is useful for ruling out nonclassic CAH in infants with mild elevations of 17-OHP levels.
 - d. **Treatment.** Chronic treatment involves supplementation (eg, hydrocortisone 10–25 mg/m²/d in 2–3 divided daily doses). In infants with salt-wasting CAH, add mineralocorticoid (fludrocortisone [Florinef] 0.05–0.2 mg) and consider supplementation with sodium chloride (2–5 g/d). In times of stress, more specialized treatment is necessary. Infants with CAH should be followed by a pediatric endocrinologist and pediatric urologist. Corrective surgery in severely virilized females may be necessary.
6. **Congenital hearing loss.** Hearing loss that is permanent and is >30 dB in the frequency region for speech recognition. It may be unilateral or bilateral and is either sensorineural or conductive. Causes include variants, ototoxic drug exposure (aminoglycosides), or bacterial or viral infections (cytomegalovirus [CMV], rubella).
- a. **Manifestations.** Seventy percent of cases are nonsyndromic (not associated with a recognized syndrome). Infant will not startle or wake up to loud noises, music, or voices.
 - b. **Screening.** Universal screening should be done before initial discharge from the hospital or no later than 1 month of age. Although **automated auditory brainstem response (ABR) and otoacoustic emission (OAE)** are the primary methods used, ABR is the recommended screening tool for infants with neonatal intensive care unit (NICU) stays >5 days because of the high risk of neural hearing loss. If the infant in the newborn nursery does not pass the initial screening test, the infant is usually rescreened before discharge.
 - c. **Follow-up.**
 - i. **Follow-up testing by an audiologist** should be performed prior to 3 months of age for all infants who do not pass the initial 2 screening tests in the newborn nursery or the initial screening test in the NICU. Rescreening of both ears is recommended.
 - ii. **Infants who have 1 or more risk factors** should have ongoing developmentally appropriate hearing screening and have at least 1 diagnostic assessment by an audiologist no later than 24 to 30 months of age regardless of initial screening results. **Risk factors include the following:** family history of permanent or sensorineural hearing loss, in utero infections (CMV, herpes, rubella, syphilis, toxoplasmosis), physical findings such as white forelock (Waardenburg syndrome), craniofacial anomalies, hyperbilirubinemia necessitating exchange transfusion, assisted ventilation, ototoxic medications (gentamicin and tobramycin), loop diuretics (furosemide) including chemotherapy, treatment with extracorporeal membrane oxygenation, culture-positive postnatal infections associated with sensorineural hearing loss (bacterial and viral meningitis, herpes, varicella),

mechanical ventilation, neurodegenerative disorders, syndromes known to include hearing loss (neurofibromatosis, osteopetrosis, or Usher, Alport, Pendred, Jervell, Lange-Nielson syndromes), caregiver concern, NICU stay >5 days, or trauma.

- E. Treatment.** A comprehensive approach to the management of infants diagnosed with congenital hearing loss is recommended, which includes a full genetic, pediatric, otolaryngology, dysmorphology, and audiological evaluation. Referral to an early intervention program or state-run program is recommended as early as possible.

17 Genetic and Genomic Testing in the Newborn Period

Genetic testing is not a new concept in neonatology. Newborn metabolic screening is the largest utilization of universal genetic testing in medicine and has been used in neonatology since 1960. It was then that Dr. Robert Guthrie developed a blood test to screen infants for phenylketonuria. It is estimated that birth defects are detected in 3% to 6% of live births and that congenital malformations, deformations, and chromosomal abnormalities are the cause of approximately 20% of deaths before 1 year of age. Many genetic conditions present in the perinatal period. Understanding of the available technology and the ability to manage all the steps involved in genomic testing have become essential tools for nongenetic specialists, including neonatologists and pediatricians. The study of genetics and genomics overlaps in the DNA analysis of specific genes, with the majority of diseases having complex genetic signatures. Genomics is a relatively new field, arising with the completion of the Human Genome Project in 2003, which mapped over 3 billion nucleotides in the 23 human chromosomes. Genomic technology advances have had a major impact on the care of newborns, especially those who are critically ill. Consequently, genomic testing is used more frequently, and as a result, pediatric providers need to be knowledgeable about the wide variety of tools that are becoming available. Information in this chapter is applicable to the newborn screening and congenital abnormalities discussed in Chapters 16 and 93.

I. Definitions

- A. Genetics versus genomics.** These terms are commonly used interchangeably but are not strictly the same thing.
1. **Genetics** refers to the study of a single or limited number of genes and their role in heredity.
 2. **Genomics** is a broader term and involves the study of the individual's complete DNA sequence (genome). It can encompass the approximately 20,000 genes the genome contains and their interaction with each other and the environment in health and disease.
- B. Exons** are parts of the DNA sequence that code for proteins, whereas **introns** are considered to be noncoding, intergenic regions, which are thought to contain regulatory elements.
- C. Exome** is the total of all the exons (whole-exome sequencing [WES]).
- D. Genome** is the complete DNA sequence, which includes the introns and exons (whole-genome sequencing [WGS]).
- E. Neome** is a term coined to include approximately 1000 genes associated with diseases often presenting in the newborn period.
- F. Genetic sequence variation.** The American College of Medical Genetics and Genomics (ACMG) has classified genetic variants on a 5-tier scale. Pathogenic, likely

pathogenic, and variant of uncertain significance (VUS) are included in the clinical report; likely benign and benign variants are not usually included. Variant classification is based on available data, which is why it can change categories with time, going between pathogenic, likely pathogenic, benign, and so on.

1. **Pathogenic variant (previously called a mutation).** A variant in a gene sequence known to cause a disorder or problem.
 2. **Likely pathogenic variant.** It is a variant in the gene strongly suspected to cause a disorder or problem, but supporting data may be somewhat limited.
 3. **Variant of uncertain significance.** It does not fit the criteria for benign or pathogenic. Testing may detect a variant that has not yet been clearly classified as either disease causing or normal in the general population.
 4. **Likely benign variant.** Studies suggest no damaging effect of the variant.
 5. **Benign variant (also called polymorphisms).** Available data show that it does not cause disease and occurs commonly in the population.
- G. Single nucleotide polymorphism.** A single nucleotide polymorphism (SNP; pronounced “snip”) is a specific variation in a single nucleotide in DNA. SNP microarray analysis can detect polymorphisms as well regions of homozygosity in the setting of uniparental disomy (UPD) as well as parental consanguinity or common ancestry.
- H. Autosomal dominant.** Only 1 pathogenic variant on 1 allele (specific version of a gene on each copy of the chromosome) needs to be present to cause the disease.
- I. Autosomal recessive.** Two pathogenic variants, 1 on each allele, are needed to cause the disease.
- J. Sanger sequencing.** The first DNA sequencing analytic technique, which is time consuming and expensive. However, it is considered the gold standard for its accuracy. Often used clinically for next-generation sequencing (NGS) confirmatory testing.
- K. Next-generation sequencing or deep sequencing.** This describes a high-throughput DNA sequencing technology that is rapid, affordable, and accurate and a standard in most testing laboratories. Usually relies on an automated gene chip microarray analyzer. It is used for genetic (single-gene and gene panel tests) and genomic testing (WES and WGS).
- II. Benefits of early identification of an underlying genetic or genomic disorder**
- A. Improved patient care.
 - B. Avoid unnecessary additional diagnostic tests.
 - C. Avoid nonbeneficial treatment.
 - D. Family counseling and reproductive planning.
 - E. Aids in the decision regarding palliative care.
 - F. Confirms the clinical diagnosis.
 - G. May give information that is relevant to making a medical decision.
 - H. Aids in specific drug treatment (genotypic drugs or pharmacogenomics) or treatment modification or management.
 1. **Vitamin therapy** (identification of *STXBP1* mutation led to the diagnosis of Ohtahara syndrome, which requires folinic acid treatment).
 2. **Ivacaftor (Kalydeco)** for some patients with cystic fibrosis.
 3. **Identification of a gene for focal familial hyperinsulinism** in an infant with refractory hypoglycemia allows planning surgery.
 4. **Cost effectiveness.** Genomic testing may save money by preventing the use of prolonged and expensive diagnostic testing and treatments.
- III. Limitations in the use of genetic or genomic testing**
- A. Positive results not predictive of clinical course.
 - B. May lead to an incorrect diagnosis.
 - C. **Incidental findings may reveal genetic mutations that predispose to cancer or neurodegeneration,** or a variant that you were not testing for may be found. Recommendations on how to address these “accidental” discoveries are being debated.
 - D. **Cost of testing.** Genomic assays can cost US \$1000 to \$10,000.

- E. **Genetic privacy issues may impact the individuals.** The Genetic Information Non-discrimination Act (GINA) of 2008 protects Americans from discrimination on their genetic information in both health insurance and employment.
- IV. **Common findings that raise suspicion of a genetic or genomic disorder in a newborn**
- A. **A critically ill infant with metabolic abnormalities** such as severe lactic acidemia or hyperammonemia.
 - B. **An isolated major anomaly or multiple congenital anomalies (see Chapter 93).**
 - C. **Dysmorphic features.**
 - D. **Growth delay.**
 - E. **Neurologic problems including hypotonia and seizures.**
 - F. **Family history of known genetic disorder.**
 - G. **Abnormal prenatal genetic testing and/or screening.**
- V. **Steps in incorporating genetic or genomic testing for diagnosis**
- A. **Obtain a detailed history and physical examination.** The physical exam helps to define the **phenotype** (description of physical characteristics) of the infant. The history with the phenotype may help narrow the differential diagnosis and guide specific testing (eg, an infant with physical characteristics suggestive of Down syndrome enables the clinician to just order 1 test, a karyotype to diagnose trisomy 21).
 1. **Family history.** Minimum of 3 generation pedigrees. Document known genetic conditions, birth defects, learning and developmental problems, autism, miscarriages, stillbirths, infant or childhood deaths, or consanguinity.
 2. **Maternal history.** Medications, drugs, alcohol, toxins, chronic maternal diseases, maternal infections during pregnancy.
 3. **Physical examination.** Perform a detailed examination with close attention to congenital anomalies (major and minor). Anthropomorphic measurements need to be done. See examples of physical findings of chromosomal syndromes, sequences, and teratogenic malformation syndromes in Chapter 93.
 - B. **Testing.** It is often difficult to decide which test to order because frequently there is no one perfect test. Some tests are better for diagnosing specific conditions. Consultation with a geneticist or genetic counselor can help identify the most appropriate test.
 1. **Genomic testing approaches**
 - a. **Targeted diagnostic testing** is the use of a specific genomic test in an infant with a suspected but unconfirmed condition, with the hope that identifying the correct genetic diagnosis will ensure appropriate management. This also facilitates recurrence risk counseling and testing for relatives. It can be helpful for infants with a suspected metabolic condition that is not detectable on newborn screening tests (mitochondrial disorders, Smith-Lemli-Opitz syndrome). Examples of targeted diagnostic testing include multigene panel for Noonan syndrome, fluorescence in situ hybridization (FISH) for Williams syndrome, or *FBN1* sequencing for Marfan syndrome.
 - b. **Rapid diagnostic broad genomic testing.** This is usually done in critically ill newborns in whom a clinical workup and targeted genetic testing did not diagnose any specific condition. Evidence supports an impact on direct care. In one study, WGS done in 23 critically ill patients who had a nondiagnostic clinical workup revealed compound heterozygous mutations in 30%.
 2. **Types of genetic testing and when to order the test.** Genetic testing is already used widely in the neonatal intensive care unit.
 - a. **American Academy of Pediatrics (AAP) and American College of Medical Genetics and Genomics recommendations for genetic testing in children**
 - i. **Genetic testing and screening should be offered in the context with genetic counseling** and only if it is in the best interest of the child.
 - ii. **If genetic testing is recommended for diagnostic testing,** the parents should give permission after hearing the benefits and risks. Pharmacogenomics testing is acceptable with permission of parents.

- iii. **American Academy of Pediatrics and American College of Medical Genetics and Genomics** support mandatory newborn screening to all children. Parents have the option of refusing the screening after education and counseling occur.
- iv. **American Academy of Pediatrics and American College of Medical Genetics and Genomics** do not support routine carrier testing in minors when the testing does not provide health benefits to the child.
- v. **Parents may allow predictive genetic testing for asymptomatic children who are at risk for a disease that occurs in childhood.** It is not recommended for adult-onset conditions unless an intervention is recommended in childhood. It is best to be cautious when providing this test to minors without parental involvement.
- vi. **The same rules of genetic testing in biologic families should apply for adopted children.** In cases of a child having a known genetic risk, prospective parents should be aware, and in rare cases, predictive genetic testing may be considered to ensure the family is willing to accept the challenges.
- vii. **Tissue compatibility testing of all minors is allowed.**
- viii. **Parents/legal guardians should inform the child** of the genetic test results at an appropriate age.
- ix. **American Academy of Pediatrics and American College of Medical Genetics and Genomics** strongly discourage direct to consumer home genetic kits.

C. Genetic test types

1. **Karyotype.** Identifies and evaluates the size, shape, and number of chromosomes. Ideal for detecting aneuploidy, such as trisomies and monosomy. Detects large deletions/duplications and translocations. Covers the whole genome but has limited ability to detect smaller deletions and duplications. **Recommended diagnostic test for infants with suspected aneuploidy** (eg, Down syndrome, Turner syndrome, trisomy 18 or trisomy 13), as well as large deletion syndromes (eg, cat eye syndrome or cri du chat syndrome).
2. **Fluorescence in situ hybridization.** Rapid analysis test with a quick turnaround that evaluates specific regions of the DNA sequence on a chromosome. Can detect large as well as small deletions; more difficult to detect duplications. Useful for detecting trisomies, microdeletions, and sex chromosome anomalies relatively quickly.
3. **Chromosomal microarray analysis/array comparative genomic hybridization.** Detects large and small (micro) deletions or duplications in part of or a whole chromosome. Does not detect a balanced chromosomal rearrangement, triplet repeat expansions, or sequence variations. **First-line test for multiple congenital anomalies and developmental disabilities, especially for patients with a specific recognizable diagnosis.** Useful for some conditions such as 22q11.2 deletion (DiGeorge/velocardiofacial syndrome), Williams syndrome (microdeletion 7q11.23), and 1p36 deletion.
4. **Single-gene sequencing and multigene panel assays.** Sequencing involves checking the DNA for sequence alterations or “spelling errors.” Targeted sequencing is preferred in the setting of a recognizable phenotype with a high suspicion for a specific diagnosis. Advantages include better coverage of the gene or genes under consideration, compared to WES or WGS, and a lower chance of unclear results. **Order single-gene sequence analysis** on an infant with suspected Marfan syndrome and a multigene panel for an infant with suspected Noonan syndrome.
5. **Epigenetic/methylation analysis.** DNA methylation abnormalities can result in inappropriate expression or silencing of some genes. **This test is used in disorders** associated with methylation abnormalities (Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes). These disorders are also associated with other genetic abnormalities, but methylation analysis is the first-tier testing recommended if there is a clinical suspicion in the newborn.

6. **Targeted deletion/duplication analysis.** Order this, for example, on an infant with suspected spinal muscular atrophy.
7. **Targeted/directed mutation analysis.** Order this on a newborn who you suspect may have achondroplasia.
8. **Mitochondrial genetic testing.** Mitochondria are the energy generators of the cell and have their own small genome. Mitochondrial diseases are extremely variable and are transmitted by several modes of inheritance. Findings in the newborn period that may suggest a mitochondrial disorder include hypotonia, feeding problems, need for respiratory support, seizures, lactic acidemia, liver disease, deafness, and ocular disease. Clinical diagnosis can be very difficult because of the overlap with numerous other diseases. Testing for mitochondrial diseases involves analyzing not only the mitochondrial genome but also some specific nuclear genes.
9. **Genomic testing.** Genomic medicine uses the application of WES and WGS data to classify human health and disease.
 - a. **When to recommend genomic testing.** ACMG recommends WES and WGS for the following 3 situations:
 - i. **Infant's presentation is strongly suggestive of a genetic etiology** but not specific enough for a targeted test.
 - ii. **Infant's presentation is consistent with a disorder** that can be caused by many different genes.
 - iii. **Infant's presentation suggests a specific condition**, but targeted testing was unsuccessful in making a diagnosis.
 - b. **Before ordering whole-exome or whole-genome sequencing, it is recommended the following be done:**
 - i. **Formal consultation with a medical geneticist/genetic counselor** for parents or legal guardians.
 - ii. **Discuss limitations of the test**, describe possible results, and discuss possibility of VUS, incidental, and secondary findings.
 - iii. **Discuss that the parents** have the option of getting or deferring the secondary/incidental findings.
 - iv. **Test the infant with parent samples** as a reference to improve the diagnostic yield of WES and WGS.
 - c. **Whole-exome sequencing analyzes most, but not all, of the protein-coding regions of the genes.** Useful test for nonspecific phenotypes and when all other tests are negative. WES has limited ability to detect copy number variations, large deletions, triplet repeat expansion, complex rearrangements, epigenetic (imprinting) disorders, and regulatory or deep intronic variants. One example is a newborn with epileptic encephalopathy who had a negative epilepsy panel. WES can be used for patients with features suggestive of a specific condition, such as congenital disorders of glycosylation, Noonan syndrome, or CHARGE (coloboma, central nervous system abnormalities, heart defects, atresia of the choanae, restricted growth and/or development, genital abnormalities, and ear anomalies) syndrome, where targeted testing is unrevealing.
 - d. **Whole-genome sequencing is the broadest test available. It analyzes the majority of the DNA sequence of an individual.** WGS has been designed to identify not only variations in single nucleotides but also large genomic rearrangements. It is thought to have the potential to replace current genetic tests, including chromosomal microarray analysis (CMA), multigene panel testing, and WES; however, there are still several limitations, similar to those described for exome sequencing. WGS is expected to become the preferred clinical practice, with a yield estimated at approximately 100 times more data than WES. At present, it is not being used clinically and is currently only considered when previous testing including microarray analysis and WES does not reveal a diagnosis. One example is a newborn with epileptic encephalopathy who has a negative microarray analysis and WES.

18 Studies for Neurologic Evaluation

Although continued improvements in neuroimaging and neuromonitoring have added insight into the developing brain and have helped the clinician to identify infants at risk for poor neurologic outcome, available techniques continue to have limited accuracy in predicting neurodevelopmental outcomes. Moreover, given the enormous plasticity of the neonate's brain, even significant detectable defects may result in "normal" neurodevelopmental outcomes. Nevertheless, imaging and monitoring modalities hold future promise in assisting clinicians to better identify and refer patients at risk for neurodevelopmental sequelae.

I. Ultrasonography

A. Ultrasonography

- 1. Definition.** Using the bone window of a fontanelle, sound waves are directed into the brain and reflected according to the echodensity of the underlying structures. The reflected waves are used to create 2- and 3-dimensional images.
- 2. Indication.** Ultrasonography is preferred for identification and observation of germinal matrix/intraventricular hemorrhage and hydrocephalus. Ultrasound is valuable in detecting midline structural abnormalities, hypoxic ischemic injury, periventricular leukomalacia, subdural and posterior fossa hemorrhage, ventriculitis, periventricular calcifications, tumors, cysts, and vascular abnormalities.
- 3. Method.** A transducer is placed over the anterior fontanelle, and images are obtained in coronal and parasagittal planes. The posterior or mastoid fontanelle is the preferred acoustic window for the imaging of the infratentorium, including the fourth ventricle, brainstem, and cerebellum. Ultrasonography's advantages include high resolution, portability, safety (no sedation, contrast material, or radiation), noninvasiveness, and low cost. Disadvantages include the lack of visualization of non-midline structures, especially in the parietal regions, and the lack of differentiation between gray and white matter.
- 4. Results.** The integrity of the following structures may be evaluated with ultrasonography: all ventricles, the choroid plexus, caudate nuclei, thalamus, septum pellucidum, and corpus callosum.

B. Doppler ultrasonography

- 1. Definition.** Doppler ultrasonography also uses a bone window to direct sound waves into the brain. The sound waves from the transducer are reflected by red blood cells in the vessel, and their frequency travels proportionally to the velocity of the circulating red blood cells. These changes are measured and expressed as the **pulsatility index and resistance index (RI)**. The angle of the probe in relation to the flow affects the Doppler shift and requires exact standards for serial measurements.
- 2. Indication.** Doppler ultrasonography of the anterior cerebral artery is a sensitive and specific tool for measuring **cerebral blood flow (CBF)** and resistance in the neonatal period.

$$\text{CBF (cm}^3/\text{time)} = \text{CBF velocity (cm/time)} \times \text{area (cm}^2\text{)}.$$

Doppler ultrasonography is of clinical value in states of cessation of CBF (eg, brain death or cerebrovascular occlusion), states of altered vascular resistance (eg, hypoxic ischemic encephalopathy, hydrocephalus, or arteriovenous [AV] malformation), and ductal steal syndrome.

- 3. Method.** Combined with conventional ultrasonography to identify the blood vessel, Doppler ultrasonography produces a color image indicating flow (red = toward the transducer; blue = away from the transducer). CBF velocity is measured as

the area under the curve of velocity waveforms. Small body weight and low gestational ages negatively influence the success rate in visualizing intracranial vasculature. Contrast-enhanced ultrasound is a novel technique, whereby intravenously injected gas-filled microbubbles (smaller than red cells) generate an increased signal, from acoustic impedance mismatch, allowing for enhanced visualization of blood vessels. This has been used for improved characterization of perfusion abnormalities in neonates with hypoxic ischemic injury.

4. **Results.** Doppler ultrasonography measurements can be compared with age-adjusted norm values for systolic, end-diastolic, and mean flow velocity. Elevated RI suggests vasoconstriction and diminished blood flow velocity. Conversely, diminished RI suggests vasodilation with increased blood flow velocity. Serial measurement of CBF and RI may be helpful in following lesions associated with increased cerebral pressure (eg, determining the need for a ventriculoperitoneal shunt in progressive hydrocephalus).

C. Computed tomography

1. **Definition.** Using computerized image reconstruction, computed tomography (CT) produces 2- and 3-dimensional images of patients exposed to ionizing radiation.
2. **Indication.** CT is the preferred tool for evaluation of the posterior fossa and non-midline disorders (eg, blood or fluid collection in the subdural or subarachnoid space). It is also helpful in the diagnosis of skull fractures. CT is used less often in neonatal units given the risks of exposure to ionizing radiation in infancy, which has been linked to development of future malignancies.
3. **Method.** The patient is advanced in small increments in a scanner, and images (cuts) are obtained. Cerebral white matter (more fatty tissue in myelin sheaths around the nerves) and inflammation appear less dense (black) than gray matter. Calcifications and hemorrhages appear white. If a patient receives contrast material, blood vessels and vascular structures (eg, falx cerebri and choroid plexus) appear white. Spaces containing cerebrospinal fluid are clearly shown in black, making it easy to identify diseases that alter their size and shape. Bones also appear white but are poorly defined, and details are better evaluated in a “bone window.” Disadvantages include radiation exposure, the need for transportation, hypothermia, and the potential need for sedation during the procedure.
4. **Results.** CT provides detailed information on brain structures not accessible by ultrasonography and is superior to magnetic resonance imaging in the diagnosis of intracranial calcifications.

D. Magnetic resonance imaging

1. **Definition.** Inside a strong magnetic field, atomic nuclei with magnetic properties (hydrogen protons being most common) align themselves and emit an electromagnetic signal when the field is terminated and the nuclei return to their natural state. Computers reconstruct the signal into 2-dimensional image cuts. A variety of contrasts can be obtained in magnetic resonance imaging (MRI) including T1- and T2-weighted imaging (reflecting 2 relaxation time constraints, longitudinal and transverse, respectively), diffusion-weighted imaging (DWI), blood-oxygen-level-dependent (BOLD) imaging, and proton-density weighted imaging. In functional MRIs (fMRI), such as BOLD and DWI, underlying brain physiology is reflected in the created images.
2. **Indication.** MRI is the preferred tool for a number of brain disorders in the neonate that are difficult to visualize by CT, such as disorders of myelination or neural migration, ischemic or hemorrhagic lesions, agenesis of the corpus callosum, AV malformations, and lesions in the posterior fossa and the spinal cord. Diffusion-based MRI is the most sensitive to acute brain injury in the first week after injury. Conventional T1- and T2-weighted MRI is preferred after 1 week following the injury. Conventional MRI has been used at term equivalent or at the time of discharge from the hospital to predict neurologic outcome.

3. **Method.** The patient is advanced in small increments in a scanner, and images (cuts) are obtained. Gray matter appears gray and white matter, white. Cerebrospinal fluid and bones appear black; however, the fat content in the bone marrow and the scalp appear white. In T1 and T2 MRI, fluid may appear dark or bright, depending on the type of weighted image. Advantages of MRI include the ability to identify normal and pathologic anatomy without ionizing radiation and insight into neurologic prognosis. Disadvantages include the need for transportation and sedation, need for a ferromagnetic-free environment, the potential for hypothermia, and difficulties in monitoring during the procedure. Ventilated infants pose a special problem, and ferromagnetic-free MRI incubators have been developed and used to help prevent motion artifact, provide improved cardiorespiratory monitoring, maintain temperature and fluid status, and improve image quality by using built-in head coils. Ferromagnetic-free tracheostomy tubes are a necessary consideration for infants with tracheostomy tubes.
4. **Results.** MRI provides high-resolution images of the brain with exquisite anatomic detail and allows diagnosis of a number of illnesses easily missed by CT. The temporal development of the prenatal brain, including the emergence of sulci and gyri and the myelination process, has been described, allowing for a more meaningful interpretation of MRI in premature infants. Quantitative volumetric MRI has been used to demonstrate the effects of postnatal dexamethasone on cortical gray matter volume and to help provide long-term prognosis for neurologic outcome. Diffusion-weighted signal abnormalities appear early after a hypoxic ischemic event, and restricted diffusion on DWI is an early predictor of outcome. The volume of restricted diffusivity has been shown to provide a measure of the severity of acute brain injury in the setting of hypoxic ischemic injury. fMRI promises new insights into the functional reorganization of the brain after injury. Newer magnetic resonance spectroscopy allows the study of metabolic mechanisms through quantitative measurements of certain metabolites.

E. Near-infrared spectroscopy

1. **Definition.** Light in the near-infrared range can easily pass through skin, thin bone, and other tissues of the neonate. At selected wavelengths, light absorption depends on oxygenated and deoxygenated hemoglobin as well as oxidized cytochrome *aa* 3, allowing for qualitative measurements of oxygen delivery, cerebral blood volume, and brain oxygen availability and consumption.
2. **Indication.** Although use of near-infrared spectroscopy (NIRS) is not generalized, it has potential as a bedside tool to follow cerebral oxygen delivery or CBF including in cardiac patients. It is a useful technique to assess the effects of diseases such as congenital heart disease and new treatments and common interventions (eg, endotracheal suction, continuous positive airway pressure) on cerebral perfusion and oxygenation.
3. **Method.** A fiberoptic bundle applied to the scalp transmits laser light. Another fiberoptic bundle collects light and transmits it to a photon counter.
4. **Results.** NIRS allows qualitative determination of oxygen delivery, cerebral blood volume, and oxygen consumption. In intubated infants, NIRS has been used to identify pressure-passive cerebral circulation, a condition associated with a 4-fold increase in periventricular leukomalacia and severe intraventricular hemorrhage.

II. Electrographic studies

A. Basic conventional electroencephalogram

1. **Definition.** An electroencephalogram (EEG) captures the electrical activity between reference electrodes on the scalp. In the neonatal period, cerebral maturation and development result in significant EEG changes during different gestational ages that must be considered when interpreting results. The minimum duration for basic EEG is 1 hour, which allows for capture of sleep-wake cycle; the average duration of basic EEG is 1 to 8 hours.

2. **Indication.** Basic EEG monitoring is indicated in infants thought to be at low risk for seizure activity and should not be used for infants who are at high risk for acute brain injury or seizure, as these infants require long-term continuous conventional EEG. Infants at low risk would include non-critically ill term infants without asphyxia, encephalopathy, or metabolic disorders and infants known to have normal central nervous system (CNS) anatomy. Basic EEG is helpful for differentiating seizure activity from paroxysmal nonepileptic events and avoidance of unnecessary medications.
 3. **Method.** Several electrodes are attached to the infant's scalp, and the electrical activity is amplified and measured. Recordings can be traced on paper or can be saved electronically. EEG waves are classified into different frequencies: delta (1–3/s), theta (4–7/s), alpha (8–12/s), and beta (13–20/s).
 4. **Results.** EEGs are sensitive to a number of external factors, including acute and ongoing illness, medications or drugs, position of the electrodes, and state of arousal. Obtaining a basic EEG for at least 1 hour allows for interpretation of the full sleep cycle, including active sleep, quiet sleep, and intermediate sleep. EEG assesses for continuity versus discontinuity, synchrony, and age-appropriate electrographic landmarks. A number of abnormal findings can be documented on the EEG of the term and preterm infant, including the following:
 - a. **Abnormal pattern of development.**
 - b. **Depression or lack of differentiation.**
 - c. **Electrocerebral silence** (“flat” EEG).
 - d. **Burst suppression pattern** (depressed background activity alternating with short periods of paroxysmal bursts). Burst suppression patterns are associated with especially high morbidity and mortality and poor prognosis.
 - e. **Persistent voltage asymmetry.**
 - f. **Sharp waves (multifocal or central).**
 - g. **Periodic discharges.**
 - h. **Rhythmic α -frequency activity.**
- B. Continuous conventional electroencephalogram**
1. **Definition.** Continuous conventional electroencephalogram (cEEG) captures the electrical activity between reference electrodes on the scalp over a prolonged period of time, ≥ 24 hours.
 2. **Indication.** Indications for cEEG includes infants with documented or high suspicion for seizure activity, acute neonatal encephalopathy, active CNS infections, CNS malformations, metabolic disorders, perinatal stroke or sinovenous thrombosis, and CNS trauma. Additionally, cEEG allows for refinement in seizure management by accurately diagnosing electrographic seizure activity and modifying treatment accordingly.
 3. **Method.** Methodology for cEEG is identical to basic EEG; however, the testing period is longer, a minimum of 24 hours in duration.
 4. **Results.** cEEG interpretation is the same as basic EEG with greater volumes of data, which allows for evolving assessment over time.
- C. Polygraphic video electroencephalogram**
1. **Definition.** Polygraphic video electroencephalogram (VEEG) adds synchronized video monitoring of the infant, whereas the EEG captures the neuronal electrical activity. Synchronized video allows for the characterization of clinical events and is helpful in assessing artifacts that may mimic electrographic seizures. Short-term VEEG lasts on average 2 to 8 hours, and long-term VEEG is done for >24 hours.
 2. **Indication.** Infants with neonatal encephalopathy, paroxysmal events concerning for seizure, or the presence of high-risk diagnoses or interventions, including hypoxic ischemic encephalopathy, ischemic stroke, acute toxic metabolic processes, and occasionally extracorporeal membrane oxygenation, are ideal candidates for continuous VEEG.

3. **Method.** An electrode cap is placed on the patient's scalp, and mounted video cameras provide continuous video, audio, and brainwave monitoring. This network can be linked to a central server and be displayed for online remote observation. A bedside observer who can mark key clinical events in a written log or electronically is recommended. Key clinical events include suspected seizure activity, initiation of cooling protocol, and administration of neuroactive drugs. Duration of VEEG is dependent on indication for testing. Ideally, VEEG should be continued until multiple "typical" events are captured. If seizure activity is captured, it is recommended that VEEG monitoring continue until the patient has been seizure-free for at least 24 hours.
4. **Results.** The EEG reading and reporting are the same as in cEEG with the advantage of utilizing video to inform the interpretation process. Assessment of background activity and specific waves and patterns indicative of brain development holds promise.

D. Amplitude-integrated electroencephalogram

1. **Definition.** Amplitude-integrated electroencephalogram (aEEG) is a method for continuous long-term monitoring of overall brain activity utilizing a single EEG lead. Cerebral function monitor (CFM) refers to the specific monitor, which produces the aEEG output. The CFM filters and compresses the detected neurologic activity and provides information on the general level of electrical activity occurring throughout the brain. The aEEG output can be interpreted by neonatal staff without full knowledge of EEG to quickly determine overall neurologic status.
2. **Indication.** aEEG is sensitive for early prediction of outcome in asphyxiated term newborns. aEEG is used for assistance in the identification of clinical and sub-clinical seizure activity. In addition, it has been used to select patients for neuro-protective measures such as head or total-body cooling and has been useful in providing information on neurodevelopmental outcome in cases of hypoxic ischemic encephalopathy and intraventricular hemorrhages. The aEEG has also been used in other conditions including metabolic disorders, congenital anomalies, extracorporeal membrane oxygenation, and postoperative monitoring.
3. **Method.** aEEG uses a single lead, consisting of 3 wires placed over the biparietal or frontal region. The signal processing attenuates activity below 2 Hz and above 15 Hz, and the bandwidth reflects variations in minimum and maximum EEG amplitude. The aEEG recording is digitally displayed on screen of the CFM. Ideally, infants monitored with aEEG also have at least 1 standard EEG to obtain additional electrocortical information.
4. **Results.** The aEEG provides information on the background pattern of electrical activity of the brain (Table 18–1), the presence or absence of the sleep-wake cycle (SWC), and/or the presence of epileptiform activity and other examples of neonatal aEEG patterns (Figure 18–1). After asphyxia, the occurrence of a moderately or severely abnormal aEEG trace has a positive predictive value >70% for abnormal neurologic outcome. Burst suppression, low voltage, and flat trace in the first 12 to 24 hours after injury are associated with a poor prognosis. SWC returning before 36 hours is associated with a good outcome, and SWC returning after 36 hours is associated with a bad outcome. The sensitivity of aEEG for neonatal seizure detection is limited; however, compared to management based on clinical seizure detection alone, use of aEEG has been shown to reduce the total seizure duration in neonates.

E. Peripheral nerve conduction velocity

1. **Definition.** Nerve conduction velocity allows the diagnosis of a peripheral nerve disorder by measuring the transmission speed of an electrical stimulus along a peripheral (median, ulnar, peroneal) nerve. Because of smaller nerve fiber diameters affecting the nerve transmission speed, neonates have a lower nerve conduction velocity than adults.

Table 18–1. SUMMARY OF NORMAL SINGLE-CHANNEL AMPLITUDE-INTEGRATED ELECTROENCEPHALOGRAPHY FEATURES IN NEWBORNS AT DIFFERENT GESTATIONAL/ POSTCONCEPTIONAL AGES

Gestational or Postconceptional Age (wk)	Dominating Background Pattern	SWC	Minimum Amplitude (mcV)	Maximum Amplitude (mcV)	Burst/h
24–25	DC	(+)	2–5	25–50 (to 100)	>100
26–27	DC	(+)	2–5	25–50 (to 100)	>100
28–29	DC/(C)	(+)/+	2–5	25–30	>100
30–31	C/(DC)	+	2–6	20–30	>100
32–33	C/DC in QS	+	2–6	20–30	>100
34–35	C/DC in QS	+	3–7	15–25	>100
36–37	C/DC in QS	+	4–8	17–35	>100
38 +	C/DC in QS	+	7–8	15–25	>100

C, continuous; DC, discontinuous background pattern; QS, quiet/deep sleep; SWC, sleep-wake cycling; SWC (+), imminent/immature; SWC +, developed SWC.

Reproduced with permission from Hellström-Westas L, Rosén I, de Vries LS, et al: Amplitude-integrated EEG Classification and Interpretation in Preterm and Term Infants, *NeoReviews*. 2006 Feb;7(2):e76–e87.

2. **Indication.** In the weak and hypotonic neonate, nerve conduction velocity is an important tool in diagnosing a peripheral nerve disorder.
 3. **Method.** A peripheral nerve is stimulated with a skin electrode, and the corresponding muscle action potential is recorded with another skin electrode. To determine the nerve conduction alone (as opposed to nerve conduction, synaptic transmission, and muscle reaction), the nerve is stimulated at 2 points, and the resulting muscle response times are subtracted. The distance between the 2 points of stimulation divided by the time difference equals the nerve conduction velocity.
 4. **Results.** Nerve conduction velocities are prolonged in disorders of myelination and in axon abnormalities and may have potential clinical value in combination with other tests (eg, muscle biopsy or electromyogram) in these disorders. Initially, infants with anterior horn cell disorders (eg, Werdnig-Hoffmann paralysis) have normal nerve conduction but may demonstrate decreased velocity later in the course. Neuromuscular junction and muscle disorders do not alter nerve conduction velocity. This test is also used for gestational age assessment.
- F. **Evoked potentials.** An evoked potential is an electrical response by the CNS to a specific stimulus. Evoked potentials are used to evaluate the intactness and maturity of *ascending* sensory pathways of the nervous system and are relatively unaffected by state, drug, or metabolic effects.
1. **Auditory evoked potential**
 - a. **Definition.** An auditory evoked potential (AEP) is an electrical response by the CNS to an auditory stimulus.
 - b. **Indication.** Brainstem AEPs may be used to detect abnormalities in threshold sensitivities, conduction time, amplitudes, and shape and may be useful as a hearing screen in high-risk infants.

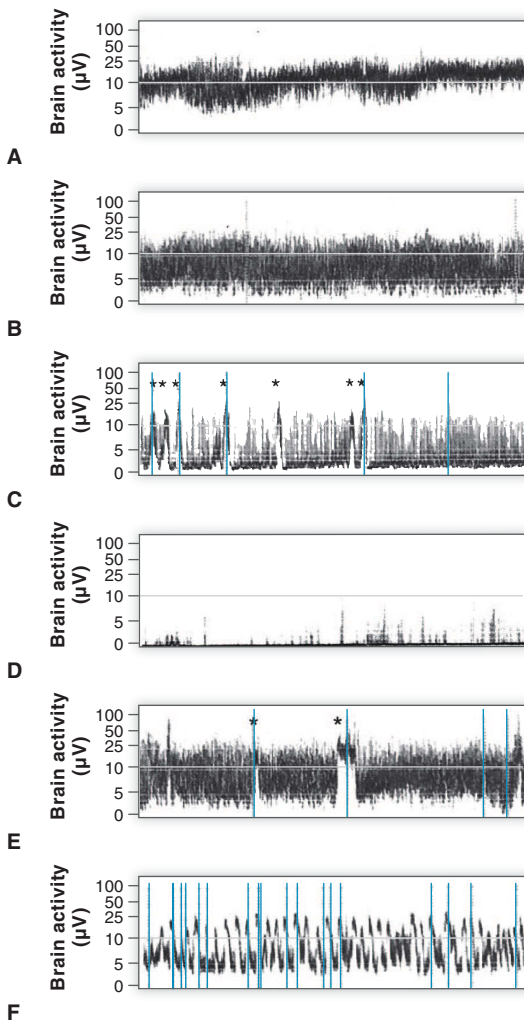

FIGURE 18-1. Sample amplitude-integrated electroencephalography (aEEG) patterns. The patterns are classified as follows: **(A) Continuous normal voltage** (normal background pattern for term infants characterized by continuous activity with lower amplitude at [5]–7–10 μV and maximum amplitudes at 10–25–[50] μV). **(B) Discontinuous normal voltage** (mildly abnormal in term infants, can be normal in some preterm infants depending on the postmenstrual age at the time of monitoring; characterized by discontinuous activity with some variability in the minimum amplitude, but mainly $<5 \mu\text{V}$ and maximum amplitude $>10 \mu\text{V}$). **(C) Burst suppression** (abnormal background pattern characterized by minimum amplitude without variability at 0–2 μV intermixed with bursts of high-voltage activity $>25 \mu\text{V}$) with 7 short seizures (asterisks). **(D) Isoelectric or flat trace** (severely abnormal background pattern with inactive background corresponding with electrocerebral inactivity). **(E) Two seizures** (asterisks) can be identified by a rise in the upper and lower margins against a discontinuous normal voltage background. **(F) Saw-tooth pattern** of status epilepticus. (Reproduced with permission from Bonifacio SL, Glass HC, Pelouquin S, et al: A new neurological focus in neonatal intensive care, *Nat Rev Neurol*. 2011 Aug 2;7(9):485-494.)

- c. Method.** Although neonates respond to an auditory stimulus with brainstem as well as cortical evoked responses, the latter are variable, depending on the state of arousal, and thus are difficult to interpret. As a result, AEPs (generated by a rapid sequence of clicks or puretones) traveling along the eighth nerve to the diencephalon are recorded by an electrode over the mastoid and vertex as brainstem AEPs, amplified, and digitally stored. The shape (a series of waves) and latency of brainstem AEPs depend on gestational age. This technique is sensitive to movement and ambient noise.
 - d. Results.** Injuries in the peripheral pathway (middle ear, cochlea, and eighth nerve) result in an increased sound threshold and an increase in latency of all waves, whereas central lesions cause only increased latency of waves originating from distal (in relation to the lesion) structures. Brainstem AEPs are used to demonstrate disorders of the auditory pathways caused by hypoxia-ischemia, hyperbilirubinemia, infections (eg, cytomegalovirus or bacterial meningitis), intracranial hemorrhage, trauma, systemic illnesses, or drugs (eg, aminoglycoside or furosemide). In low birthweight infants, brainstem AEPs have a high false-positive rate secondary to known gestational differences (longer latency, decreased amplitude, and increased threshold in preterm infants). Up to 20% to 25% of infants in the neonatal intensive care unit have abnormal (failed) tests, and most have normal tests at 2 to 4 months. In asphyxiated infants, abnormal brainstem AEPs are associated with neuromotor impairments. Because infants with congenital infection and persistent pulmonary hypertension may experience progressive hearing loss, they require serial hearing evaluations even if results are normal.
- 2. Visual evoked potential**
- a. Definition.** A visual evoked potential (VEP) is an electrical response by the CNS to a visual stimulus.
 - b. Indication.** A VEP may provide information on disorders of the visual pathway and has been used as an indicator for cerebral malfunctioning (eg, hypoxia).
 - c. Method.** An electrical response to a visual stimulus (eg, light flash in neonates or checkerboard pattern reversal in older children) is measured via a surface electrode. The electrical response is complex and undergoes significant developmental changes in the preterm infant.
 - d. Results.** When corrected for conceptional age, visual evoked responses allow the detection of various visual pathway abnormalities. Although generalized insults such as severe hypoxemia may result in temporary loss of visual evoked responses, local abnormalities may have similar results (eg, compression of the pathway in hydrocephalus). Persistent visual evoked response abnormalities in postasphyxiated infants have been strongly correlated with poor neurologic outcomes. Although VEPs may aid in the prognosis of long-term neurodevelopmental outcomes, they may not be helpful in predicting blindness or loss of vision. Improvements in visual evoked responses have also been applied to determine the success of interventions such as a ventricular-peritoneal shunt. The prognostic value in preterm infants is *controversial*.
- 3. Somatosensory evoked potential**
- a. Definition.** A somatosensory evoked potential (SEP) is an electrical response by the CNS to a peripheral sensory stimulus.
 - b. Indication.** SEPs allow insight into disorders of the sensory pathway (peripheral nerve, plexus, dorsal root, posterior column, contralateral nucleus, medial lemniscus, thalamus, and parietal cortex).
 - c. Method.** SEPs have been recorded over the contralateral parietal scalp after providing an electric stimulus to the median or the posterior tibial nerve. SEPs are technically more difficult to obtain than auditory brainstem evoked

potentials and are age dependent with significant changes occurring in the first months of life.

- d. **Results.** SEPs may allow evaluation of peripheral lesions such as spinal cord trauma and myelodysplasia as well as cerebral abnormalities such as hypoxia, ischemia, hemorrhage, hydrocephalus, hypoglycemia, and hypothyroidism. SEP abnormalities in term infants have a high positive predictive value for neurologic sequelae and abnormal neurodevelopmental outcome. The significance of SEP remains *controversial* in the preterm infant.

III. Clinical neurodevelopmental examination

- A. **Definition.** The clinical neurodevelopmental examination combines the assessment of posture, movement, extremity and axial muscle tone, deep tendon reflexes, pathologic reflexes (eg, Babinski sign), primitive (or primary) reflexes, cranial nerve and oromotor function, sensory responses, and behavior by an *experienced* clinician.
- B. **Indication.** All infants should undergo a brief neurologic examination, including tone and reflex assessment, as part of their initial physical examination. A more detailed neurodevelopmental examination should be performed on high-risk infants. Important risk factors include prematurity, hypoxic ischemic encephalopathy, congenital infection, meningitis, significant abnormalities on neuroimaging studies (eg, intraventricular hemorrhage, ventricular dilatation, intraparenchymal hemorrhage, infarct, or cysts), and feeding difficulties.
- C. **Method.** The experienced clinician should examine the infant when stable, preferably during the recovery phase. However, the examination may also be quite useful when performed serially, as with hypoxic ischemic encephalopathy. The infant's state of alertness may affect many responses, including sensory response, behavior, tone, and reflexes. Normal findings change according to age (actual and postconceptional).
 1. **The full-term neonate.** The normal full-term neonate has flexor hypertonia, hip adductor tone, hyperreflexia (may have unsustained clonus), symmetric tone and reflexes, good trunk tone on ventral suspension, some degree of head lag on pulling to a sitting from a supine position with modulation of forward head movement, presence of pathologic (eg, Babinski sign) and primitive reflexes (eg, Moro, grasp, and asymmetric tonic neck reflexes), alerting to sound, visual fixation, and a fixed focal length of 8 in.
 2. **The preterm neonate.** Before 30 weeks' postconceptional age, the infant is markedly hypotonic. Extremity flexor and axial tone and the reflexes emerge in a caudocephalad (ie, lower to upper extremity) and centripetal (ie, distal to proximal) manner. Visual attention and acuity improve with postconceptional age. The extremely preterm infant can suck and swallow, but coordination of suck with swallow occurs at approximately 32 to 34 weeks' postconceptional age. Flexor tone peaks at term and then becomes decreased in a caudocephalad manner. In comparison with full-term neonates, preterm infants at term have less flexor hypertonia, more extensor tone, more asymmetries, and mild differences in behavior.
- D. **Results.** Abnormalities on neurodevelopmental examination include asymmetries of posture or reflexes (especially significant if marked or persistent), decreased flexor or extremity tone or axial tone for postconceptional age, cranial nerve or oromotor dysfunction, abnormal sensory responses, abnormal behavior (eg, lethargy, irritability, or jitteriness), and extensor neck, trunk, or extremity tone. A normal neonatal neurodevelopmental examination is reassuring, but an abnormal examination cannot be used to diagnose disability in the neonatal period. The more abnormalities that are found on examination and the greater the degree of abnormality (eg, marked neck extensor hypertonia), the higher the incidence of later disability, including cerebral palsy and intellectual disability.

19 Blood Component Therapy

I. Blood banking procedures

A. Type and screen. Whenever possible, serum or plasma samples from both mother and infant should be obtained for initial ABO group and Rh(D) type determinations.

1. Investigations of the maternal sample should include:

a. **ABO group and Rh(D) type.**

b. **Screen for unexpected red cell antibodies** by an indirect antiglobulin technique (IAT).

i. **Unexpected (or atypical) red cell antibodies** are clinically significant alloantibodies (alloantibodies) other than the isohemagglutinins, anti-A and/or anti-B, whose presence may be expected depending on the ABO group.

ii. **If possible, review maternal antenatal records** regarding antibody evaluations.

2. Investigations of the infant (or umbilical cord) sample should include:

a. **ABO group and Rh(D) type.**

b. **Direct antiglobulin test (DAT)** performed on neonatal red cells.

c. **In the absence of maternal serum or plasma**, the infant's serum or plasma is screened for unexpected antibodies by an IAT.

i. **Infants very rarely make alloantibodies during the first 4 months of life**, but they may have maternal alloantibodies acquired transplacentally.

ii. **Repeat ABO group and Rh(D) type determinations may be omitted** throughout the remainder of the neonate's hospital admission or until age 4 months is attained, whichever occurs sooner.

d. **If a non-group-O neonate is to be transfused with non-group-O erythrocytes**, which are incompatible with the maternal ABO group, then the neonate's serum or plasma must be tested for anti-A and anti-B using an IAT. If either antibody is detected, then donor erythrocytes that lack the corresponding antigen must be chosen for transfusion.

B. Type and cross-match red blood cells

1. **Perform an initial screen** for unexpected (or atypical) red blood cell (RBC) antibodies.

a. **Test donor candidate red blood cells against infant's serum or plasma** (from umbilical cord [preferred] or venous blood) and inspect for agglutination and/or hemolysis after incubation at 37°C (98.6°F).

b. **Alternatively, if mother and neonate are ABO compatible**, then maternal serum or plasma may be used (to limit neonatal venipunctures).

c. **If this initial screen for red cell antibodies is negative**, then there is no need to perform cross-matching during the remainder of the neonate's hospital admission or until age 4 months is attained, whichever occurs sooner. **If the initial screen for RBC antibodies is positive, then additional testing must be done.**

2. **Perform tests to determine the specificity** of any antibodies identified.

a. **Using an indirect antiglobulin technique, test maternal or infant serum or plasma** against a panel of group O reagent erythrocytes of known antigenic phenotype.

3. **Transfused red cells** used typically must lack the corresponding antigen(s) and be compatible by antiglobulin phase cross-match with maternal or infant serum or plasma. In case of antibodies to extremely rare antigens, antigen-typed red cells may not be available, but antiglobulin phase cross-match must still be compatible.

- a. **Cross-matches are needed with each transfusion** until antibodies are no longer demonstrable in the neonate's serum or plasma.
- b. **The presence of multiple antibodies** increases the difficulty of identifying compatible donors and delays blood availability.

II. Routine blood donation

A. Voluntary blood donations. These are from donors with both a negative history for and negative screening tests for transfusion-transmissible diseases. All blood donors are tested using serologic enzyme immunoassays (EIAs) and nucleic acid amplification tests (NATs) for viral risks that include HIV (1 and 2), hepatitis viruses B and C (HBV and HCV), human T-cell lymphotropic viruses (HTLV [I and II]), West Nile virus (WNV), and Zika virus. The only screening assay for parasites currently is an EIA for antibodies to *Trypanosoma cruzi* (cause of Chagas disease; once in donor's lifetime). In addition, EIA or microhemagglutination testing for *Treponema pallidum* (syphilis) is still required. Testing obviously is not performed for all blood-borne threats; testing for the following viruses is *not* routinely done: cytomegalovirus (CMV), parvovirus B19, hepatitis A virus (HAV), Epstein-Barr virus (EBV), and human herpes virus-8 (HHV-8 or Kaposi sarcoma-associated herpes virus [KSHV]).

B. The residual risks of transfusion per unit transfused are estimated to be:

1. **Human immunodeficiency virus types 1 and 2.** 1 per 1,467,000.
2. **Hepatitis C virus.** 1 per 1,149,000.
3. **Hepatitis B virus.** 1 per 280,000 to 1 per 843,000 depending on length of infectious period
4. **Human T-cell lymphotropic virus types I and II.** 1 per 2,993,000 to 1 per 4,364,000 (2007–2008 estimate). An accurate risk estimate applicable to the United States is not currently possible.
5. **West Nile virus.** Risk for WNV varies with location, date, and test method (mini pool NAT vs individual NAT) and has been decreasing in recent years, so a single risk estimate applicable to the United States is not possible. Similar considerations apply to **Zika virus**, except incidence has been increasing in recent years.
6. **Risk for transfusion-transmitted *T. cruzi* is unknown;** 20 cases have been reported as transfusion transmitted globally in nonendemic areas. Prevalence in blood donors is estimated as 1 per 38,500.
7. **For perspective, selected comparative mortality odds ratios are: anesthesia—**1 per 7000 to 340,000; **blood—**1 per 455,000; and **lightning strike—**1 per 10,000,000.

III. Donor-directed blood products.

Blood provided by a relative or friend of the family for a specified infant.

- A. **This technique cannot be used in an emergency setting** because it takes up to 48 hours to process the blood for use.
- B. **There is no evidence that donor-directed transfusion is safer than blood provided by routine donation.** In fact, donor-directed transfusions are positive for transmissible disease markers at the same rate as first-time donors (higher than the rate for repeat volunteer donors).
- C. **Mothers are not ideal donors because maternal plasma frequently contains a variety of antibodies (against leukocyte and platelet antigens) that could interact with antigens expressed on neonatal cells.** Similarly, transfusions from paternal donors present a risk because the neonate may have been passively immunized against paternal blood cellular antigens (by transplacental transfer of maternal antibodies against paternal antigens).

IV. Autologous blood donation.

In adults, safety of transfusion is enhanced by the use of autologous blood collected preoperatively.

- A. **The fetoplacental blood reservoir** contains a blood volume of approximately 110 mL/kg, with 30% to 50% of this volume contained in the placenta. Thus, placental blood is autologous blood. Approximately 20 mL/kg can be harvested at birth and used for future transfusions.

1. **The potential for bacterial contamination** and the additional expense of collection have limited the widespread adoption of placental autologous blood transfusion.
 2. **Placental autologous blood**, in selected cases, is collected and stored as umbilical cord blood and used as a source of hematopoietic progenitor cells for transplantation.
- B. As an alternative, delayed cord clamping** for 30 to 60 seconds after birth allows the transfer of a significant amount of blood from the placenta to the infant. The blood volume of a newborn subjected to delayed cord clamping is 15 to 30 mL/kg larger than that of neonates with early cord clamping. **Beneficial effects** from this procedure are a reduction in transfusions needed, decreased iron deficiency at a later age, decreased hospital mortality, and possibly decreased risk of intraventricular hemorrhage in preterm infants.

V. Irradiated/filtered blood components

A. The following adverse outcomes to blood transfusion are caused by contaminant leukocytes (white blood cells [WBCs]), whose numbers are maximal when fresh blood is used.

1. **Sensitization** to human leukocyte antigens (HLAs).
2. **Febrile transfusion reactions.**
3. **Immune modulation**, which may increase the risk of postoperative infection.
4. **Transmission of cytomegalovirus** and other herpes and retroviral leukocyte passenger viruses.
5. **Transfusion-associated graft-versus-host disease** (TA-GVHD) from engraftment of donor T lymphocytes.

B. Human leukocyte antigen sensitization and febrile transfusion reactions are unusual in infants, whereas transfusion-transmitted CMV and TA-GVHD can be life threatening.

1. **At greatest risk of severe cytomegalovirus infection** are preterm infants (<1200 g) born to CMV-seronegative mothers and infants with immunodeficiency. For these high-risk patients, transfused blood components must be processed to remove passenger WBCs.

a. Leukoreduction (removal of passenger white blood cells)

i. Such so-called leukoreduction is almost always performed by filtration of the blood component through proprietary hollow-fiber filters to which intact WBCs adhere. (Centrifugation-based techniques are outdated.) Leukocyte counts can be reduced from 10^9 to $4\text{--}6 \times 10^5$ per RBC unit (4-log unit reduction) with fourth-generation filters.

ii. Leukoreduction is effective in reducing HLA alloimmunization and transmission of cell-associated viruses, especially herpes viruses (eg, CMV, HHV-8, and EBV), as well as preventing some febrile transfusion reactions.

2. **Patients at risk for TA-GVHD** include recipients of donor-directed units from first- and second-degree blood relatives, HLA-matched platelets, intrauterine transfusions, and massive fresh blood transfusions or exchange transfusions, as well as patients with suspected or proven severe T-lymphocyte immunodeficiency states (eg, DiGeorge syndrome).

a. Gamma-irradiation of cellular blood components delivers a dose of 25 Gy and prevents subsequent WBC mitoses, and thereby TA-GVHD.

VI. Emergency transfusions. For patients >4 months old, uncross-matched (or “emergency release”) blood is rarely transfused, because most blood banks can complete an IAT cross-match within 1 hour. In cases of massive exsanguinating hemorrhage, “type-specific” blood (wherein ABO and Rh[D] match the patient’s antigens) is given as either uncross-matched or “immediate spin” cross-match compatible (directly tested in saline without anti-human globulin) and is usually available in 10 minutes. If this delay is too long (as in severe fetomaternal hemorrhage), type O Rh(D)-negative RBCs should be used.

VII. Blood bank products

A. Red blood cells

1. Packed red blood cells (PRBCs)

- a. **Indications.** PRBC transfusions are given to maintain hemoglobin (Hgb)/hematocrit (Hct) at levels judged “best” for the clinical condition of the baby. Dueling proponents are split between those favoring “restrictive” Hgb thresholds (“transfusion triggers”) of 7 to 8 g/dL and those favoring “liberal” Hgb thresholds of 9 to 10 g/dL. In general, restrictive practice has been shown (in randomized controlled trials [RCTs]) not to be inferior to liberal practice (since it was not associated with higher rates of adverse outcomes) and to result in fewer total transfusions.
- b. **In the multicenter Premature Infants in Need of Transfusion randomized controlled trial,** 451 very low birthweight infants were assigned to transfusions using either restrictive or liberal criteria. Outcome rates for death, severe retinopathy, bronchopulmonary dysplasia, and brain injury supported the use of restrictive transfusion criteria. In addition, 11% of infants in the restrictive group avoided transfusion completely compared to 5% in the liberal group.
- c. **In a single-center randomized controlled trial,** Bell et al assigned 100 preterm infants to either restrictive or liberal transfusion practice. Again, a reduction in the number of transfusions in the restrictive group was seen but with more episodes of apnea and neurologic events than in the liberal group.
- d. **More recent meta-analysis** contrasting documented benefits of a restrictive transfusion practice (decreased number of transfusions and exposure to fewer RBC donors) to those of a liberal transfusion practice (decreased apnea and brain injury) called for additional clinical studies to clarify the impact of practice type on long-term neonatal outcomes.
- e. **Currently, the selected posttransfusion hemoglobin/hematocrit target** is quite *controversial* and may vary greatly among neonatal units. In general, an advocate of a liberal transfusion practice would list Hct goals as:
 - i. **>35% to 40%** in the presence of severe cardiopulmonary disease. The severity of cardiopulmonary disease is assessed based on the level of respiratory support required (intermittent positive pressure ventilation [IPPV], continuous positive airway pressure [CPAP], FiO_2), symptoms of unexplained apnea and/or tachycardia, and/or poor growth.
 - ii. **30% to 35%** for moderate cardiopulmonary disease or major surgery.
 - iii. **20% to 25%** for infants with stable, so-called asymptomatic anemia (primarily due to iatrogenic blood loss for laboratory testing and/or inadequate hematopoiesis).
- f. **Administration**
 - i. **Type.** PRBCs transfused throughout infancy should be screened in order to exclude donations from blood donors containing Hgb S.
 - ii. **Dosage.** 10 to 20 mL/kg given over 1 to 3 hours (4 hours maximum). **Use the following formula as a guide:**

$$\text{Volume PRBC to transfuse (mL)} = 1.6 \times \text{weight (kg)} \times \text{desired rise in Hct (\%)}$$

2. **“Adsol” packed red blood cells.** The traditional use of relatively fresh RBCs (<7 days in storage) has been largely replaced by the practice of transfusing aliquots of RBCs from a dedicated unit of PRBCs stored for up to 42 days. This requires a sterile connecting device and is done to diminish the number of donor exposures among infants expected to require numerous transfusions during their stay in the neonatal intensive care unit (infants whose birthweight is <1500 g).
 - a. **Packed red blood cells are suspended** in a citrate-anticoagulated storage solution at an Hct of 55% to 60% stored at 1°C to 6°C.

- b. **These additive solutions** (AS or Adsol-1, -3, or -5) contain various combinations of preservatives (dextrose, sodium chloride, phosphate, adenine, and mannitol) with citrate anticoagulant.
- 3. **Citrate phosphate dextrose packed red blood cells.** Because of concern about potential hepatorenal toxicity of adenine and mannitol, units of RBCs without extended storage AS media are used for large-volume transfusions such as exchange transfusion and transfusions for major surgical procedures.
 - a. **Citrate phosphate dextrose with adenine** (CPDA-1) PRBC units with only small amounts of adenine and devoid of mannitol have an Hct of 65% to 80% and a shelf life of 35 days.
 - b. **Citrate phosphate dextrose** (CPD) PRBC units lacking both adenine and mannitol also have an Hct of 65% to 80% but a shelf life of only 21 days.
 - c. **Washed AS or Adsol PRBC units** are an alternative if these other PRBC units are unavailable.
- 4. **Washed packed red blood cells.** During storage, potassium is progressively released from RBCs so that, by the end of the storage period, extracellular (plasma) potassium levels approximate 50 and 80 mEq/L for Adsol and CPD units, respectively. This leakage is increased in irradiated blood. For small-volume transfusions, the amount of infused potassium is, in general, of little clinical significance (0.3–0.4 mEq/kg per 15 mL/kg RBC transfusion). But it may become hazardous for larger transfusion volumes such as in exchange transfusion. In such an event and in the absence of fresh whole blood (<2–3 days old), RBCs (typically O Rh[D] negative) washed free of their potentially hyperkalemic supernatant using normal saline and then resuspended to an Hct of 50% to 55% with fresh frozen plasma (typically AB, termed “reconstituted whole blood”) can be used. Irradiated reconstituted whole blood should be used for total (or “double blood volume”) exchange transfusions.
- 5. **Fresh PRBCs.** RCTs demonstrating advantages of fresh PRBCs compared to standard-issue (within licensed time frame) PRBCs have not been replicated or dominated meta-analyses.
- B. **Plasma—fresh-frozen plasma, thawed plasma.** Donated whole blood is centrifuged to separate the cells (RBCs, WBCs, and platelets) and the liquid (plasma). Plasma separated and frozen within 8 hours of the blood being donated is called fresh-frozen plasma (FFP); plasma separated and frozen within 24 hours is called plasma frozen 24 (PF24). Beyond 24 hours after thawing, FFP and PF24 are known as thawed plasma, which is usable for 5 days after donation. Plasma contains albumin, immune globulins, and clotting factors. Some clotting factors retain much of their activity after thawing (eg, von Willebrand factor [vWF]), but the activity of others is progressively reduced during refrigerated storage after thawing (factors V, VII, and VIII).

1. Indications

- a. **Correction of coagulopathy** due to deficiencies of multiple clotting factors in vitamin K deficiency (hemorrhagic disease of the newborn) or disseminated intravascular coagulation (DIC).
- b. **Prophylaxis for or treatment of bleeding** for a known single coagulation factor deficiency for which no concentrate is available.
 - i. **When available, clotting factor concentrates** are preferred to plasma in case of a single, inherited clotting factor deficiency.
 - ii. **There are no US Food and Drug Administration–approved single factor concentrates available** in the United States for factors II, V, and XI.
 - iii. **Concentrate for treatment of acute angioedema or preoperative prophylaxis** in hereditary C1-inhibitor deficiency may not be immediately available.
- c. **Prothrombin complex concentrates** (PCC) containing factors II, VII, IX, and X are used for factor II and X deficiencies and warfarin reversal in

case of severe bleeding or pending surgical procedures. If PCC is unavailable, use FFP.

- d. **Prophylaxis for or treatment of dilutional coagulopathy** (“coagulopathic bleeding”) that may ensue during massive RBC transfusion administered for replacement of blood loss in excess of half of the blood volume.
- e. **Preparation of reconstituted whole blood from washed PRBCs** for total exchange transfusion.
- f. **Although fresh-frozen plasma provides excellent colloid volume support**, it is not recommended for volume expansion, albumin supplementation, or antibody replacement because safer components (albumin, intravenous immunoglobulin) are available for these purposes.
- g. **Fresh-frozen plasma should not be given for abnormal coagulation screen results** in the absence of bleeding or for coagulopathies that can be corrected by adjusting warfarin dose and/or administration of vitamin K.

2. Administration

- a. **Transfused plasma should be ABO compatible with the patient’s blood group.** Incompatible antibodies in the donor plasma (eg, anti-A or -B antibodies in group O plasma) may rarely, if given in sufficient volume, result in an acute hemolytic reaction in the transfused patient.
- b. **Dosage:** 10 to 20 mL/kg over 1 to 2 hours (4 hours maximum).
- c. **Rapid transfusion may result in transient hypocalcemia due to the sodium citrate anticoagulant that is added to donated blood.** If rapid infusion of FFP is needed, a small bolus of calcium chloride (3–5 mg/kg) may be considered.

C. Cryoprecipitate. This is prepared from FFP by thawing it at 1°C to 6°C. In this temperature range, a cryoprecipitate forms and is separated from so-called cryo-poor supernatant plasma by centrifugation at 1°C to 6°C. The pellet is then frozen as cryoprecipitate. Prior to use, it must again be thawed and dissolved off the interior surface of its plastic bag with sterile, normal saline (total volume of 10–15 mL). Cryoprecipitate is a concentrated source of the following blood clotting proteins: factor VIII, vWF, fibrinogen, and factor XIII (with some other proteins, eg, fibronectin).

1. Indications

- a. **To restore fibrinogen levels** in patients with acquired hypofibrinogenemia (as occurs in DIC and massive transfusion)
- b. **Factor XIII in deficient patients**, if Food and Drug Administration–approved Corifact concentrate is unavailable.

2. Administration

- a. **Unlike plasma, it does not need to be ABO compatible with the recipient’s blood group.**
- b. **Dosage:** 10 mL/kg (0.1–0.2 U/kg raises fibrinogen by 60–100 mg/dL).
- c. **Infusion should be completed within 6 hours of thawing.**

D. Platelets. This component is prepared from whole blood donations by centrifugation (termed *random donor*) or by automated apheresis (termed *single donor* or *platelets, pheresis*). Each random donor unit contains 5.5×10^{10} platelets in 50 to 70 mL of anticoagulated plasma. Each single-donor unit contains 3×10^{11} platelets, typically in 200 to 300 mL of anticoagulated plasma. Both are stored at room temperature (20–24°C) with agitation for a maximum of 5 days.

1. Indications. There are no absolute guidelines regarding platelet counts that necessitate transfusion.

- a. **In general, prophylactic platelet transfusions are indicated** for platelet counts of $<20,000/\mu\text{L}$ for stable neonates at term or $<30,000/\mu\text{L}$ for stable premature neonates.
- b. **For high-risk neonates at an increased risk of intraventricular hemorrhage**, prophylactic platelet transfusions may be given at $<30,000/\mu\text{L}$ at term or $<50,000/\mu\text{L}$ if premature.

- i. **Such high-risk neonates** include those with extremely low birthweight, perinatal asphyxia, sepsis, ventilatory assistance with an $\text{FiO}_2 > 40\%$, or clinical instability.
 - c. **In the presence of clinically significant, active bleeding or prior to undergoing invasive or surgical procedures**, this “transfusion trigger” may be raised to $< 50,000/\mu\text{L}$.
 - d. **Infants on extracorporeal life support/extracorporeal membrane oxygenation** are usually prophylactically transfused to maintain a platelet count of $> 80,000$ to $100,000/\mu\text{L}$.
 - e. **In septic patients**, platelet increments after transfusion may only be transient.
 - f. **Because of room temperature storage, bacterial contamination of platelet units** is actively sought, typically by culture or direct testing of each component.
 - g. **Increased mortality and morbidity** have been described among preterm infants receiving multiple platelet transfusions; causality is unclear.
2. **Administration**
- a. **Infant and donor should be ABO identical if possible.** When ABO-identical platelets are unavailable, group AB platelets are the most suitable substitute. However, the frequent unavailability of group AB platelets causes the use of group A platelets for group B recipients and vice versa. Group O platelets are the least suitable for non-group-O infants, because passively transfused anti-A or anti-B antibodies may lead to hemolysis.
 - b. **Rh(D)-negative platelets should be given whenever possible to Rh(D)-negative patients**, especially female infants. If this is impossible, consider administration of Rh immune globulin.
 - i. **The Alloimmunization After D-Incompatible Platelet Transfusions study** in nonneonates, which included Rh(D)-negative recipients with hematologic, oncologic, and various other conditions who received Rh(D)-positive apheresis platelets, found anti-D antibody in approximately 1.4% of recipients upon follow-up after a median of 77 days.
 - c. **For infants with alloimmune thrombocytopenia (AIT)**, platelets lacking human platelet antigens (HPAs) to which antibodies are directed are required. If such platelets are unavailable, then HPA-1a/5b-negative platelets may be given since these will be compatible in 95% of AIT cases among white patients. For Asian patients, HPA-4a-negative platelets would be chosen. If anti-HPA antibodies are not demonstrated, then anti-HLA antibodies may be present, requiring HLA-matched platelets.
 - d. **Dosage:** 10 to 20 mL/kg intravenously should raise neonatal platelet counts by 60,000 to 100,000/ μL .

VIII. Transfusion reactions

- A. **Acute intravascular hemolysis.** Occurs due to incompatibility of donor RBCs with antibodies in the patient plasma. The most common antibodies responsible for complement-mediated acute hemolysis are isohemagglutinins (anti-A, anti-B). Newborns do not all make isohemagglutinins in high titer until 4 to 6 months of age.
1. **However, transfusion of ABO-incompatible donor red blood cells (most commonly due to clerical error)** may result in hemolysis if isoagglutinin titers are high enough. Accordingly, some neonatal units may transfuse all neonates with O Rh(D)-negative PRBCs (if the blood supplier can support this policy).
 2. **Incompatible isohemagglutinins are more often found in the neonatal circulation** due to transfusion of the ABO-incompatible plasma in platelet units.
 3. **Transplacental passage of group O maternal isohemagglutinins to a non-group-O fetus** may also cause hemolysis of the neonate’s own RBCs in the absence of transfusion (often mild; hemolytic disease of the fetus and newborn). Note that passively acquired anti-A and anti-B, whether of blood donor or maternal origin, are not detected by antibody screens but do cause incompatible

cross-matches. Accordingly, cross-matches using an IAT are always necessary when clinically significant RBC antibodies, including isohemagglutinins, are present in neonatal plasma.

4. **Red cell T-antigen is present on all human erythrocytes** but expressed only after exposure to neuraminidase produced by a variety of infectious organisms—in particular *Streptococcus*, *Clostridium*, and influenza viruses. Anti-T antibodies are present in almost all adults but are not present in the plasma of infants until 6 months of age. Anti-T may be associated with hemolysis in patients whose RBCs are “activated” (eg, infants with necrotizing enterocolitis [NEC] or sepsis). When intravascular hemolysis occurs and T activation of neonatal RBCs is identified through peanut lectin testing, donor RBCs and platelets should be washed prior to use.
 5. **Possible symptoms of intravascular hemolysis include** hypotension, fever, tachycardia, hematuria, and hemoglobinuria. Diagnosis may be confirmed by an elevated free serum Hgb, absent haptoglobin (if it is not congenitally absent, as in about 10% of African-American infants), as well as the presence of schistocytes on a peripheral blood smear.
- B. Nonhemolytic febrile reactions.** Usually mild and due to transfusion of cytokines released from donor WBCs during storage or of fragmented donor WBCs.
- C. Allergic transfusion reactions.** Unusual in neonatal transfusion recipients. Due to antibodies in the patient’s plasma reacting to epitopes on donor plasma proteins.
- D. Transfusion-associated acute lung injury.** Transfusion-related acute lung injury (TRALI) is typically due to antibodies in donor plasma that react with the patient’s HLA antigens. More likely to occur with blood components containing a large volume of plasma such as FFP or platelets.
- E. Bacterial contamination.** There is a small but potentially fatal risk of bacterial infection on the order of 1 per million for PRBCs but of 1 per 100,000 for platelets (because of room temperature storage). Platelet components are bacterially contaminated at a rate of 1 per 1000 to 3000; false-negative results of platelet screening for bacterial contamination are unavoidable. (To address the risk, the AABB Standard 5.15.1 was first added on March 1, 2004 to “implement measures to limit bacterial contamination in all platelet components.”) Transfusion-transmitted sepsis with culture confirmation occurs in at least 1 per 100,000 recipients, and 1 of every 5 cases has an immediate fatal outcome (1 in 500,000 recipients).
1. **For several consecutive years, bacterial contamination of platelets has been the top transfusion-transmitted infection in the United States and the second leading cause of blood transfusion-related death in the United States** (after TRALI). However, it is widely suspected that bacterial contamination of blood components is underreported.
 2. ***Escherichia coli*, *Pseudomonas*, *Serratia*, *Salmonella*, *Enterobacter*, and *Yersinia*** are the most commonly implicated gram-negative bacteria causing severe or fatal infections. Gram-positive bacteria (eg, *Staphylococcus epidermidis*) are the most frequent contaminants of platelet units (from blood donor’s skin).
 3. **Immediate notification of public health authorities is required for:**
 - a. **Bacterial category A agents of bioterrorism:** *Bacillus anthracis*, *Yersinia pestis*, *Francisella tularensis*, and *Clostridium botulinum*. Individual isolates of these organisms must be saved for confirmatory testing at public health laboratories.
 - b. **Multiple other, selected bacteria are listed as nationally notifiable diseases;** consult the Centers for Disease Control and Prevention’s National Notifiable Diseases Surveillance System for a complete list.
- F. Hypothermia.** Large-volume transfusions of either reconstituted whole blood (exchange transfusion) or PRBCs (major surgery, large fetomaternal hemorrhages), which are stored at 1°C to 6°C, will result in hypothermia unless a blood warmer is used.

- G. Hyperkalemia.** At risk are infants receiving a large transfusion of RBCs such as in exchange transfusion, major surgery, or extracorporeal life support (ECLS). Reconstituted whole blood (washed PRBCs [<14 days old] with Hct adjusted using FFP) is recommended. In some neonatal units, fresh whole blood (2–3 days old) may be available.
- H. Necrotizing enterocolitis.** In the past 15 years, several case reports and retrospective studies have reported that up to one third of all very low birthweight (VLBW) infants who develop NEC may have received 1 or more RBC transfusions in the 24 to 72 hours prior to onset of NEC. The causality of the “transfusion-associated” NEC has been hypothesized to share the same TRALI immunologic mechanisms, such as transfusion of biologic response mediators such as donor antibodies against the HLA, biologically active lipids, free Hgb, RBC membrane fragments, and inflammatory cytokines present in stored blood.

More recently, 2 published prospective studies failed to demonstrate this association between RBC transfusion and NEC, with 1 of the studies suggesting that it is the underlying anemia, not the transfusion, that may increase the risk of NEC.

20 Extracorporeal Life Support in the Neonate

- I. Introduction.** Extracorporeal life support (ECLS), also referred to as extracorporeal membrane oxygenation (ECMO), provides either direct cardiac/pulmonary support (venoarterial [VA] ECLS) or indirect cardiac/pulmonary support (venovenous [VV] ECLS) by providing oxygen (O_2) delivery and carbon dioxide (CO_2) removal in neonates with reversible life-threatening respiratory or cardiac disease. While on ECLS, blood is drained from the right atrium through a cannula with the aid of a pump and then propelled through an oxygenator where gas exchange occurs. From there, it is returned to the aorta (VA) or right atrium (VV) (Figure 20–1). Uniform guidelines have been established to describe essential equipment, procedures, personnel, and training required for ECLS and can be found in *Extracorporeal Life Support: The ELSO Red Book*, 5th Edition, and *Extracorporeal Membrane Oxygenation (ECLS) Specialist Training Manual* published by the Extracorporeal Life Support Organization (ELSO) and on the ELSO website.
- II. Indications.** ECLS is used in critically ill term and late preterm newborns with reversible respiratory and/or cardiac failure who have failed maximal medical management. Neonatal conditions supported with ECLS include meconium aspiration syndrome (MAS), congenital diaphragmatic hernia (CDH), persistent pulmonary hypertension of the newborn (PPHN), respiratory distress syndrome (RDS), sepsis, pneumonia, severe air leak, and airway anomalies awaiting surgical repair and postoperatively during recovery. VV-ECLS is preferred in most neonates with respiratory failure because it appears safer. VA-ECLS is used in patients with cardiac failure due to congenital heart disease, postcardiotomy heart failure, cardiomyopathy, cardiac failure due to sepsis, severe rhythm disturbances, situations of cardiac arrest, and as a bridge to cardiac transplantation. VA-ECLS is often favored in patients with CDH where vessel anatomy prevents cannulation with a double-lumen venous catheter. (However, comparison studies provide data supporting successful VV-ECLS use in the CDH population). VA-ECLS is also preferred in patients with septic shock in whom higher flow rates may be required to provide support.

FIGURE 20–1. Extracorporeal life support circuit.

III. Appropriate patients for extracorporeal life support

A. Weight ≥ 1800 to 2000 g and/or gestational age ≥ 32 to 34 weeks. The cannula size is determined by the infant's weight; the lower limit in weight is based on the limitation of cannula sizes available.

B. Cardiopulmonary criteria for extracorporeal life support

1. Oxygenation index. Most centers use a combination of persistently elevated oxygenation index (OI) calculations (OI of 30–40) and the inability to wean from 100% oxygen within a period of time as criteria for initiating ECLS support.

$$OI = \frac{FiO_2 \times MAP \times 100}{PaO_2}$$

(FiO₂, fraction of inspired O₂; MAP, mean airway pressure; PaO₂, partial pressure of oxygen, arterial)

FIGURE 20–2. Maquet Cardiohelp (Maquet Cardiopulmonary, Hirrlingen, Germany) incorporates the pump, gas exchanger, and heat exchanger into a single unit. Oxygenator (red) and centrifugal pump (silver) are in one unit. The arterial limb is above the venous limb (shown as tubes on the left). Hand crank is pictured to the lower left. (Maquet Cardiopulmonary, Hirrlingen, Germany.)

2. **Acute deterioration with intractable hypoxemia.** Neonates who have a $\text{PaO}_2 < 30\text{--}40$ mm Hg or a preductal $\text{SaO}_2 < 80\%$ for greater than an hour with no response to conventional therapies should be considered for ECLS support.
3. **Barotrauma.** Severe air leak from pneumothoraces that is not responsive to low tidal volume conventional ventilation or high-frequency ventilation may benefit from lung rest on ECLS.
4. **Severe lactic acidosis.** Indicators of circulatory failure including hypotension and a rising lactate despite circulatory support strategies including volume expansion and inotropic/vasopressor support should prompt ECLS as well.
5. **Cardiac arrest.** ECLS during cardiopulmonary resuscitation (ECPR) is available in many centers for patients with or without primary heart disease in situations where the cardiac arrest is witnessed.

IV. Relative contraindications to extracorporeal life support. Decisions for determining contraindications to ECLS are institution based.

- A. **Gestational age <32 to 34 weeks and/or a birthweight <1800 to 2000 g** are relative contraindications to ECLS due to increased mortality and morbidity. ECLS may be accomplished in neonates <34 weeks if their vessels are large enough to accommodate the cannula/cannulae. A Doppler ultrasound of the internal jugular vessel and carotid artery may help determine if the vessel size is appropriate. Current ECLS circuit technology requires the use of systemic heparinization for anticoagulation, increasing the risk for developing an intraventricular hemorrhage or parenchymal hemorrhage, particularly during the first week of life. Preterm neonates older than a week of life appear to gain some cerebrovascular stability and are less likely to have an intracranial hemorrhage when on ECLS. Newer technologies, improved anticoagulation strategies, and smaller cannulae sizes are being developed that may allow ECLS support in younger and smaller patients.

FIGURE 20-3. Venoarterial extracorporeal life support cannulae placement. The echogenic dot denoting the end of the venous cannula is shown near the arrow.

- B. Intracranial hemorrhage grade >II due to a higher risk of extending the hemorrhage.** Neonates with grade III or IV intracranial hemorrhages and those with severe brain damage are likely to have significant neurologic sequelae and may extend the area of central nervous system (CNS) hemorrhage if placed on ECLS. Generally, ECLS support is weaned off under circumstances of a grade III or IV intracranial hemorrhage or extending parenchymal hemorrhage.
- C. Severe congenital anomalies** incompatible with long-term survival.
- D. Cardiac lesions** that cannot be corrected or palliated.

- E. **Neonates with congenital diaphragmatic hernia** who have never had a preductal saturation $>80\%$ or $\text{PaCO}_2 < 80$ mm Hg may be excluded from ECLS therapy in some centers.
- F. **Marked perinatal asphyxia** with severe neurologic sequelae (ongoing stupor, flaccidity, dilated and fixed pupils, and absent primitive reflexes) persisting after respiratory and metabolic resuscitation will not benefit from ECLS.
- G. **Multiple organ dysfunction** in neonates can develop with septic shock, hypoperfusion, or hypoxia. Such neonates often develop respiratory failure, metabolic acidosis, and coagulopathy that do not resolve with transfusion therapy, as well as cardiac, renal, and gastrointestinal dysfunction. Although ECLS can support infants in multiorgan failure and provide time for improvement, neonates in extremis with such significant multiple-organ derangements that are not likely to survive should not receive ECLS. Interdisciplinary discussions are important when making a decision about placing an infant on ECLS and, if placed on ECLS, throughout the ECLS course.
- V. **Transfer of neonates possibly needing extracorporeal life support.** Neonates should be transferred early in their course, if possible. An OI of >25 suggests significant hypoxic respiratory failure and equates to a neonate on a mean airway pressure of 15 with an FiO_2 of 1.0 who achieves a PaO_2 of only 60 mm Hg. Any neonates requiring 100% oxygen without signs of improvement on conventional or high-frequency ventilation and inhaled nitric oxide within 4 to 6 hours or those who have persistent hypotension, respiratory acidosis, and/or lactic acidosis despite vasopressor/inotropic therapy should be considered candidates for transport to an ECLS center.
- VI. **Parental consent.** Prior to ECLS initiation, parents or guardians should be made aware of the risks and benefits of ECLS. The physician should emphasize that ECLS provides supportive treatment rather than curative therapy and that neonates may not survive.
- VII. **Potential complications to discuss with parents**
 - A. **Difficulties may arise during cannulation**, including the inability to achieve adequate venous drainage or infusion secondary to a venous web, valve, or vessel spasm. Perforation of the right atrium leading to pericardial tamponade can occur suddenly and be life threatening, requiring massive transfusion of blood products and immediate surgical evacuation.
 - B. **Hemorrhage may develop in any organ.** Blood accumulation in the pericardium, abdomen, retroperitoneum, or chest can result in decreased pulse pressure, low venous oxygen saturations (SvO_2), hypotension, and inability to maintain ECLS flows and may need to be evacuated. Significant intracranial hemorrhage may necessitate discontinuation of ECLS.
 - C. **Thrombosis or emboli in the circuit** may lead to an infarction in the brain. This is usually seen with VA-ECLS but can occur in VV-ECLS when an intracardiac shunt is present.
 - D. **Infectious risks** increase with prolonged ECLS and are more common in VA-ECLS patients. Coagulase-negative staphylococci and *Candida* are the most common organisms identified. However, routine prophylactic antibiotics while on ECLS are not warranted.
 - E. **Acute kidney injury** (AKI) can increase the length of time on ECLS and is independently associated with mortality. Continuous renal replacement therapy is used for AKI or for massive fluid overload.
 - F. **Development of chronic lung disease** may lead to future hospitalizations and have long-term effects on pulmonary function. Data suggest that allowing the lung to rest using minimal ventilator settings and by supporting with ECLS in the interim limits pulmonary complications. Evaluations at 1 year show slightly better lung function in those treated with ECLS than with conventional therapy.

- G. Extracorporeal life support survivors are at risk for neurologic sequelae** resulting from the underlying disease process and/or their treatments. See Section XXIII.
- H. Accidental decannulation, arrhythmias** (due to the venous catheter being positioned in the atrium), **and mechanical problems** (eg, oxygenator failure, fracture of the tubing or connector sites) are other possible ECLS complications.
- VIII. Pre-extracorporeal life support studies, preparation, and monitoring**
- A. Before initiating extracorporeal life support**, patients should be evaluated for structural heart disease and intracranial hemorrhage with an **echocardiogram and head ultrasound** if time allows. Ninety percent of intracranial hemorrhages occur in the first 5 days of ECLS therapy, so serial ultrasound studies should be done daily for 5 days followed by an every-other-day regimen at a minimum.
- B. Screening lab assessments** should include electrolytes, ionized calcium, blood urea nitrogen, creatinine, glucose, complete blood count, differential, coagulation studies including international normalized ratio (INR), total and direct bilirubin, arterial blood gas, lactate, heparin assay, antithrombin III antigen assay, blood culture, and a blood type and screen. Lab assessments should be followed daily to twice daily.
- C. A bladder catheter, enteral feeding tube or gastric sump tube, and a rectal temperature probe (if the patient is undergoing therapeutic hypothermia) should be inserted as needed.** It is extremely important to place these tubes prior to the initiation of anticoagulation for ECLS given the risks of bleeding when they are placed while on ECLS. Generally, gastric sump tubes are placed to gravity to avoid any risk of bleeding that low intermittent suction may cause.
- D. For venovenous extracorporeal life support, a percutaneously placed internal jugular central line** can serve as a guide for placement of the VV cannula. Other access for IV infusions or radial arterial, femoral venous, or umbilical catheters should be placed prior to the initiation of ECLS, if possible.
- E. Monitoring.** Because of the administration of sedatives, or muscle relaxants for severe illness, seizures may be difficult to detect in this population. Patients benefit from monitoring amplitude-integrated electroencephalogram or continuous electroencephalogram (especially after ECPR), near-infrared spectroscopy (NIRS), and oximetry prior to and during support on ECLS.
- IX. Pretreatment with glucocorticoids.** During ECLS, patient blood, exposed to plastic, silicone, polymethylpentene, and other circuit components, causes activation of the immune system, which releases inflammatory mediators (complement, leukotrienes, cytokines, and leukocytes). The coagulation cascade, complement, and fibrinolytic systems are also activated, and capillary leak ensues. Consumption of platelets by the oxygenator or filter used for continuous renal replacement can exacerbate the coagulopathy and inflammatory reaction. This process may be mitigated somewhat by pretreating neonates with glucocorticoids, but the evidence for this has not been well established. Some centers use **dexamethasone** (generally 0.1–0.5 mg/kg prior to the initiation of ECLS or with circuit changes). If patients are on hydrocortisone due to hypotension associated with adrenal insufficiency, dosing with hydrocortisone should be continued, but additional steroid therapy is unnecessary for the initiation of ECLS or circuit changes.
- X. Gas exchange devices (extracorporeal lungs): hollow-fiber oxygenators and membrane oxygenators.** The oxygen concentration from the wall source is adjusted via the gas flow blender and delivered to both types of oxygenators via the gas flow blender tubing (Figure 20–1). To increase the removal of CO₂, the **flow** to the oxygenator is increased, analogous to increasing alveolar ventilation in the native lung. This provides gas flow or “sweep gas” through the gas exchange unit and serves to wash out CO₂.
- A. Hollow-fiber oxygenators.** Gas exchange occurs in the hollow fibers. **Blood flows** around the fibers, in constant contact with the fiber surface. **Oxygen flow,**

on the other hand, occurs through the hollow fibers. The microporous nature of the fibers allows gas exchange by diffusion across the fiber based on concentration gradients, allowing O₂ delivery and CO₂ removal. Most oxygen is carried by hemoglobin, with the dissolved fraction being a relatively minor component.

B. Membrane oxygenators. Membrane oxygenators are designed to allow blood to flow on one side of the membrane while gas flows on the other side. Again, concentration gradients determine the driving force for diffusion of gases. Membrane oxygenators are more likely to have complications with plasma leaks, air emboli, water vapor condensation, and thrombus formation.

C. Factors affecting oxygen delivery on extracorporeal life support

1. Oxygen content of the blood after it passes through the **oxygenator**.

2. Oxygen content of the blood after it passes through the **neonate's lung**.

3. Native cardiac output in combination with circuit flow on extracorporeal life support

4. Patient hemoglobin

D. Factors affecting oxygenation through the circuit:

1. Driving concentration gradient: the amount of O₂ in the gas phase.

2. Permeability: the ease with which O₂ crosses the hollow fibers or membrane

3. Solubility: the ability of O₂ to diffuse through the blood layer. Because there is more O₂ in the sweep gas than in the blood, there is always a large concentration gradient favoring oxygen diffusion into the blood. The sweep gas flow rate has little influence on oxygen exchange, again similar to native alveolar ventilation.

4. In hollow-fiber oxygenators, gas exchange is rapid at all degrees of flow. However, in **membrane oxygenators,** where the surface area and blood path mixing determine the maximum oxygenation capacity, oxygenation may be influenced by the rate of blood flow. If the blood flows faster than the time it takes to achieve complete saturation of the hemoglobin with oxygen, blood will leave the **oxygenator** incompletely saturated. The **rated flow** is the pump blood flow rate at which maximal O₂ delivery is achieved (ie, where venous blood with a saturation of 75% and hemoglobin of 12 g/dL achieves a saturation of 95% when exiting the membrane oxygenator). Oxygenation decreases at flows that exceed the rated flow. In addition, the likelihood of hemolysis increases directly proportional to high flows. Oxygenators have a flow-rated graph on the manufacturers' websites.

E. Factors affecting carbon dioxide exchange on extracorporeal life support

1. The concentration of carbon dioxide is usually at least 45 to 50 mm Hg in the venous blood and 0 in the sweep gas of the oxygenator, allowing efficient transfer of CO₂.

2. The movement of gas through the oxygenator or sweep gas flow rate constantly refreshes the concentration gradient, determining ventilation.

3. The surface area of the hollow fibers or membrane allows for rapid gas exchange. Because the diffusion of CO₂ through blood and the hollow fibers or membrane occurs rapidly (6 times faster than O₂), it remains independent of blood flow rate through the oxygenator. Factors that decrease the functional surface area, however, will limit CO₂ transfer before affecting oxygenation.

XI. Comparison of venoarterial and venovenous extracorporeal life support

A. Venoarterial extracorporeal life support provides cardiopulmonary bypass that runs in **parallel** to the native cardiac output. Access for VA-ECLS is usually through the **right internal jugular vein** and **right common carotid artery**, each using a single lumen cannula. (Central cannulation is generally used after cardiac surgery in neonates). Venous blood from the right atrium serves as the source for ECLS pump preload that is oxygenated and then infused into the systemic circulation via the brachiocephalic artery. The path of this blood flow augments the native cardiac output. In VA-ECLS, the majority of blood flows into the aorta,

but some blood continues to flow through the heart and lungs. Because there is less blood ejected from the left ventricle, the pulse contour decreases.

1. **Advantages of venoarterial extracorporeal life support**
 - a. **Provides full cardiac and respiratory support for the nonfunctioning heart and/or lungs.** Oxygen delivery is enhanced because of the extracorporeal output.
 - b. **Decreases the load on the heart, allowing for recovery.**
 2. **Disadvantages of venoarterial extracorporeal life support**
 - a. **Results in increased left ventricular afterload that can delay myocardial recovery.** With very poor left ventricular function, increased afterload may cause acute cardiac dilation, resulting in pulmonary hemorrhage and death.
 - b. **Necessitates ligation of the carotid artery when cervical cannulation is used; reconstruction may or may not be possible.** VA-ECLS causes temporary interruption of isohemispheric cerebral blood flow patterns when carotid cannulation is used. To date, studies following NIRS during cannulation do not demonstrate long-standing asymmetric effect on cerebral oxygenation or hemodynamics.
 - c. **Appears to cause a higher incidence of central nervous system injury** because any emboli entering the arterial circulation can potentially cause CNS infarction.
 - d. **May compromise organ tolerance to hypoxia** (especially in the brain, myocardium, splanchnic bed, and kidneys) because of the lack of pulsatility in blood flow.
- B. Venovenous extracorporeal life support** provides respiratory support that runs in **series** with the native cardiac output. For VV-ECLS, the right internal jugular vein is cannulated with a dual lumen cannula. Venous blood from the drainage ports in the right atrium serves as the source for ECLS pump preload that is oxygenated, then infused back into the right atrium via the other side of the cannula, the reinfusion port; consequently, there is no net effect on the right atrial volume, intracardiac flow, or aortic blood flow. **Ideally, the output from the reinfusion port should be directed toward the tricuspid valve.** The native cardiac output propels oxygenated blood from the pump forward to the systemic arterial system and tissues. Saturations depend on the amount of ECLS flow, native venous flow, lung function, and cardiac output.
1. **Venovenous extracorporeal life support advantages**
 - a. **Maintains function of the carotid artery** since it is not used for cannulation.
 - b. **Delivers highly oxygenated blood to the pulmonary vascular bed** that can help attenuate high pulmonary pressures, improve hypoxic vasoconstriction, and decrease right ventricular afterload, potentially allowing faster recovery.
 - c. **Increases the availability of oxygen to the coronary circulation,** which can improve myocardial function as blood is ejected from the left ventricle.
 - d. **Preserves pulsatile flow,** which may better protect organ function and reverse organ failure.
 - e. **Is protective of the systemic circulation from emboli because the lungs serve as filters** (unless intracardiac shunts are present).
 2. **Venovenous extracorporeal life support disadvantages**
 - a. **Provides only indirect circulatory support by improving myocardial oxygenation** but does not provide additional cardiac output. Patients may continue to require vasopressors.
 - b. **May not provide full oxygen delivery.** The oxygen delivery is dependent on the mixing of extracorporeal oxygen content with the oxygen content of the body. Maintaining some degree of lung expansion helps keep the pulmonary vascular resistance lower and may allow some patient contribution

to gas exchange in circumstances where perfect cannula placement cannot be achieved and recirculation limits oxygenation. In this case, some native lung function may be necessary to sustain appropriate gas exchange, so the lung cannot fully be “rested.”

- c. **Is more prone to challenges with flow due to the risk of the cannula being malpositioned compared to venoarterial extracorporeal life support.** Blood flow can be limited by the resistance to flow in the venous side of the cannula, the suction produced by the pump, and the size of the cannulated vessel.
- d. **Provides less support for gas exchange than venoarterial extracorporeal life support** due to **recirculation** caused by oxygenated blood coming from the circuit through the reinfusion port then streaming back into the drainage side of the double lumen cannula. In situations where there is a high degree of recirculation causing suboptimal oxygen delivery, the cannula should be adjusted. (See Section XIX.B.3.)

XII. Cannulation guidelines and preparation

- A. **Circuit preparation.** Once a patient has been determined to be a candidate for ECLS, the circuit tubing is “primed,” generally with leukoreduced, irradiated packed red blood cells, fresh-frozen plasma (FFP), sodium bicarbonate, calcium gluconate, and heparin. Albumin is used instead of FFP for ECLS initiated while a neonate is undergoing cardiopulmonary resuscitation (ECPR).
- B. **Neonatal vascular access.** For **cervical cannulation**, neonates should be positioned with the head turned to the left and the neck extended using a small neck roll under the shoulders to achieve appropriate surgical access. In many centers, a pediatric cardiologist is present for the cannulation to verify correct placement of the catheter(s) with an echocardiogram due to difficulty confirming correct placement using x-ray alone. Other centers use fluoroscopy. **Because adverse events can occur during cannulation, such as perforation of the atrium by the guidewire in the cannula with accompanying cardiac tamponade, teams should be prepared to provide medications and volume for resuscitation during the cannulation.**
- C. **Medications.** To provide analgesia/anesthesia and surgical preparedness, neonates should receive a narcotic and a neuromuscular blocking agent before the procedure and subsequent narcotic doses during the cannulation procedure. Sedatives and narcotics are usually provided throughout the ECLS course; however, most patients do not require ongoing therapy with neuromuscular blocking agents after cannulation. When neuromuscular blockade is used for cannulation or during the course with VV-ECLS, the ventilator settings should be adjusted and the end-tidal CO₂ followed closely.
- D. **X-ray placement.** Some centers place an x-ray cassette under the patient before initiation of surgical placement of the cannula(e). Others may simply insert it in the warmer tray at the time the x-ray is taken.
- E. **Heparin anticoagulation.** Neonates should be given a **heparin bolus between 50 and 100 U/kg immediately prior to the insertion of the cannula(e)** to prevent clot formation in the cannula(e). It is paramount to correct a coagulopathy prior to the initiation of ECLS if there is time. Nevertheless, even in situations where a coagulopathy is present, it is still important to give the loading dose of heparin prior to cannulation, but a dose adjustment may prove advisable. The initial bolus is followed by a continuous heparin infusion at 10 to 20 U/kg/h typically, and a steady-state infusion rate between 20 and 40 U/kg/h is common.
- F. **Appropriate cannula positions/sizes** (see Figures 20–3 and 20–4).
 - 1. **Venoarterial cannulation.** Generally, a wire-wound, kink-resistant 8- to 10-F Bio-Medicus arterial cannula with a single end hole and a 12- to 14-F Bio-Medicus venous cannula (Medtronic, Dublin, Ireland) with several side holes are used. The arterial cannula tip is advanced 2 to 3 cm in the

brachiocephalic artery, at or just above the junction of the aortic arch. Optimal positioning is achieved when the cannula tip is at T3–4 on x-ray (just above the carina) after the neck roll is removed. If the arterial cannula is positioned high in the right common carotid artery, streaming of blood can occur into the right subclavian artery, causing the right arm to appear more oxygenated than the rest of the body and invalidating any arterial blood gas sampling from the right radial artery. In this case, adjusting the catheter position may be necessary.

The tip of the venous cannula should be advanced 6 to 8 cm in the right atrium near the junction of the inferior vena cava (IVC). On x-ray, the opaque metal “dot” on the cannula should be located about 1 cm above the diaphragm.

2. **Venovenous cannulation.** The size of the venous cannula is critical because restricted flow due to high resistance may cause high shear forces resulting in hemolysis and may also limit flow to the oxygenator. Commonly used VV catheters include the 13- or 16-F OriGen dual lumen PEBAX wire reinforced atrial cannula (OriGen Biomedical, Austin, TX) and the 13-F Avalon Elite bi-caval dual lumen cannula (Maquet Cardiovascular, Wayne, NJ). The 13-F OriGen catheter is used in neonates weighing 2 to 5 kg and advanced to a maximum insertion length of 8.2 cm. The 16-F OriGen catheter is used in neonates weighing 5 to 8 kg and advanced to a length of 9.5 cm. The 13- or 16-F OriGen catheter cannula tip should be well into the right atrium at T7–8 or about 1 to 2 cm above the diaphragm. The 13-F Avalon catheter should be positioned slightly into the IVC using echocardiography or fluoroscopy (Figure 20–4).

Removal of the neck roll may advance the VV catheter as much as 1 cm. Proper cannula position helps maintain appropriate flows, a critical feature of VV-ECLS. Flows of 120 mL/kg/min should be achievable following intravascular volume expansion and removal of the neck roll.

It is imperative to assess the position of the cannula with echocardiography to assure directed flow toward the tricuspid valve. If the cannula is not ideally placed to achieve optimal drainage and appropriate directed flow, there can be significant recirculation.

Recirculation occurs when oxygenated blood being delivered to the patient loops back to the drainage ports of the cannula, lowering the oxygenation potential of the blood flow. It can be detected by decreased saturations in the patient and increased saturations in the venous catheter. When this occurs, venous saturations may be >85% to 90% and arterial saturations lower than their baseline levels. (See Section XIX.B.3.)

Problems with flow after VV cannulation can also occur if the cannula is butting up against the Eustachian valve, impeding venous drainage. Echocardiography should help identify this problem, prompting adjustment of the cannula position.

- G. **Intravascular volume needs at the time of cannulation.** Before connecting the ECLS cannula(e) to the circuit, surgeons may allow backflow of the neonate’s blood in the cannula(e) to assure that there is no air in the circuit. During these times, blood pressures may be low momentarily, and administration of intravascular volume may be necessary.
- H. **Pericardial tamponade** can occur due to malposition of the cannula at the time of cannulation or subsequently on ECLS. If there is hemodynamic compromise with inability of the circuit to flow, an echocardiogram should be obtained immediately to diagnose the problem. Sometimes the circuit may be flowing and the only clue to pericardial tamponade may be decreased pulse pressures and diminished heart tones. An emergent pericardiocentesis or drainage with a pericardial tube and repair of the intracardiac injury via a median sternotomy may be necessary.

FIGURE 20–4. Venovenous extracorporeal life support cannulae placement showing the Origen catheter on x-ray and graphically. The Avalon catheter would extend farther into the inferior vena cava.

XIII. Monitoring and ongoing management during extracorporeal life support

A. Managing coagulation/anticoagulation on extracorporeal life support

- 1. Role of unfractionated heparin administration for anticoagulation.** The artificial surfaces of the ECLS circuit activate coagulation factors, platelets,

complement, and leukocytes, leading to clot formation. Flow through the circuit creates turbulence and shearing of cells, causing platelet activation with clot formation as well, particularly in areas of low flow and stasis. To prevent excessive clot formation, unfractionated heparin (UNFH) is used. UNFH is a mixture of mucopolysaccharide chains ranging from 5000 to 30,000 Daltons that undergoes hepatic metabolism and renal excretion with a plasma half-life of 30 to 60 minutes. UNFH anticoagulates by binding to and accelerating the activity of the enzyme antithrombin. This complex then inactivates thrombin and other proteases, especially factor Xa, decreasing clot formation by preventing the conversion of fibrinogen to fibrin and formation of a cross-linked fibrin clot.

2. Measures of coagulation/anticoagulation

a. **Activated clotting time.** Anticoagulation with heparin is a balance between the heparin activity mediated through binding to antithrombin and coagulation factor levels. An **activated clotting time (ACT)** is a whole blood clot assay that relies on contact activation by activating factor XII. Because the hematocrit, platelets, factors, and inhibitors can affect the clotting time in the ACT assay, it may track the actual heparin level directly and thus is not the best measure of heparin-dependent anticoagulation during ECLS.

For centers using ACTs, the desired range depends on the type of monitoring equipment and institution-specific standards. Common ACT targets are **between 200 and 220 seconds**. When disseminated intravascular coagulation (DIC) or bleeding occurs, clinicians may target a lower ACT goal, typically between 180 and 200 seconds. A heparin bolus may be necessary if the ACT falls below 180 seconds.

b. **Unfractionated heparin (antifactor Xa, anti-Xa) assay.** Several centers are using a more reliable measure of heparin effect to titrate heparin, the anti-Xa assay. This test is a chromogenic plasma assay that is sensitive to the level of both antithrombin and heparin. Anti-Xa activity is based on the ability of the heparin-antithrombin complexes to inhibit a predetermined amount of factor Xa in vitro. This test measures residual factor Xa activity that is inversely proportional to the heparin concentration in the sample. Use of the anti-Xa assay to monitor heparin effect has been shown to decrease blood product use, decrease hemorrhagic complications, and increase circuit life. Increased plasma free hemoglobin and hyperbilirubinemia can interfere with the anti-Xa assay and result in the underestimation of anti-Xa activity. (See Section XIII.F.)

Anti-Xa activity goals are generally between **0.2 and 0.5 U/mL**. If the anti-Xa is at the lower end or below the target range, a bolus of heparin (5–10 U/kg) may be needed, or the drip may need to be increased by 10% to 20%. The reverse is true if the anti-Xa activity is above the range, allowing the heparin drip to be decreased by 10% to 20%. One approach to maintaining the anti-Xa activity in goal range is to treat the neonate with 25 U/kg of heparin prior to transfusing platelets.

The anti-Xa activity can help to determine whether a prolonged ACT is due to overheparinization or coagulopathy and should be used in conjunction with the prothrombin time (PT) to assess coagulation factors (Table 20–1). If the PT is normal, the coagulation factor concentrations can be presumed to be normal and the heparin activity can be maintained with anti-Xa activity in the reference range. If the PT is prolonged, the neonate probably has low concentrations of coagulation factors, and treating with 10 mL/kg of FFP can correct this.

Because the circuit flow rate also has an impact on thrombus formation, an attempt should be made to maintain ECLS flows >80 mL/kg/min whenever the anti-Xa activity or ACT is low.

Table 20–1. HEPARIN MONITORING DURING ECLS

Test	Treatment
Anti-Xa assay	Measures the activity of the heparin–AT complex. Base the heparin dose adjustments on heparin activity. Goal level is 0.2–0.5 U/mL.
PT normal (heparin independent)	Used to assess coagulation factor levels. If normal, coagulation factors are normal. Maintain heparin activity in the targeted range.
PT prolonged	Indicates that factors are low; consider treating with FFP. Use PTT to assess combined coagulation factors and heparin effect. Keep PTT <150 and keep heparin in the targeted range.
AT level <50	If the heparin is not increasing as expected with dose changes, check the AT antigen and consider an AT infusion.

AT, antithrombin; ECLS, extracorporeal life support; FFP, fresh-frozen plasma; PT, prothrombin time; PTT, partial thromboplastin time.

If ongoing bleeding and coagulopathy remain a concern or if the neonate has recently had surgery, heparin administration can be decreased and a balance between coagulation and anticoagulation achieved with infusions of FFP. For neonates requiring surgery on ECLS, aminocaproic acid, an antifibrinolytic agent, can be used. The loading dose of aminocaproic acid is 100 mg/kg IV to be given immediately prior to surgery with a maintenance dose of 30 to 33 mg/kg/h for 40 to 72 hours after surgery.

3. **Factor and blood replacement.** Aberrations in coagulation labs should be corrected. However, a balance needs to be maintained between overaggressive therapy to correct a coagulopathy or anemia and fluid overload.
 - a. **Fibrinogen concentrations.** The normal goal while on ECLS is >150 mg/dL and is most often maintained using infusions of 1 unit of cryoprecipitate.
 - b. **International normalized ratio levels.** The normal goal while on ECLS is ≤1.4; levels >1.5 to 2 are generally treated with 10 to 15 mL/kg of FFP and/or 1 unit of cryoprecipitate.
 - c. **Platelet counts.** The normal goal while on ECLS is >80,000/μL or >100,000/μL if there is bleeding. A 10- to 15-mL/kg volume of platelets will increase the platelet count by 50,000 to 100,000/μL.
 - d. **Hematocrit levels.** To avoid volume overload, values for neonates can be maintained at >30% to 35% for VA-ECLS and >35% to 40% for VV-ECLS (generally kept higher because oxygen delivery is not as efficient as in VA-ECLS). If a coagulopathy is observed in neonates, hematocrit values are generally kept toward the higher side due to concerns for possible hemorrhage.
 - e. **Antithrombin levels.** Antithrombin, a serine protease inhibitor produced by the liver, is essential to endogenous anticoagulation by inhibiting the activity of thrombin and factor Xa. It also inactivates plasmin and factors IXa, XIa, and XIIa. Antithrombin is necessary for an adequate response to heparin. Heparin is a glycosaminoglycan produced by basophils and mast cells that works by binding to and upregulating the catalytic activity of antithrombin 1000-fold.

Some centers strive to keep antithrombin antigen levels >60% of normal, especially with excessive clot buildup in the circuit, and/or a high heparin infusion rate (eg, >40 U/kg/h). The evidence for this remains inconclusive. Infants demonstrate physiologically low antithrombin levels until 6 to 9 months of age depending on their gestational age and other illnesses. Furthermore, low antithrombin levels may result from DIC, endothelial injury,

ongoing protein losses from a chylothorax or nephrotic syndrome, dilutional effects of cardiac bypass, liver disease with synthetic failure, or rarely congenital deficiencies.

FFP has approximately 1 U of antithrombin/mL. Antithrombin concentrate, however, increases the serum level with a much smaller volume, so it may be appropriate to use if a goal antithrombin antigen level is targeted. Larger protein losses, with the loss of other coagulation factors, may be treated more efficiently with FFP.

- B. Managing edema.** Neonates on ECLS frequently develop edema because of diffusely increased permeability and reduced lymphatic function. Furosemide may be used to promote diuresis and improve fluid balance. Diuresis increases heparin clearance, often necessitating an increase in the heparin infusion rate. Likewise, a spontaneous increase in urine output, continuous renal replacement therapy, or platelet transfusions often require an increase in the heparin rate to maintain the target ACT or anti-Xa activity. Some centers use intermittent furosemide, whereas others use a continuous infusion. **If continuous furosemide is used, caution must be taken to avoid intravascular volume depletion that can affect circuit flow and increase inlet pressures, setting off alarms.** (See Section XIII.H.)
- C. Monitoring centrifugal pump inlet pressures.** Large negative pressure spikes at the inlet and outlet of the centrifugal pump can occur when there is an abrupt cessation of venous flow and can lead to intimal damage at the venous cannula site, especially in circumstances where excessive negative pressures collapse the vasculature around the drainage cannula. Prepump negative pressures in the drainage line can be monitored by the incorporation of a Better Bladder (Circulatory Technology, Oster Bay, NY), a safety device housing a flexible balloon within a rigid chamber with a noninvasive pressure transducer placed between the drainage line and pump inlet. The bladder serves as a reservoir or pressure buffer by providing compliance in the venous line, reduces large negative pressure inflections at the pump inlet, and protects from accidental air entrapment. This safety measure can prevent negative pressures from developing when the pump flow exceeds the return. Measurement of the inlet pressure allows time for the centrifugal pump to servo-regulate the flow, reducing the negative pressure.
- D. Managing circuit thrombi and monitoring pre- and postoxygenerator pressures.** During the ECLS course, a balance between bleeding and clotting can be difficult to achieve. Clot formation in the circuit occurs commonly during the ECLS course. A thrombus in the oxygenator is suspected when there is an increase in the preoxygenator pressure and a fall in the postoxygenerator pressure (see Figure 20-1). Trends in the change in pressures across the oxygenator (Δ pressure) should be followed. If the Δ pressure value doubles, one should investigate oxygenator performance. If it increases above acceptable parameters, the oxygenator or circuit should be changed.

Depending on the estimated length of time needed for ECLS therapy, the oxygenator or entire circuit may need to be changed. In addition, evidence for excessive consumption of clotting factors and platelets along with hematuria suggests the presence of thrombi in the circuit, so-called “circuit disseminated intravascular coagulation.” This often requires a change of the entire circuit. Ideal flow through the circuit can be gauged by achieving the lowest Δ pressure with the lowest revolutions per minute of the centrifugal pump.

Clots in the cannula(e) can be challenging to manage because removal of these by flushing out the cannula(e) with normal saline requires temporary discontinuation of ECLS. The neonate may not be ready to efficiently exchange gases even with increased ventilator settings providing full support. Flushing the clots can result in dislodgement of small thrombi not removed by this process that may inadvertently be infused into the neonate when the cannula is reattached to the circuit.

Table 20–2. DECREASED SvO₂ LEVELS DURING ECLS

O ₂	Causes	Etiologies
↓ O ₂ delivery	↓ CO	Heart failure, cardiac depressants, arrhythmias, ↑ PEEP, ↓ preload
	↓ SaO ₂	↓ Respiratory function, poor native lung function, and desaturated pulmonary venous return, oxygenator failure, insufficient ECLS flow, ↓ ECLS blender FIO ₂
	↓ Hb	Anemia, methemoglobinemia (abnormal Hb)
↑ O ₂ demand	↑ VO ₂	Fever, shivering, agitation, pain, seizures, infection
	↑ CO	↑ Work of breathing

CO, cardiac output; ECLS, extracorporeal life support; Hb, hemoglobin concentration; PEEP, positive end-expiratory pressure; VO₂, oxygen consumption.

E. Monitoring the mixed venous oxygen saturation. During ECLS, the mixed venous oxygen saturation (SvO₂) reflects the degree of O₂ extraction and should normally be in the **65% to 70% range for VA- and VV-ECLS**. SvO₂ <60% indicates a marginal oxygen delivery and critical level of O₂ extraction, suggesting that the rate of tissue metabolism is approaching the rate of O₂ delivery. Once the balance between delivery and extraction reaches the critical level, cells begin to use anaerobic metabolism, producing lactic acid. The SvO₂ presents a useful parameter to follow in VA-ECLS. Due to recirculation in VV-ECLS, the SvO₂ may sometimes be more difficult to interpret but can provide a useful trend. (See Tables 20–2 and 20–3.)

F. Monitoring blood pressures

- Hypertension.** Elevated blood pressures are common with VA-ECLS in neonates. Nicardipine is a common drug used under these circumstances. The initial dose is 0.5 mcg/kg/min by continuous infusion and titrated every 10 minutes to maintenance doses of 0.5 to 5 mcg/kg/min to achieve the desired blood pressure.
- Hypotension.** Because VV-ECLS does not provide direct cardiovascular support, neonates can have lower blood pressures that may require vasopressor/inotropic support. Dopamine has traditionally been a first-line choice for many centers, starting at 5 mcg/kg/min and titrated upward 2 to 5 mcg/kg/min every few minutes to 20 mcg/kg/min. Epinephrine has also been used as a primary agent or added to dopamine. The starting dose is 0.1 mcg/kg/min and titrated upward 0.1 mcg/kg/min to 1 mcg/kg/min. In situations of distributive shock

Table 20–3. INCREASED SvO₂ LEVELS DURING ECLS

O ₂	Causes	Etiologies
↑ O ₂ delivery	↑ CO	Improved cardiac function
	↑ SaO ₂	Improved lung function, excess ECLS flow, ↑ FIO ₂
	↑ Hb	Blood transfusion
	↑ Flow	Recirculation with VV-ECLS
↓ O ₂ demand	↓ VO ₂	Hypothermia, anesthesia, muscle relaxation
	↓ Utilization	Sepsis, cyanide toxicity (from sodium nitroprusside), severe neurologic injury

CO, cardiac output; ECLS, extracorporeal life support; Hb, hemoglobin concentration; VO₂, oxygen consumption; VV, venovenous.

from sepsis associated with systemic vasodilation, normal saline volume and the initiation of norepinephrine at 0.1 mcg/kg/min titrating to 1 mcg/kg/min or vasopressin starting at 10 milliunits/kg/h and titrating to 50 milliunits/kg/h can be therapeutic. Many centers also start hydrocortisone in neonates with hypotension regardless of the etiology.

- G. Monitoring for hemolysis.** Plasma free hemoglobin (pfHb) measures hemoglobin that has leaked into the serum when red blood cells undergo hemolysis. A normal pfHb is <10 mg/dL. The ELSO registry defines **hemolysis** as pfHb concentrations >50 mg/dL. pfHb can increase dramatically due to increased ECLS pump flows causing extreme negative pressures, elevated temperature in the water bath, clots in the oxygenator, or kinks in the circuit leading to high shear stresses from turbulent flow. Differences in tubing sizes and connection points throughout the circuit add to the shear stress and turbulence, further damaging red blood cells and causing local thrombus formation. Hemolysis also occurs when using centrifugal pumps due to the shearing force on blood components created by the vortex in the pump head. Elevated pfHb can cause vasoconstriction in the pulmonary vascular bed, direct injury to the kidney by obstructing the renal tubules, and damage to other organs as well. Neonates are particularly prone to hemolysis because of the differences in flow and pressure dynamics as well as small cannula sizes. Studies suggest that neonates on centrifugal pumps have higher rates of hemolysis, hyperbilirubinemia, hypertension, and acute renal failure than those on roller pumps. Centrifugal pumps designed more recently have less stagnation in the pump head and decreased hemolysis. Measures to alleviate high pfHb levels should be undertaken, in particular avoiding high flow rates. Circuit changes may be necessary if the pfHb level is extremely high (>200 mg/dL), although lower levels are of concern as well.
- H. Monitoring for loss of pump flow, retrograde flow, air embolism, chattering, and cavitation.** Loss of pump flow is an emergency and can be due to malposition of the cannula, low volume status, air in the circuit, or cardiac tamponade. Measures to recover pump flow include lowering flow rates, repositioning the patient, and, if persistent, evaluating for the possibility of cardiac tamponade with an echocardiogram. Frequently fluid boluses are used to increase venous filling when pump flow is challenged. However, the benefit is short lived and can lead to fluid overload. Attempts should be made to adjust a malpositioned cannula, if this is the cause, rather than using excessive volume.
- 1. Retrograde or reversed flow** can occur if the pump flow is too low or if a shunt is open. In this situation, the distal pressure exceeds the pressure generated by the pump. It can be detected by the flow alarm and alleviated by running the pump flow faster.
 - 2. Air embolism** can occur when air is introduced inadvertently into the circuit through loose connections on the circuit. Emergent ventilator settings providing full support need to be used while these problems are alleviated. The problem is corrected by tapping the circuit line to get the air bubbles to the pump head or connector site where the air can be extracted with a syringe. The oxygenator has an escape port for air as well.
 - 3. “Chattering” or surging of the drainage line** of the circuit can occur when the centrifugal pump flow rate is excessive, causing a high negative pressure that occludes the blood flow returning to the neonate. Chattering is caused by hypovolemia, changes in the cannula position, and changes in intrathoracic pressure induced by coughing or moving and results in a fall in blood flow. If blood flow is interrupted but the pump rotor continues to spin at a high speed, the pump head ejects blood, but no volume refills the voided space. A vacuum forms within the pump head, and cavitation occurs.
 - 4. “Cavitation” or “outgassing”** appears when dissolved gases, oxygen and carbon dioxide, come out of solution during times of excessive negative pressure

generated by the centrifugal pump. **Cavitation can create gaseous microemboli that cause hemolysis of the red blood cells.** When the pressure normalizes, the gas will go back into solution; however, free hemoglobin remains in circulation. Generally, flows are run so that inlet pressures do not become more negative than -40 mm Hg in neonates.

XIV. Lung rest during extracorporeal life support. Neonates who receive ECLS usually have substantial primary lung disease complicated by ventilator-associated lung inflammation and injury. An important benefit of ECLS is to provide cardiopulmonary support while on “resting” or decreased ventilator settings. Although rest ventilator settings vary, for **VA-ECLS**, widely accepted settings for neonates include a rate of 10 breaths/min (10–20), positive end-expiratory pressure (PEEP) of 8 to 14 cm H₂O, and peak inspiratory pressure (PIP) in the 12 to 20 cm H₂O range. With VA-ECLS, a ventilator FiO₂ of approximately 0.3 to 0.4 may improve oxygenation of coronary blood, which is dependent on the blood flow and saturations from the left ventricle.

Higher ventilator settings may be required in VV-ECLS compared to VA-ECLS. Blood in VV-ECLS flows from the circuit to the right heart and must either go through the pulmonary vascular bed or extrapulmonary shunt pathways. Some degree of lung inflation and tidal ventilation is probably necessary to enhance pulmonary blood flow. Additionally, since VV-ECLS may not add as much oxygen content to the blood due to suboptimal cannula position and/or recirculation (see Section XIX.B.3), the rest settings are frequently higher than on VA-ECLS (ie, conventional rate of 20–30 breaths/min, PIP 15–25 cm H₂O, PEEP 8–14 cm H₂O, and FiO₂ 0.3–0.5). High-frequency ventilation can also provide more cardiopulmonary support to the patient yet maintain gentle ventilatory assistance. For the Life Pulse High-Frequency Ventilator (Bunnell Incorporated, Salt Lake City, UT), general settings would include a rate of 420 (360 if the neonate has CDH), PIP of 16–20 cm H₂O, I time of 0.02, and PEEP of 10 to 14 cm H₂O from the corollary conventional ventilator without a conventional rate. On high-frequency oscillatory ventilation (3100A Neonatal and Pediatric High-Frequency Ventilator; CareFusion, Yorba Linda, CA), routine settings would include a mean airway pressure of 10 to 14 cm H₂O with low amplitudes of 15 to 20 cm H₂O and frequency between 8 and 10 Hz.

Higher vent settings to achieve improved gas exchange should be discouraged and are inappropriate in situations where ventilator-induced injury or air leak has occurred. The goal of ECLS is to avoid exacerbating lung injury, so noxious stimuli to the lungs should be avoided as much as possible. Improving oxygen delivery from ECLS can be accomplished by administering sedatives and, on occasion, neuromuscular blockers or converting to VA-ECLS when poor gas exchange, hypotension, and elevated lactate levels occur, suggesting that VV-ECLS is not sufficient.

Inhaled nitric oxide is generally discontinued when patients are placed on ECLS. To date, no studies have shown a benefit of inhaled nitric oxide (iNO) in decreasing pulmonary hypertension when the lung volumes are small. However, once the inflammatory process wanes and lung inflation improves, theoretically iNO could help lower pulmonary pressures and expedite successful transition off ECLS.

XV. Renal function during extracorporeal life support. Because fluid overload commonly occurs with critical illness, ECLS patients frequently require pharmacologic diuresis once capillary leak subsides. Furthermore, when using VA-ECLS, the kidneys may be perfused with nonpulsatile flow, resulting in a decrease in renal function. For patients with preexisting or developing AKI and/or those with anasarca, hemofiltration may be added in parallel to the ECLS circuit via a small shunt. This system allows for removal of excess fluid and stabilizes electrolyte abnormalities. (See Figure 20–1.) Studies have reported increased mortality associated with AKI in the setting of ECLS.

XVI. Medications and nutrition. Antibiotics, sedatives, narcotics, proton pump inhibitors, and total parenteral nutrition should be delivered directly to the patient, and not via the ECLS circuit, if possible. However, in neonates with limited vascular access, these agents can be delivered into the ECLS circuit at venous access locations. Because the

volume of distribution is higher with the added ECLS circuit volume, higher doses may be needed to achieve therapeutic concentrations, particularly for sedatives and narcotics, regardless of where the medications are delivered. Sedatives are particularly beneficial because of the risk that excessive movements may have on circuit flow and function and are useful in reducing oxygen consumption. Medications used most frequently include morphine, lorazepam, fentanyl, and dexmedetomidine. Due to the fact that fentanyl binds to the plastic in the circuit, many centers avoid using it. With AKI, dosing may need to be decreased with medications cleared by the kidney. Discussion with a pharmacist will help with correct dosing.

Because of hypotension, neonates are often treated with fluid resuscitation. However, caution should be taken not to fluid overload prior to the initiation of ECLS or during ECLS. Adequate nutrition can generally be provided with fluids running at 100 to 120 mL/kg/d with an increase in protein daily by 1 g/kg/d to a goal of 4 g/kg/d. Enteral nutrition is of vital importance and should be started once infants have stabilized.

XVII. Myocardial dysfunction. Initiation of VA-ECLS is associated with an increased afterload because the extracorporeal flow is delivered to the aortic arch. This can lead to decreased myocardial contractility and dysfunction.

Myocardial stun, an extreme form of cardiac dysfunction, is a transient phenomenon that can be recognized by a **dampening of the arterial waveform** and **patient PaO₂ that approximates the postoxygenator PO₂**. It is more likely to occur in neonates with myocardial dysfunction prior to being placed on ECLS from disorders such as myocarditis and intractable arrhythmias and after cardiac surgery or cardiopulmonary arrest. Patients usually recover in 3 to 7 days.

Myocardial stun is less likely to occur with the initiation of VV-ECLS because there is no increase in left ventricular (LV) afterload and there is higher oxygen content provided to the coronary arteries than with VA-ECLS. Echocardiography has shown similar function of the ventricles before and after the initiation of VV-ECLS. However, cardiac stun will lead to cardiovascular collapse or arrest if it occurs on VV-ECLS because, in contrast to VA-ECLS, there is no cardiovascular support. Under these circumstances, a neonate would need to be converted to VA-ECLS.

Myocardial stun may be confused with **poor cardiac output due to hypovolemia, pneumothorax, pneumopericardium, hemothorax, or hemopericardium**. An echocardiogram showing minimal LV wall motion can confirm the diagnosis.

Right ventricular (RV) dysfunction can occur, particularly in neonates with severe pulmonary hypertension before the initiation of ECLS. In some cases, even while on VV-ECLS, the RV becomes further dilated with poor function, causing it to bow into the LV and compromising LV filling and cardiac output. Assessment by echocardiography may diagnose poor RV function and the use of agents to reduce RV afterload, such as iNO, milrinone, and/or medications such as sildenafil (Revatio; Pfizer), treprostinil (Remodulin; United Therapeutics Corporation), or epoprostenol (Flolan; GlaxoSmithKline) may be warranted.

On occasion RV, LV, or biventricular dysfunction or the need for higher flows due to sepsis may necessitate conversion from VV-ECLS to VA-ECLS. If the neonate is too unstable to be off ECLS for more than a few seconds, the arterial cannula can be placed and then both lumens of the VV cannula used for drainage. Under these circumstances, the arterial lumen of the VV catheter is at risk for clotting. Alternatively, the VV arterial limb can continue to be used for patient inflow, but this may be limited by venous return. If lung function can support the infant for a few minutes, VA-ECLS can be accomplished by placing the arterial cannula and then replacing the venous cannula.

XVIII. Circuit changes. Circuit changes are undertaken if there is large thrombus formation or excessive need for blood products and/or hematuria suggesting circuit DIC or poor oxygenator function, indicated by a need to increase the sweep gas flow to achieve the appropriate goal CO₂ or noting a decrease in the postoxygenator PaO₂. During

circuit changes, a large percentage of blood volume is exchanged, potentially causing electrolyte imbalances and arrhythmias. Drug doses may need to be adjusted. Narcotics, in particular, may need to be redosed or increased significantly.

XIX. Practical considerations for extracorporeal life support management

A. Venoaerterial extracorporeal life support

1. Venoaerterial extracorporeal life support blood flows. After cannulation, ECLS flow is increased gently over several minutes. After initiation of ECLS and particularly during cardiopulmonary arrest when ECPR is initiated, care should be taken to minimize hyperoxia and hypocarbia. Adjustments should be made in the FiO_2 and sweep gas flow to normalize gases and saturations.

Typically VA-ECLS flow is maintained at approximately 100 to 150 mL/kg/min, and the pulse pressure is often approximately 10–20 mm Hg if the heart contracts effectively. As more blood is routed through the circuit with a high flow rate, the systemic arterial **pulse contour may become dampened** and then flatten if total bypass is achieved. In this situation, more blood drains into the circuit, decreasing both right and left heart preload and resulting in a decrease in the left ventricular stroke volume. Despite the lack of pulsatility, the mean blood pressure remains fairly constant and is the best gauge of blood pressure. Flow should be optimized to attain reasonable saturations and arterial pulse pressures as well as appropriate venous saturations, the best indicator of adequate oxygen delivery. As noted earlier, severe cardiac dysfunction may cause the arterial pulse contour to flatten.

2. Oxygen delivery/carbon dioxide removal. In VA-ECLS, part of the blood from the right atrium also circulates through the neonate's lungs into the left heart and out through the aorta, returning again to the right heart. This blood will be exposed to variable ventilation depending on lung function and status of the disease process. With improvement in native lung function and cardiac output, the oxygen content of the blood returning to the right heart will increase.

A major strategy to improve oxygen delivery includes maintaining a high hemoglobin concentration. Increasing the ECLS flow rate increases oxygen delivery as well. However, increasing the ECLS blender O_2 or ventilator FiO_2 will only minimally improve arterial saturations. A failing oxygenator with markedly reduced functional surface area may decrease oxygen content, but generally because of the large surface area in current oxygenators, this is rarely an issue.

Increasing the sweep gas flow rate to the oxygenator lowers the arterial PaCO_2 . An increasing PaCO_2 level may be the first sign that the oxygenator is malfunctioning.

3. Trialing off Venoaerterial extracorporeal life support. Patients should be ready to wean off VA-ECLS after the initial disease processes and inflammatory responses have subsided, appropriate fluid balance is achieved, and lungs have cleared. The surgical team should be notified of the estimated time of possible decannulation.

a. Starting 12 hours prior to the anticipated trial off, the extracorporeal life support blood flows are decreased slowly and ventilator settings adjusted as needed to maintain gas exchange. Conventional ventilator settings may include a rate of 40 to 60 breaths/min, PEEP level of 8 to 10 cm H_2O , and PIP of 25 to 30 cm H_2O . Acceptable high-frequency oscillator settings generally include a mean airway pressure of 14 to 16 cm H_2O , amplitude of 30 to 35 cm H_2O , and frequency of 8 to 10 Hz. Life Pulse high-frequency ventilator settings are similar with a rate of 420 (360 in CDH patients), PEEP of 14 to 16 cm H_2O , PIP of 25 to 30 cm H_2O , and inspiratory time of 0.02 (which may vary depending on the disease process).

In conducting the trial, all dextrose, antibiotic, and sedative or narcotic infusions should be moved from the ECLS circuit to the patient. Heparin

may be split, so that half is infused to the patient and half to the circuit, or given all to the patient. Centers may also choose to give a single bolus dose to help prevent cannula thrombosis during this time or increase the rate of anticoagulation.

The pump flow can be weaned hourly by 10 to 20 mL/min while gradually increasing ventilator support. ECLS blood flows can be weaned to a target “idling” flow of approximately 100 mL/kg/min. A bridge (connecting the venous and arterial sides of the circuit) is used to allow continued flow through the circuit but not to the patient. Continued flow through the circuit prevents clotting while the cannulae are clamped for the trial. The bridge can be part of the circuit or added at the time of the trial off. The venous and arterial cannulae are then clamped and the sweep gas line removed from the oxygenator.

To maintain the integrity of the cannulae and circuit while trialing off, the cannulae are flushed every 10 to 15 minutes per institutional guidelines to avoid stagnation. Patient blood gases are obtained every 10 to 15 minutes as well to assure adequate lung function throughout the trial. The low-flow state of the trial increases the possibility of thrombus formation in the circuit; the length of time for the trial may depend on cannulae and circuit integrity as well as patient response. If the neonate does well for 60 to 90 minutes and is not at the limits of acceptable ventilator support, he or she is ready to be separated from ECLS.

B. Venovenous extracorporeal life support

- 1. Venovenous extracorporeal life support blood flows.** As with VA-ECLS, the initiation of VV-ECLS flow is gradually increased to 100 to 120 mL/kg/min. O₂ delivery can be augmented by increasing the O₂ content of the venous blood in the right atrium (increasing the FiO₂ to the oxygenator) or by maneuvers that decrease recirculation (eg, increasing native cardiac output, repositioning the cannula). Because oxygenated blood entering the right atrium mixes continuously with desaturated venous blood, the final O₂ content of the blood reaching the aorta and tissues is limited by the amount of blood that can be drained into the ECLS circuit, oxygenated, and returned to the venous system. The optimal pump flow rate is one that provides the highest effective pump flow at the lowest revolutions per minute of the pump, resulting in the highest O₂ delivery and causing the least degree of hemolysis.
- 2. Oxygen delivery/carbon dioxide removal on venovenous extracorporeal life support.** Neonates usually have arterial saturations between 80% and 95% and PaO₂ of 40 to 80 mm Hg on VV-ECLS. During VV-ECLS, only indirect circulatory support is achieved, and lower PaO₂ and oxygen saturations often need to be tolerated as long as there are indications of adequate oxygen delivery. No evidence exists to show that this is detrimental. Major strategies to improve oxygen delivery include increasing the hemoglobin concentration, increasing ECLS flow, and augmenting native cardiac output. PaO₂s often rise as native pulmonary function improves. Increasing the sweep gas flow rate lowers the PaCO₂.
- 3. Recirculation.** During VV-ECLS, recirculation occurs when oxygenated blood from the ECLS circuit delivered to the reinfusion lumen is siphoned back to the venous drainage side of the cannula instead of flowing across the tricuspid valve. When pump flow rises above optimal flow, recirculation increases and effective forward flow through the tricuspid valve decreases. **Clinically significant recirculation is recognized by decreased neonatal arterial saturations and a rise in SvO₂ with increasing pump flow.** Higher degrees of recirculation decrease the effective O₂ delivery from the circuit, possibly contributing to increased hemolysis as well. Factors that increase recirculation include the following:

- a. **Decreased right atrial volume** causes a higher percentage of returned oxygenated blood to be drained back to the pump.
 - b. **Inappropriate positioning of the outflow ports of the arterial side of the cannula may result in blood being directed away from the tricuspid valve**, thus increasing the **recirculation fraction**. Catheters may migrate with changes in lung volume, changing edema of the neck, alterations in patient positioning, or movement, necessitating adjustment of the cannula to maintain adequate flows and minimize recirculation. Appropriate catheter position is critical in VV-ECLS and should be assessed by echocardiography.
 - c. **Poor cardiac output** leads to greater recirculation because a smaller fraction of the oxygenated pump blood is propelled forward out of the right atrium.
 - d. **Pump flows** need to be adjusted to achieve the least amount of recirculation. High flows can cause collapse of the right atrium, loss of pump flow, and hemolysis.
4. **Trialing off venovenous extracorporeal life support.** Given the flow and physiology of VV-ECLS, weaning of circuit flow provides no benefit. Blood flow may remain constant (usually 100–120 mL/kg/min) followed by weaning the FiO₂ sweep gas flow rate and oxygen. During this time, the ventilator settings are increased to those expected to achieve suitable gas exchange. Then the sweep gas tubing is disconnected from the blender source (the oxygenator is “capped off”), which functionally removes the patient from ECLS. Blood gases and SvO₂ are followed, and once assured of success after 1 to 2 hours, the patient may be separated from ECLS and the heparin drip discontinued. Since the integrity of the cannula and circuit is maintained during the trial off because blood continues to flow through the entire circuit, longer trials are possible. If a percutaneous technique was used for VV cannula insertion, simply removing any sutures and then pulling the cannula and holding pressure at the insertion site for 15 to 20 minutes should achieve adequate hemostasis. In some cases, patients require a suture to close the skin over the entry site.
- XX. **Length of extracorporeal life support therapy.** Typically, neonatal patients with MAS, PPHN, and sepsis require ECLS for 5 to 7 days. Patients with respiratory syncytial virus may require 2 to 4 weeks. Those with CDH usually require longer courses (10–14 days), but may need up to 21 days if the pulmonary pressures are slow to fall. If there is lack of improvement within 10 to 14 days in non-CDH neonates, a lung biopsy while on ECLS should be considered to rule out lethal anomalies such as alveolar capillary dysplasia or acinar dysplasia. If the suspicion for anomalies is high at birth, biopsies should be done sooner. Antifibrinolytics generally are not necessary for the biopsy. The heparin infusion can be decreased to a rate where the ACT or anti-Xa levels are in the low range of normal, or heparin can be discontinued for a period of time. Platelet counts are most frequently kept >100 to 150,000 and the fibrinogen >150 mg/dL. Air leaks are generally a rare complication.
- XXI. **Complications of extracorporeal life support**
- A. **Patient complications of ECLS** per the Extracorporeal Life Support Organization (ELSO) International Summary data as of January 2019 for neonatal respiratory patients are as follows: acute renal failure (continuous renal replacement required, 31.1%); hypertension requiring vasodilators, 8.4%; hypotension requiring inotropes, 32.9%; CNS infarction, 3.2%; CNS hemorrhage 10.1%; culture-proven infection, 4.1%; surgical bleeding, 6.4%; pulmonary hemorrhage, 4.8%; pneumothorax requiring treatment, 5.2%; DIC, 4.6%; hemolysis, 15.3%; seizures by EEG, 3.7%; brain death, 0.3%.
 - B. **Mechanical problems** include the following: circuit component clots, 36.8%; cannula problems, 12.8%; oxygenator failure, 4%; air in the circuit, 4%; pump malfunction, 0.9%.

XXII. Prognosis. As of January 2019, the Neonatal ECLS Registry lists 41,707 neonatal runs. From 2014 to current, the overall cumulative neonatal survival rate is 67% for pulmonary cases, 49% for cardiac, and 42% for ECPR. The cumulative drop in survival rates over the years reflects a larger proportion of patients treated with more severe disease. CDH accounts for the majority of respiratory mortality. Survival rates for specific diseases are: MAS, 92%; PPHN, 73%; RDS, 82%; sepsis, 50%; pneumonia, 53%; air leak syndrome 88%; CDH, 50%; congenital heart defect, 46%; cardiac arrest, 40%; cardiogenic shock, 55%; cardiomyopathy, 55%; and myocarditis, 52%. While 77% of neonates with pulmonary disease survived VV-ECLS, only 63% survived VA-ECLS. The diagnosis of CDH in neonates with lower birth weight treated for respiratory failure are factors associated with increased mortality and morbidity.

XXIII. Outcomes. Head ultrasounds should be obtained during the ECLS course and an MRI post ECLS to better define potential injury.

Bilateral sensorineural hearing loss (SNHL) can occur when pre-ECLS risk factors are present such as seizures, $\text{PaCO}_2 < 30$ mmHg, $\text{pH} > 7.5$, and is associated with the use of furosemide, aminoglycosides, or neuromuscular blocking agents. Early audiologic evaluations are necessary and should be continued throughout childhood because late presentation of SNHL can occur.

Despite neuropsychological development showing favorable trends, hyperactivity, or behavioral difficulties can occur at later ages so children need to be followed long term. Difficulties in visual-spatial and memory tasks can occur in those evaluated at age 5. Adolescents with a history of being treated with ECLS have been noted to have problems with short- and long-term verbal memory, visual-spatial memory, and working memory. This group also reported more withdrawn/depressed behavior, somatic complaints, and social problems. Problems with gross motor function may become more obvious as the child ages. Despite these stated complications, many children can have excellent morbidity-free outcomes.

21 Follow-Up of High-Risk Infants

Whenever an infant requires neonatal intensive care, concerns about survival are followed by concerns about the infant's quality of life. Neonatal intensive care follow-up clinics are a necessary adjunct to neonatal intensive care. They provide families with the support and advice they need following neonatal intensive care unit (NICU) discharge. They provide feedback regarding the child's ongoing health and development to families, pediatricians, neonatologists, and obstetricians. Most important, to optimize neurodevelopmental outcomes, serial developmental assessments facilitate early diagnosis and referral for specific early interventions when neuroplasticity may be at its peak.

I. Goals of a neonatal follow-up clinic

A. Early identification of neurodevelopmental disability. High-risk NICU infants need comprehensive neurodevelopmental evaluations and appropriate intervention services. There is a growing body of evidence suggesting that early detection can take advantage of periods of the most active neuroplasticity after brain injury. **Neuroplasticity** refers to the ability of the central nervous system (CNS) to change both structurally and functionally in response to experience and to adapt following injury. In the postnatal brain, there is a very active period of proliferation and pruning of synapses through neurogenesis and apoptosis. This period of neuroplasticity is most active during the first 3 years. An additional mechanism of brain plasticity in the developing child is activity-dependent shaping of neuronal circuits by experience

or injury. There is growing evidence extracted from adult and animal literature that there is a finite period of injury-induced neuroplasticity where most recovery occurs. This will be missed without early identification and appropriate intervention services in high-risk infants.

- B. Assessment of a child's need for early interventions.** Although NICUs refer many infants directly to community early intervention programs, a child's needs change with neuromaturation, requiring periodic review of community service needs.
 - C. Parent counseling.** Reassurance that their child is making good neurodevelopmental progress is always welcome, as the anxiety of uncertainty is a heavy burden for parents. Parents of children with developmental delay need realistic information about its significance and whether it will lead to impairment. A comprehensive neurodevelopmental evaluation can provide parents with essential information and recommendations for how to promote their child's neurodevelopment. Physical and occupational therapists provide valuable suggestions regarding positioning, handling, and feeding infants. Even if their infant does well, parents of high-risk infants should be warned about their child's risk for and early indicators of school or behavior problems.
 - D. Identification and treatment of medical complications** that were not recognized or anticipated at the time of discharge from the NICU (eg, hypertension, sleep problems).
 - E. Referral for comprehensive evaluations and services as indicated.**
 - F. Feedback for neonatologists, pediatricians, obstetricians, pediatric surgeons, and others** regarding neurodevelopmental outcomes, ongoing medical problems, and unusual or unforeseen complications in these infants is essential.
- II. Staff of the neonatal follow-up clinic.** Pediatricians, neurodevelopmental pediatricians, and neonatologists make up the regular staff of the clinic, and many clinics include neuropsychologists and physical, occupational, and/or speech and language therapists. In addition, many need referrals to audiologists, social workers, ophthalmologists, neuropsychologists, pulmonologists, nutritionists, gastroenterologists, orthopedic surgeons, or other subspecialists.
- III. Risk factors for developmental disability.** It is virtually impossible to diagnose developmental disability with certainty in the neonatal period, but a number of perinatal risk factors have been identified for selecting high-risk infants for close follow-up.
- A. Preterm birth.** The risks of cerebral palsy, intellectual disability, and sensory deficits increase with decreasing gestational age and severity of brain injury. Risk of disability, especially cognitive impairments, is highest in survivors born at the limit of viability (at or before 25 weeks' gestation). Children born preterm have higher rates of language disorders, visual perception problems, minor neuromotor dysfunction, attention deficits, executive dysfunction, learning disabilities, social-communicative problems, and emotional difficulties than full-term controls. Although most do well, children born at 33 to 36 weeks' gestation have higher rates of cognitive impairments, cerebral palsy, and school problems than children born full term. Besides gestational age, predictors of neurodevelopmental disability include poor growth (especially head growth), asphyxia, sepsis (especially meningitis), chronic lung disease, necrotizing enterocolitis, and retinopathy of prematurity. Risk is highest in infants with signs of brain injury on neonatal neurodevelopmental examination and neuroimaging studies (see Chapter 18).
 - B. Intrauterine growth restriction (IUGR).** Full-term infants who are small for gestational age (SGA) have a higher risk of motor or cognitive impairments, attention deficits, specific learning disability, and school and behavior problems than appropriate for gestational age (AGA) infants. The etiology and severity of their IUGR, timing of the insult, and subsequent perinatal complications (eg, asphyxia, hypoglycemia, feeding difficulties, polycythemia, brain injury) influence their degree of risk (see Chapter 104). After 30 weeks' gestation, compensatory mechanisms for adverse intrauterine circumstances include accelerated maturation to improve survival if

born preterm. Adverse intrauterine circumstances, preterm birth, and accelerated neuromaturation can adversely influence neurodevelopmental (especially cognitive) outcomes in preterm SGA infants.

- C. **Neonatal encephalopathy.** Neonatal encephalopathy (NE) is a clinical syndrome characterized by a constellation of findings, including seizures and abnormalities of consciousness, muscle tone, reflexes, respiratory control, and feeding. Etiologies include infection, inflammation, metabolic errors, drug exposures, brain malformations, stroke, hypoxia, ischemia, or any combination of these conditions. Etiology, severity of clinical symptoms, abnormal electroencephalogram (EEG) pattern (especially low voltage or burst-suppression patterns), and patterns of brain injury (eg, injury to the basal ganglia and thalamus) are much stronger predictors of neurodevelopmental disability than signs of fetal distress, cord pH, or Apgar scores. Infants with mild or moderate NE who do not develop major disability are at risk for more subtle disorders, including attention deficit, learning disability, and other school problems. Infants with severe NE have a high mortality rate; many of the survivors have severe multiple disabilities, including intellectual disability, spastic quadriplegia, microcephaly, seizures, and sensory impairment. Treatment of infants with moderate to severe NE with hypothermia improves neurodevelopmental outcomes.
- D. **Respiratory failure.** Some late preterm and full-term infants develop respiratory failure that can be due to pulmonary hypoplasia, pneumonia, meconium aspiration, and/or persistent pulmonary hypertension. Outcome studies for randomized controlled trials of treatments for severe respiratory failure (eg, inhaled nitric oxide, ECLS) report cognitive impairment in up to one-quarter of survivors, cerebral palsy in up to 15%, and hearing impairment in up to 30%. When followed to school age, many have problems with attention deficit, specific learning disability, minor neuromotor dysfunction, and behavior problems. Health sequelae include poor growth, reactive airway disease, and increased frequency of respiratory infections. Some survivors have demonstrated progressive hearing loss, so these children need serial hearing assessments.
- E. **Infection and/or inflammation.** Maternal, fetal, and neonatal infection or inflammation has been implicated as an etiology of preterm birth, brain injury (eg, white matter injury), cerebral palsy, and cognitive impairments.
- F. **Other risk factors**
 1. **Congenital infections (TORCHZ—toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus, and now Zika virus).** Infants with congenital cytomegalovirus infection, toxoplasmosis, rubella, or Zika virus who are symptomatic at birth have a high incidence of neurodevelopmental disability. Asymptomatic infants are at risk for sensory impairment and learning disability.
 2. **In utero exposures.** Maternal drugs reported to influence fetal development include narcotics, cocaine, alcohol, phenytoin, trimethadione, valproate, warfarin, aminopterin, retinoic acid, and environmental toxicants.
 3. **Complex medical healthcare needs.** Children discharged home from NICUs with complex medical healthcare needs have a high risk of neurologic impairment and need close follow-up of their neurodevelopment.
- IV. **Terminology.** Communicating about preterm outcomes entails consistent definitions.
 - A. **Gestational age.** Time between mother's first day of the last menstrual cycle and birth.
 - B. **Postmenstrual age (PMA).** Infant's gestational age (GA) plus chronological age (from birth).
 - C. **Corrected age.** Calculated from the infant's due date, the infant's age corrected for degree of prematurity (ie, chronological age minus number of weeks born preterm).
 - D. **Use PMA for preterm infants in a NICU and corrected age for preterm follow-up.**
- V. **Parameters requiring follow-up**
 - A. **Growth (height, weight, head circumference, weight for height).** Assess at each follow-up visit. Poor head growth is associated with lower cognitive scores. Most

preterm infants “catch up” in growth, but some infants with IUGR, extremely preterm birth, chronic lung disease, or short gut syndrome remain smaller than their peers. Too rapid weight gain and overweight raise concerns for increased risk for metabolic syndrome.

- B. Vital signs with blood pressure.** High blood pressure is a serious NICU sequela and occurs more frequently in infants who had umbilical catheters or renal problems.
- C. Breathing disorders**
 - 1. Apnea.** For infants discharged home on monitors, there is often uncertainty as to when to discontinue the monitor.
 - 2. Chronic lung disease.** Infants with chronic lung disease have higher rates of respiratory infections, reactive airway disease, rehospitalization, and neurodevelopmental disability. Those on supplemental oxygen, monitors, diuretics, and other medications need subspecialty follow-up.
 - 3. All infants need protection from secondhand smoke** and anticipatory guidance against ever smoking themselves.
- D. Hearing.** Hearing is essential for language acquisition, so it should be identified as early as possible. Before hospital discharge, all neonates should have their hearing screened (eg, **brainstem auditory evoked potentials, transient evoked otoacoustic emissions**) and referred for a comprehensive audiologic evaluation if there are concerns. Hearing aids, cochlear implants, and other treatment strategies have had a profound effect on language acquisition. Infants who had congenital or perinatal (eg, TORCHZ) infection, congenital malformations of the head or neck, persistent pulmonary hypertension, chronic otitis, a family history of hearing impairment, or a language delay warrant serial hearing assessments.
- E. Vision.** Retinopathy of prematurity (ROP) is a disease of the developing retina in preterm infants (see Chapter 118). Infants at risk for ROP need serial eye examinations until their retinas are fully vascularized. Ophthalmologic examinations are also indicated in infants with congenital infection, congenital anomalies, and NE. All high-risk infants should have their visual acuity assessed when 1 to 5 years old. Infants with injury to the visual cortex need to be assessed for signs of cortical visual impairment (CVI) because early intervention for CVI can improve their visual function.
- F. Neuromaturation, the functional development of the central nervous system,** is a dynamic process: what is typical at one age is often abnormal at another age. Extremely preterm infants are hypotonic at birth and typically develop flexor tone, first in the legs then in the arms (eg, in a caudocephalad direction) as they approach term. Typical preterm infants at term and full-term infants have strong flexor tone (ie, flexor hypertonia), as well as a number of primitive (eg, Moro) and pathologic (eg, Babinski) reflexes. In the months following term, emergence of higher cortical control suppresses flexor tone and pathologic and primitive reflexes. Examiners must know typical infant development and the significance of deviations from the norm.
- G. Neurodevelopmental examination.** Includes an assessment of posture, extremity and axial (neck and trunk) muscle tone, deep tendon reflexes, primitive reflexes, pathologic reflexes, postural reactions (eg, automatic movements that keep the body upright), and quality of motor function.
- H. Neuromotor abnormalities.** Abnormalities on neuromotor exam are common in high-risk infants during the first year, but they often resolve or become less prominent by age 1 to 2 years. They persist and are accompanied by motor delay in infants who develop cerebral palsy. These infants should have a comprehensive multidisciplinary evaluation because infants with cerebral palsy may have associated deficits that interfere with function. Infants with neuromotor abnormalities and mild or no motor delay have minor neuromotor dysfunction, which signifies increased risk of balance and coordination difficulties (developmental coordination disorder), learning disability, attention deficit, and behavior problems.
 - 1. Hypotonia (generalized or axial hypotonia) is common in preterm infants,** infants with chronic lung disease, and infants with genetic syndromes.

2. **Hypertonia is most common at the ankles and hips.** Persistent hypertonia (especially extensor) and hyperreflexia indicate spasticity. In preterm children, spastic diplegia (ie, of both lower extremities) is the most common type of cerebral palsy. Avoid standing activities until infants can pull themselves up to stand against furniture.
 3. **Asymmetry of function, tone, posture, or reflexes.** Encourage parents to position infants in their crib so they will turn their head to each side, as a strong head preference can influence neuromuscular and motor milestone development. Some NICU infants develop such a strong head preference that they develop torticollis and plagiocephaly. Infants generally do not develop a hand preference until between 1 and 2 years. Spastic hemiplegia is spasticity of an arm and ipsilateral leg. Early handedness and significant persistent asymmetry are indications for referral for intensive physical therapy, including possible constraint-induced therapy.
 4. **Neck, trunk, and lower extremity extensor hypertonia and shoulder retraction** (ie, excessive arching, shoulders back) can interfere with head control, hand use, rolling over, sitting, and getting in and out of a sitting position. Encourage families to hold and position infants with their head and shoulders in line with their body and to avoid standing activities until their children pull themselves up to stand.
 5. **Fine motor dysfunction** is difficulty using the hands for manipulating objects. Fine motor milestones include reaching and grabbing for toys, transferring them from hand to hand, and developing a pincer grasp (using index finger and thumb).
 6. **Feeding problems.** Tube-fed infants need oromotor stimulation programs to prevent oral aversion (eg, not tolerating anything in their mouth). Coughing, choking, and/or gagging with feedings are indications for referral for an oral motor evaluation.
- I. **Cognitive development.** Language and visual attention are early signs of cognitive development. Refer infants with language delay for an audiologic evaluation to be sure there is no subtle hearing impairment. The primary way that infants and young children learn is by face-to-face interactions with family. Encourage families to talk and read to their infant, reinforce vocalizations, and by 9 to 10 months, identify objects by name. Avoid any screen time before 2 years. Accuracy of cognitive assessments improves with age.
 - J. **Developmental assessment.** A number of standardized tests are available for developmental screening or assessment. Many of them are easy to learn and administer.
 1. **Infant developmental milestones.** History and observation of language, motor, and adaptive milestone attainment provide a quick overview of developmental progress.
 2. **Standardized screening and assessment tests.** A number of standardized tests are available for use in infants and children at different ages.
- VI. **Correction for degree of prematurity.** Most agree that one should correct for degree of prematurity in preterm infants, but correcting beyond 2 to 3 years is **controversial**. The older a child, the less important correction is: by 5 years, arithmetically a difference of 4 months (eg, 60 vs 56 months) matters little. Motor milestone attainment up to independent walking proceeds according to age corrected for degree of prematurity. Some data suggest correction influences cognitive scores in children born extremely preterm beyond age 2 to 3 years.
- VII. **Comprehensive evaluations.** Recognizing delay or disability is an indication for comprehensive evaluation of all areas of function. Brain damage is seldom focal and often diffuse. A comprehensive multidisciplinary evaluation recognizes areas of a child's strength and challenges, helps develop strategies for intervention, provides realistic information for parent counseling, and provides recommendations for promoting the child's neurodevelopment during critical periods of infancy and early childhood.

22 Complementary and Integrative Medical Therapies in Neonatology

I. Introduction. The use of complementary and alternative therapies continues to grow in this country and abroad. **Integrative medicine** is a newer term that emphasizes integration of complementary therapies with conventional medicine. In integrative medicine, health professionals are expanding their view of Western medicine to a more holistic perspective. Integrative care has emerged in neonatal intensive care units (NICUs) throughout the globe as an attempt to create a more neuroprotective environment and provide a more nurturing, family-friendly environment.

Early exposure to the ex utero environment, long before development is capable of handling it, has a myriad of sequelae. We cannot escape the evolving realization of environmental and epigenetic influences on the development of the immature brain. These infants require developmental care equal to their acute and chronic medical care. Integrative therapies give us some options that might help ameliorate some of the routinely expected morbidities.

This chapter briefly describes some of the most popular and promising integrative therapies, explores how these options are used in the NICU, provides some evidence-based support of integrative therapies, and presents ideas on potential future integrative expansions. **Broad categories that integrative therapies address include the following:**

A. Lifestyle therapies (called “developmental care” in neonatology). Examples include light and color therapies, music therapy, aromatherapy, kangaroo care, and attention to environmental influences, such as bright lights and loud noises.

B. Biomechanical therapies. Example include massage, reflexology, and osteopathy/craniosacral therapy.

C. Bioenergetic therapies. Examples include acupuncture/acupressure, therapeutic/healing touch, and reiki.

D. Biochemical therapies. Examples include homeopathy and herbal medicine.

II. Lifestyle therapies. Lifestyle therapies are more commonly referred to in the NICU as developmental care intervention. Research shows that the environment of a newborn is an important influence on sensory, neural, and behavioral development.

A. Developmental care includes many interventions, both on the macro- and micro-environmental level. Many neonatal units have made tremendous efforts to modify existing nurseries or have designed new units with environmental modifications that include particular attention to noise levels, light exposure, organization of care, and family-centered care.

1. Noise. Adverse environmental auditory stimuli are a common concern. Many NICUs incorporate a system of noise assessment and regulation. Ex utero, the auditory system is not shielded by the maternal tissues, which significantly attenuate frequencies. Ambient noise in the NICU may cause distress, and attempts have been made to minimize the noise using ear plugs or using sound to negate other sounds, called sonic acoustic masking. Single-family rooms create a more home-like environment and have proved to be successful in terms of noise abatement. However, there is concern of lack of stimulation for infants who do not have regular visitation by family members.

2. Light. Regulation of ambient light in the NICU is also an important concern. Constant exposure to light can result in disorganization of an infant's state. Unit lighting is now designed or modified to regulate light and to include developmentally supportive circadian dark/light cycling. Focused lighting for procedures and the use of eye covers or incubator drapes are all great adjuncts.

3. **Care organization.** Infant-specific care plans help better regulate the myriad intrusions of intensive care. Positioning, handling, and interactions should be coordinated when possible with cues of readiness from the infant. This is felt to help the infant minimize energy losses and allow for more optimal conditions for neurodevelopment maturation. Infants need more conscious developmental care when the situation allows.
4. **Family involvement.** Having an infant in intensive care not only causes acute stress but also can lead to posttraumatic stress disorder, which can continue or manifest months later. There is a current trend that allows parents to be present 24/7 and to participate in the daily rounds on their infant. Many professionals, who would not otherwise even consider some of the integrative therapies that follow, now look at these therapies as opportunities that allow more parental participation and connection, encourage parent–neonate interactions, and enhance bonding. Parents can create a loving environment, instill a sense of security, and foster a trusting responsiveness; however, when they are met with an authoritarian, “You can’t touch your baby,” they can feel pushed aside and confused.

Parents are integral team members who should be included in our expanded focus on the developmental aspects of care. What parents need is a context for their interactions; they need someone to teach them how to titrate interactions while becoming aware of their infant’s cues. The **Newborn Individualized Developmental Care and Assessment Program (NIDCAP)** has been especially influential in encouraging awareness of the use of an infant’s communications as a basis for individualized care delivery. These can be detected by reading the infant’s sign language or state-related behaviors such as finger splaying, frequent fistling, trunk arching, gaze aversion, or more typical behaviors such as cooing, babbling, or fussing with a frowning face. Awareness of these states has changed our understanding from thinking of an infant as a passive organism to an active partner in a feedback system of rich human interactions.

Maternal administration of physical activity such as passive limb movements has been shown to enhance bone mineral acquisition in very low birthweight (VLBW) infants. This could be a great way for a father to also feel included in the care of his baby. These care practices can also provide an opportunity for infants to hear their parents’ voices, as speech and language development are believed to be influenced by prenatal maternal speech.

5. **Kangaroo care (KC)** is usually used to promote bonding and attachment between the infant and the parent (the infant is usually wearing nothing more than a diaper while held on the parent’s bare chest). KC was originally developed for a different purpose. Preterm infants in Bogota, Colombia, were dying of infection caused by cross-contamination from shared bedding space and equipment in the nursery. Colombian physicians decided to try having mothers stay in the hospital and incubate their infants next to their bodies until the babies were stable and discharged home.

KC has many cogent justifications. It supports the growing consumer interest in participation in the care of hospitalized infants while giving a significant feeling of autonomy to the parents. When a parent holds their infant against his or her skin, the infant’s breathing, oxygen saturation, heart rate, and tone improve. It has also been shown that skin-to-skin care results in less episodes of apnea, less disorganized sleep states, and a doubling in the periods of quiet regular sleep. In addition, varying body positions seems to affect gastric emptying and reflux. Recent evidence confirms that KC promotes physiologic stability with very immature and ventilated infants.

6. **Aromatherapy.** Researchers have reported that newborns have an acute sense of smell. Odor forms part of the complex bonding process. The soothing effects of a mother’s odor are in stark contrast to the noxious odors of alcohol, skin cleansers,

and adhesives normally found in a NICU. In some cultures, familiar odors are often left in a newborn's crib to calm an infant in the mother's absence.

Through the use of aromas, neurotransmitters are released that calm, sedate, and decrease painful sensations or can be used for stimulation. **Lavender** has been the most studied; for example, when lavender is placed on pillows of adults, it is known to alleviate insomnia and stress. Aromatherapy could be helpful for NICU staff as well. A recent study showed that aromatherapy with lavender oil decreased stress levels in nurses who worked in the adult trauma intensive care setting. In a study from Japan, male college students who were exposed to lavender scent during work showed improved concentration. In another Japanese study, female students exposed to lemon fragrance had diminished fatigue.

Several recent articles address the role of olfaction as a tool in preterm infant care. A study published in 2016 showed that **Rosa damascena (rose) distillate** reduced the incidence of apnea, bradycardia, and decrease in oxygen saturation in preterm infants. Other studies have shown a decrease in apnea and apnea with bradycardia using **vanillin**. The explanation for the reduction in apnea and bradycardia is unclear but may be due to a direct or indirect effect on the respiratory centers and the ability of these compounds to be absorbed by the nasal mucosa, allowing a direct pathway to the brain centers. Another explanation is that the presence of a pleasant odor in the environment may help the infant to self-regulate. Aromatherapy with **lavender and mother's breast milk** has also been shown to reduce the pain with blood drawing in newborns.

7. Music therapy. Lullabies have been linked with infants throughout history; music therapy carries this tradition over into the NICU. Music therapy has also been shown to calm distress after painful stimuli, resulting in a faster return to a more organized state and improving the hypersensitivity that is associated with stimulation. A number of studies have documented improvements in feedings and weight gain, decreased salivary cortisol levels, and enhanced development and parental bonding. We know that by 16 to 18 weeks of gestation, the auditory capabilities of the fetus are present. In utero, the uterine blood flow provides a soothing musical waterfall, and the maternal heartbeat provides a continuous tick-tock.

In a recent study, Loewy et al reported that intentional, therapeutic use of live sounds, inclusive of breath, rhythm, and parent-preferred lullabies, applied by a certified music therapist can influence cardiac and respiratory function. Particularly when entrained with a premature infant's observed vital signs, sound and lullaby can enhance quiet alert and sleep states, sucking patterns, and oxygen saturation. Parent-preferred lullabies, sung live, and contextualized in a 6/8 meter, can enhance bonding and have the potential to significantly reduce parental stress. Music therapists can work with fathers as well and thereby increase their presence in the NICU, implementing a family-centered approach. Dr. Loewy is the founder of the Rhythm, Breath, and Lullaby (RBL) international training.

Music, both live and recorded, has been studied in a variety of conditions and contexts. Music may alleviate some of the distress infants sustain with suctioning and heel sticks. In the first meta-analysis of music therapy in the NICU, Standley reported heart and respiratory rates, oxygen saturations, weight gain, length of stay, and sucking and feeding ability as all being positively influenced. A recent meta-analysis replicated these findings and found that live music therapy and early music therapy showed the greatest benefit. The Pacifier-Activated Lullaby (PAL) is a medical device that has been used to reinforce sucking patterns, which may lead to enhanced sucking patterns. Studies involving the live use of music therapy as integrative in the treatment of neonatal abstinence syndrome are ongoing and compelling because they involve parents in the discipline, which ensures continuity of care at home, enhancing bonding potential for infants with parents.

Environmental music therapy involves the intentional use of music and sound to modulate the soundscape of a noisy hospital area such as the NICU.

A noxious sound environment is converted into a quieter treatment area, one that is more conducive to healing and well-being. Infants, families, and staff reap the benefits.

8. **Color and light therapy.** Healthcare workers tend to dismiss color and light therapy as something from the distant annals of medicine, but certainly neonatologists could expand awareness in this area due to the near omnipresent use of phototherapy in neonatal units. Research on phototherapy has shown the biologic significance of light exposure. Aside from the classically recognized effects of diminishing bilirubin and activation of vitamin D, numerous studies have shown other metabolic alterations with phototherapy, including thyroid stimulation, alterations in renal and vascular parameters, and increased gut transit times. Could it be that other wavelengths of light might have other physiologic effects? This has become the basis for the field of study for color and light therapy.

The current interest for light therapy in the NICU has less emphasis on the effect of different wavelengths (colors) on an infant's metabolic milieu; rather, it focuses on generalized lighting in the unit. Establishing circadian rhythmicity by varying light cycles in the infant's environment seems to minimize endocrine fluctuations, as well as the states of disorganization that come from constant light stimulation. One study used acrylic helmets to reduce infant exposure to light on a defined schedule. Infants in the intervention group had improved weight gain and earlier hospital discharge. Another study that used a special light filter placed over the incubator for a specified time each day found similar improvements in weight gain prior to 28 weeks; when not using incubator covers or eye patches, it has been suggested that overexposure to light may interfere with the development of the other senses.

III. Biomechanical therapies

- A. **Massage therapy** has been used in the care of premature infants for many years, and a significant body of research has already shown its effectiveness. Tiffany Fields has conducted infant massage research since the 1970s, much of which has focused on the premature infant. Fields reported that massaged infants have improved weight gain and better organized sleep states; they become more responsive to social stimulation, have more organized motor development, and are commonly discharged 6 to 10 days earlier from the hospital. Fields's studies suggest that massage increases vagal activity, which in turn releases gastrin and insulin and also increases levels of insulin-like growth factor-1. These findings may explain the weight gain in massaged premature infants. Recent studies have shown that massaged infants are found to be calmer upon discharge with improved neurodevelopmental outcome at 2 years of corrected age.

The amount of massage or stimulation applied should be altered according to the infant's maturation, acuity, engagement cues, and response to touch. There are many types of massage and touch therapy, including gentle stroking, gentle touch without stroking, M-technique (structured touch), Yakson touch (a Korean therapeutic touch), containment, kinesthetic (bicycling) stimulation, or even confinement holds mimicking the womb. Being aware of the infant and his or her receptivity and alertness is important in determining the best time for a massage rather than relying on a predetermined time. Numerous studies have shown benefits of all types of massage, including improved weight gain, improved sleep, and decrease in stress hormone levels and reduced hospital stay. A Japanese study showed that touch modified changes of cerebral oxygenation in response to a sensory punctate stimulus using near-infrared spectroscopy.

A significant emphasis has been placed on fathers performing massage as a bonding tool, similar to what breast feeding would be for the mother. It can also be a great way to get other family members, such as grandparents, involved. Data suggest that the masseuse also benefits, with lower stress hormone levels and decreased postnatal depression and anxiety. KC is probably the most widely accepted and used form of touch therapy.

B. Osteopathy/craniosacral therapy. Osteopaths believe that many problems begin at birth. Labor is seen as quite traumatic, and an infant may be altered both physically and psychologically by the experience. A multicenter Italian trial of osteopathic manipulative treatment on preterm infants showed decreased length of stay. A study exploring the effectiveness of osteopathic treatment in reducing pain in a sample of preterm infants is ongoing.

Craniosacral therapists feel that misalignment of structure that is not corrected can lead to potential alterations in function. Problems such as sucking/swallowing difficulties, suboptimal breast feeding, and recurrent reflux after birth are so common that many mothers and doctors consider them to be normal; however, in osteopathy, they are believed to be based in craniosacral abnormalities. Recognition and treatment of these dysfunctions in the immediate postpartum period are considered an essential preventive measure. According to craniosacral theory, these can be easily rectified.

The occipital area is thought to sustain most of the trauma at delivery. A complex study by osteopath Viola Frymann explored the relationship between symptomatology in the newborn and anatomic disturbances. The study suggested that strains within the unfused fragments of the occipital bones produce problems in the nervous system, such as vomiting, reflux, hyperactive peristalsis, tremor, hypertonicity, and irritability. Frymann notes that compression at the point of the hypoglossal nerve egress can cause an infant to suck ineffectively. Symptoms left untreated may result in tongue thrust, deviant swallowing, speech problems, and, in later life, malocclusion. If the condylar parts of the occiput are decompressed, the vomiting stops. In temporal bone development, misalignment may cause recurrent otitis media. If the sphenoid sinuses are involved, the child may have headaches. When the vagus nerve is compressed, recurrent vomiting or reflux can occur.

Craniosacral therapy has been used successfully in the NICU to improve feeding. Since adequate feeding is an important criterion for safe discharge, this therapy may be a useful adjunct to care. Craniosacral therapy has also been shown to be beneficial for infants with colic, improving sleep and reducing crying.

IV. Bioenergetic therapies

A. Acupuncture is part of the traditional system of Chinese medicine. The main concept behind this system is that of chi (body energy not currently measurable by current instrumentation), which underlies and supports all aspects of the physical body. This chi/energy circulates throughout the body along specific pathways called meridians. Obstructions in the flow of chi may cause disease. By gently placing thin, solid, disposable, metallic needles into the skin along the meridians where chi is blocked, acupuncturists rebalance the flow of energy.

Acupuncture has shown promising results in use for anesthesia, postoperative pain, and addiction recovery. A study from Turkey concluded that acupuncture decreased pain scores in preterm infants and crying time during heel prick. However, noninvasive electrical stimulation of acupuncture points did not reduce pain from heel stick in another study. Auricular acupuncture has been used since the early 1970s for various forms of maternal addiction and withdrawal prenatally. It is also used to help reduce the effects of neonatal drug withdrawal. In a study conducted in Austria, laser acupuncture, using a **LABpen MED 10** (Behounek Medizintechnik GMBH, Graz, Austria) and a specific protocol on ear and body points, was found to be an effective in reducing the duration of morphine therapy in infants with neonatal abstinence syndrome.

Currently in China, acupuncture is used to treat infants with jaundice (augmenting hepatic chi), skin problems, teething, ear infections, constipation, conjunctivitis, and peripheral nerve injury. It is also used in intraoperative and postoperative pain control. Auricular acupuncture is used in China for the treatment of hypogalactia in mothers.

- B. Acupressure**, similar to acupuncture but without the needles, is popular in pediatrics. Acupressure involves applying pressure along the 14 major energy meridians to promote the flow of chi. Noninvasive acupuncture can also be used as an adjunctive treatment for infants with neonatal abstinence syndrome. However, noninvasive electrical stimulation of acupuncture points did not reduce heel stick pain in a recent study. More research is needed.
- C. Healing touch (HT) and therapeutic touch (TT)** are energy-based therapies based on clearing, aligning, and balancing the human energy system through touch or near-body touch to promote health and healing. The treatments are based on the idea that a universal life force energy flows through all of us. HT was developed by Janet Mentgen and the American Holistic Nurses Association. One example of an HT technique that can empower parents to feel like they are actively participating in care of their infant is called **comfort infusion** and is used to relieve pain. Parents are taught to place their left palm over the infant, encouraging any pain the infant may be having to move up from the infant to the parent's palm and then through their body to drain out of their right hand. When parents no longer sense pain, the right hand is placed over the infant and the left one turned upward to infuse healing energy. When the parents are at a point of feeling totally helpless in their infant's plight, this can restore a feeling of energetic connection with no touch involved, so they can do this no matter how ill their infant may be.

TT was developed by Dora Kunz, a healer, and Dolores Krieger, a professor of nursing. TT does not require physical contact. Through the compassion and intention of the practitioner, the flow of energy between the practitioner and the infant is modulated to promote the infant's natural energy flow and support the infant's own healing abilities. The steps in TT include centering, assessment, unruffling (clearing extraneous energy), balancing and rebalancing, and closure. Limited studies have shown that TT improves vital signs, decreases pain scores, and promotes relaxation.

- D. Reiki** is a form of noninvasive energy healing, similar to HT, in which energy is transferred from the hands of a reiki master to a patient using a sequence of hand positions above the body. Reiki relaxes and heals by clearing energy meridians and chakras (vortices of energy along the spine). Energy blockages are dissolved, allowing the vibration frequency of the body to increase, thus restoring balance. As a calming balance occurs, respirations slow, blood pressure normalizes, and pain is relieved—all of which are felt to accelerate the healing process. Reiki is beneficial to the practitioner as well, increasing relaxation and enhancing focus.
- E. Reflexology** is an ancient form of healing, somewhat similar to traditional acupuncture. In this modality, chi is restored by manipulation of reflex points in the hands and feet that have specific correlates to organs, glands, and body parts. Reflexology may benefit infants by increasing blood flow to specific organs such as increasing perfusion to the kidneys or increasing cardiac output.
- V. Biochemical interventions**
- A. Homeopathy.** The basic idea behind homeopathy is that the body's internal wisdom will defend and heal itself by choosing the most beneficial response. Homeopathy is based on the "like cures like" principle: a symptom in a patient is treated with a remedy that causes this same symptom, thus further stimulating the body's natural responses (similar in philosophy to a vaccine). Homeopathy can be considered a catalyst to jumpstart the body's healing process.

Homeopaths prescribe medicine that is very patient specific, and they base these prescriptions on past health history, past medical treatments, genetic inheritance, and a constellation of physical, emotional, mental, and spiritual symptomatology. Apparently, titrating individualized medicine(s) for newborns is not always easy. Chubby infants require different constitutional remedies than small or low birth-weight infants, as do infants who sleep through the night compared to those who do not. Although homeopathic preparations are used globally, there is concern regarding efficacy and safety.

Some examples of homeopathic therapies are for infants who endure traumatic labors with bruising or other injuries (eg, postnatal intravenous infiltrates). They are considered to benefit from a remedy called **arnica** and **Hypericum perforatum**, which are thought to optimize the body's attempts to heal wounds, both physical and psychological. In Europe, where homeopathic remedies are much more commonly used, **carbovege** is used for apnea and bradycardia. **Aethusa** is used for milk intolerance as well as for reflux. **Nux vomica** and **chamomilla** are used for colic. **Magnesium phosphorica** is used to relieve symptoms of gas, bloating, and burping. **Topical calendula** is used for diaper dermatitis. Topical emollient therapy (vegetable oil, sunflower oil, and coconut oil) has been studied in preterm infants and newborns and was associated with improved weight gain and linear growth (vegetable oil).

- B. Herbal medicine.** The World Health Organization (WHO) considers herbal medicine part of traditional medicine, which is “the knowledge, skills and practices based on the theories, beliefs and experiences indigenous to different cultures, used in the maintenance of health and in the prevention, diagnosis, improvement or treatment of physical and mental illness.” The WHO estimates that approximately 80% of the world's population relies on botanical medicines; indeed, 30% of Americans also use botanical remedies. It behooves healthcare professionals to be familiar with the expanding field of herbal medicine. Many mothers use herbal remedies during pregnancy. They are especially popular among breast-feeding women. Knowing what, if any, herbal remedies nursing mothers use is essential because the substances can be passed through breast milk to children. **Galactagogue herbs** have gained a reputation for increasing breast milk, but must be used with caution and more selectively because recent studies have shown limited benefits and possibility of significant side effects. (See Section VI.C.) **St. John's wort** is commonly used for postpartum depression. **Caffeine** is probably the herbal medicine most used in neonatal care. Many consider the use of probiotics, a hot topic in neonatology, for prevention of necrotizing enterocolitis as originating from the field of herbal medicine. A recent study showed that **arnica echinacea powder** applied to the umbilical cord after birth was safe and effective in preventing infection after umbilical cord detachment. Many others are herbal folk remedies. **Aloe vera** is used as a skin protectant or for burns and skin irritations. Creams made from **comfrey**, **plantain**, or **marigolds** are used for treatment of rashes and cradle cap. **Thyme tea solution** was studied retrospectively for treatment of staphylococcal skin infection in preterm and term newborns and found to be effective. **Calendula** is used in Russia for conjunctivitis. **Tree tea oil** is used as an antifungal.

VI. Supportive care

- A. Palliative care and hospice care.** Neonatal palliative care has been evolving within the auspices of neonatal intensive care. Palliative care is focused on the prevention and relief of suffering and includes medical treatments intended to improve the baby's life. Increasingly, NICUs are developing palliative, comfort care programs to care for families whose infants have life-limiting conditions. Palliative care is multidisciplinary and interdisciplinary. Teams typically consist of medical and nursing personnel, spiritual advisors, social service personnel, and therapists, including child life and music. Advances in technology and genetics have made it easier to detect a fetus with a life-limiting abnormality. Other NICU populations who benefit from palliative care are infants born at the limits of viability, infants with overwhelming illness not responding to disease-directed intervention, and infants with chronic life-limiting conditions.

Integrative medicine therapies used in palliative care include family-centered care with attention to environmental light and noise, KC, infant massage, and music therapy. Palliative care and hospice care are often used synonymously. However, in general, hospice care falls under the umbrella of palliative care. Hospice care is a particular form of palliative care delivered in the United States by licensed hospice agencies. Palliative care is discussed in detail in Chapter 24.

- B. Emotional care.** Parents are at risk for acute stress as well as posttraumatic stress disorders and depression. Support groups can help parents cope. A study conducted by Shaw et al showed that trauma-focused therapy reduced symptoms of trauma and depression in mothers of preterm infants. Shaw also showed that fathers may manifest symptoms of posttraumatic stress disorder several months after the infant is discharged. Support groups may also be helpful to meet the often overlooked needs of siblings.
- C. Galactagogues.** Therapies in the management of inadequate breast milk supply are of special concern to neonatologists. Prescription galactagogues and increased fluid intake are traditional mainstays, but many mothers prefer more natural therapies when breast feeding. Herbal galactagogues include **fenugreek, goat's rue, milk thistle (*Silybum marianum*), oats, dandelion, millet, seaweed, anise, basil, blessed thistle, fennel seeds, marshmallow, and trobangun leaves** (thought to antagonize the dopamine receptors, thereby increasing prolactin release). **Milk thistle** and **fenugreek** have limited safety data, and the evidence for using other herbs has grown weaker. Eidelman cites a recent human study showing benefits of **ginger supplements** in the immediate postpartum period, and a study in animals using traditional Chinese herbal mixture was shown to increase breast milk production and aquaporins in the mammary tissue. (Aquaporins are a family of membrane proteins that facilitate water transport and may have a possible role in milk secretion). More studies are needed.
- VII. Conclusion.** As neuroprotective care in neonatology continues to evolve as neonatology's new frontier, integrative therapies challenge us to think of the many options for supporting and nurturing the complexities of health and healing in infants. Many of these provide the possibility of using structured stimuli to help reduce stress and other noxious environmental factors. Family-focused integrative therapies may also mitigate the toxic stress of the infant as well as the parent. As mainstream medicine is embracing integrative therapies, research will be needed to demonstrate the efficacy of these therapies as well as to assess the short- and long-term benefits and burdens.

23 Neonatal Bioethics

- I. Introduction.** Neonatology has evolved significantly in the past 30 years. Although care of premature infants and their specific disease processes has been studied for the past century, it was the development of the ventilator that truly birthed the field of neonatology. This occurred in the 1960s and was a time of rapid technologic development. These technologies were applied to this new field of neonatology rapidly. We were able to care for children who had previously had no hope of survival. Many of these new technologies had never been used before, and innovation was the hallmark of neonatal care. Although this was essential in saving the lives of literally millions of premature infants during this time period, it also made it difficult to predict outcome or effectiveness of treatment. Issues such as effectiveness of treatment, potential risk to the patient, or quality of life were difficult to determine. However, any treatment was considered better than the hopelessness that these children faced before this era. This "frontier" mentality spurred the application of technology, even in instances where we were unsure of the outcome. This sometimes caused conflict in choosing the best course of action. It was difficult to know when application of technology might be ineffective or might have unintended consequence on the patient's quality of life.

The present day of neonatology is quite a bit different. We now have a much better idea of quality of life and prognosis. Indeed, the neonatal intensive care unit (NICU) for the most part has become a field of fairly routine but technologically advanced care where the expectation is a minimum of complications and a quality of life and development that are indistinguishable from children who did not require this care. This has allowed us to look more closely at the effectiveness of care and quality of life. We are able to back away from the idea that any care is better than no care and look at our treatment of these patients in a more standard and less pressured framework. As in any field of medicine, this is not to say that there are not ethical dilemmas that occur. There are still significant issues related to the benefits of treatment versus risk and questions about long-term disability, cost of care, and harm to the patient who cannot speak for himself or herself. To answer some of these questions, we would need for framework to discuss the ethical issues involved as well as the medical decision making.

II. Bioethical framework. Ethical discussion in medicine has been highly influenced by the ideas of principlism, which have been eloquently described in the foundational textbook of bioethics, *Principles of Biomedical Ethics*, by Beauchamp and Childress. They describe 4 overriding principles that must be considered when making ethical decisions for patients. These principles are beneficence, nonmaleficence, respect for autonomy, and justice.

A. Principles that must be considered when making ethical decisions for patients

1. **Beneficence** means that the action or treatment provides some benefit to the patient. This idea encompasses the concept of effectiveness as well. Beneficial actions or treatment may be short term or long term.
2. **Nonmaleficence** means the action or treatment must not harm the patient. This certainly includes the concept that we should not intentionally harm patients but also that we should evaluate possible unintended outcomes or complications related to treatment.
3. **Respect for autonomy.** We should always respect patients' wishes to guide their own fate. If the patients are competent, their wishes and matters of treatment should never be abrogated. In neonatal care, this respect for autonomy is usually for the parents and their decisions for their young child.
4. **Justice.** Justice defines the social and legal obligations we have in applying action or treatment. This principal includes a broader idea of what is fair within society.

In ethical decision making, these 4 principles are weighed against one another to discern which might be superior in resolving various aspects of conflict. This is proven to be very useful in focusing bioethical dialogue and decision making on the patient and avoiding bias and conflicting values that are not in the patient's best interest. However, this process is not without difficulties. In many instances, it is difficult to find complete resolution between the tensions of the 4 overriding principles. Indeed, there are times when these principles will be in direct conflict with one another, making the dilemma appear insolvent. Another issue with the principlism approach is that it does not account for the other participants in the healthcare process. How does the integrity or virtue of the healthcare provider influence the patient's welfare? Should we factor in the cost of care and impact to society in making decisions?

Jonsen and colleagues have developed a practical case-based approach to ethical decision making that builds on the 4 principles. They proposed the idea that ethical decision making is much like clinical decision making and that information must be sorted and prioritized to make a practical decision. Their method is directed much more toward a practical solution for individual cases as opposed to the finding overarching answers for every case. The proposed 4 topics provide a way to collect, sort, and prioritize data to provide a practical solution and are reviewed here.

Table 23–1. CASE-BASED APPROACH TO ETHICAL DECISION MAKING (4-BOX PARADIGM)

Medical Indications	Patient Preferences
<p><i>Principle: Beneficence and Nonmaleficence</i></p> <p>Examples:</p> <ul style="list-style-type: none"> • What is the patient’s medical problem? Acuity? Prognosis? • What are the goals of treatment? • Are there circumstances in which treatment is not indicated? • How likely is it that medical treatment(s) will be successful? • How can the patient be benefited by medical care? How can harm be avoided? 	<p><i>Principle: Respect for Autonomy</i></p> <p>Examples:</p> <ul style="list-style-type: none"> • Is the patient mentally capable and legally competent? <ul style="list-style-type: none"> ◦ Has the patient stated preferences? ◦ If incapacitated, did the patient previously state preferences? ◦ Who is the appropriate proxy (surrogate) to make decisions? ◦ Is the patient unwilling or unable to cooperate? • Has the patient been informed of benefits, risks, and possible complications, and does the patient understand the information and give consent?
Quality of Life	Contextual Features
<p><i>Principle: Beneficence, Nonmaleficence, and Respect for Autonomy</i></p> <p>Examples:</p> <ul style="list-style-type: none"> • What are the prospects of returning to a normal life? What deficits might the patient incur? • Can a surrogate make reasonable judgment about the patient’s quality of life? • Are there biases or prejudice that might influence the healthcare provider? • Does improving quality of life create ethical issues? • Does quality-of-life assessment influence treatment plan? • What quality-of-life assessment would be grounds to forgo life-sustaining treatment? 	<p><i>Principle: Justice and Fairness</i></p> <p>Examples:</p> <ul style="list-style-type: none"> • Are there conflicts of interest (professional, business, social)? • Are there other parties affected by the clinical decisions? • Are there financial factors? • Are there issues with allocation of scarce health resource? • Are there religious issues? • Are there legal issues? • Are there public health issues?

B. Practical case-based approach to ethical decision making (Table 23–1)

1. **Medical indications.** Medical indications refer to the diagnostic and therapeutic interventions that are being used to evaluate and treat the medical problem in the case.
2. **Patient preferences.** Patient preferences state the express choices of the patient about his or her treatment or the decisions of those who are authorized to speak for the patient when the patient is incapable of doing so.
3. **Quality of life.** Quality of life describes the degree of satisfaction, pleasure, and well-being or the degree of distress and malfunction that people experience in their life prior to and following treatment.
4. **Contextual features.** Contextual features identify the social, institutional, financial, and legal setting within which any particular case of patient care takes place, in so far as these influence medical decisions.

The case-based approach to ethical decision-making method allows the clinician to gather information about the ethical issues involved with the case in a

nonbiased manner and place them in a priority schema that will help provide a practical answer in the individualized case (Table 23–1). Once this has been performed, a final step is to reflect on the dilemma as well as a resolution with cases that have occurred in the past. These “paradigm cases” serve as a way to test the decision making and reasoning involved in the case resolution. The resolution does not necessarily have to agree with the paradigm case; however, it will be useful to make sure the participants have thought of all aspects of the case.

III. Specific issues in Neonatology

A. Delivery room resuscitation. Neonatal care in the delivery room requires rapid assessment and quick decision making. In infants with severe congenital anomalies or extreme prematurity, these first few moments of life are critical. In these instances, the pediatrician is called on to make critical decisions within seconds concerning viability, quality of life, and prognosis. Care during this period should be guided by the following general principles.

- 1. Discuss as fully as possible with the parents their wishes and expectations before actual delivery of the child.** Coordination between the pediatricians and obstetricians can facilitate this dialogue (counseling parents before high-risk delivery is discussed in Chapter 55).
- 2. Err on the side of life.** If the mother is unable to express her wishes, then emergency therapy must be performed. It is much better to err on the side of life-sustaining therapy than to withhold such therapy. If in the aftermath of this crisis, it is discovered that the parents wish no such therapy, then it is appropriate to withdraw therapy. This gives the parents the opportunity to form their own opinion and exercise their right in protecting the child’s best interest.
- 3. Noninitiation of resuscitation in the extremely immature infant or in cases of severe congenital anomaly is a challenging problem in neonatology.** According to guidelines from the American Heart Association and American Academy of Pediatrics, noninitiation of resuscitation appears appropriate in confirmed gestation of <23 weeks or birthweight <400 g, anencephaly, or confirmed trisomy 13 or 18. In these cases, all data suggest that resuscitation of these infants is highly unlikely to result in survival or survival without severe disability. In cases in which the antenatal information may be unreliable or with uncertain prognosis, options include a period of resuscitation with the option of discontinuation of the resuscitation if assessment of the infant after delivery does not support the continued efforts. Initial resuscitation and subsequent withdrawal of support may allow time to gather key clinical information and to counsel the family appropriately.
- 4. Discontinuation of resuscitation may be appropriate if the infant fails to have return of spontaneous circulation within 15 minutes.** This is based on strong data suggesting that after a period of 10 minutes of asystole, survival or survival without severe disability is highly unlikely. The Guideline Committee of the American Academy of Pediatrics and American Heart Association recommends that each institution develop local discussions of these issues based on the availability of resources and outcome data.

B. Withholding or withdrawing care

- 1. Withholding care.** There is sometimes a feeling among family members and/or healthcare providers that, to provide optimal care, patients should be offered every technologic treatment or procedure possible. In many cases, however, the application of highly technical procedures is not in the best interest of the patient. Frequently, critically ill infants who are not responding to present therapy should have further therapy or have more advanced therapy withheld. The decision in these cases rests on whether further therapy will **have its intended effect, reverse the process, or restore the quality of life that is acceptable to the patient or the caregivers.**

With these goals in mind, one can see that it is as important to obtain informed consent for withholding care as it is for the application of procedures. The

physician should not withhold care without discussing this course of action with the parents. Likewise, the decision to withhold care should be discussed with the other physicians and nursing staff involved. The indications for and benefits of withholding care should be clearly defined.

2. **Withdrawing care.** In some cases, care can and should be withdrawn for a number of reasons.
 - a. **The care or treatment rendered no longer accomplishes its intended purpose** (ie, futility of care).
 - b. **Ongoing evaluations or tests reveal information changing the diagnosis or prognosis of the patient.** In these cases, reevaluation and discussion with the patient's parents are required to provide for the patient's best interest with this new information.
 - c. **Care given in an emergency should be withdrawn if it is contrary to the parents' wishes when they are informed.** As noted, there are a few legal exceptions to this rule. Overall, the withdrawal of care hinges on the idea of futility. Does the patient benefit from such care? Can we expect the therapy to accomplish both short- and long-term goals? As an example, the use of vasopressor agents in a moribund infant may reach the point of futility. If the short-term goal (ie, raising the blood pressure) is not accomplished and neither is the long-term goal (ie, restoring health), then therapy is no longer useful and should be withdrawn. At every step, the patient's parents should be clearly informed of the decisions and possible outcomes.
3. **Nutrition and patient comfort.** Nutrition has been classified as a therapy, that is, as a medicine that could potentially be withdrawn or, in other instances, as one of the patient's basic rights for comfort. In any discussion of ethics and patient care, there is consensus that the patient should be provided some basic comforts despite what other circumstance may be in question. The comfort of nursing care, cleanliness, pain relief, and mere presence are factors considered to be basic to human life and not subject to diminution or withdrawal, secondary to end-of-life issues. In most cases, nutrition (ie, food and water) is classified as one of these basic comfort cares. This has been contested in the legal system in a variety of cases, with a broad spectrum of opinions. With this in mind, it is probably wise to assume nutrition and feeding to be basic rights for patient care and to challenge this position only in extreme circumstances. The parents' understanding of nutrition as therapy or as a basic right is important. Agreement among the parents, caregivers, administration, and legal authorities must be obtained if the withdrawal of nutrition is contemplated. The activation and opinion of the institution's bioethics committee may be very helpful in resolving these issues.
- C. **Determining quality of life.** Although quality of life is often a focal point of ethical dilemmas in the NICU, it is very difficult to define this term. The word *quality* can be used in many different ways. It can describe the efficiency or usefulness of an object. Another use of the descriptor would be to describe how closely this subject of the description matches the ideal. ("The quality of the metal is like pure gold"). None of these definitions applies directly to a human life. **A broad definition in this instance could be as follows: the ability to lead an unencumbered life to its fullest potential.**

There have been several attempts to measure quality of life. These can be difficult due to the subjective nature of quality. Self-reporting of quality of life is problematic in the NICU because children are not able to give an account for themselves. Even in older patients, there is little correlation between disability and subjective evaluation of individual quality of life. This "disability paradox" makes it very difficult to use potential disability or loss of function as a measure of quality of life or personal sense of significance.

In many cases, health professions view quality as a biologic process. They are biased by their clinical thinking in this perspective. There are certainly cases in the NICU where we can easily predict a poor biologic quality. Examples would be

high-grade interventricular hemorrhage or short gut syndrome. However, this biologic certainty does not necessarily correlate with the predicted quality of life both from the patient's perspective and the family's. Although it is important for us to define these issues clearly for the family, we must be careful not to transpose this perspective to the patient and parents.

Because the concept of quality of life is both conceptually difficult and subjective in nature, neonatologists and NICU nurses should be careful in how they frame their interpretation of these issues. Instead of stating that a patient may have a "poor quality of life," it would be more helpful to state the biologic difficulties the child might have and how that might impact the patient's ability to function normally. This leaves the subjective judgment concerning these issues to the parents and their thoughts on their child's life.

IV. Ethics resources. Conflict is any dispute or disagreement of opinion. This may occur between the physician and the patient or the patient's guardian. Alternatively, conflicts can arise between the physician and the nursing staff, healthcare workers, and administrative staff, or any combination of these. Most ethical issues arise as conflict between differing values or moral ideals. Therefore, the identification of conflict is a key or essential ingredient in bioethical decisions. Conflict is best identified by ongoing communication. Normally, we think of this as communication between physician and patient. However, this is just the first step. Continued communication among members of the healthcare team, parents, family members, and others involved in the case will uncover unvoiced concerns and opinions. These should be dealt with in an open and honest fashion to obtain consensus about ethical issues.

A. Family conference. When there is disagreement about the best course of action for a patient, the first step in resolution is to have an open and clear conversation about all of the issues that are involved. To accomplish this, it is often best to have all of the involved parties meet and discuss the issue itself as well as the patient's history and surrounding social issues. In many instances, there is an incomplete knowledge about treatment or prognosis by the parents or the healthcare team, which can be rectified in such a meeting. The goals of the meeting should be clearly stated, and all members should be reassured that there is not a pejorative nature to the discussion. At the conclusion of discussion, a clear action plan with each step detailed should be formulated. This helps to ensure continued open conversation and increases trust between the family and healthcare team in times of disagreement.

B. Bioethics consultation. Most institutions have standing bioethics committees or departments that can aid in resolving bioethical conflicts. Despite our best intentions, we are sometimes unable to resolve conflict with patients or cannot fully explain the necessity of action to patients, causing confusion. In these instances, an outside perspective may be of value. A consultation from the bioethics committee is simply an outside review of the facts and values associated with a particular crisis. This outside observer may be a physician, another healthcare worker, or a member of the clergy. The purpose of the consult is not to render a "more expert" opinion but to uncover differing moral values and miscommunication that lead to conflict. In many instances, this is all that is needed to resolve these problems. If consensus cannot be obtained in this manner, further interventions are warranted.

C. Bioethics committee. The bioethics committee is usually multidisciplinary in membership. Composed of administrators, lawyers, physicians, nursing staff, and clergy, the committee reviews ethical dilemmas put before it. Many bioethics committees also have a standing role in monitoring the ethical behavior of physicians and healthcare workers at their institution. Activation of the bioethics committee, as opposed to a consult, is a more involved process. The committee's purpose is to not only resolve conflict in particular instances, but also to provide policy and general guidelines for ethical behavior at that institution. Because of the potential legal ramifications, this group may routinely consult the judiciary system for further advice. It is the usual policy of most committees that physicians or other healthcare workers, family

members, clergy, or other interested parties may query the group. These queries can be put forth without fear of retribution or chastisement from other staff members. The procedure for activating the bioethics committee should be posted in the residents' or physicians' handbook or nursing manual for that patient unit.

D. Legal intervention. On occasion, conflict arises that cannot be resolved by the physician, bioethics consult, or committee opinion. In these instances, outside judiciary opinions should be sought. The bioethics committee can usually be helpful in obtaining this legal opinion. Not only does the committee have familiarity with accessing the judiciary system, but they should also be able to frame the question in such a way to provide the most concise legal response. Activation of the legal system in this way also protects the physician from direct consequence from legal action.

V. Summary. The field of neonatal bioethics, much like neonatology itself, has changed and evolved over the past 30 years. The NICU is now an environment where most patients have a fairly predictable outcome, and many of the dilemmas we faced in the pioneering days of neonatology have much less impact. However, we continue to care for very ill children who have a variety of potential medical complications that will impact them throughout their life. These issues require good communication concerning both objective biologic processes and prediction of outcome as well as subjective understanding of issues such as quality of life. When these dilemmas arise, employment of a practical clinical decision-making tool as described by the 4-box method (Table 23–1) can be very useful in identifying all of the issues involved and finding practical solutions. If the dilemma remains unresolved, outside reflection by a bioethics consultation or discussion via a bioethics committee can be helpful.

24 Neonatal Palliative Care

I. General principles

A. The World Health Organization's definition of palliative care (PC) is as follows:

"Palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual."

1. **Provides relief from pain** and other distressing symptoms.
2. **Affirms life and regards dying** as a normal process.
3. **Intends neither to hasten** nor postpone death.
4. **Integrates the psychological** and spiritual aspects of patient care.
5. **Offers a support system** to help patients live as actively as possible until death [and] to help the family cope during the patient's illness and in their own bereavement.
6. **Uses a team approach** to address the needs of patients and their families, including bereavement counseling, if indicated.
7. **Will enhance quality of life**, and may also positively influence the course of illness.
8. **Is applicable early in the course of illness**, in conjunction with other therapies that are intended to prolong life.

B. World Health Organization's definition of palliative care for children:

1. **The active total care of the child's body, mind, and spirit**, and also involves giving support to the family.
2. **Begins when illness is diagnosed** and continues regardless of whether or not a child receives treatment directed at the disease. HCP must evaluate and alleviate

a child's physical, psychological and social distress. Requires a broad multidisciplinary approach that includes the family.

3. **Can be provided at home**, community health centers or in tertiary care facilities.
- C. American Academy of Pediatrics definition of pediatric palliative care:** "Pediatric palliative care addresses the needs of *infants*, children, and the needs of their families, providing treatments that aim to:
1. **Relieve suffering across multiple realms**, including the physical, psychological, social (isolation), practical (home-based services or financial stress), and existential/spiritual (why is this happening?).
 2. **Improve the child's quality and enjoyment of life** while helping families adapt and function during the illness and through bereavement.
 3. **Facilitate informed decision-making** by patients, families, and health care professionals.
 4. **Assist with ongoing coordination** of care among clinicians and across various sites of care."

D. Hospice

1. **All hospice care is palliative care, but not all palliative care is hospice.**
 - a. **Hospice care is palliative care.** For example, the family of a baby with trisomy 18 and complex congenital heart disease receiving nasogastric feedings may choose to care for their baby at home instead of in the neonatal intensive care unit (NICU) during the baby's expected shortened life span. With a skilled in-home hospice supportive program, the family's goal of having meaningful time with their child at home may be supported with intermittent nursing visits, multidisciplinary support, and bereavement support. Nasogastric feedings and attention to the baby's comfort level can be continued at home, and the family may or may not choose to pursue hospitalizations or surgical interventions if the baby's respiratory status deteriorates.
 - b. **Not all palliative care is hospice care.** For example, a 23-week-old baby with bilateral grade 4 intraventricular hemorrhages with a predicted high mortality or poor neurodevelopmental outcome can benefit from a PC model of extra support. PC for this baby and family includes skilled supportive communication to establish unique goals of care, shared decision making surrounding all reasonable options in care (continuation of life-prolonging interventions, placing limits on care such as do not resuscitate/do not attempt resuscitation orders, or discontinuation of life-sustaining interventions), and intentionally making memories and creating opportunities for parenting experiences.
2. **Hospice is not a place; it is a model of care** that ideally is a comprehensive multidisciplinary team approach with a focus on quality of life. It can include physicians, nurses, clergy, social workers, genetic counselors, midwives, traditional hospice professionals, and others.
3. **Professionals skilled in pediatric hospice** may provide supportive in-home outpatient hospice care for neonates and families whose goal is to continue care outside of a hospital setting. Hospice resources vary for neonates, and it is important to be aware of local resources. Hospice care can begin to be integrated during an inpatient hospitalization; there is increasing overlap with inpatient hospice models and outpatient PC resources.
4. **Historically, a predicted life expectancy of <6 months** is a criterion to meet hospice eligibility.

E. Patient criteria

1. **Diagnoses.** Neonatal patients with a **life-limiting or life-threatening condition or uncertain prognosis benefit from a PC approach.**
 - a. **Life-limiting diagnoses** such as trisomy 13 or 18, anencephaly, holoprosencephaly, hydranencephaly, renal agenesis, or multiple congenital anomalies with severe differences.

FIGURE 24–1. Schematic of palliative care planning. NICU, neonatal intensive care unit. (Reproduced with permission from Bidegain M, Younge N: *Comfort Care vs Palliative Care: Is There a Difference in Neonates?* *NeoReviews* 2015 June;16(6):e3333-339.)

- b. **Life-threatening diagnoses** such as extreme prematurity, overwhelming sepsis, severe hypoxic ischemic/neonatal encephalopathy, overwhelming necrotizing enterocolitis totalis, or severe pulmonary hypoplasia.
 - c. **Patients not responding** to aggressive medical interventions.
 - d. **Families with an established birth plan** after a prenatal diagnosis.
2. **Timing.** A PC approach is appropriate for both families that choose to pursue full aggressive medical interventions and families that choose limits on care—at any age and any stage of illness—and can be provided along with curative treatment (Figure 24–1).

II. Components of neonatal palliative care support

- A. **Palliative care implementation.** Interhospital variation exists regarding available **integrated** PC resources and practices versus **consultative** PC team structures.
 1. **Determine local resources.**
 2. **Multidisciplinary palliative care teams** may include physicians, neonatal nurse practitioners, nurses, social work, hospital chaplains, and others.
 3. **Palliative care teams support both the primary medical team and patient** and often work in collaboration to optimize quality of care, communication, and neonatal quality of life as defined by each individual family.
 - a. **Provide time** to devote to intensive family meetings and patient/family counseling.
 - b. **Provide expertise** in managing complex physical symptoms such as pain and symptoms around the end of life.
 - c. **Provide skilled communication and support** for resolving patient/family/physician questions concerning goals of care.
- B. **Skilled communication.** The PC “procedure” is skilled communication to establish neonatal goals of care, offer support, and guide decision making.
 1. **Use honest, compassionate, and clear communication** in establishing a supportive relationship to enable shared decision making.

- a. **Parents want to be heard.** Explore understanding and invite questions. A helpful phrase is: “Can you share with me how others have explained . . . ?”
- b. **Parents want to be validated that their baby’s life has meaning.**
 - i. Use baby’s first name in conversations.
 - ii. Be aware of the baby’s gender prior to conversations.
2. **Avoid euphemisms or medical jargon.**
 - a. **Be mindful** to avoid complicated medical terminology.
 - b. **Avoid phrases** such as “passed away” or “moved on.” Instead, use unambiguous terms or phrases such as “is dying,” “has died,” or “I’m worried will die.”
 - c. **Parents report terminology such as “lethal” or “not compatible with life” as hurtful** (life-limiting or life-threatening is preferred).
3. **Avoid misleading, potentially hurtful language such as:**
 - a. “We can’t do anything else” or “We’ve done everything we can.”
 - i. Care can be redirected to focus on comfort and loving.
 - b. “Withdraw support”
 - i. Support is not withdrawn; medical interventions are.
 - c. “You will have another baby” or “It will be okay.”
4. **Spiritual. Respect cultural, religious, and spiritual beliefs and/or life philosophy. Parents often desire inquiry into how these beliefs contribute to medical decision making. Helpful phrases include:**
 - a. “From where do you obtain your strength in hard times?”
 - b. “How do you make sense out of what is happening?”
 - c. “What guides decision making for you and your family?”
 - d. “What religious or spiritual beliefs are important for the medical team to be aware of to incorporate in your care?”
5. **Social.** Identify important and helpful individualized family support and other stressors.
 - a. **Determine who the parents or decision makers** request to be present for important conversations or family meetings.
 - b. **Identify other supportive resources** such as friends/family, hospital chaplain and/or religious leader, hospital/local support groups, social work, or supportive literature/online resources.
- C. **Decision making** (see also Chapter 23, “Neonatal Bioethics”)
 1. **Palliative care teams may offer assistance with shared decision making** (between family and medical providers) and establishment of goals of care for a patient, weighing the risks and benefits of care/interventions.
 2. **Avoid providing a menu of options or being directive in care.** Recommend a path forward after assessing family values and goals.
 3. **Recognize that parents** (or surrogate decision maker) use the best interest standard in decision making.
- D. **Around the time of death**
 1. **Provide anticipatory guidance about what to expect:** visual changes, next steps, necessary decisions to make, and so on.
 2. **Identify a provider whose primary role** is communication with the family.
 3. **Parental presence is most often appropriate** during an acute resuscitation.
 4. **Restore control where possible.** Helpful phrase: “We cannot control that your baby is dying, but we can control . . .” (eg, where, how, when, who).
 5. **Consider pharmacologic and nonpharmacologic pain management.** (See also Chapter 81, “Sedation and Analgesia.”)
 - a. **Adequate pain control** does not hasten death in limited studies.
 - b. **Rule of Double Effect** states that given the intent is to do good, foreseeable yet undesirable consequences are acceptable.
- E. **Postmortem support**
 1. **Be aware of local guidelines regarding the timing of final decision making,** postmortem care, and the potential use of cooling blankets. Allow desired time

for parents and family to hold their deceased baby prior to transfer to the morgue or other location.

2. **Autopsy considerations** (see also Chapter 57, “Death of an Infant”)
 - a. **Review potential benefits and available options** (partial or directed vs full autopsy, radiology autopsy, molecular autopsy).
 - b. **Discuss expectations for timing of results and plan follow-up.**

III. Communication frameworks. Skilled communication is essential to establish neonatal goals of care and guide decision making regarding options in care.

A. Helpful phrases

1. **“I’m sorry . . .” or “I wish . . .”** (empathizes with a family’s hope/wish if their desire is not possible while acknowledging the reality of the situation).
2. **“Tell me more about . . .”** (rather than make an assumption, explore any uncertainty).
3. **“What are you hoping for?”**
4. **“What is important to you as you face these hard times?”**
5. **“What outcomes are you willing to accept/go through?”**
6. **NURSE statements for articulating empathy:**
 - a. **Naming:** “It sounds like you are very upset.”
 - b. **Understanding:** “This helps me understand what you are thinking,” but do not say, “I know how hard this is.”
 - c. **Respecting:** “I can see you have really been trying to show your baby as much love as possible,” or “I think you’ve been so thoughtful in your decisions.”
 - d. **Supporting:** “We will do our best to make sure you have what you need and to help you through this.”
 - e. **Exploring:** “Could you say more about what you mean when you say . . .” or “Tell me more about . . .”

B. Sharing bad news

1. **Setting.** Find a quiet location that is private if possible, invite the important people to be present, have tissues available, have enough chairs, and turn off the ringer on your phone or pager.
2. **Assess understanding about the upcoming news.** “What have the other doctors told you about why we obtained an ultrasound for your baby?”
3. **Ask permission.** “Would it be okay for me to discuss the results of the tests with you now?” “Is there anybody else who needs to be present?”
4. **Give a warning.** “I have something serious we need to discuss.” “I was hoping I would have better news to share today.”
5. **Say “the news” simply and stop.**
6. **Wait quietly for the family** to start speaking.
7. **Follow the family’s guidance** about what to discuss next and invite questions.
8. **Describe next steps** and discuss a follow-up plan.
9. **Ensure understanding.** “I want to be sure I communicated as well as possible about what I just told you. Can you please tell me what you heard me say?” Use the “Ask, Tell, Ask” framework.

C. Goals of care. All possible medical interventions are thoughtfully considered, focusing on the likely benefits and burdens of each intervention and the family’s interpretation of acceptable quality of life.

1. **Determine short- and long-term goals** such as:
 - a. **Resuscitation status** (do not resuscitate/do not attempt resuscitation, allow a natural death, full attempts at resuscitation and medical interventions, or consider a trial of interventions with frequent reassessment).
 - b. **Any treatment limitations** (intubation/mechanical ventilation, continuation or limitation of intravenous hydration/nutrition or enteral nutrition, or options such as “do not escalate care”).
 - c. **Withdrawal of life-prolonging interventions** already initiated (compassionate extubation/removal of endotracheal tube or other life-sustaining interventions, discontinuation of vasopressors).

- d. **Location of care or location of death** (hospital NICU, home with or without hospice, or less acute inpatient setting).
 - e. **Pain management** (oral or systemic analgesia).
 - f. **Memory-making experiences** to accomplish (see Section IV).
2. **Helpful phrases**
- a. “Given this news, it seems like a good time to talk about what to do now.”
 - b. “We’re in a different place.”
 - c. “Tell me more about that. What are you worried about?” “Is it okay for us to talk about what this means?”
 - d. “Given this situation, what’s most important for your family?”
 - e. “As I listen to you, it sounds like the most important things are”
- IV. **Memory-making opportunities** should be considered during goal setting or during care for a baby using a PC approach. (see also Chapter 57, “Death of an Infant”).
- A. **Offer “normal” parenting experiences** to encourage bonding and memory making, such as holding, bathing, dressing, changing the diaper, sleeping together in a “family bed” within the hospital, reading special books, listening to music/meaningful songs, tasting breast milk or other tastes, or going outside.
 - B. **Offer memorabilia** to be obtained such as foot or hand prints (in special places such as a meaningful text/religious text), foot or hand impressions (molds), a lock of hair, or pictures. Considerations for pictures:
 - 1. With family/siblings (with twin or triplet, etc, if multiple gestation)
 - 2. With special stuffed animal (parent may hold while leaving the hospital)
 - C. **Ritualistic experiences to consider**
 - 1. Religious ceremony such as baptism, blessing, naming ceremony, or prayer
 - 2. Meeting other family members or friends
- V. **Other relevant literature**
- A. Cummings J. Antenatal counseling regarding resuscitation and intensive care before 25 weeks of gestation. *Pediatrics*. 2015;136(3):588-595.
 - B. Nakagawa TA, Ashwal S, Mathur M, et al. Guidelines for the determination of brain death in infants and children: an update of the 1987 task force recommendations. *Ann Neurol*. 2012;71(4):573-585.
 - C. Diekema DS, Botkin JR, Committee on Bioethics. Clinical report: forgoing medically provided nutrition and hydration in children. *Pediatrics*. 2009;124(2):813-822.

25 Principles of Neonatal Procedures

- I. **Informed consent.** Upon admission to the neonatal intensive care unit (NICU), most facilities provide a parental blanket or general informed consent for routine procedures performed on newborns (eg, phlebotomy, intravenous placement) and emergency procedures for life-threatening situations. For nonemergent invasive bedside procedures that may carry significant risk, parental or guardian permission should be obtained. Risks, benefits, and alternative procedures, if appropriate, should be discussed. Major surgical procedures require informed consent. Refer to your local unit policy manual for detailed guidance.
- II. **Standard precautions.** Standard precautions integrate and expand the elements of the previously adopted universal precautions and are designed to protect both healthcare workers and patients. Standard precautions apply to contact with all body fluids including blood, secretions, and excretions (except sweat), nonintact skin, and mucous membranes. Standard precautions must be used in the care of all patients, regardless of their infection status. In the case of a known transmissible infection, additional precautions known as expanded or transmission-based precautions are recommended. These are used to interrupt the spread of diseases that are transmitted by airborne, droplet, or contact transmission. Most bedside procedures incorporate principles of standard precautions. Refer to your local unit policy manual for detailed guidance.

A. Standard precautions key components

1. **Hand hygiene** before and after patient contact.
 - a. **Hand washing** (40–60 seconds): Wet hands and apply soap; rub all surfaces; rinse hands and dry thoroughly with a single-use towel; use towel to turn off faucet.
 - b. **Hand rubbing** (20–30 seconds): Apply enough product (alcohol-based products gels, rinses, foams) to cover all areas of the hands; rub hands until dry.
 - c. **Wearing gloves without correct hand hygiene can contaminate the gloves.** Studies show that less direct patient care also occurs when clinicians wear gloves. A randomized trial found that wearing gloves after hand washing protects premies from infections. Infants <8 days old, <29 weeks, and <1000 g who were handled with nonsterile gloves after handwashing had less late-onset invasive infections, less necrotizing enterocolitis, less gram-positive infections, and less central line–associated bloodstream infections when compared to infants handled with hand washing only.
 - d. **Clean versus sterile gloves.** The World Health Organization (WHO) recommends that **clean gloves** are to be worn prior to insertion of peripheral intravascular catheterization and that **sterile gloves** are to be worn for insertion of arterial, central, and midline catheters, when guidewire exchanges are performed. Wear either clean or sterile gloves when changing the dressing on intravascular catheters. **Nonlatex gloves** are recommended for contact with blood, body fluids, secretions, contaminated items, mucous membranes, and nonintact skin.
2. **Personal protective equipment (masks, goggles, and/or face masks).** Assess the risk of exposure to body substances or contaminated surfaces **before** any healthcare activity when contact with blood and body fluids is likely. **For facial protection (eyes, nose, and mouth)**, wear a surgical or procedure mask and eye protection (eye visor, goggles) or a face shield to protect mucous membranes of the eyes, nose, and mouth during activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions.

3. **Gowns.** Wear gowns for blood or body fluid contact and to prevent soiling of clothing. Remove soiled gown as soon as possible, and perform immediate hand hygiene.
4. **Sharps precautions.** Avoid recapping used needles; avoid bending, breaking, or manipulating used needles by hand; and place used sharps in puncture-resistant containers. Use self-shielding safety needle devices whenever possible.
5. **Respiratory hygiene and cough etiquette.** Persons with respiratory symptoms should apply source control measures: cover their nose and mouth when coughing/sneezing with tissue or mask, dispose of used tissues and masks, and perform hand hygiene after contact with respiratory secretions.

III. Time out. The Joint Commission has produced a universal protocol for the prevention of wrong site, wrong procedure, and wrong person surgery. The 3 principal components of the universal protocol include a preprocedure verification, site marking, and a time out. Originally developed for the operating room, many facilities use this before bedside invasive procedures. All activity ceases, a moment will be taken (“time out”), and the following will be verified verbally by each member of the team:

- A. **Correct patient identity**
- B. **Correct side and site**
- C. **Agreement on the procedure to be done**
- D. **Correct patient position**
- E. **Availability of correct equipment and/or special requirements**

IV. Neonatal intensive care unit procedure considerations

- A. **Latex allergy.** There is a growing concern over latex exposure in the hospital. Certain pediatric populations are at higher risk for latex allergies such as in spina bifida. Only latex-free equipment (including gloves) should be used in the NICU.
- B. **Hand hygiene.** Hand hygiene is the single most effective method of decreasing healthcare-related infections. The term *hand hygiene* includes both hand washing with either plain or antiseptic-containing soap and water and use of alcohol-based products (gels, rinses, foams) that do not require the use of water. In the absence of visible soiling of hands, approved alcohol-based products for hand disinfection are preferred over antimicrobial or plain soap and water because of their superior microbicidal activity, reduced drying of the skin, and convenience. WHO has instituted the “Clean Care Is Safer Care” campaign to improve compliance because studies still show it is unsatisfactory. Artificial fingernails should not be worn by healthcare providers with direct patient contact in neonatal intensive care since they have been associated with *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and fungi. Always follow your hospital-based infection prevention protocols.

1. **A 3- to 5-minute scrub (washing up to the elbows) is usually required before entering the neonatal intensive care unit.** This is also necessary before all major procedures (eg, lumbar puncture, chest tube, central line placement, or cut down).
2. **A 2- to 3-minute scrub (up to elbows) is recommended for a minor procedure** (eg, bladder aspiration, blood drawing, intravenous placement).
3. **A 30-second hand wash or shorter alcohol-based hand rub** is indicated before and after each patient contact.

- C. **Minimal sterile barrier precautions.** These precautions include sterile gloves and small drape.
- D. **Maximum sterile barrier precautions.** These precautions are defined as wearing a sterile gown, sterile gloves, cap, and full-body drape (entire patient is covered, with a small opening for the site of insertion). Using these precautions during a central venous catheter insertion resulted in fewer episodes of infection and colonization as compared to using a minimal sterile barrier.
- E. **Antiseptic solutions.** The use of topical antiseptic agents for skin disinfection is important in reducing and preventing healthcare-associated infections. The Centers for Disease Control and Prevention (CDC) has specific recommendations for cannulation and central venous catheter insertion in infants age 2 months or older,

but no recommendations for infants <2 months. The stratum corneum, which is the epidermal barrier, is not developed until 32 to 34 weeks' gestation; therefore, preterm infants are prone to infection. There is a paucity of evidence in neonates to state which topical antiseptic agent is preferred prior to blood culture, venipuncture, or intravenous cannulation. General rules for procedure site preparation include the following:

1. **A 30-second cleansing was more effective than 5- to 10-second cleansing in decreasing bacterial colony counts from skin swabs.**
 - a. **Always allow antiseptics to dry on the site** (at least 30 seconds is recommended). Read manufacturers' recommendations on time to dry.
 - b. **Remove iodophor solutions off the wider area at the end of the procedure** except right at the procedure insertion site.
 - c. **Verify that antiseptic is not collecting under the infant because it can cause skin damage.**
2. **Commonly used antiseptics.** The most commonly used agents in the NICU are alcohols, iodine preparations, and chlorhexidine solutions.
 - a. **Alcohol** (70%–90% ethyl or isopropyl) is effective against gram-positive and gram-negative bacteria, methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), mycobacteria, and fungi. It is commonly used for skin prep of minor procedures (eg, phlebotomy), not for mucous membranes. It can be used alone or in combination (with CHG). Apply 3 times in a circle starting at the center of the site and going outward. Alcohol is not used for major procedures and may cause burns in premature infants.
 - b. **Iodine preparations** have broad-spectrum antimicrobial activity (bacteria, viruses, fungi, spores).
 - i. **Topical iodine** (1%) is not recommended because it can cause skin hypersensitivity, iodine overload, and transient hypothyroidism. Topical iodine has been replaced by iodophors.
 - ii. **Iodophor solutions** (iodine plus a solubilizing agent such as surfactant or povidone). One example is **povidone-iodine** (polyvinylpyrrolidone plus elemental iodine), which releases iodine slowly. It is not recommended for antisepsis in extreme premature newborns, but can be used in term newborns (small risk of transient hypothyroidism with large area of the body or >5 days of use). Typically, 10% solutions of povidone-iodine (Betadine, Wescodyne) are recommended for major procedures.
 - c. **Chlorhexidine solutions are the most widely used antiseptic agent.** These solutions are effective against gram-positive bacteria, but less effective against gram-negative bacteria, MRSA, VRE, streptococci, and *Pseudomonas*. CHG 2% was more effective than 0.5%, and CHG 0.5% was superior to 0.05%. Studies show that alcohol-containing CHG is more effective than aqueous solution, but it has not been studied in neonates. Alcohol can cause chemical burns, and a recent review showed that alcohol and aqueous solutions are similar in effectiveness. CDC states that no recommendation can be made for the safety or efficacy of chlorhexidine in infants <2 months old.
 - i. **Hibiclens** (CHG 4% solution) is good for hand washing and used in the following procedures in preparation or maintenance: central venous catheter insertion, umbilical venous catheter prep, and others. Use with care in premature infants or infants <2 months old. May cause irritation or chemical burns.
 - ii. **ChlorPrep** (2% chlorhexidine gluconate in 70% isopropyl alcohol) is used on the skin prior to peripheral intravenous lines, peripherally inserted central catheters, umbilical line arterial puncture, and chest tube insertion. Do not use on nonintact skin, below neck, in infants <26 weeks, in infants <1000 g, for lumbar punctures, or for urethral catheter. Approved for infants >2 months of age.

- d. pHisoHex (brand of hexachlorophene)** is effective against gram-positive organisms (especially *Staphylococcus* strains) but is less effective against gram-negative organisms, fungi, and mycobacteria. Infants in the 1970s were bathed with hexachlorophene, and some developed vacuolar degeneration (nonlipid vacuoles form in the cytoplasm). Infants who have had 6% hexachlorophene powder applied have developed irritability, dermatitis, generalized clonic muscular contractions, decerebrate rigidity, and death. Indications per the US Food and Drug Administration (FDA) are as follows: “Bacteriostatic skin cleanser for surgical scrubbing or handwashing as part of patient care, for topical application to control an outbreak of gram positive infection where other infection control procedures have been unsuccessful. Use only as long as necessary for infection control.” The FDA states that hexachlorophene is “not for routine prophylactic total body bathing, and not for use on burned or denuded skin or on mucous membranes.” Some sources note that hexachlorophene should not be used in infants <2000 g or in infants with a high bilirubin. It should never be used on skin excoriations or burns or on any mucous membranes.
- e. Octenidine hydrochloride** is effective against gram-positive and gram-negative organisms, MRSA, vancomycin-resistant *S aureus*, extended-spectrum β -lactamase-producing bacteria, and *Pseudomonas* and is mainly used in Europe.

V. Assist devices for procedures

A. Transillumination. See Chapter 44. Transillumination is the use of a strong light source as a noninvasive tool to aid in procedures. It can help localize a vessel for cannulation or blood sampling, verify the presence of urine in the bladder, aid in oro/nasoduodenal feeding tube insertion and document the success of air removal in thoracentesis or pericardiocentesis.

B. Point-of-care ultrasound. See Chapter 44. Point-of-care ultrasound (POCUS) is the use of a portable ultrasound at the bedside by a nonradiologist imager (eg, neonatologist) that can be used to help with a procedure. Two techniques are used in such procedures:

- 1. Static technique** involves the use of ultrasound prior to the procedure and can identify anatomy (eg, key landmarks for lumbar puncture), locate a vessel (eg, a peripheral artery for arterial line placement), locate the position of the endotracheal tube or catheter tip (eg, PICC, UVC, UAC), determine needle placement (eg, suprapubic aspiration), or determine if the procedure should be done (eg, POCUS of the bladder to identify urine volume amount).
- 2. Dynamic technique** involves the use of the ultrasound during the procedure: such as seeing the needle go into the bladder in suprapubic aspiration or helping guide the needle into the interspace while doing a lumbar puncture or direct visualization of the needle into the pericardial space.

C. Near-infrared spectroscopy imaging. These devices (VascuLuminator, Vein Viewer Vision, AccuVein AV300) are all noninvasive methods used to locate an artery or vein for phlebotomy or cannulation. A near-infrared light source is used that transilluminates the puncture site, which is processed by a camera that projects the 2-dimensional image on the skin or on a display (VascuLuminator). The bulk of research using these devices has been inconclusive. In a randomized controlled trial, the vein viewer was found to improve successful placement, with the greatest benefit in infants of greater gestational age.

VI. Pain management in the neonate. The American Academy of Pediatrics (AAP) has recommended that every healthcare facility caring for neonates have an effective pain prevention program that includes strategies to reduce the number of painful procedures performed, and the use of pharmacologic and nonpharmacologic therapies to prevent pain with procedures. Procedures in this manual each discuss pain management. This information is based on the AAP recommendations plus a review of international guidelines (see Selected References). Chapters 15 and 81 provide additional details on neonatal pain management.

26 Arterial Access: Arterial Puncture

I. Indications

- A. **To obtain blood** for arterial blood gas measurements.
- B. **When blood is needed and venous or capillary blood samples cannot be obtained.** Not preferred.
- C. **To obtain ammonia levels.** Venous blood can be used if it is collected, transported appropriately, and done quickly, but because ammonia levels in peripheral venous blood can be affected by many variables, arterial blood is preferred.
- D. **To obtain lactate and pyruvate levels.** Free-flowing arterial blood; stasis of blood increases lactate.
- E. **To obtain a large quantity of blood that would be difficult to obtain from a peripheral vein.**

- II. **Equipment.** Sterile gloves, a 23- (preferred for term infants) or 25-gauge (preferred for preterm infants) butterfly needle with extension tubing or venipuncture needle (safety-engineered self-shielding), 1- or 3-mL syringe, povidone-iodine and alcohol swabs, 4 × 4 gauze pad, preheparinized syringes (if not available, use a thin coat of 1:1000 IU/mL heparin in the syringe and plunger to prevent coagulation) or self-contained blood gas kit, high-intensity fiberoptic light for transillumination, Doppler ultrasound, a portable ultrasound (can be useful to locate the artery). Use a cap, mask, sterile gloves, and small sterile drape if obtaining a blood culture.

III. Procedure

- A. **For a blood gas, most hospitals have kits with 1-mL syringes coated with heparin.** If this is not available, draw a small amount of heparin (1:1000) into the blood gas syringe (coat the surfaces and discard excess heparin from the syringe). The small amount of heparin coating the syringe is sufficient to prevent coagulation. Excessive heparin may falsely lower pH and PaCO₂. If any other laboratory test is to be performed, use another syringe without heparin. **Available arteries to use:**

1. **Low-risk preferred sites. Radial, posterior tibial, and dorsalis pedis arteries.**
 - a. **Radial artery.** The radial artery is the **most frequently used site**, is the recommended site, and is described in detail here. The radial artery lies superficially at the underside of the forearm between the radial styloid process and lateral to the flexor carpi radialis tendon. **Advantages of the radial artery site include the following:** its superficial location is easily accessed, it is easy to palpate and puncture, there are no large veins nearby, there is good collateral circulation, and there are no nerves adjacent to the artery that could be injured.
 - b. **Posterior tibial artery** (preferred second site). The posterior tibial artery lies posterior to the medial malleolus and is in the best position for puncture when the foot is in dorsiflexion. It has good collateral circulation, it is easy to puncture, and there are no large veins nearby.
 - c. **Dorsalis pedis artery** (preferred third site). The dorsalis pedis artery is on the dorsal surface of the midfoot, draw an imaginary vertical line between the first and second toe. It has good collateral circulation, but because it is a small artery, it may be difficult to puncture. If using this artery, do an Allen test to assess collateral circulation of the posterior tibial artery.
2. **High-risk not preferred sites. Femoral, brachial, temporal, and ulnar arteries.**
 - a. **Femoral arteries** should be avoided in newborns and only used for emergency situations. There are serious complications that can occur; embolus, spasm, or significant thrombus could cause damage to the leg because there is no collateral circulation (loss of the extremity or infection at the hip joint).

FIGURE 26-1. Technique of radial arterial puncture in the neonate.

- F. Clean the puncture site.** Clean with antiseptic solution per hospital policy. If doing a blood culture, sterile technique is required.
- G. Puncture the skin at about a 30-degree angle.** Then slowly advance the needle and penetrate the artery with the bevel up until blood appears in the tubing (see Figure 26-1). If the entire artery is perforated (anterior and posterior wall) and no blood is obtained, slowly withdraw the needle until blood is obtained. Because the artery can spasm, you may need to wait for blood return. **For a more superficial artery or in a premature or extremely low birthweight infant,** puncture the skin at approximately 15 degrees with the bevel down. With arterial blood samples, little aspiration is usually needed to fill the syringe. If there is no return of blood, withdraw the needle slowly because the artery may have been punctured through and through. Best to limit to 2 attempts.
- H. Collect the least amount of blood needed.** The volume of blood taken at one time should not exceed 3% to 5% of the total blood volume (the total blood volume in a neonate is ~80 mL/kg).
- I. Withdraw the needle and apply firm, but not occlusive, pressure to the site for a minimum of 3 minutes (≥5 minutes in very sick infants or those with a prolonged clotting time) with a 4 × 4 gauze pad to ensure adequate hemostasis.** Shield and dispose of the needle in an appropriate container. Check fingers for adequate circulation.
- J. If the hand starts to discolor or turn white during or after the procedure,** this occurs when the artery has a spasm. Wrap the opposite arm and hand with a warm, not hot, compresses. This will cause the blood vessels to dilate in the unaffected arm and hand and may cause the vessels in the affected hand to dilate (sympathetic response). Do not wrap the affected hand because this will increase the metabolic demand and blood flow in an area where there is already compromise.

- K. Before submitting an arterial blood gas sample, expel air bubbles from the sample and tightly cap the syringe.** Failure to do this can lead to errors in testing.
- L. Take the sample to the laboratory immediately or place it on ice if there is a delay.** Note the collection time and the patient's temperature and hemoglobin on the laboratory slip.
- M. Inaccurate blood gas results.** Excessive heparin in the syringe may result in a falsely low pH and PaCO₂. Remove excess heparin before obtaining the blood sample. Air bubbles caused by failure to cap the syringe may falsely elevate the PaO₂ and falsely lower the PaCO₂. **Blood gases by intermittent arterial punctures may not accurately reflect the infant's respiratory status.** A sudden decrease in the PaCO₂ and PaO₂ can occur during the puncture. Crying during an arterial puncture can change the respiratory pattern and significantly alter the blood gas values. Infants can either hyperventilate or stop ventilating. Hyperventilation can cause a decrease in the PaCO₂, HCO₃⁻, and PaO₂ and oxygen saturation. Holding their breath or stopping ventilating can cause an increase in PaCO₂ and a decrease in PaO₂ and pH. **Note:** Neutrophil counts are lower in samples from arterial blood than venous samples. Blood glucose levels are 10% higher than venous blood levels.

IV. Complications

- A. Bleeding/hematoma.** A local hematoma is caused by bleeding from the vessel into the surrounding tissue. It can occur from repeated punctures or probing or not enough pressure applied to the artery after the procedure. To minimize hematoma risk, use the smallest gauge needle possible and hold pressure for 5 minutes immediately after withdrawing the needle. Hematomas usually resolve spontaneously.
- B. Vasospasm, thrombosis, and embolism.** These can cause distal ischemia and can be minimized by using the smallest gauge needle possible. With thrombosis, the vessel usually recanalizes over a period of time. Temporary arteriospasm can occur but usually resolves spontaneously (see Chapter 84).
- C. Infection.** Risk is rare and can be minimized by using strict sterile technique. Infection is commonly caused by gram-positive organisms such as *Staphylococcus epidermidis*, which should be treated with nafcillin or vancomycin and gentamicin (see Chapter 155). Drug sensitivities at the specific hospital should be checked. Osteomyelitis can occur if the bone is penetrated but is very rare.
- D. Arteriovenous fistula.** May occur after multiple arterial punctures and is treated surgically. Because the brachial artery and median cubital vein are anatomically very close, a single puncture can cause a fistula. Diagnosis is by Doppler flow of the brachial vessels.
- E. Nerve damage.** Nerves usually run parallel to the arteries and may be damaged if punctured multiple times. Median nerve damage has been reported after brachial artery puncture (high incidence of median nerve damage, ~13%). Posterior tibial and femoral nerve damage have also been reported. Nerve damage can also be caused by pressure from a hematoma.
- F. Rare complications. Forearm compartment syndrome** can occur with a brachial artery puncture. **Extensor tendon sheath injury** can occur from repeated radial artery punctures. **Pseudoaneurysm** formation is a rare complication of an arterial puncture. It can occur from trauma to the wall of the artery and may require surgical treatment (removal with primary end-to-end anastomosis).

27 Arterial Access: Percutaneous Arterial Catheterization

I. Indications

A. Frequent arterial blood sampling is required and an umbilical arterial catheter cannot be placed or has been removed.

B. Intra-arterial blood pressure monitoring.

C. Measure preductal PaO₂. Requires right upper extremity catheterization.

D. Exchange transfusions (removal of blood only). Used in peripheral vessel exchange transfusion (PVET) when drawing blood from a peripheral artery and infusing through a peripheral vein.

II. Equipment. Safety-engineered catheter over needle access device based on local practices (22 or 24 gauge; 24 gauge preferred for infants <1500 g), arm board (or 2 tongue blades taped together), adhesive tape, cap, mask, sterile fenestrated drape, povidone-iodine or skin disinfectant, sterile gloves, suture material (optional; needle holder, suture scissors, 4–0 or 5–0 silk sutures) or Steri-Strips or Tegaderm, 0.5% or 0.25% normal saline flush solution (0.25% preferred in premature infants to decrease hypernatremia risk) with heparin (0.5–2 units of heparin/mL saline), pressure bag (to prevent backflow and keep the line free of clots), connecting tubing, pressure transducer for continuous blood pressure monitoring, fiberoptic light for transillumination, a Doppler device or a portable ultrasound to locate the artery.

III. Procedure. The radial, dorsalis pedis, and posterior tibial sites are the preferred sites. Two methods are described here using the **radial artery**, which is the most common access site because of low complication rates. Methods can be adapted to other arteries. Another common site is the **posterior tibial artery**, as both the radial and posterior tibial arteries have good collateral circulation. The **dorsalis pedis** artery can be used as an alternative site but is often too small. The temporal, brachial, and femoral arteries are **not** recommended. Temporal artery catheterization may have adverse neurologic sequelae. The brachial artery is not recommended because it does not have good collateral flow and the median nerve can be damaged. The ulnar artery should also not be used because of poor collateral circulation or potential for damage to the ulnar nerve.

A. Locate the artery by palpation, transillumination Doppler auditory assistance, or point-of-care ultrasound (POCUS). Palpation of the artery can be done at the following sites: radial artery (lateral wrist), ulnar artery (medial wrist), posterior tibial artery (posterior to the medial malleolus), and dorsalis pedis artery (on top of the foot). For technique in transillumination see Chapter 44. Doppler device can identify the artery by a characteristic high sound. Using POCUS, one can find the artery which will be pulsatile and will not collapse like the vein when compressed.

B. Point-of-care ultrasound during cannulation. The use of ultrasound during radial arterial cannulation is considered standard of care in adults and pediatrics. Use in neonates depends upon the clinician's training and experience and availability of equipment. It can help guide the catheter during the procedure, can lead to a shorter procedure time, a higher first and second attempt success rate, and a decrease in complications (hematoma or ischemia) as compared to palpation or Doppler auditory assistance as noted in a 2016 Cochrane review. The procedure involves using a linear probe transverse to the artery to first find the vessel. The artery will appear pulsatile and will not collapse with compression. Place the small linear probe over the vessel, insert the needle near the probe, and advance the needle until the vessel wall is punctured. The advantage is that one can directly visualize the needle passing into the vessel on the image.

- C. Verify adequate collateral circulation in the hand using the modified Allen test or Doppler evaluation.** (See Chapter 26.) Do this also on the foot for the dorsalis pedis and posterior tibial arteries, but it is not as reliable as in the hand. Raise the foot, occlude both the dorsalis pedis and posterior tibial artery, release them one at a time, and see if perfusion comes back within 10 seconds.
- D. Pain management.** Oral sucrose, breast milk, and/or pacifier are recommended with other nonpharmacologic pain prevention and relief techniques. Use of topical local anesthetic agents (eutectic mixture of lidocaine and prilocaine [EMLA]) or subcutaneous infiltration of lidocaine can also be considered. Consider a dose of opioids if intravenous access is available. (See Chapters 15 and 81.)
- E. Place the infant's wrist in a slightly hyperextended position.** Some choose to use a board with gauze under the wrist (Figure 27-1).

FIGURE 27-1. When placing an indwelling arterial catheter, the wrist should be secured as shown. The catheter assembly is introduced at a 30- to 45-degree angle.

F. Perform hand hygiene and put on sterile gloves. The Centers for Disease Control and Prevention recommend a minimum of cap, mask, sterile gloves, and a small sterile fenestrated (opening in the center) drape. During axillary or femoral insertion, maximum sterile precautions are recommended to include a gown and larger sterile field. **Cleanse the site** with antiseptic solution, and place sterile drapes around the puncture site.

G. Methods of arterial catheter insertion

1. Standard method; preferred for any newborn infant who is not premature.

- a. Puncture (with bevel up) both the anterior and posterior walls of the artery** at a 30- to 45-degree angle and remove the stylet. There should be little or no backflow of blood.
- b. Pull the catheter back slowly until blood is seen;** this signifies that the arterial lumen has been entered.
- c. Advance the catheter** after attaching the syringe and flush the catheter. Never use hypertonic solutions to flush an arterial catheter.
- d. Securely tape the catheter** with Steri-Strips and Tegaderm (preferred), or secure the catheter with 4-0 or 5-0 silk sutures in 2 places (may promote skin infection and is not recommended). Always allow for visualization of insertion site.
- e. Connect the tubing with or without the transducer** from the heparinized saline pressure bag to the catheter.
- f. Iodophor or other iodine-based ointments** on the area are no longer recommended because they can obscure the site and may promote infection.

2. Premature infant method

- a. With the bevel down, at an angle of 10 to 15 degrees, puncture the anterior wall of the artery until blood return is seen.** At this point, the catheter should be in the lumen of the artery. Vasospasm is common, and the procedure should be performed slowly.
- b. Advance the catheter into the artery while simultaneously withdrawing the needle.** The blood should be flowing freely from the catheter if the catheter is properly positioned.
- c. Attach the syringe and flush the catheter.** Secure the line as in the standard method described earlier.

IV. Additives

- A. Heparin is recommended in the flushes and the pressure line.** Dosage range: 0.5 to 2 U/mL, per Pediatric Advanced Life Support for the American Heart Association. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend continuous heparin infusion at 0.5 U/mL at 1 mL/h for neonates with peripheral arterial catheters. Follow your institution's guidelines.
- B. Papaverine.** Added to the arterial line infusion (30 mg/250 mL), papaverine may prolong patency and reduce the risk of failure of peripheral arterial lines (*controversial*).
- C. Lidocaine.** Sometimes given intra-arterially to prevent vasospasm or treat vasospasm (*controversial*).

V. Radial artery catheter removal

- A. Remove the dressing** and sutures if present.
- B. Slowly remove the catheter.** Have sterile gauze available.
- C. Apply pressure to the site for 5 to 10 minutes** and dress site.

VI. Complications

A. Vasospasm/embolism/thrombosis. Temporary arteriospasm can occur but usually resolves spontaneously (see Chapter 84).

Vascular endothelium, injured from catheters, reacts by eliciting an inflammatory response with hemostasis and thrombus formation, resulting in tissue ischemia and release of potent vasoconstrictors. Use the smallest gauge catheter possible, minimize the infusion rate, and avoid large or rapid infusions and withdrawals. Avoid hypertonic solutions and blood products. Remove catheter

at the earliest signs of ischemia. These events can cause a wide spectrum of complications:

1. **Temporary blanching of the extremity.**
 2. **Skin ulcers** with sloughing of skin.
 3. **Tissue ischemia, skin necrosis, gangrene, and partial loss of digits.** Transient ischemia of the forearm and hand has been reported with radial artery cannulation. Topical 2% nitroglycerin ointment on the site (dose 4 mm/kg) has been used to reverse tissue ischemia in infants who do not respond to noninvasive treatments (warming of the contralateral limb to promote reflex vasodilation). Intra-arterial administration of lidocaine and papaverine has also been used to reverse skin discoloration and tissue ischemia. See Chapter 84.
 4. **Cerebral embolization** from a clot from a catheter in the radial or temporal artery and retrograde thrombosis of the posterior auricular artery have been reported from a temporal artery catheterization. Retrograde embolization of air or thrombus to the central nervous system can occur if the catheter is flushed too vigorously.
 5. **Temporary occlusion.** Reversible total occlusion of the artery has been reported after a radial arterial catheterization.
- B. Air embolism.** Can be prevented by making certain that air is not introduced into the catheter and the catheter is flushed with heparinized saline.
- C. Hemorrhage/hematoma at puncture site.** If the catheter becomes dislodged, bleeding can occur. Tightly secure connections.
- D. Infection.** Low infection risk; rarely associated with bloodstream infection. Local infection, sepsis, cellulitis, and abscess have been reported. Prophylactic antibiotics are not recommended
- E. Extravasation/infiltration of solution.** See Chapter 42.
- F. Nerve damage.** Median, ulnar, posterior tibial, and peroneal nerve damage based on the catheter site.
- G. Hypernatremia.** Use 0.25% normal saline in low birthweight infants.
- H. Pseudoaneurysm.** Rare.

28 Arterial Access: Umbilical Artery Catheterization

I. Indications

- A. **Frequent or continuous measurements of arterial blood gases.**
- B. **Continuous arterial blood pressure monitoring.**
- C. **Access for exchange transfusion (to withdraw blood).**
- D. **Angiography.**
- E. **Infusion of maintenance solutions.**
- F. **Administration of emergency resuscitation medications and emergency infusion of volume expanders and fluids.** (*Note:* Umbilical vein preferred.)
- G. **Short-term infusions, parenteral nutrition, and/or medications (controversial).** Parenteral nutrition can be given through an umbilical artery catheter (UAC) and has been used in some centers, especially in very low birthweight (VLBW) infants; however, the umbilical artery is not preferred and should be used with caution. The maximum dextrose concentration that can be administered using this method is 15%. Antibiotics can be given via UAC, but this also is not preferred. Indomethacin,

vasopressor medications (epinephrine, dopamine, dobutamine), calcium boluses, and anticonvulsants **should not** be given via the UAC.

H. Blood products (controversial, emergency only) Blood products can be given via a UAC (less preferred, as this may enhance risk of thrombosis).

II. Equipment

A. Basic. Prepackaged UAC trays (usually include sterile drapes, tape measure, a needle holder, suture scissors, hemostat, forceps, scalpel, 3-way stopcock), umbilical tape, 2–0 to 4–0 silk suture, gauze pads, antiseptic solution, sterile gown, gloves, mask, hat, 10-mL syringe, 0.5% normal saline (NS) flush solution (0.25% NS for very small infants to reduce hypernatremia risk), and NS with heparin (0.25–1.0 U/mL) in continuous infusion calibrated pressure transducer for pressure monitoring; point-of-care ultrasound (if available) to guide catheter insertion and verify location of the catheter.

B. Umbilical artery catheter (sizes 3.5 and 5F). Size recommendations vary based on institutional guidelines. Some general guidelines:

- 1. UAC size:** infant <1.5 kg, use 3.5F; infant >1.5 kg, use 5F.
- 2. Perinatal Continuing Education Program recommendations:** <1000 g, use 3.5F; >1000 g, use 5F. Recommend use of single-lumen UAC.
- 3. End-hole catheters** are preferred and are associated with a decreased risk of aortic thrombosis when compared with side-hole catheters based on a Cochrane review.
- 4. Feeding tubes used as umbilical artery catheters** are associated with increased thrombosis risk and should be avoided.
- 5. Cochrane review notes that there is no benefit of using a heparin-bonded polyurethane catheter versus the standard polyvinyl chloride catheter.** A catheter made of Silastic (silicone) is more difficult to use because it is softer but may reduce aortic thrombosis compared with polyvinyl chloride (PVC) tubing. Teflon or polyurethane catheters have been associated with fewer infections and thrombogenicity than PVC or polyethylene catheters.

III. Procedure

A. Umbilical artery catheterization practical tips

- 1. The 2 umbilical arteries** (1 umbilical artery in ~1% of births) are muscular walled vessels (2–3 mm) that carry deoxygenated blood from the fetus to the placenta. The umbilical arteries are the direct continuation of the internal iliac arteries. The catheter enters the umbilical artery at the umbilicus; it courses downward into the internal iliac artery and then superiorly into the common iliac and then the aorta.
- 2. The umbilical arteries usually constrict within seconds after birth and close a few minutes later.** They can be dilated and used for the first 3 to 4 days after birth and are easiest to place on the first day. After the first day, it helps to place a saline-soaked gauze on the umbilical stump for 45 to 60 minutes before attempting the procedure.
- 3. Unless it is an emergency (in which case you put the umbilical vein catheter (UVC) in first), put the umbilical artery catheter in first if putting in both an umbilical artery catheter and umbilical vein catheter.** The UAC is the more difficult one to insert, and often a second amputation of the umbilical stump needs to be done when inserting a UAC.
- 4. Blood cultures can be drawn** from the UAC for up to 6 hours after insertion (right after insertion preferred; venipuncture preferred overall).
- 5. Heparin use.** Cochrane reviews note the use of heparin (as low as 0.25 U/mL) is recommended to prolong the life of the catheter by decreasing the incidence of catheter occlusion or thrombosis. Heparinization with intermittent flushes alone is ineffective in preventing occlusion. Using heparinized fluid does not decrease the incidence of aortic thrombosis or affect the frequency of intraventricular hemorrhage.

The **American Academy of Pediatrics (AAP)** recommends low doses of heparin (0.25–1.0 U/L) through the UAC. The **American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (2012)** recommend prophylaxis with a low-dose unfractionated heparin infusion via the UAC (heparin concentration of 0.25–1.0 U/mL; total heparin dose of 25–200 U/kg/d) to maintain patency. The Centers for Disease Control and Prevention (CDC) recommends low doses of heparin (0.25–1.0 U/mL) added to the fluid infused through the UAC.

6. **Prophylactic antibiotic use (controversial).** One review found that there was not enough evidence to support or refute the use of prophylactic antibiotics when UACs are inserted or to continue antibiotics once initial cultures rule out an infection.
 7. **Point-of-care ultrasound in UAC placement.** **Ultrasound guided umbilical catheter insertion allows for direct visualization and localization of the vessel and can help guide catheter placement and accurately place the catheter in the optimal position.** It resulted in a faster method of placement (average saving 64 min in one study per Fleming et al) and required fewer x-rays and a decreased number of manipulations when compared to routine placement without ultrasound guidance. Technique in one study involved using a linear probe placed over the middle of the chest with scanning done in the sagittal plane. Malpositioned catheters could be seen and manipulations of the umbilical artery catheter could be done real time based on images seen. Injection of sterile saline helped locate the tip by seeing turbulence on the ultrasound. Use of POCUS is limited by many factors including lack of training in neonates, medicolegal issues lack of availability, and high cost of equipment.
- B. High versus low umbilical artery catheter**
1. **High catheter/line.** UAC tip lies above the diaphragm at the level of T6–9. This position is above the celiac artery (T12), the renal arteries (L1), and the superior mesenteric artery (T12–L1).
 2. **Low catheter/line.** UAC tip lies between the level of L3 and L4 (above the L4–5 aortic bifurcation).
 3. **Catheter position was once determined by institutional guidelines.** High catheters were previously thought to be associated with a higher risk of vascular complications, but a recent analysis showed a decreased risk of vascular complications and no increased risk of hypertension, necrotizing enterocolitis (NEC), intraventricular hemorrhage, or hematuria. High catheters may be associated with glucose abnormalities. Low catheters are associated with an increased risk of lower extremity vasospasms. **Cochrane review states there is no evidence to support the use of low UACs.** They found that high catheters have fewer complications (decreased ischemic complications and decreased aortic thrombosis) and lesser need for replacement and reinsertion. The **American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (2012)** suggest high UAC placement. A low position may only be needed if there is a problem placing a high catheter. See Figure 28–1 for vascular landmarks.
- C. Determining the length** of UAC can be obtained from multiple methods, with no universally accepted and no universal formula that applies to all infants. Remember to add the umbilical stump length. There are various methods (eg, birthweight, body measurements, surface anatomy) to determine the length of UAC placement. **Lean et al (2018) did a study of 11 published formulas to guide UAC placement and found that the formulas using body part measurements (not body weight) were the most accurate. Weight based formulas tend to overestimate the distance of insertion and do not do a good job at predicting catheter placement in smaller preterm infants.** Follow institutional guidelines.
1. **Dunn method (1966).** Uses the shoulder to umbilicus length and a nomogram to determine the insertion length. (Do not measure from the shoulder to the umbilicus on a diagonal.) It can be used for **high or low UAC** placement (Figure 28–2).

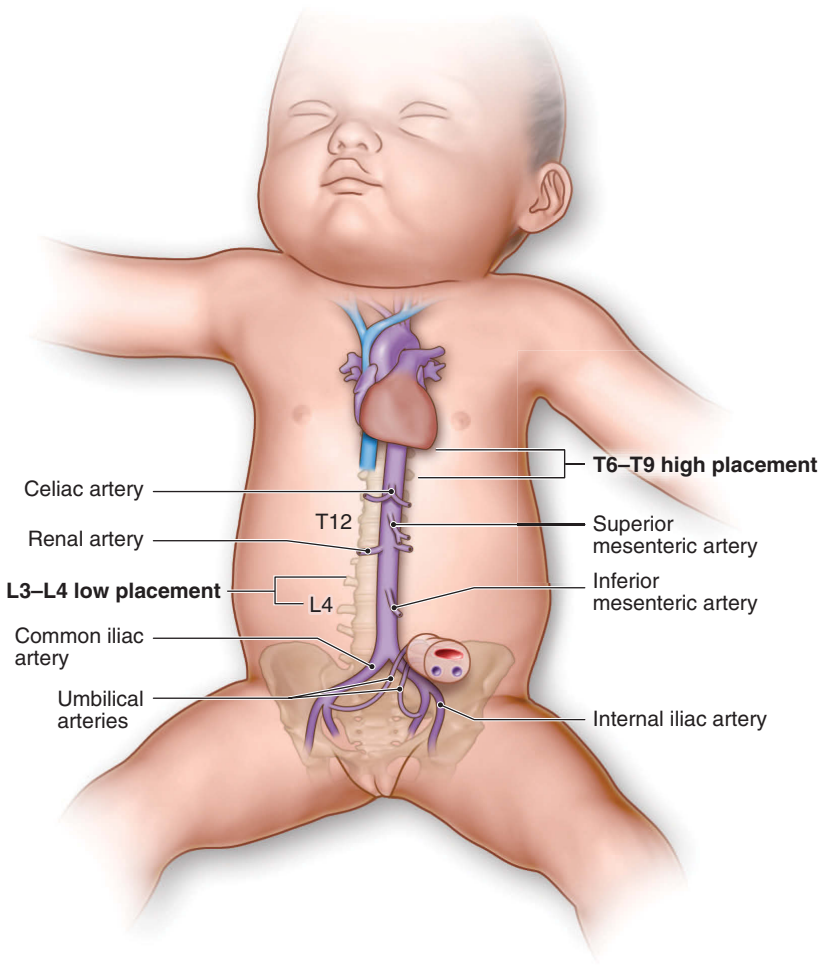

FIGURE 28-1. Important landmarks, related vessels, and the path of the umbilical artery. The internal iliac is also called the hypogastric artery.

- Shukla and Ferrara method(1986)** is more accurate for UAC than the Dunn method. It consistently overestimates the length in VLBW infants. Uses the birthweight and the following formula for a **high UAC**:

$$\text{UAC insertion length (cm)} = 3 \times \text{Birthweight (kg)} + 9$$

- Wright et al formula (2008).** The Wright formula in VLBW infants was found to be superior to the Shukla method. The correct insertion rate was higher in the Wright formula than the Dunn method for term newborns, low birthweight (LBW) newborns, VLBW newborns, and small for gestational age (SGA) newborns. The Wright formula in VLBW infants involves less repositioning than using the Shukla method. This formula results in more accurate placement and less overinsertion in VLBW newborns, especially in infants <1000 g. A study by

FIGURE 28-2. The umbilical artery catheter can be placed in 1 of 2 positions. The **low catheter** is placed below the level of L3 to avoid the renal and mesenteric vessels. The **high catheter** is placed between the thoracic vertebrae from T6 to T9. The graph is used as a guide to help determine the catheter length for each position. The **low line** corresponds to the aortic bifurcation in the graph, whereas a **high line** corresponds to the diaphragm. To determine catheter length, measure (in centimeters) a perpendicular line from the top of the shoulder to the umbilicus. This determines the shoulder-umbilical length. Plot this number on the graph to determine the proper catheter length for the umbilical artery catheter. Add the length of the umbilical stump to the catheter length. (Modified with permission from Dunn PM: Localization of the umbilical catheter by post-mortem measurement, Arch Dis Child. 1966 Feb;41(215):69-75.)

Kumar and colleagues found there is no universal formula but that the Wright formula is the closest and can be applied to all neonates.

$$\text{UAC length (cm)} = (\text{Birthweight in kg} \times 4) + 7 \text{ cm}$$

D. Surface anatomy measurements to determine high umbilical artery catheter insertion. Gupta et al described a new method for estimation of insertion length that provided a better estimate in all birthweights than birthweight-based formulas.

$$(\text{UN} - 1 \text{ cm}) + 2 \times \text{USp}$$

UN is the distance from the umbilicus to the nipple, and USp is distance from the umbilicus to the symphysis pubis.

E. Other measurements used

1. **Total body length (Weaver and Ahlgren formula, 1971):** One-third of total body length in centimeters.
 2. **Suprasternal notch to left superior iliac spine length (Sritipsukho and Sritipsukho, 2007).** Measure suprasternal notch to superior iliac spine.
 3. **Shoulder to umbilicus length.** Shoulder to umbilicus + 2 cm.
- F. Pain management.** Because the umbilical cord is denervated, pain will be minimal. Avoid placement of the hemostat or any sutures on the skin around the umbilicus, as this will cause pain. Consider any nonpharmacologic methods of pain relief (see Chapter 15).

G. Umbilical artery catheterization technique

1. **Place the patient supine.** Wrap a diaper around both legs and tape the diaper to the bed. This stabilizes the patient for the procedure and allows observation of the feet for vasospasm. Another option is to use commercial prefabricated restraints on all 4 extremities.
2. **Put on sterile gloves, a mask, a hat, and a sterile gown.** Prepare a sterile field for the supplies.
3. **Prepare the umbilical artery catheter.** Attach the stopcock to the catheter. Fill the 10-mL syringe with flush solution, and inject it through the stopcock and catheter.
4. **Clean the umbilical cord area with antiseptic solution (povidone-iodine). Avoid tincture of iodine because of effect on the thyroid.** Place sterile drapes around the umbilicus, leaving the feet and head exposed.
5. **Tie a piece of umbilical tape around the base of the umbilical cord tight enough to minimize blood loss** but loose enough so that the catheter can be passed easily through the vessel.
6. **Cut off the excess umbilical cord with a scalpel,** leaving a 1-cm stump (Figure 28–3A). There are *usually* 2 umbilical arteries (1 and 7 o'clock positions). The vein usually has a large floppy thin wall at the 12 o'clock position (Figure 28–3B). If there is difficulty determining the vessels by observation, rub the flat side of the scalpel across the stump; the arteries can be felt with resistance, the vein cannot. Bloom et al and Gupta et al have described an alternative method: the umbilical stump is incised from the side and not the top.
7. **If bleeding occurs,** tighten the umbilical tape or pinch base of the umbilicus tightly for a minimum of 5 minutes.
8. **Using the curved hemostat, grasp the end of the umbilicus to hold it upright and steady.**
9. **Use the iris forceps to open and dilate the umbilical artery.** Remember, the diameter is only 2 to 3 mm. First, place 1 arm of the forceps in the artery, and then use both arms to gently dilate the vessel (Figure 28–3, C and D).
 - a. **An alternative technique** described by Wallenstein and Stevenson (2015) is useful for 1 practitioner performing the procedure. Pass a 4–0 or 5–0 silk suture needle directly into the arterial lumen and then drive the needle out of the sidewall 3 to 4 mm below the opening of the lumen. The needle is then brought back to the surface of the transected stump. When the suture is pulled upward, the lumen of the artery is opened and the catheter can be inserted.
10. **Once the artery is sufficiently opened or dilated, insert the catheter caudally or toward the feet.** It is common to have some resistance at either the abdominal wall or at the level of the bladder. If resistance is met, apply gentle pressure for about 30 to 60 seconds. Avoid repeated probing. Approximately 5% to 10% will have difficulty passing the catheter. If there is spasm of the vessel, some centers recommend inserting the catheter 2 cm into the lumen and dripping 0.5 mL of 2% lidocaine hydrochloride solution without epinephrine into the vessel to dilate it. Topical nitroglycerin (NTG), used on peripheral veins to make them easier to cannulate, has been used to enhance UAC passage. Dose ranges from 0.12

FIGURE 28-3. (A) The umbilical cord should be amputated, leaving a 1-cm stump. (B) Identification of the umbilical cord vessels. (C–D) A forceps is used to gently dilate the umbilical artery.

to 0.6 mg/kg, and application time is 5 to 10 minutes. One study suggests that topical application of NTG does not increase cannulation of umbilical arteries.

- a. **The most common cause of failure to catheterize** an umbilical artery is inadequate dilation of the artery.
 - b. **Use of the “double catheter technique,”** as often used for UVC is **not recommended** due to greater risk of perforation.
 - c. **If in a false channel suggested by no blood return,** remove and use other artery.
 - d. **Incorrect path.** Rarely, the UAC will go from the umbilical artery to the femoral artery (by way of the internal, common, and external iliac arteries) or to the gluteal artery (by way of the internal iliac artery). Using too small a catheter in a large infant increases the risk of the gluteal artery entry. These incorrect path lines are not usable and should be removed.
- 11. Once the catheter is in position, aspirate to verify blood return.** Never advance the catheter once sterile technique is broken. It is better to have it too high and withdraw it. Connect to the tubing and transducer if appropriate.

12. **Secure the catheter.** It is very important that the umbilical artery catheter is securely placed because an unrecognized hemorrhage can lead to death if it accidentally dislodges. Catheters that can move and become malpositioned can cause serious complications (myocardial perforation, liver injury, intestinal necrosis and thrombosis, cardiac arrhythmias, pleural or pericardial effusions). **There are 4 methods of securing an umbilical catheter, and the literature does not state that one method is better than another.** The goal is to keep the line secure while protecting the integrity of the abdominal skin. Choosing which method depends on the infant, the infant's health status, the healthcare provider inserting it, and what each institutional guideline recommends.
 - a. **Method 1. Anchoring (with or without stitches).** The silk tape is folded over part way, the catheter is placed, and the remaining portion of the tape is folded over (Figure 28–4A). Suture the silk tape to the base of the umbilical cord (through the Wharton jelly, not the skin or vessels) using 3–0 silk sutures. No special dressing is needed. The umbilical stump with the catheter in place is left open to the air. Once the catheter is secure, loosen the umbilical tape.
 - b. **Method 2. “Tape bridge” or “goal post” method (most popular method).** Secure the catheter with a tape bridge. (See Figure 28–4B, “goal post” method.) Make 2 tabs from tape and place on either side of the umbilicus. Then take another piece of tape and wrap it around the 2 tabs to make a T shape. This technique has 2 disadvantages: skin irritation and infection may occur, and sometimes the tape does not adhere to the skin well and does not last.
 - c. **Method 3. DuoDERM technique.** This is the easiest and quickest method of securing an umbilical line. A DuoDERM (ConvaTec, Bridgewater, NJ) patch is cut and placed over the coiled up umbilical catheter. Skin irritation may sometimes occur. Image not shown.
 - d. **Method 4. A commercially available umbilical line securement device** (eg, NeoBridge; Neotech, Valencia, CA) can also be used (Figure 28–5). It is an umbilical catheter holder that attaches to the skin with a hydrocolloid gel; 2 flaps come up from the base that hold 2 catheters. Advantages are that the flaps can be opened and closed repeatedly. This is the most expensive method of securing the line. Skin irritation and infection can occur.
13. **Do not use topical antibiotic ointment or creams on the umbilical catheter insertion site.** This can promote fungal infections and antimicrobial resistance.
14. **Obtain a radiograph of either abdomen (verify position of a low catheter) or chest (verify position of a high catheter).** Best position for low catheter: between L3–4, just above the aortic bifurcation and to avoid the renal and mesenteric arteries. Best position for high catheter: between T6–9, above the origin of the celiac axis. Radiographs showing positioning can be found in Chapter 12 (high UAC, see Figure 12–15; and low UAC, see Figure 12–16).
15. **Point-of-care ultrasound confirmation of UAC tip placement.** A bedside ultrasound can be used to assess catheter tip position and was found to more accurately confirm the position than a radiograph. Because catheters are often not placed at the correct position (Lean et al found that >25% UACs placed needed manipulation), some suggest that ultrasound should be the gold standard to confirm correct catheter placement. Evidence shows that ultrasound has good sensitivity, specificity, and positive and negative predictive value when comparing it to a radiograph. Place the linear transducer in the subxiphoid position aimed toward the left of the midline pointed toward the back to the aorta. The aorta is pulsatile and straight. The UAC tip will pass up the descending aorta and end near the diaphragm.

FIGURE 28-4. (A) The umbilical artery catheter is secured with silk tape, which is attached to the base of the cord (through the Wharton jelly, not the skin or vessels). (B) The umbilical catheter is secured with a tape bridge (“goal post” method). (Reproduced with permission from Tshudy MM, Arcara KM: *The Harriet Lane Handbook*, 19th ed. Philadelphia, PA: Elsevier; 2012.)

Figure 28–5. NeoBridge (inspiration-healthcare.com) is an umbilical catheter holder that attaches to the skin.

- 16. The Centers for Disease Control and Prevention recommends that UACs stay in for no more than 5 days.** Other sources state 5 to 7 days. The duration of UACs is a risk factor for aortic thrombosis. CDC states that a malfunctioning umbilical catheter can be replaced if the total duration is not greater than 5 days and there is no other indication for catheter removal.

IV. Umbilical artery catheter removal

- A. **Make sure the umbilical tie is lightly tied around the stump.** Cut any sutures or tape that holds the catheter.
 - B. **Withdraw the catheter slowly** until about 5 cm remains in the vessel.
 - C. **Tighten the umbilical tie.**
 - D. **Discontinue the infusion, and pull the catheter slowly (1 cm/min).**
 - E. **If bleeding, apply pressure to the base of the cord.**
- V. **Complications of umbilical artery catheterization** have been reported in the range of 5% to 32%.
- A. **Infection (septic emboli, cellulitis, omphalitis, sepsis).** The catheter disrupts the integrity of the skin, introducing bacteria or fungi and causing an infection; minimize by using strict sterile technique. **No attempt should be made to advance a catheter once it has been placed in position; instead, if needed, the catheter should be replaced.** AAP and CDC recommend the catheter to be removed and not replaced if there are any signs of central line–associated bloodstream infection. Prophylactic antibiotics are not recommended. VLBW infants who received antibiotics for >10 days were at increased risk for catheter-related bloodstream infections in one study.
 - B. **Vascular complications. Vasospasm, thrombosis, embolism, and infarction can occur.** Heparin use in UACs did not decrease the rate of aortic thrombi. Air embolism has also been reported. Doppler ultrasound is useful to examine the aorta and renal vessels. AAP and CDC recommend removing the UAC if thrombosis is present. See Chapter 84 for other treatment plans for vasospasm and thromboembolism.
 1. **Arterial vasospasm** can cause blanching and cyanosis of the buttocks, legs, feet, and toes. It is increased in low-lying catheters. Loss of extremity is rare but can occur. If the leg blanches, warm the other leg to cause reflex vasodilatation.

2. **Thrombosis.** This can cause dampening of the arterial tracing and is further classified as follows:
 - a. **Femoral artery thrombosis.** Limb ischemia, gangrene.
 - b. **Renal artery thrombosis.** Hematuria, hypertension, renal failure.
 - c. **Mesenteric artery thrombosis.** Ischemia of the gut, NEC.
 - d. **Aortic thrombosis.** Congestive heart failure, hematuria, paraplegia, renovascular hypertension, leg-growth discrepancy.
- C. **Hemorrhage.** This can be secondary to perforation of the vessel, umbilical cord site bleeding around the catheter, disconnection of the catheter at any point in the system, or accidental line dislodgment. The tubing stopcocks must be securely fastened.
- D. **Vessel perforation.** The catheter should never be forced into position. If the catheter cannot be easily advanced, use of the other vessel should be attempted. If perforation occurs, surgical intervention may be necessary.
- E. **Gastrointestinal complications.** UACs may lead to gastrointestinal ischemia, intestinal necrosis (embolization to the gut), or localized perforation. Data do not support that UACs alter the incidence of NEC whether they are high or low or regardless of enteral feeding status.
- F. **Improperly placed catheter** can cause perforation of a vessel, false aneurysm, perforation of the peritoneum, hematoma formation, sciatic nerve palsy, retrograde arterial bleeding, and refractory hypoglycemia (catheter tip opposite celiac axis).
- G. **Hematuria** can occur secondary to renal vein thrombosis or injury to the bladder.
- H. **Hypertension secondary to renal artery embolus** can occur as a long-term complication caused by stenosis of the renal artery as a result of improper catheter placement near the renal arteries.
- I. **Patent urachus.** If the urachal tract is not obliterated during embryonic development, a patent urachus can result. If urine is obtained from a UAC and not blood, there may be a patent urachus. Urology or pediatric surgery consult is required.
- J. **Other complications.** Urinary ascites, scrotal hypoperfusion (may be secondary to catheter-induced vasospasm of pudendal arteries), Wharton jelly or cotton fiber embolus, hypernatremia, peroneal nerve palsy, broken umbilical artery catheter fragment causing thrombosis, infection, distal embolization, factitious hypernatremia or hyperkalemia, and hypoglycemia.

29 Bladder Aspiration (Suprapubic Urine Collection)

- I. **Indication.** To obtain urine for culture when a less invasive technique is not possible. It is the most invasive method of urine collection, but also the most accurate culture source for infants and children <2 years of age when compared with urethral catheterization and bag urine specimens. It is considered the **gold standard of urine specimen collections** because it has a relative rate of urine culture contamination of only 1%. Any bacteria or growth (unless clearly a contaminant) from a suprapubic culture is considered abnormal and may indicate an infection. The American Academy of Pediatrics (AAP) has made recommendations for infants age 2 to 24 months to obtain a catheterization or suprapubic aspiration for any urine specimen (urinalysis and urine culture) obtained in a febrile ill infant who has no apparent source for the fever and who is planning on receiving antibiotics.

II. Equipment. Safety-engineered needle: 23- or 25-gauge 5/8- or 1-inch needle or 21-, 22-, or 23-gauge 1.5-inch needle (larger infant) or 23-gauge butterfly (for preemie), 3- or 5-mL syringe, sterile gloves, antiseptic solution, 4 × 4 gauze pads, sterile urine culture container (per institutional guidelines), topical anesthetic cream, 1% lidocaine (with or without epinephrine), transillumination light source, or portable ultrasound (optional).

III. Procedure

A. Contraindications. Empty bladder, significant bleeding disorders, significant abdominal distention, massive organomegaly cellulitis/infection at the puncture site, major genitourinary anomalies, or recent lower abdominal or urologic surgery.

B. Verify that voiding has not occurred within the previous hour so there will be enough urine in the bladder for the procedure by one of the following methods:

1. Palpate or percuss the bladder. Dullness to percussion 2 fingers above the pubic symphysis suggests urine in the bladder. The neonatal bladder extends above the pubic symphysis as it fills.

2. Transillumination can determine bladder height and verify the presence of urine. With the lights dim, the transillumination source is pointed at the bladder. The area will glow red if urine is present. (See Chapter 44.)

3. Point-of-care ultrasound of the bladder can be used to help determine the presence and volume of urine in the bladder before attempting the procedure, thus increasing the likelihood of a successful tap. Using a high frequency linear-array transducer probe, apply it in a transverse position in the midline of the lower abdomen to locate the bladder. The bladder will be a dark cavity (if filled with urine) just below the abdominal musculature, usually round, with bright margins. A minimum volume on ultrasound of 10 mL in children <2 years of age is associated with a 90% successful bladder aspiration. If the cephalocaudal diameter of the bladder (sagittal view) is >20 mm and the anteroposterior diameter is >15 to 20 mm, the success rate approaches 100%.

C. Pain management. The majority of studies found that pain scores were significantly higher in suprapubic aspiration when compared to transurethral catheterization.

1. Nonpharmacologic pain reduction procedures can be used such as sucrose on a pacifier.

2. Topical local anesthesia. EMLA (eutectic mixture of lidocaine and prilocaine) can be used. In one study, EMLA use 1 hour before the suprapubic aspiration was found to reduce pain scores more than without EMLA.

3. Local injection of lidocaine can be used, but it is often reserved for older infants with thicker abdominal walls.

4. EMLA plus local injection of lidocaine.

D. Point-of-care ultrasound can also be used to assist one in performing the procedure. It can identify the site of needle insertion in the bladder (static technique, mark location with a sterile pen) and guide the needle insertion and puncture of the bladder wall (dynamic technique). When used, fewer needle insertions are necessary. Using the linear probe, apply it in a transverse position in the lower midline of the abdomen. Locate the bladder and mark the site of insertion. Leave the probe on the abdomen, while imaging in the sagittal plane. The needle can be inserted just inferior to the probe site in the plane of the ultrasound beam. The needle tip can be seen on the ultrasound screen as it advances through the skin and then the bladder. Ultrasound-guided suprapubic bladder aspiration is more successful than a blind suprapubic bladder aspiration in infants <4 months old, especially if the anterior-posterior and transverse diameter of the bladder is >2 cm.

E. An assistant should hold the infant in a supine position with the legs in the frog-leg position. The arms and legs need to be held.

F. Locate the site of bladder puncture, which is approximately 1 to 2 cm above the pubic symphysis in the midline of the lower abdomen (look for the transverse lower abdominal skin crease just above the pubic symphysis). **Note:** The urinary bladder of

the neonate and infant is more of an abdominal organ and easier to access since as it fills it rises above the level of the pubic symphysis. As the infant grows, the bladder assumes more of a pelvic position. The bladder lies posterior to the pubic symphysis and anterior to the female uterus. See Figure 29-1A.

FIGURE 29-1. Technique of suprapubic bladder aspiration. (A) Landmarks and recommended site for suprapubic bladder aspiration. (B) Technique of suprapubic aspiration.

- G. **To avoid the bladder from emptying** (reflex urination) when the needle is inserted, have an assistant apply gentle pressure at the base of the penis in a male infant, or in a female infant, apply anterior rectal pressure with a fingertip in the anus.
 - H. **Put on sterile gloves**, and clean the entire suprapubic area of skin (from pubic symphysis to the umbilicus) with antiseptic solution 3 times. Place sterile drapes around the insertion site.
 - I. **Palpate the pubic symphysis**. Insert the needle with syringe attached 1 to 2 cm above the pubic symphysis (at the transverse lower abdominal skin crease in the midline) at a 90-degree angle (Figure 29–1B). Some suggest angling the needle slightly caudad (10–20 degrees posteriorly).
 - J. **Advance the needle approximately 2 to 3 cm while aspirating**. Do not advance the needle once urine is seen in the syringe to reduce the risk of posterior wall bladder perforation. Use only gentle aspiration to prevent suctioning the posterior bladder wall.
 - K. **If no urine appears**, do not advance or redirect the needle. Withdraw the needle and reattempt the procedure in a minimum of 1 hour; consider ultrasound to more accurately evaluate bladder filling.
 - L. **Collect sample**, withdraw the needle, maintain pressure over the site of puncture, and apply a bandage (optional). Place a sterile cap on the syringe or transfer the specimen to a sterile urine cup, and submit the specimen to the laboratory.
- IV. **Complications**. Serious complications are rare.
- A. **Bleeding and hematomas**. Hematuria is the most common complication; it is usually microscopic, rarely causes concern, and usually resolves. Gross hemorrhage is more likely if there is a bleeding disorder; transient gross hematuria is reported in up to 3.4% of cases. Hematomas (abdominal wall, pelvic, and bladder wall), massive hemoperitoneum, and vaginal bleeding are rare.
 - B. **Infection**. Rare and not likely to occur if strict sterile technique is used. Sepsis, bacteremia, abdominal wall abscess, cellulitis of the abdominal wall, suprapubic abscess formation, and osteomyelitis of the pubic bone have all been reported.
 - C. **Perforation of the bowel**. With careful identification of the landmarks, preferably using ultrasound guidance, and not advancing the needle too far, this complication is rare. Bowel perforation can occur if a loop of the bowel is over the bladder. Usually the perforation is not clinically significant because the small puncture rarely causes peritonitis. If the bowel is perforated (aspiration of bowel contents), one can reattempt the procedure with a new sterile needle and syringe.

30 Bladder Catheterization

I. Indications

- A. **To collect a urine specimen for culture when a suprapubic aspiration is contraindicated or cannot be performed and a clean-catch specimen is unsatisfactory**. Bladder catheterization is an alternative to suprapubic aspiration. It has a higher false-positive rate than suprapubic aspiration (relative rate of urine culture contamination of 6%–12%) and can also introduce bacteria and cause a urinary tract infection. The American Academy of Pediatrics (AAP) has made recommendations to obtain a catheterization or suprapubic aspiration for any urine specimen (urinalysis and urine culture) obtained in a febrile ill infant who is >2 months of age, who has no apparent source for the fever, and who is planning on getting antibiotics.
- B. **To monitor urinary output, relieve urinary retention, or to instill contrast** to perform cystourethrography.

C. **To determine a bladder residual urine volume.**

D. **To place contrast for diagnostic cystography.**

II. **Equipment.** Sterile gloves, cotton balls, povidone-iodine solution, sterile drapes, lubricant gel, a sterile collection bottle (often packaged together as a commercial set), and choice of catheter (see below); point-of-care ultrasound, if available.

A. **Urethral catheters. Use the smallest catheter possible.** (*Note:* balloon retention catheters [eg, Foley] are not used in newborns.) Recommendations on urethral catheter choice vary widely; follow your institution's guidelines if available.

1. **Commercially available urethral catheter sizes:** 3.5, 5.0, 6.5, and 8F.

2. **Urethral catheter size recommendations by weight**

a. 3.5F for weight <1000 g.

b. 5F for weight 1000 to 1800 g.

c. 6.5F for weight 1800 to 4000 g.

d. 8F for weight >4000 g.

3. **National Association of Neonatal Nurses (NANN) recommendations:** 3.5F for weight <1000 g; 5F for weight 1000 to 1800 g; 8F for weight >1800 g.

4. **Feeding tubes.** When used as an alternative, they may increase the risk of trauma or knotting (commercial urethral catheters are softer and not as long). A 5F feeding tube is sometimes used but not generally preferred.

5. **Umbilical catheter.** May be used as an alternative: 3.5F for weight <1000 g; 5F for weight >1000 g.

III. Procedure

A. **When performing catheterization to obtain a specimen,** it is best to wait until 1 to 2 hours after voiding.

B. **POCUS of the bladder.** Ultrasound of the bladder can help determine if there is sufficient urine in the bladder. Use a high frequency linear array transducer probe and apply it in a transverse position in the midline of the lower abdomen to locate the bladder. The bladder will be a dark cavity with a thin wall that is echogenic. Measure the **urinary bladder index measurement** (product of anteroposterior and transverse diameters, expressed in centimeters squared), which will identify whether there is sufficient urine in the bladder. A urinary bladder index <2.4 cm² means there is lack of urine volume and the catheterization may be unsuccessful. A urinary bladder index >2.4 cm² suggests an adequate urine volume. An ultrasound of the bladder at the bedside led to an increased success rate of urethral catheterization in children <2 months of age. **Ultrasound directed bladder catheterization** has been used in pediatrics for guiding the catheter in the bladder and is more successful than blind catheterization.

C. **Pain management.** Nonpharmacologic pain-reducing methods are recommended (see examples in Chapter 15). Intraurethral lidocaine gel 1% can also be considered (*controversial*). A recent study showed that lidocaine gel did not reduce pain from urethral catheterization versus nonanesthetic gel in children <4 years of age.

D. **Technique for male catheterization.** See Figure 30–1.

1. **Place the infant supine, with the thighs abducted** (frog-leg position).

2. **Wash hands thoroughly,** put on sterile gloves, and drape the area with sterile towels.

3. **The newborn male infant has a physiologic phimosis, and the foreskin cannot be retracted fully.** Gently retract the foreskin just enough to expose the meatus with the nondominant hand (now considered contaminated); do not force retraction of the foreskin. The meatus can usually be aligned with the opening in the prepuce.

4. **Cleanse the penis with povidone-iodine solution using your free sterile hand.** Begin with the meatus and move in a proximal direction. Clean it 3 times in a circular fashion.

5. **Place the tip of the catheter in sterile lubricant gel.**

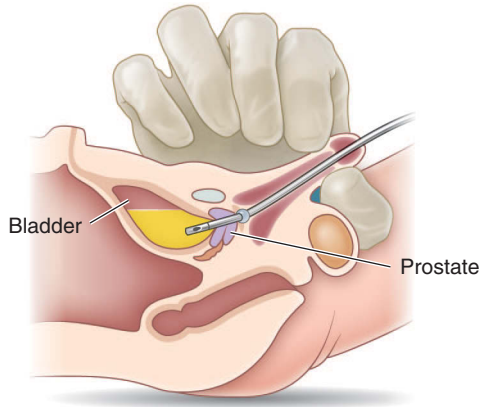

FIGURE 30–1. Bladder catheterization in the newborn male.

6. **Hold the penis approximately perpendicular to the body to straighten the penile urethra and help prevent false passage.** Use a small amount of pressure at the base of the penis to avoid reflex urination.
 7. **Advance the catheter until urine appears. A newborn male urethra (preterm to term) measures 3.5 to 7 cm. Length of catheter insertion in males** is generally as follows: weight <750 g, <5 cm; weight >750 g, approximately 6 cm. A **slight resistance may be felt** as the catheter passes the external sphincter; therefore, hold the catheter in place with minimal pressure. Gentle continuous pressure enables the catheter to pass when the sphincter relaxes. Never force the catheter because urethral trauma or false passage can occur.
 8. **Collect the urine specimen.** Discard the first few drops of urine to avoid any chance of contamination of the early stream of urine. If the catheter is to remain in place, connect it to a closed urinary collection system. It should be taped to the lower abdomen rather than to the leg in males to help decrease stricture formation caused by pressure on the posterior urethra. Contrast can be injected at this point if the catheter has been placed for a radiographic study.
- E. Female catheterization.** See Figure 30–2.
1. **Supine position technique**
 - a. **Place the infant supine, with the thighs abducted** (frog-leg position).
 - b. **Wash hands thoroughly**, put on sterile gloves, and drape sterile towels around the labia.
 - c. **Separate the labia with the nondominant hand (now considered contaminated)**, and cleanse the area around the meatus with povidone-iodine solution 3 times. Use anterior-to-posterior strokes to prevent fecal contamination.
 - d. **Keep the labia spread with the nondominant hand** with 2 fingers. See Figure 30–2 for landmarks. The meatus is found between the clitoris and vagina and may be difficult to see if the vaginal introitus is covering it. Lubricate the catheter, and advance it in the urethra until urine appears. A newborn female (preterm to term) urethra measures 1 to 2 cm. **General length of catheter insertion:** weight <750 g, generally <2.5 cm; weight >750 g, approximately 5 cm.
 - e. **Collect the urine.** Discard the first few drops of urine to avoid any chance of contamination of the early stream of urine.
 - f. **Tape the catheter to the leg** if it is to remain in position.
 - g. **If urine does not appear in the catheter, the catheter may be in the vagina.** Check the catheter position and replace if necessary.

FIGURE 30–2. Landmarks used in catheterization of the bladder in newborn females in supine position.

2. Prone position technique. Used for a female infant who cannot be placed in the supine position (eg, infant with meningomyelocele).

a. Place the infant prone on blankets, so the upper body is elevated as compared with the lower body.

b. Tape a gauze pad over the anus to avoid contamination. Place sterile drapes.

c. Then proceed from step b as for supine position (see Section III.E.1.b).

IV. Catheter removal. Once urine has been obtained and flow has stopped, gently withdraw the catheter. Observe after the procedure for urine output.

V. Complications

A. Infection. Sterile technique is necessary to prevent infection. There is a risk of introducing bacteria into the urinary tract and then the bloodstream. “In-and-out” catheterization carries a small (<5%) risk of urinary tract infection. The longer a catheter is left in place, the greater is the infection risk. Infections that can occur include sepsis, cystitis, pyelonephritis, urethritis, and epididymitis.

B. Trauma to the urethra or the bladder. Urethral tear, urethral false passage, erosion, stricture, meatal stenosis, or bladder injury (perforation) is more common in males. Minimize by adequately lubricating the catheter and stretching the penis to straighten the male urethra. Never force the catheter if resistance is felt. Use the smallest catheter possible, and advance only until urine is obtained.

C. Hematuria is usually transient but may require irrigation with normal saline solution. Gross hematuria on insertion may indicate a false passage.

D. Urethral stricture. A longer term complication more common in males. It is usually caused by a catheter that is too large or by prolonged or traumatic catheterization. In males, taping the catheter to the anterior abdominal wall helps decrease the pressure on the posterior urethra.

E. Urinary retention. Secondary to urethral edema.

F. Catheter knot. Rare (0.2 per 100,000 catheterizations) but can happen if the catheter advances too far (too long of a flexible catheter may form a loop and knot on itself). More common if feeding tubes are used. Overdistension of the bladder and bladder

spasm are also a risk. This is also more common in males, neonates, and children rather than adults. Using appropriate lengths based on age and sex may help prevent this complication. Removal (traction under general anesthesia, unraveling the knot using a guidewire through the catheter under fluoroscopy, suprapubic cystostomy, and endoscopic retrieval) can cause significant morbidity involving general anesthesia, fluoroscopy, and transient hematuria. If this occurs, a urology consultation may be necessary.

- G. **Malpositioned catheter.** In males, the catheter may coil in the urethra before it reaches the bladder. The catheter can be accidentally placed in the vagina in females. If this happens during cystography, the vagina can mimic the bladder. The clue to this is that fluid is in the peritoneal cavity (contrast material flowed through the uterus and fallopian tubes into the peritoneal cavity).
- H. **Obstructive bilateral hydroureteronephrosis.** Rare.

31 Chest Tube Placement

I. Indications

- A. **Evacuation of pneumothorax** compromising ventilation and causing increased work of breathing, hypoxia, and increased PaCO₂.
- B. **Relieve tension pneumothorax** causing respiratory compromise and decreased venous return to the heart, resulting in decreased cardiac output and hypotension. **This is an emergency that should be handled by immediate needle aspiration before chest tube placement.** (See Chapter 75.)
- C. **Drainage of significant pleural fluid** (pleural effusion, empyema, chylothorax, hemothorax, extravasation from a central venous line).
- D. **Postsurgical drainage** after repair of a tracheoesophageal fistula, bronchopleural fistula, esophageal atresia, or other thoracic procedure.

- II. **Equipment.** Prepackaged chest tube tray (typically includes sterile towels, gauze pads, 3–0 silk suture, a needle holder, curved hemostats, a no. 15 scalpel, scissors, antiseptic solution, antibiotic ointment, 1% lidocaine, 3-mL syringe, 25-gauge needle), sterile gloves, mask, eye protection, hat, gown, suction-drainage system (eg, Pleur-Evac system). A high-intensity fiberoptic light for transillumination or point-of-care ultrasound unit is helpful (see Chapter 44). Chest tube types and sizes are as follows:

- A. **Standard (traditional) chest tube insertion.** Requires a skin incision with blunt chest wall dissection and sutures. Use polyvinyl chloride chest tubes with or without trocars (8, 10, or 12F). Recommended chest tube size for weight: <2000 g, 8 or 10F; >2000 g, 12F.
- B. **Percutaneous chest tube with pigtail catheter.** Does not require a skin incision. The pigtail catheter is inserted through a needle. This is an easier and less invasive technique requiring less anesthesia. Disadvantages are that the catheter may kink and become obstructed since they are softer. **Pigtail catheter sizes** range from 5 to 12F, with 8 or 10F most commonly used.

III. Procedure

- A. **The site of skin insertion** for the elective chest tube insertion is the same for both air and fluid, but the direction of the tube is determined by examining the anteroposterior (AP) and cross-table lateral or lateral decubitus chest films for air or fluid. Air collects in the uppermost areas of the chest, and fluid in the most dependent areas. **For air collections, place the tube anteriorly. For fluid collections, place the tube posteriorly and laterally.**

- B. Transillumination** of the chest may help detect a pneumothorax but not a small pneumothorax (see Chapter 44). It can also document the success of air removal. With the room lights turned down, a strong light source is placed on the anterior chest wall above the nipple and in the axilla. The affected side usually appears hyperlucent (“lights up”) and radiates across the chest as compared with the unaffected side. Unless the infant’s status is rapidly deteriorating, a chest radiograph (both AP and lateral decubitus or cross-table lateral) should be obtained to confirm pneumothorax before the chest tube is inserted. If air is suspected, the infant should be lying on his or her side with the suspect side up; if fluid is suspected, the infant should be placed with the suspect side down. See Figure 12–24 for a radiograph showing a left tension pneumothorax.
- 1. False-positive transillumination.** Can occur in infants with subcutaneous air, severe pulmonary interstitial emphysema, congenital lobar emphysema, pneumomediastinum, large air bubble in the stomach, and a weak light source.
 - 2. False-negative transillumination.** Can occur in infants with a small pneumothorax, thick chest wall with increased subcutaneous fat or edema, thick skin folds, dark pigmented skin, and a weak light source and bright room lights.
- C. Use of point-of-care ultrasound for diagnosis.** Lung ultrasound is useful in identifying a **pneumothorax** in a newborn and is just as accurate a chest x-ray. Findings include lung sliding disappearance (100%), a pleural line and the A line (100%), absence of B lines (100%), no area of lung consolidation in the area of the pneumothorax (100%), and lung point (75%). Ultrasound findings of a **pleural effusion** include: absent lung sliding, absent A lines, present anechoic zone, +/- jellyfish sign, sinusoid sign, or quad sign. These findings are described in detail in Chapters 44 and 75.
- D. Use of POCUS during the procedure.** POCUS (static and ultrasound guidance) in adult thoracentesis is recommended and a standard of care to increase the success rate and decrease complications. It is used in pediatrics and there are some reports in neonatology. POCUS static technique can be used to identify landmarks and the optimal location of the needle or chest tube insertion. Dynamic technique can be used to aid in doing the thoracentesis for air or fluid with direct visualization of the needle and increases the rate of success and decreases the rate of complications. See Chapter 44 for technique.
- E. Position the patient** so the site of insertion is accessible. Place the infant with the affected side at a 60-degree upright angle using a towel roll behind the infant’s back to evacuate air. Use a 15- to 30-degree angle for fluid, chyle, blood, or pus evacuation. Make sure the arm is over the head because this position allows air to rise. Secure the infant’s arm above his or her head.
- F. Select the appropriate site.** Make sure the team takes a “time out” to confirm the side that you plan to aspirate.
- 1. Emergency needle aspiration (tension pneumothorax).** Needle aspiration is done at the **second intercostal space in the midclavicular line** on the suspected side of the pneumothorax. The needle is inserted above the third rib. See Chapter 75 and Figure 75–1. The **fourth intercostal space at the anterior axillary line** can also be used (needle would be inserted above the fifth rib).
 - 2. Emergency needle aspiration (pleural effusion)** (per American Heart Association Neonatal Resuscitation, seventh edition): Needle aspiration is done at the fifth and sixth intercostal space along the posterior axillary line. For needle aspiration, make sure the infant is supine to allow fluid to collect in the posterior position of the chest.
 - 3. Chest tube placement (for air or fluid).** The chest tube should be at the **fourth or fifth intercostal space at the anterior axillary line in between the anterior axillary line and midaxillary line (modified Buelau position)**. This site is safe for both thoracic sides, for both preterm and term infants, as only lung

FIGURE 31–1. Recommended site for skin incision and chest tube insertion in the neonate: fourth and fifth intercostal space between the anterior and midaxillary line. ICS, intercostal space.

parenchyma and no organ structures are found. See Figure 31–1. This lateral site avoids a scar on the anterior chest and nipple area.

a. Air. Insert the tube anteriorly (upward) and toward the apex.

b. Fluid. Insert the tube posteriorly (downward) and inferiorly.

- 4. The nipple is a landmark for the fourth intercostal space. Do not place the tube in the nipple area or surrounding breast tissue** (especially in females, as this can cause future asymmetrical breast tissue development.) Avoid the mid-clavicular approach in females.

G. Put on a sterile gown, mask, hat, and gloves. Cleanse the area of insertion with antiseptic solution, and drape appropriately.

H. Prophylactic antibiotics for newborn infants with chest tubes. Because chest tubes breach the skin barrier, there is a risk of infection. Some neonatologists use preventive antibiotics. Cochrane review states: “There is no data from randomized trials to either support or refute the use of antibiotic prophylaxis for intercostal catheter insertion in neonates.”

I. Pain management. There are no prospective studies on pain management for chest tube insertion. The American Academy of Pediatrics (AAP) recommends routine pain management during chest tube insertion.

- 1. The American Academy of Pediatrics recommends slow infiltration of the area with a local anesthetic before incision** (unless life-threatening instability) and the use of systemic analgesia with a rapidly acting opiate (fentanyl). If there is not enough time to infiltrate before the chest tube is inserted, infiltration should be done after the chest tube is in (may decrease later pain responses).

a. Local anesthetic. Slowly infiltrate the area superficially with 0.125 to 0.25 mL of 1% lidocaine and then down to the rib. Infiltrate into the intercostal muscles and along the parietal pleura. Do not use more than 0.5 mL of 1% lidocaine.

b. Systemic analgesia with a rapidly acting opiate (fentanyl).

c. General nonpharmacologic measures should also be used.

J. Standard (traditional) chest tube insertion (with incision)

1. **Make a small incision** (approximately the width of the tube, usually 3–4 mm) in the skin over the rib just below the intercostal space where the tube is to be inserted (see Figure 31–1).
2. **Insert a closed curved hemostat into the incision**, and spread the tissues down to the rib. Using the tip of the hemostat, **puncture the pleura just above the rib** (avoids the subcostal blood vessels and minimizes vascular injury) and spread gently. The intercostal vein, artery, and nerve lie below the ribs (Figure 31–2A). This creates a subcutaneous tunnel that aids in closing the tract when the tube is removed. This tunnel can be carried superiorly over the next rib, anteriorly (for air) or posteriorly (for effusion) parallel to the ribs, or obliquely.
3. **When the pleura has been penetrated, a rush of air is often heard or fluid appears.** Insert the chest tube through the opened hemostat (Figure 31–2B). Be certain that the side holes of the tube are within the pleural cavity. The presence of moisture in the tube usually confirms proper placement in the intrapleural cavity in a pneumothorax. Use of a trocar guide is dependent upon the institution and the operator. Some feel it is unnecessary and may increase the risk of complications such as lung perforation. **The chest tube should be inserted 2 to 3 cm for a small, preterm infant and 3 to 4 cm for a term infant.** (These are guidelines only; the length of tube to be inserted varies based on the size of the infant.) An alternative approach to tube insertion is to measure the length from the insertion site to the apex of the lung (approximately the mid clavicle) and tie a silk suture around the tube the same distance from the tip. Position the tube until the silk suture is just outside the skin.

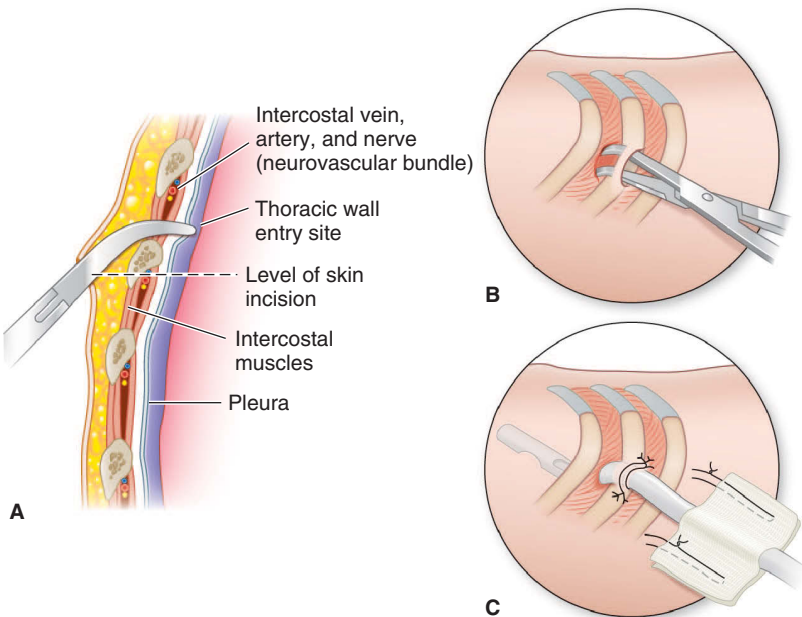

FIGURE 31–2. Standard chest tube insertion. (A) Level of skin incision and thoracic wall entry site in relation to the rib and the neurovascular bundle. (B) Opened hemostat, through which the chest tube is inserted. (C) The chest tube is then secured to the skin with silk sutures.

4. **Hold the tube steady first**, and then allow an assistant to connect the tube to a water seal vacuum drainage system (eg, Pleur-Evac system). Five to 10 cm of suction is usually used. Start at the lower level of suction and increase as needed if the pneumothorax or effusion does not resolve. Some recommend starting at 10 cm and increasing 20 cm, if necessary. Excessive suction can draw tissue into the side holes of the tube. Systems such as the Pleur-Evac provide both continuous suction and a water seal. A water seal prevents air from being drawn back into the pleural space.
 5. **Secure the chest tube** with 3–0 silk sutures and silk tape (Figure 31–2C). Close the skin opening with sutures, if necessary. Use a purse-string suture around the tube or a single interrupted suture on either side of the tube.
 6. **Obtain an immediate chest radiograph (anteroposterior and lateral) to verify placement** and check for residual fluid or pneumothorax. One can also use transillumination to document success of air removal. Figure 31–3 shows a standard chest tube in position.
 7. **Place a sterile clear occlusive dressing at the site.**
- K. Percutaneous chest tube placement (modified Seldinger technique using a pigtail [Fuhrman] catheter).** Pigtail catheters are a safe and effective alternative to traditional chest tubes. Advantages include speed and ease of placement, safety (fewer complications), less discomfort, and easily learned. **This is the preferred chest tube placement in premature infants.** The catheter is a coiled, single-lumen polyurethane catheter (5–12F), with 8- or 10F being commonly used.
1. **Follow the site and anesthetic selections as noted earlier.**
 2. **Insert an 18-gauge needle with the syringe attached** (or an 18-gauge intravenous [IV] catheter) into the skin over the top of the rib at the designated site into the pleural space. Pull back on the syringe while inserting the needle. Do not advance >2 cm in depth. Stop insertion when air or fluid is obtained.
 3. **Secure the needle and remove the syringe; keep the lumen occluded.** If an 18-gauge IV catheter is used, the IV catheter will act as the introducing needle.

FIGURE 31–3. Straight chest tube on the right side.

4. **Straighten the J tip of the guidewire and insert into the hub of the needle or the intravenous catheter.** Advance the guide wire into the needle about 2 to 3 cm past the tip of the needle or until the colored line on the wire is at the level of the hub.
5. **Withdraw the needle or intravenous catheter while holding the guidewire.**
6. **Thread the dilator down over the guidewire.** Twist the dilator to dilate the skin, muscles, and pleura. The site has to be well dilated so the catheter will fit. Once dilated, remove the dilator while securing the guidewire.
7. **Straighten the pigtail catheter and insert over the guidewire.** Advance until all holes are inside the skin and pleural cavity and then 1 to 2 cm further.
8. **Slowly remove the guidewire while holding the tube in place.** The pigtail catheter will curl up inside the pleural cavity. Immediately connect the tube to the underwater sealed drainage (see Section III.J.4).
9. **Secure the tube using suture and tape and** place a sterile clear occlusive dressing at the site.
10. **Obtain an immediate chest radiograph (anteroposterior and lateral)** to verify placement and check for residual fluid or pneumothorax (see Section III.I.6). **One can also use transillumination to document success of air removal.** Figure 31–4 shows a pigtail catheter in position.

IV. Chest tube removal

- A. **Pain management.** Removing a chest tube is known to be painful. AAP recommends routine pain management during chest tube removal, including general nonpharmacologic measures and a short-acting rapid-onset systemic analgesic.
- B. **For pneumothorax.** If there is no more bubbling in the underwater seal or presence of air for 24 to 48 hours, discontinue the suction and leave to water seal for 4 to 12 hours (some units will leave it for 24 hours). Transilluminate, or preferably check an x-ray. If there is no air on x-ray or transillumination, it is okay to remove the chest tube. *Never* clamp a chest tube (tension pneumothorax risk).

FIGURE 31–4. Pigtail catheter chest tube on the right side.

- C. **Clean the skin area around the chest tube with an antiseptic solution.** Remove any tape or sutures but leave the wound suture. Cover entry site with gauze and your fingertips to prevent air from entering the chest as the tube is withdrawn, and then cover with petroleum gauze. Keep pressure on it. Cover with gauze and remove sutures when healed.
 - D. **Clinical signs and symptoms of respiratory distress** will identify almost all patients with significant pneumothoraces following chest tube removal. Monitor for tachypnea, dyspnea, increasing oxygen requirement, hypotension, or worsening arterial blood gas. Transillumination and chest x-ray may be necessary.
- V. **Complications**
- A. **Infection.** Strict sterile technique minimizes infections. Cellulitis is common. Intrapleural inoculation of *Candida* has been reported after chest tube placement. Many institutions recommend prophylactic antibiotics (eg, nafcillin) when a chest tube is placed (**controversial**). Empyema requires antibiotics and drainage.
 - B. **Bleeding.** May occur if a major vessel (intercostal, axillary, pulmonary, or internal mammary) or the myocardium is perforated or if the lung is damaged during the procedure. It can cause a hematoma or hemothorax. This complication can be avoided if landmarks are properly identified. Bleeding is less likely if a trocar is not used. Bleeding may stop during suctioning; however, if significant bleeding continues, immediate surgical consultation is necessary. Bleeding can be more significant with a coagulopathy.
 - C. **Nerve damage.** Passing the tube over the top of the rib helps avoid injury to the intercostal nerve running under the rib. Horner syndrome, diaphragmatic paralysis, or eventration from **phrenic nerve injury** has been reported. The medial end of the chest tube should be no less than 1 cm from the spine on frontal chest radiograph (phrenic nerve paralysis is related to the abnormal location of the medial end of the chest tube).
 - D. **Trauma.** The premature lung is at a greater risk of trauma because the chest wall is thin and the lung tissue is fragile. Lung trauma (perforation or laceration) can be minimized by never forcing the tube into position. Trauma can also occur to the breast tissue. Iatrogenic tracheobronchial perforation (tube through esophagus, carina, or right main bronchus) and tracheoesophageal fistula have been reported.
 - E. **Subcutaneous emphysema.** Secondary to a leak through the pleural opening.
 - F. **Chylothorax.** Results if the catheter causes trauma to the thoracic duct. It is best to avoid penetration into the posterior superior mediastinum.
 - G. **Cardiac tamponade.** See Chapter 41.
 - H. **Fluid and electrolyte imbalance/hypoproteinemia.** Secondary to significant pleural fluid output.
 - I. **Rare complications.** Myocardial perforation, severing the phrenic nerve, subclavian vessel tear with blood loss, thymic trauma with blood loss, trauma to the liver with hemoperitoneum, traumatic arteriovenous fistula, aortic obstruction, compression of the aorta, and displacement of the trachea can all occur.
 - J. **Complications from percutaneous thoracostomy (pigtail catheter).** Percutaneous thoracostomy with pigtail catheters has always been felt to be safer with less complications than straight chest tubes. Recent reviews from autopsy cases suggest that complications from pigtail catheters are more prevalent than previously believed. These complications may be from tubing that is too long. The pigtail catheters enter structures outside of the pleural cavity. These include lung perforation (usually upper), pleural effusion, and tube entering and wrapping around cardiac and mediastinal structures.

32 Defibrillation and Cardioversion

Defibrillation and cardioversion are procedures that involve giving a controlled electrical shock to the heart through the chest wall and are used for rapid termination of a tachyarrhythmia (a fast, abnormal rhythm originating either in the atrium or ventricle) that is unresponsive to baseline treatment or is causing the patient to have cardiovascular compromise (inadequate systemic perfusion). Baseline treatment consists of correcting metabolic problems, use of vagal maneuvers which work by stimulating the vagal tone that slows the heart rate (eg, diving reflex, bag filled with ice and cold water applied on the whole face for 15–30 seconds without obstructing the airway, rectal stimulation using a thermometer, bending legs and bringing the knees to the chest for 15–30 seconds), use of medications (adenosine, digoxin, propranolol, verapamil, amiodarone, procainamide, lidocaine, or magnesium sulfate), or transesophageal pacing. It is best to try these maneuvers or medical therapy if intravenous access is available. **Neonatal arrhythmias are rare, and the majority can be treated with these initial measures.**

Current defibrillators can deliver 2 modes of shock: synchronized and unsynchronized. **Synchronized shocks are lower dose and used for cardioversion. Unsynchronized shocks are higher dose and used for defibrillation. Pediatric cardiology consultation is recommended for all infants with a tachyarrhythmia.**

I. Indications

A. Cardioversion (synchronized delivery of energy [shock] during the QRS complex)

1. **Unstable patients** with tachyarrhythmias who have a perfusing rhythm but evidence of poor perfusion, heart failure, or hypotension (signs of cardiovascular compromise). Tachyarrhythmias appropriate for cardioversion include:

- a. **Supraventricular tachycardia or ventricular tachycardia** with a pulse and poor perfusion.
- b. **Supraventricular tachycardia with shock** and no vascular access.
- c. **Atrial flutter with shock.**
- d. **Atrial fibrillation with shock** (very rare in infants).

2. **Elective cardioversion** in infants with **stable supraventricular tachycardia (SVT), ventricular tachycardia (VT), or atrial flutter** (good tissue perfusion and pulses) unresponsive to other treatments. This is always done under the close supervision of a pediatric cardiologist. Sedation and a 12-lead electrocardiogram are recommended before cardioversion.

B. **Defibrillation (asynchronized, random delivery of energy [shock] during the cardiac cycle).** Used in pulseless arrest with a shockable rhythm (VT and ventricular fibrillation) and in between cardiopulmonary resuscitation (CPR) but **not in asystole or pulseless electrical activity (PEA)**. The most common cause of a ventricular arrhythmia in a neonate is electrolyte imbalance. Defibrillation will not stop the arrhythmia in these patients. **Defibrillation is recommended and is the most effective treatment for documented ventricular fibrillation and pulseless ventricular tachycardia.**

II. Equipment

A. **Manual external defibrillator, (where the operator preselects the energy to be used); two paddle electrodes of the correct sizes, and conductive gel pads.** For infants, use the smallest size of paddle (usually measuring 4.5 cm) or hands-free, multifunction, self-adhesive electrode pads (SAEP) can be used instead of paddles for cardioversion, defibrillation, and monitoring. It is important to be familiar with your institution's equipment because there are many different types and models. Pediatric-capable automated external defibrillators (AEDS) (adult automated external defibrillators with pediatric attenuated pads are recommended for children ages 1 to 8 years but may be used in infants <1 year of age if a manual external defibrillator (preferred) is not available.

- B. Other equipment.** Heart rate monitor, airway equipment, resuscitation medications, antiarrhythmic medications, and equipment used in basic and advanced life support.

III. Procedure

- A. Preoxygenation and continuous heart monitoring are essential.** Emergency airway equipment should be readily available.
- B. Adequate systemic sedation and pain management (may not be possible in emergency situations).** During an emergency cardiac event, pain relief is not a focus. Depending on the type of procedure, sedation may be considered.
- 1. Planned cardioversion.** Use propofol (short acting; side effects are rare). Induction dosing: 2.5 to 3.5 mg/kg over 20 to 30 seconds, then 200 to 300 mcg/kg/min.
 - 2. Emergent cardioversion.** These patients are usually too unstable to wait for appropriate sedation. It is best to proceed with cardioversion without sedation.
 - 3. Defibrillation.** These patients are unconscious and thus do not require sedation.
- C. Wipe any cream or soap off the chest.**
- D. Place the electroconductive pads firmly on dry clean skin of the chest wall.** To prevent skin burns, be sure the conductive pad totally covers the paddle and that the skin is not in contact with any noninsulated part of the paddle. The pads must not touch each other, at least one inch is required between electrodes for safe use. If the pads are in contact with each other, this can cause the electric current to arch across the chest instead of toward the heart. Alternatively, self-adhesive electrode pads can be used in place of the paddles. If pediatric pads are too large for the neonate, handheld paddles may need to be used as pediatric pads should not be folded, crushed, or bent. There are 2 different positions for pad placement.
- 1. Anterolateral positioning (Figure 32-1).** The anterior pad is placed to the right of the upper sternum, and the posterior pad is placed below the left nipple toward the axilla.
 - 2. Antero-posterior positioning (Figure 32-2).** This may be preferred in atrial tachycardia. The anterior pad is placed on the midsternal border, and the posterior pad is placed between the scapulae. The paddles or pads should not be in contact with one another. **With dextrocardia, the pads need to be placed across the right chest.**

FIGURE 32-1. Location for anterolateral pad or paddle placement.

FIGURE 32-2. Anteroposterior pad or paddle placement.

E. Charge the defibrillator

- 1. Cardioversion uses lower energy.** Charge the defibrillator to **0.5-1.0 J/kg** (initial charge) and synchronize. The SYNC button must be activated each time because the default setting on a defibrillator is on the asynchronized setting.
- 2. Defibrillation uses higher energy.** Charge the defibrillator to **2 J/kg** (initial charge).
- 3. Once charged, make sure everybody is clear of the patient, including the person holding the oxygen.** Ask if everyone is clear, and visually check while they answer. Use the accepted phrase, **“I’m clear, you’re clear, oxygen clear.”** Verify that oxygen is not flowing across the area. It is best to disconnect the bag and verify that no one is touching the endotracheal tube or any part of the ventilation circuit. The machine will indicate that it is charged and ready for discharge with an audible signal and/or a flashing red light either on the machine or the end of the paddle based on the model.

F. Deliver the shock by pressing both buttons together

- 1. Cardioversion.** If the first attempt does not work, additional attempts should be made. **Repeat steps C to E using 2 J/kg per the Pediatric Advanced Life Support (PALS) algorithm.**
- 2. Defibrillation.** In pulseless infants, continue CPR with appropriate compressions, ventilation, and medications between attempts. Additional attempts should be made by repeating steps C to E. **The second and any subsequent shocks should have a dose of 4 J/kg (per PALS algorithm).** Acidosis and hypoxia decrease the success of defibrillation, and correction increases the likelihood of success.

IV. Complications. Risk of complications is increased when there is an increased energy dose, multiple shocks, increased impedance, or decreased interval between shocks.

- A. Altered skin integrity.** Soft tissue injury, chest wall lesions, skin burns, bruising, and pain can occur. Burns can be moderate to severe in 20% to 25% of patients. They are usually due to improper pad placement.
- B. Pulmonary edema (rare).** It is most likely due to left ventricular dysfunction, but true mechanism is unknown.

- C. **Neurologic impairment.** This can occur from a stroke from a thromboembolic event after cardioversion, most often when cardioverting atrial flutter or atrial fibrillation. A preelective cardioversion echocardiogram to evaluate for atrial clots could aid in determining whether the patient is at risk for an embolic event.
- D. **Cardiac arrhythmias.** Dysrhythmias due to enhanced automaticity, such as digitalis toxicity or catecholamine-induced arrhythmias, have increased risk of VT or ventricular fibrillation with shock. Premature beats can occur. Ventricular fibrillation can also occur with poor synchronization of the shock administration.
- E. **Myocardial necrosis.** When excessive energy is delivered, heart tissue can be damaged. This can cause necrosis with elevated ST segments seen on electrocardiogram. If myocardial damage is severe enough, this can cause shock.
- F. **Cardiogenic shock.** Patients can develop transient decreased cardiac output with left ventricular diastolic dysfunction and damage of the myocardium after cardioversion or defibrillation.
- G. **Fire (rare).** Fire has resulted from sparks with flammable material (eg, oxygen). Most reports involve the use of older paddles. If using older paddles, make sure there is good contact with the body surface and no other metallic surfaces are near the paddles. If the infant is on oxygen, place the oxygen source at least 1 meter away from the patient before defibrillation.
- H. **Electrical shock to healthcare providers.** This can result in tingling, minor burns, or transient lethargy.

33 Endotracheal Intubation and Extubation

I. Indications

- A. **Provide mechanical respiratory support.**
- B. **Administration of surfactant.**
- C. **Management of apnea.**
- D. **Alleviate upper airway obstruction (subglottic stenosis).**
- E. **Assist in the management of congenital diaphragmatic hernia** to avoid bowel distention.
- F. **Administer medications** (see Section III.R.) in the emergency setting.
- G. **Obtain aspirates for culture.**
- H. **Assist in bronchopulmonary hygiene** (“pulmonary toilet”).
- I. **Selective bronchial ventilation.**

- II. **Equipment.** Correct endotracheal tube (ETT) (Table 33–1), a pediatric laryngoscope handle with a Miller blade (“No. 00” blade for extremely preterm infants, “No. 0” blade for preterm infants, “No. 1” blade for term infants), an ETT adapter, a suction apparatus, suction catheters, tape, scissors, tincture of benzoin, a malleable stylet (*optional*), personal protection equipment, a stethoscope, bag-and-mask apparatus, humidified oxygen/air source and blender, and pressure manometer should be available at the bedside. A colorimetric device or capnograph should be available to confirm the position of the tube. The mechanical ventilator set up should be ready. Cardiorespiratory monitoring is essential if not an emergent intubation.

III. Procedure

A. Orotracheal versus nasotracheal intubation

- 1. **Orotracheal intubation.** More commonly performed emergently and is described here. It is easier and quicker than nasotracheal intubation.

Table 33–1. GUIDELINES FOR ENDOTRACHEAL TUBE (ETT) SIZE AND SUCTION CATHETER SIZE BASED ON WEIGHT AND GESTATIONAL AGE

Weight (g)	Gestational Age (wks)	ETT Size, Inside Diameter (mm)	Suction Catheter Size (based on inner diameter of ETT)
<1000	<28	2.5	5–6F
1000–2000	28–34	3.0	6–8F
>2000	>34	3.5	8F

Data from American Academy of Pediatrics, American Heart Association, Weiner GM, et al: *Textbook of Neonatal Resuscitation*, 7th ed. Chicago, IL: American Heart Association and American Academy of Pediatrics Chicago; 2016.

2. **Nasotracheal intubation.** More commonly performed in the elective setting or if anatomy precludes the oral route. Nasotracheal intubation can be used in overly active infants or in those infants who have copious secretions. It offers tube stability but can be associated with an increase in postextubation atelectasis and a risk of nasal damage. In nasotracheal intubation, the procedure is similar except the lubricated nasotracheal tube is passed into the nostril and then pharynx and into cords following to the back of the throat. Small doses of intranasal 2% lidocaine gel can be used. Postextubation atelectasis maybe more frequent after nasal intubation, but one route of intubation does not seem to be preferable over the other.
- B. **Video laryngoscopy.** A newer technique that uses a video laryngoscope (eg, GlideScope AVL Preterm/Small Child Video Laryngoscope; Verathon) to assist in the placement of the ETT. There is a high-resolution micro camera mounted on the blade that is connected to a small portable digital monitor. It is a form of indirect laryngoscopy that allows enhanced visualization of the glottis. It has also been used in teaching neonatal trainees with improvement in intubation success rates. A Cochrane review (2015) notes there was insufficient evidence to recommend or refute the use of video laryngoscopy for endotracheal intubation in neonates.
- C. **Pain/premedication**
 1. **Premedication is not necessary** for an emergency intubation in the delivery room or after an acute deterioration in a neonatal intensive care unit. It is also not necessary in some cases of infants with upper airway anomalies (such as Pierre Robin sequence) or in infants in whom the instrumentation of the airway is presumed to be extremely difficult.
 2. **If intravenous access is not available**, the intramuscular route should be considered for premedications.
 3. **Premedication can decrease pain and discomfort of a nonemergent intubation. Practical evidence suggests that it may also improve intubation success, decrease the time it takes to intubate, and prevent some of the complications.** Neonates who undergo “awake intubation” without premedication have the following physiologic responses: systemic hypertension, bradycardia, hypoxemia, and increased intracranial pressure. Premedication for nonemergency intubation in the neonate is safer and more effective than when awake, but the ideal combination of premedication has not been established. No validated scoring systems to assess the level of sedation prior to intubation exist in the literature. Preferred medications have rapid onset and short duration of action. One preferred sequence is as follows:
 - a. **Administer oxygen** to maximize levels.
 - b. **Vagolytic agents prevent reflex bradycardia during intubation.** Atropine is the American Academy of Pediatrics (AAP) preferred vagolytic agent.

- c. **Analgesia agents decrease pain and discomfort during intubation.** Fentanyl is the AAP preferred agent. Other acceptable medications are remifentanyl and morphine but only if no other option is feasible.
 - d. **Sedative/hypnotic agents depress the activity of the brain.** The AAP does not list any preferred agents and notes that propofol and thiopental are acceptable hypnotic agents for preterm and term infants and that midazolam is the only acceptable sedative for term infants along with an analgesic agent.
 - e. **Neuromuscular blocking agents (ie, muscle relaxants) block the transmission of neurotransmitters between neurons resulting in paralysis.** The AAP states that no ideal muscle relaxant exists. The preferred agent is vecuronium or rocuronium with succinylcholine and pancuronium also acceptable agents.
4. **Because optimal protocols and medications have not been established,** each unit should adopt its own pain and premedication protocols. See Table 33–2 for a listing of elective intubation medications reviewed by the AAP. The AAP recommends to either give an analgesic or hypnotic medication and to consider vagolytic agents and rapid-onset paralytics. They recommend to not give a sedative or paralytic agent by itself. The Canadian Pediatric Society recommends the combination of atropine, fentanyl, and succinylcholine for premedication of intubation. Key premedication points:
- a. **Do not use a muscle relaxant** without an analgesic agent.
 - b. **Analgesic or anesthetic dose of a hypnotic drug** should be given.
 - c. **Vagolytic and muscle relaxants (rapid onset)** should also be considered.
5. **Rapid sequence intubation.** Involves premedication prior to intubation with atropine, an analgesic, and a neuromuscular blocker. It is commonly used in the emergency department for rapid intubation. When rapid sequence intubation (RSI) is used in neonates, there is better visualization of the airway and no movement from the infant, and intubation is quicker with fewer attempts. One recommendation is atropine intravenous (IV) push (0.01–0.03 mg/kg, minimum dose 0.1 mg), fentanyl (2–3 mcg/kg per dose), and lastly vecuronium (0.1 mg/kg per dose). Further research is needed before definite recommendations can be made on using RSI in the neonate.
- D. **Confirm that the laryngoscope light source is working** before beginning the procedure. Check to make sure the integrity of the equipment is okay (no loose laryngoscope parts).
- E. **Stylets. A stylet is a malleable metal wire that is inserted into the endotracheal tube. Malleable stylets** are optional but may aid intubation and help guide the tube into position more efficiently (*controversial*). A Cochrane review (2017) suggests that use of a stylet during neonatal orotracheal intubation does not significantly improve success rates of neonatal trainees. However, only 1 brand of stylet and ETT has been tested, and therefore, the results cannot be generalized. **If using a stylet, place it in the ETT and be sure the tip of the stylet does not protrude out of the end of the ETT.** The stylet should be 1 to 2 cm proximal to the distal end of the ETT.
- F. **Place the infant in the “sniffing position”** (the neck slightly extended); a small roll behind the neck may help with positioning. Hyperextension of the neck in infants may cause the trachea to collapse. It displaces the cords anteriorly and makes it difficult to pass the ETT. The infant’s head should be at the same level as the operator.
- G. **Cautiously suction the oropharynx** as needed to make the landmarks clearly visible. Routine suctioning is not recommended as excessive secretions were found to be rare in elective and premedicated intubations in neonates.
- H. **Preoxygenate the infant with a bag-and-mask device,** and monitor the heart rate, color, and oxygen saturations. **To decrease hypoxia, limit each intubation attempt to <20 seconds before reoxygenation. Infants frequently deteriorate during an intubation attempt.**
- I. **Hold the laryngoscope with your left hand.** Insert the scope into the right side of the mouth, and sweep the tongue to the left side. Some practitioners move the tongue

Table 33–2. PREMEDICATIONS FOR NONEMERGENCY INTUBATION

Drug	Route/Dose	Onset of Action	Duration of Action	Common Adverse Effects	Comments ^a
Analgesic					
Fentanyl	IV or IM ^b : 1–4 mcg/kg	IV, almost immediate; IM, 7–15 minutes	IV, 30–60 minutes; IM, 1–2 hours	Apnea, hypotension, CNS depression, chest wall rigidity	Preferred analgesic Effects reversible with naloxone Give slowly (preferably over 3–5 minutes, at least over 1–2 minutes) to avoid chest wall rigidity Chest wall rigidity can be treated with naloxone and muscle relaxants
Remifentanyl	IV: 1–3 mcg/kg; may repeat in 2–3 minutes if needed	IV, almost immediate	IV, 3–10 minutes	Apnea, hypotension, CNS depression, chest wall rigidity	Acceptable analgesic Short duration of action and limited experience in neonates Effects reversible with naloxone Give slowly over 1–2 minutes to avoid chest wall rigidity Chest wall rigidity can be treated with naloxone and muscle relaxants Rapid administration
Hypnotic/sedative					
Morphine	IV or IM: 0.05–0.1 mg/kg	IV, 5–15 minutes; IM, 10–30 minutes	IV, 3–5 hours; IM, 3–5 hours	Apnea, hypotension, CNS depression	Acceptable analgesic agent Use only if other opioids are not available; if selected, must wait at least 5 minutes for onset of action Effects reversible with naloxone
Midazolam	IV or IM: 0.05–0.1 mg/kg	IV, 1–5 minutes; IM, within 5–15 minutes	IV, 20–30 minutes; IM, 1–6 hours	Apnea, hypotension, CNS depression	Acceptable sedative for use in term infants in combination with analgesic agents Hypotension more likely when used in combination with fentanyl Not recommended in premature infants Effects reversible with flumazenil

Thiopental	IV: 3–4 mg/kg	IV, 30–60 seconds	IV, 5–30 minutes	Histamine release, apnea, hypotension, bronchospasm	Acceptable hypnotic agent Hypotension more likely when used in combination with fentanyl and/or midazolam
Propofol	IV: 2.5 mg/kg	Within 30 seconds	3–10 minutes	Histamine release, apnea, hypotension, bronchospasm, bradycardia; often causes pain at injection site	Acceptable hypnotic agent Limited experience in newborns Neonatal dosing has not been well established
Muscle relaxant					
Pancuronium	IV: 0.05–0.10 mg/kg	1–3 minutes	40–60 minutes	Mild histamine release, hypotension, tachycardia, bronchospasm, excessive salivation	Acceptable muscle relaxant Relatively longer duration of action Effects reversible with atropine and neostigmine
Vecuronium	IV: 0.1 mg/kg	2–3 minutes	30–40 minutes	Mild histamine release, hypotension/hypotension, tachycardia, arrhythmias, bronchospasm	Preferred muscle relaxant Effects reversible with atropine and neostigmine
Rocuronium	IV: 0.6–1.2 mg/kg	1–2 minutes	20–30 minutes	Mild histamine release, hypotension/hypotension, tachycardia, arrhythmias, bronchospasm	Preferred muscle relaxant Effects reversible with atropine and neostigmine
Succinylcholine	IV: 1–2 mg/kg; IM ^b : 2 mg/kg	IV, 30–60 seconds; IM, 2–3 minutes	IV, 4–6 minutes; IM, 10–30 minutes	Hypertension, hypotension, tachycardia, arrhythmias, bronchospasm, hyperkalemia, myoglobinemia, malignant hyperthermia	Acceptable muscle relaxant Contraindicated in presence of hyperkalemia and family history of malignant hyperthermia

(Continued)

Table 33–2. PREMEDICATIONS FOR NONEMERGENCY INTUBATION (CONTINUED)

Drug	Route/Dose	Onset of Action	Duration of Action	Common Adverse Effects	Comments ^a
Vagolytic					
Atropine	IV or IM: 0.02 mg/kg	1–2 minutes	0.5–2 hours	Tachycardia, dry hot skin	Preferred vagolytic agent
Glycopyrrolate	IV: 4–10 mcg/kg	1–10 minutes	~6 hours	Tachycardia, arrhythmias, bronchospasm	Acceptable vagolytic agent Limited experience in newborns Contains benzyl alcohol as preservative

Note: Most of these drugs have limited pharmacokinetics data from newborns and are not approved for use in the newborn, but they have been used in newborns. Rapid administration of remifentanyl provided inadequate sedation and is associated with chest wall rigidity in preterm infants.

CNS, central nervous system; IM, intramuscularly; IV, intravenously.

^aPreferred and acceptable designation of medications is based on consensus opinion after review of available evidence.

^bConsider only if no intravenous access.

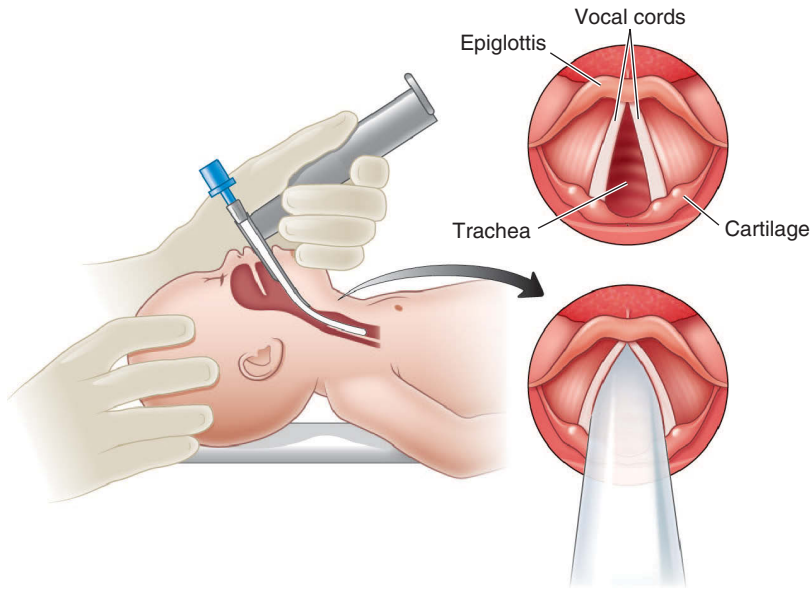

FIGURE 33-1. Endotracheal intubation in the neonate.

to the left by using the index finger of the right hand placed alongside the head. To perform this maneuver, stabilize the head and hold the mouth open. (**Do not use the laryngoscope blade to open the mouth.**)

- J. **Advance the blade a few millimeters**, passing it beneath the epiglottis.
- K. **Lift the blade vertically to elevate the epiglottis** and visualize the glottis (Figure 33-1). *Note:* The purpose of the laryngoscope is to lift the epiglottis vertically, not to pry it open. To better visualize the vocal cords, an assistant may place gentle external pressure on the thyroid cartilage. If the cords are together, wait for them to open (never force a tube between closed cords). Do not touch the closed cords because this may cause spasm.
- L. **Pass the endotracheal tube along the right side of the mouth** and down past the vocal cords during inspiration. Advance the tube *only* 2 to 2.5 cm into the trachea to avoid placement in the right mainstem bronchus (no more than 1–2 cm below the vocal cords). If a stylet was used, it should be removed gently while the tube is held in position.

M. Multiple endotracheal tube depths of insertion methods have been described:

1. **7-8-9 rule (Tochen rule)/(weight plus 6).** Most commonly used formula in one study. The depth of ETT insertion in centimeters (“tip to lip”) is estimated as 6 plus the weight in kilograms. Tape the ETT at the lip when the tube has been advanced 7 cm in a 1-kg infant, 8 cm in a 2-kg infant, 9 cm in a 3-kg infant, or 10 cm in a 4-kg infant (“**1, 2, 3, 4 – 7, 8, 9, 10**”). Do not use this in infants <750 g (it overestimates the depth of insertion) or in infants with severe neck or orofacial deformities. Infants weighing <750 g may only require a 6-cm insertion (see Table 33-3). Interestingly Tochen’s rule was not found to be suitable for neonates in Taiwan, as the final ideal ETT depth was shallower.
2. **Endotracheal tube length based on gestation-based guidelines.** (NRP recommended.) ETT length is more related to gestation in a linear manner than to birth-weight. Using gestation-based guidelines is associated with a decrease in uneven lung expansion and a decrease in the number of tubes that need to be repositioned.

Table 33–3. ENDOTRACHEAL TUBE (ETT) LENGTH BASED ON GESTATIONAL AGE–BASED GUIDELINES

ETT Length at Lips (cm; “tip to lip”)	Gestational Age (wks)	Actual Weight ^a (kg)
5.5	23–24	0.5–0.6
6.0	25–26	0.7–0.8
6.5	27–29	0.9–1.0
7.0	30–32	1.1–1.4
7.5	33–34	1.5–1.8
8.0	35–37	1.9–2.4
8.5	38–40	2.5–3.1
9.0	41–43	3.2–4.2

^aActual weight is weight at intubation.

Reproduced with permission from Kempley ST, Moreiras JW, Petrone FL: Endotracheal tube length for neonatal intubation, *Resuscitation*. 2008 Jun;77(3):369-373.

Using gestational age or a weight-based chart outperformed the nasal tragus length (NTL) formula, described below, in a recent study. See Table 33–3.

3. **Nasal-tractus length and sternal length.** (NRP recommended.) One method that allows length assessment in approximately 10 seconds and does not require weight is the NTL (base of the nasal septum to the tragus of the ear); the other method is the sternal length (STL; suprasternal notch to the tip of the xiphoid process). The NTL method has been validated in both term and preterm infants.
 - a. **Orotracheal route.** NTL or STL plus 1.
 - b. **Nasotracheal route.** NTL or STL plus 2.
- N. Regardless of technique used, rapidly confirm the position of the tube immediately after insertion.** Detection of exhaled carbon dioxide plus clinical assessment (rapidly increasing heart rate) are considered the most primary initial methods of confirming the ETT is within the trachea. A Cochrane review (2014) states: “There is insufficient evidence to determine the most effective technique for the assessment of correct ETT placement either in the delivery room or the neonatal intensive care unit.”
1. **Auscultation.** The resuscitation bag or Neopuff Infant T-Piece Resuscitator (Fisher & Paykel Healthcare) is attached to the tube using the adapter, and an assistant provides mechanical breaths while the operator listens for equal breath sounds on both sides of the chest. Auscultate the stomach to be certain that the esophagus was not intubated. **Caution is necessary** because breath sounds heard over the anterior part of the chest can come from the stomach or esophagus. If correctly intubated, there should be an increase in heart rate and color. There should be vapor condensing on the inside of the tube during exhalation. Other clinical observations that the tube is in the trachea include no air entering over the stomach (no gastric distension), little or no air leak from the mouth, symmetrical and slight rise of chest movement with breathing, and equal bilateral breath sounds near both axillae.
 2. **External digital tracheal palpation of the suprasternal notch.** The suprasternal notch corresponds to the interclavicular midpoint on a chest x ray and midpoint of the trachea which approximates the correct ETT tube position. Suprasternal palpation is a simple and safe method of confirming ETT placement in neonates. During

ETT intubation, palpate the tip in the suprasternal notch with the index finger of the left hand while holding the tube with the right hand. One can adjust the tube so the edge is palpable in the notch. It was found to be as accurate as the 7-8-9 rule.

3. Carbon dioxide detectors

a. Colorimetric devices change color in the presence of carbon dioxide (CO₂) and are the most commonly used devices. End-tidal CO₂ detectors connected to the ETT are commercially available that rapidly confirm proper endotracheal placement. One such device (Pedi-Cap CO₂ detector; Nellcor) displays violet in the absence of CO₂ and yellow in the presence of CO₂ (tube in trachea).

b. Capnographs have a special electrode at the ETT connector, and a waveform shows oscillation with each breath if the tube is in the correct place. A flat wave usually means the ETT is in the esophagus but other clinical scenarios may also show this (ETT obstruction, prolonged cardiac arrest, technical malfunction of the monitor).

c. Limitations of endotracheal tube carbon dioxide detectors. Recent studies have shown that end-tidal CO₂ monitoring did not correctly identify ETT placement in up to 30% of cases in the delivery room. With some cyanotic congenital heart disease, they may underestimate the true arterial CO₂ level. If the cardiac output is low, the infant has a low heart rate, there is no heartbeat, the lungs are not adequately ventilated, the lungs are collapsed, there are secretions in the ETT or trachea that are causing an obstruction, or there are large bilateral pneumothoraces, the CO₂ monitor may not change color because not enough CO₂ is exhaled to detect. Any acidic substance (gastric acid, endotracheal epinephrine) can contaminate the colorimetric device and cause a false-positive result. If the detector is yellow in the package, it means it changed color in the package, is defective, and should not be used.

4. Respiratory function monitor (RFM) is a newer method used to detect the accurate position of ETT by measuring the airway pressure and gas flow in and out of the ETT. It can identify if the ETT is in the trachea by showing inspiratory as well as expiratory flow. Difficulties with this include operator experience in interpretation of flow signals and judging the depth of the ETT.

O. Secure the endotracheal tube in place. There are many ways to secure an ETT in a ventilated infant. Some of these include water-resistant tape, sutures, silk ties, ETT holders, head restraints, bonnets, umbilical cord clamps, or a combination of techniques. A Cochrane review (2014) indicates that “evidence is lacking to determine the most effective and safe method to stabilize the ETT in the ventilated neonate.”

1. Paint the skin with tincture of benzoin, and tape the tube securely in place.

2. Commercial devices may be provided in your unit for securing an ETT without tape. Some examples include the NEO-fit tube grip (Cooper Surgical, Trumbull, CT), which eliminates the need for tape use and provides stabilization for ETT sizes 2.5 to 4.0 mm. The Neobar (Neotech, Valencia, CA) is another device.

P. After the endotracheal tube is secured, obtain a chest radiograph with the infant’s head in neutral position to confirm proper placement of the tube. Figure 12–11 shows proper placement of a neonatal ETT. Some sources indicate that the ETT tip should be placed at the level of the body of the **first to second thoracic vertebra** and to not use the medial end of the clavicles (most common reference point) because their position may be variable. Others state that the ETT tip should be placed 2 cm above the carina. Thayyil et al found that infants who had a ETT tip lower than T1–T2 were more likely to have localized PIE, pneumothorax, and right upper lobe collapse. **Bedside ultrasound (POCUS) of the chest** (due to a cartilaginous sternum in newborns) allows one to directly visualize the ETT position in preterm and term infants and can be used to identify the ETT position. It can also be used for the rapid assessment of the ETT position (as quick as 17 seconds) using a US curvilinear probe. It is well tolerated but less studied in infants and children than in adults. It was found to be as accurate as capnography and a chest x ray. See Technique in Chapter 44.

- Q. Best position for newborns on assisted ventilation.** A Cochrane review (2016) states that the prone position is favored for slightly improved oxygenation in neonates undergoing mechanical ventilation.
- R. Certain emergency medications can be given through the endotracheal tube** if IV access is limited. These medications are lidocaine, atropine, naloxone, and epinephrine. These can be remembered by the mnemonic “LANE” or “NEAL.” **Epinephrine given by IV route is recommended as the most effective route, since absorption by the lungs is slow and unpredictable;** however, it can be given emergently by the ETT route while the vascular access is obtained. A higher dose of epinephrine (0.5–1 mL/kg of 1:10,000) is necessary even though studies have not validated the safety of this. There are no studies confirming that endotracheal naloxone is effective.
- S. Other drug therapy administered by endotracheal tube.** Efficacious inhaled drugs in infants include the following: **proven:** surfactant, nitric oxide; **unproven:** diuretics, bronchodilators, mucolytics; **more evidence needed:** inhaled corticosteroids, prostacyclin, budesonide with surfactant, colistin, heliox, pentoxifylline, superoxide dismutase, xenon.

IV. Endotracheal extubation

- A. The decision to remove an endotracheal tube is a complex clinical decision.** Issues surrounding ventilatory support are discussed in Chapter 9. When adequate ventilation is maintained with minimal settings, extubation should be attempted. Manage postextubation atelectasis intensively with chest physiotherapy.
- B. Use of medications prior to extubation**
- 1. Dexamethasone use is controversial.**
 - a. Stridor.** Some advocate systemic dexamethasone given before and after extubation to reduce the incidence of stridor. A Cochrane review (2009) states: “Using corticosteroids to prevent (or treat) stridor after extubation has not proven effective for neonates or children. However, given the consistent trends towards benefit, this intervention does merit further study, particularly for high risk children or neonates.”
 - b. Reintubation risk.** Dexamethasone IV given prior to extubation reduces the need for reintubation in high-risk neonates. A Cochrane review (2017) states that it is best to use in infants at risk (repeated and prolonged intubations) for airway edema and obstruction.
 - c. Systemic corticosteroids.** Early corticosteroid therapy (first 2 weeks after birth) reduced the risk of bronchopulmonary dysplasia/chronic lung disease (BPD/CLD) and shortened the time to extubation. However, a Cochrane review (2017) notes that the benefits of early postnatal corticosteroid treatment (≤ 7 days), particularly dexamethasone, may not outweigh adverse effects associated with this treatment (gastrointestinal bleeding, intestinal perforation, hyperglycemia, hypertension, hypertrophic cardiomyopathy, and growth failure). Another Cochrane review (2017) states that late corticosteroids (after 7 days) for BPD/CLD reduced mortality without significantly increasing risk of adverse long-term neurodevelopmental outcomes, but there is still concern about the limitations of these studies. Therefore, late corticosteroid use should be reserved for infants who cannot be weaned from mechanical ventilation and to minimize the dose and duration of any course of treatment.
 - d. Inhaled steroids.** In infants on invasive mechanical ventilation with birth-weight ≤ 1500 g or gestational age ≤ 32 weeks, a Cochrane review (2017) suggests that there is no evidence that inhaled steroids compared to systemic steroids prevented the primary outcome of death or BPD. The number of days the baby needed mechanical ventilation support or additional oxygen were increased in infants who received inhaled steroids versus infants who received systemic steroids.

2. **Methylxanthines (caffeine)** used prophylactically increase the chance of successful extubation of preterm infants within 1 week of life. The caffeine group had lower rates of patent ductus arteriosus ligation, cerebral palsy, death, BPD/CLD, or major disability at 18 to 21 months. The majority of preterm infants are given caffeine before extubation and are maintained on this medication while on nasal continuous positive airway pressure (nCPAP) or nasal ventilation.
3. **Other medications.** A Cochrane review (2000) indicates: “The evidence does not support the routine use of doxapram to assist endotracheal extubation in preterm infants who are eligible for methylxanthine and/or CPAP [continuous positive airway pressure].” It also notes the following: “There is no evidence either supporting or refuting the use of inhaled nebulized racemic epinephrine in newborn infants.”

C. Extubation procedure

1. **Perform chest physiotherapy and suction.**
 2. **Remove tape and any devices** that are holding the ETT in place.
 3. **Remove the tube.** It is best to use your own unit’s recommendation on how and when to remove the tube. Recommendations vary:
 - a. **Give positive-pressure inspiration** while slowly removing the tube.
 - b. **Suction, give positive-pressure breaths,** and remove the ETT.
 - c. **Using manual ventilation,** give the infant a sigh breath, and withdraw the tube during exhalation.
 4. **Chest physiotherapy.** Some studies have found that fewer babies had to go back on ventilator support when chest physiotherapy was used after extubation, but these were older studies that did not use modern humidification systems. The use of physiotherapy in this setting is unclear.
- D. Other postextubation procedures.** Level of respiratory support varies and depends on the clinical status of the patient (see also Chapter 9). Possibilities include:
1. **Supplemental oxygen by hood or high-flow nasal cannula >3 to 6 L/min.** Limit flows in extremely low birthweight infants to <6 L/min (*controversial*). Cochrane review (2016) states that high-flow nasal cannula (HFNC) has similar rates of efficacy as other forms of noninvasive respiratory support in preterm infants for preventing treatment failure, death, and CLD. HFNC is also associated with less nasal trauma and potentially less pneumothorax compared with nCPAP. Further evaluation is needed for extremely preterm infants.
 2. **Nasal continuous positive airway pressure.** A Cochrane review (2016) indicates that short binasal prongs are more effective than single prongs after weaning in reducing reintubation. nCPAP is used with a nasal interface such as nasal prongs (eg, Hudson type). Other forms of postextubation support are **bubble CPAP**, and **nasal biphasic positive airway pressure**.
 3. **Nasal intermittent positive pressure is better than nasal continuous positive airway pressure** in preventing reintubation on extubated infants. Both nasal intermittent positive-pressure ventilation (NIPPV) and synchronized NIPPV (SNIPPV) seem to be equally effective.
- E. Observe for atelectasis.** If the infant has an increasing oxygen requirement and signs of respiratory distress, a chest radiograph should be obtained.

V. Complications

- A. **Hypoxia, apnea, hypoventilation, and bradycardia can all occur during the intubation process.** This can be secondary to a prolonged attempt or vagal reflex.
- B. **Hypopharyngeal or tracheal perforation/rupture and trauma.** Tracheal perforation is a rare complication requiring surgical intervention and is prevented by careful use of the laryngoscope and the ETT. Hemorrhage, edema of the larynx, and injury to the vocal cords can occur. Tracheal injury usually presents with rapid occurrence of subcutaneous emphysema, pneumomediastinum, and respiratory failure. Contusions of the gums, tongue, and airway can occur.

- C. Esophageal perforation.** Usually caused by traumatic intubation, and treatment depends on the degree of perforation. Most injuries can be managed conservatively by use of parenteral nutrition until the leak seals, use of broad-spectrum antibiotics, and observation for signs of infection. A barium swallow contrast study may be necessary after several weeks to evaluate healing and rule out stricture formation.
- D. Laryngeal edema.** Usually seen after extubation and may cause respiratory distress. A short course of steroids (eg, dexamethasone) can be given intravenously before and just after extubation.
- E. Improper tube positioning (esophageal intubation, right mainstem bronchus).** Signs of esophageal intubation include poor chest movement, no breath sounds heard, no condensation in the tube, continued cyanosis, gastric distension, and air heard over the stomach. Signs of right mainstem bronchus intubation include breath sounds heard over the right chest and none heard over the left and no improvement in color. ETT in right mainstem bronchus causes overventilation of the right lung and hypoventilation or atelectasis of the left lung. If the tube is in the right mainstem bronchus, it needs to be pulled back to the position where the breath sounds become equal on both sides of the chest.
- F. Tube obstruction or kinking.** Try suctioning or possibly reintubation.
- G. Infection.** Pneumonia and tracheobronchitis can occur.
- H. Palatal/alveolar grooves.** Palatal and alveolar grooves are usually seen in cases of long-term intubation and typically resolve with time.
- I. Subglottic stenosis.** Subglottic stenosis is most often associated with long-term (>3–4 weeks) endotracheal intubation. It is the most serious long-term complication and is secondary to posttraumatic fibrosis of the infant larynx. Surgical correction is usually necessary. With prolonged intubation, consideration may be given to surgical tracheostomy to help prevent stenosis (*timing is controversial*).
- J. Ingestion of the laryngoscope light bulb** (very rare complication reported during intubation).
- K. Other complications.** Aspiration, atelectasis, pneumothorax, increased intracranial pressure, and hypertension can all occur.

34 Exchange Transfusion

I. Indications

- A. Unconjugated hyperbilirubinemia.** Exchange transfusion (ET) is most commonly performed for infants with hyperbilirubinemia of any origin when the serum bilirubin level reaches or exceeds a level that puts the infant at risk for central nervous system toxicity (see Chapters 63 and 99). Double-volume ETs (DVEs) taking 50 to 70 minutes are usually recommended for removal and reduction of serum bilirubin. Efficiency of bilirubin removal is increased in slower paced exchanges to allow for time of extravascular and intravascular bilirubin equilibration. The American Academy of Pediatrics (AAP) has recommendations for indications of ET for unconjugated hyperbilirubinemia (see Figure 99–3).
- B. Hemolytic disease of the newborn (HDN)** results from destruction of fetal red blood cells (RBCs) by passively acquired maternal antibodies. ET aids in removing antibody-coated RBCs and replaces them with uncoated donor RBCs that lack sensitizing antigen, thereby prolonging intravascular RBC survival. It also reduces a potentially toxic bilirubin concentration, the result of the antibody destruction

of RBCs. Intravenous immunoglobulin administration has been shown to decrease the need for ET in infants with hemolytic disease of the newborn caused by Rhesus (Rh) or ABO incompatibility and is recommended by the AAP if the total serum bilirubin level is rising with intensive phototherapy or within 2 to 3 mg/dL of the exchange level. Recent Cochrane review (2018) feels further studies are needed before recommending the use of IVIG for the treatment of alloimmune HDN.

- C. **Severe anemia** (normovolemic or hypervolemic) causing congestive cardiac failure, as in hydrops fetalis, or chronic fetal–maternal or fetal–fetal posthemorrhagic anemia, which is best treated by partial ET (PET) using packed RBCs.
- D. **Polycythemia/hyperviscosity syndrome** is best treated by PET using normal saline. Normal saline is preferred because it reduces both the polycythemia and the hyperviscosity of the infant's circulating blood volume. A Cochrane review (2010) states that “there are no proven clinically significant short or long term benefits of PET in polycythemic newborn infants who are clinically well or who have minor symptoms related to hyperviscosity. PET may increase the risk of NEC [necrotizing enterocolitis]. The true risks and benefits of PET are unclear.”
- E. **Other less common indications**
 1. **Metabolic disorders** causing severe acidosis or hyperammonemia (organic acidemia, hyperammonemia).
 2. **Extreme thrombocytosis**
 3. **Congenital leukemia.** ET is effective in improving hyperleukocytosis.
 4. **Neonatal sepsis.** Recent studies indicate that mortality rate was lower (36%) in infants with septic shock treated with ET than with standard of care treatment (51%). In infants <1000 g with severe sepsis, DVET was associated with a 21% decrease in mortality.
 5. **Malaria**
 6. **Neonatal hemochromatosis**
 7. **Severe fluid or electrolyte imbalance** (eg, hyperkalemia)
 8. **Renal failure**
 9. **Drug overdose/toxicity**
 10. **Removal of abnormal proteins or antibodies**

II. Types of exchange transfusions

A. Three types of ETs are commonly used: single-volume, double-volume, and partial exchange.

1. **Single-volume exchange blood transfusion** refers to replacing 1 times the estimated blood volume at 60% of infant's blood volume.
2. **Double-volume exchange blood transfusion** refers to replacing 2 times the estimated blood volume at 85% of the infant's blood volume. Recommended for infants with severe hyperbilirubinemia and Rh hemolytic disease. Cochrane review states there is insufficient data to support or refute the use of single-volume exchange transfusion as opposed to double-volume exchange transfusion in jaundiced newborns.
3. **Partial exchange transfusion** with normal saline is indicated in neonates with polycythemia to decrease the hematocrit and whole blood viscosity. A partial exchange with packed RBCs is used to treat severe anemia (usually associated with congestive cardiac failure.)

B. Two methods can be used for the exchange transfusion procedure: isovolumetric method or push-pull method.

1. **Isovolumetric double-volume exchange blood transfusion** is the simultaneous pulling of blood out of the umbilical artery or peripheral arterial line (usually radial arterial line) and pushing blood into the umbilical vein or peripheral intravenous (IV) catheter. It is indicated in sick and unstable neonates because of less fluctuation of blood pressure and cerebral hemodynamics and in cases where only peripheral vascular access is available. It is the **preferred method** and can be done automatically using infusion pumps.

2. Push-pull method (classical “one-way” exchange transfusion). This method uses the same vascular access (usually central access through the umbilical vein) to push in and pull out the volume of blood to be removed and transfused. Blood is withdrawn and then replaced with equal volume from the donor blood. If the infant is hypovolemic or has a low CVP, start with a transfusion of the donor blood; if the infant is hypervolemic or has a high CVP, start the exchange by withdrawing blood. This was the standard or traditional technique used and may cause fluctuations in blood volume and intravascular pressure.

III. Equipment. Radiant warming bed or hybrid incubator; infant restraints; equipment for cardiorespiratory monitoring, support, and resuscitation; immediate access to blood gas determinations; equipment for umbilical artery and umbilical vein catheterization (see Chapters 28 and 48) or equipment for peripheral venous and arterial access; nasogastric tube for evacuating the stomach before beginning the transfusion; preassembled disposable ET set or a nonassembled set with two 3-way stopcocks, 5- to 20-mL syringes, waste receptacle, IV connecting tubing, and appropriate blood product or fluid. A temperature-controlled device must be used for warming of the blood/fluid (37°C) before and during the transfusion. There must be an assistant whose role is to help maintain a sterile field, monitor and assess the infant, and record the procedure and exchanged volumes.

IV. Choice of blood product for exchange transfusion

A. Blood collection

- 1. Homologous blood.** Blood donated by an anonymous donor with a compatible blood type is most commonly used. Donor-directed blood (blood donated by a selected blood type-compatible person) is another option.
- 2. Cytomegalovirus.** Seronegative donor blood is preferred. White blood cells harboring cytomegalovirus (CMV) can be removed using leukodepletion filters during blood preparation.
- 3. Hemoglobin S (sickle cell trait).** Precautions should be taken to avoid ET with donor blood from a carrier. If the donor blood with sickle trait becomes acidic, sickling can occur with expected complications to the patient.
- 4. Graft-versus-host disease.** Consideration should be given for using irradiated donor blood to avoid graft-versus-host disease in known immunocompromised infants and low birthweight infants. Preterm infants who have been transfused in utero or who have received >50 mL of transfused blood are candidates for irradiated blood.

B. Blood typing and cross-matching

- 1. Infants with Rh incompatibility.** The blood must be type O, Rh-negative, low-titer anti-A, anti-B blood. It must be cross-matched with the mother's plasma and RBCs.
- 2. Infants with ABO incompatibility.** The blood must be type O, Rh-compatible (with the mother and the infant) or Rh-negative, low-titer anti-A, anti-B blood. It must be cross-matched with both the infant's and mother's blood.
- 3. Other blood group incompatibilities.** For other hemolytic diseases (eg, anti-Rhc, anti-Kell, anti-Duffy), blood must be cross-matched to the mother's blood to avoid offending antigens.
- 4. Hyperbilirubinemia, metabolic imbalance, or hemolysis not caused by isoimmune disorders.** The blood must be cross-matched against the infant's plasma and RBCs.

C. Freshness and preservation of blood. Fresh blood (<24 hours old) is preferred, as older blood may have higher potassium values and lower pH. For newborn infants, it is preferable to use blood that has been collected in citrate phosphate dextrose (CPD). Use of irradiated blood is recommended to decrease graft-versus-host disease.

D. Hematocrit. Most blood banks can reconstitute a unit of blood to a desired hematocrit (Hct) of 50% to 65%. The blood should be agitated periodically during the transfusion to maintain a constant Hct.

- E. **Potassium levels in donor blood** should be determined if the infant is asphyxiated or in shock or renal impairment is suspected. If potassium levels are >7 mEq/L, consider using a unit of blood that has been collected more recently.
- F. **Temperature of the blood.** Warming of blood (37°C) is especially important in low birthweight and sick newborn infants.

V. Procedure

A. Double-volume exchange transfusion used for uncomplicated hyperbilirubinemia

1. **The normal blood volume in a full-term newborn infant is 80 mL/kg.** In an infant weighing 2 kg, the volume would be 160 mL, and twice the volume of blood is exchanged in a 2-volume transfusion. Therefore, the amount of blood needed for a 2-kg infant would be 320 mL. Blood volume of low birthweight and extremely low birthweight newborns, which may be up to 95 mL/kg, should be taken into account when calculating exchange volumes.
 2. **Allow adequate time for blood typing and cross-matching.** The infant's bilirubin level increases during this time, and this increase must be taken into account when ordering the blood.
 3. **Perform the transfusion in an intensive care setting.** Place the infant in the supine position. Restraints must be snug but not tight. A nasogastric tube should be passed to evacuate the stomach and should be left in place to maintain gastric decompression and prevent regurgitation and aspiration of gastric juices. Feedings should be held for 2 to 3 hours prior to the procedure.
 4. **Intensive phototherapy** should be continued as much as possible during the preparation and the ET procedure.
 5. **Give albumin infusion (1 g/kg of 25% albumin) (controversial) 1 to 2 hours before the procedure.** Albumin causes a shift of extravascular bilirubin into the circulation so more bilirubin can be removed. Using albumin did not decrease the incidence of repeat ET. Studies are conflicting on whether this decreases phototherapy duration or bilirubin amount removed. A randomized controlled trial found that in healthy late preterm and term neonates with nonhemolytic hyperbilirubinemia, giving albumin did not reduce post-ET phototherapy duration or bilirubin amount removed.
 6. **Scrub and put on a sterile gown and gloves.** Perform a procedure time-out.
 7. **Perform umbilical vein catheterization** (see technique Chapter 48) and confirm the position by radiograph. If an isovolumetric exchange is to be performed, then an umbilical artery catheter (Chapter 28) must also be placed and confirmed by radiograph. Radiographs of catheter positions can be found in Chapter 12.
 8. **Alternatively,** a peripheral IV can be used for infusion of blood and a peripheral arterial line for removal of blood.
 9. **Have the unit of blood prepared.**
 - a. **Check the blood types of the donor and the infant.**
 - b. **Check the temperature of the blood and warming procedures.**
 - c. **Check the hematocrit of the product.**
 10. **Attach the bag of blood to the tubing and stopcocks according to the directions on the transfusion tray.** The orientation of the stopcocks for infusion and withdrawal must also be checked by the assistant as part of the procedure time-out.
 11. **Establish the volume of each aliquot** (Table 34–1).
- B. Isovolumetric double-volume exchange transfusion.** Isovolumetric DVET is performed using a double setup, with infusion via the umbilical vein (or peripheral IV) and withdrawal via the umbilical artery (or peripheral arterial line). This method is preferred when volume shifts during simple exchange might cause or aggravate myocardial insufficiency (eg, hydrops fetalis). Two operators are needed; one to perform the infusion and the other to handle the withdrawal.
1. **Perform steps 1–6** as in a simple 2-volume ET. In addition, perform umbilical artery catheterization (Chapter 28) or peripheral arterial line insertion (Chapter 27). Confirm the blood product parameters (see step V.A.9 above).

Table 34–1. ALIQUOTS USUALLY USED IN NEONATAL EXCHANGE TRANSFUSION

Infant Weight	Aliquot (mL)
>3 kg	20
2–3 kg	15
1–2 kg	10
850 g–1 kg	5
<850 g	1–3

2. **Attach the unit of blood to the tubing and stopcocks attached to the umbilical vein catheter or peripheral intravenous line.** The umbilical catheter may be left in place after the ET to monitor central venous pressure.
 3. **The tubing and the stopcocks of the second setup** are attached to the umbilical artery catheter and to a sterile plastic bag for discarding the exchanged blood.
 4. **If isovolumetric exchange is being performed because of cardiac failure,** the central venous pressure can be determined via the umbilical vein catheter placed in the inferior vena cava above the diaphragm.
- C. Partial exchange transfusion** is performed in the same manner as DVET. If a partial exchange is for polycythemia (using normal saline) or for anemia (using packed RBCs), the following formulas can be used to determine the volume of the transfusion. (*Note:* Estimated blood volume is 80 mL/kg for term and 95 mL/kg for preterm.)

1. To calculate volume to exchange for polycythemia:

$$\text{Volume of exchange (mL)} = \frac{\text{Estimated blood volume (mL / kg)} \times \text{Weight (kg)} \times (\text{Observed Hct} - \text{Desired Hct})}{\text{Observed Hct}}$$

2. To calculate volume to exchange for anemia:

$$\text{Volume of exchange (mL)} = \frac{\text{Estimated blood volume (mL / kg)} \times \text{Weight (kg)} \times (\text{Desired Hct} - \text{Observed Hct})}{\text{Packed RBC Hct} - \text{Observed Hct}}$$

- D. Isovolumetric partial exchange transfusion** with packed RBCs is the best procedure for severe hydrops fetalis.
- E. Ancillary procedures**
1. **Laboratory studies.** Blood should be obtained for laboratory studies before and after ET.
 - a. **Blood chemistries:** Total calcium, sodium, potassium, chloride, pH, PaCO₂, acid-base status, bicarbonate, and serum glucose.
 - b. **Hematologic studies:** Hct, platelet count, white blood cell count, and differential count. Blood for retyping and cross-matching after exchange is often requested by the blood bank to verify typing and re-cross-matching and for study of transfusion reaction, if needed.
 2. **Administration of calcium gluconate.** The CPD buffer in stored blood binds calcium and transiently lowers ionized calcium levels. Treatment of suspected hypocalcemia in patients receiving transfusions is *controversial*. Some physicians routinely administer 1 to 2 mL of 10% calcium gluconate by slow infusion

after 100 to 200 mL of exchange donor blood. Others maintain that this treatment has no therapeutic effect unless hypocalcemia is documented by electrocardiogram showing a change in the QT interval. Cochrane review states the following: “Due to very low quality of evidence available, it is difficult to support or reject the continual use of prophylactic intravenous calcium in newborn infants receiving exchange blood transfusion.”

3. **Monitor serum bilirubin levels after transfusion at 2, 4, and 6 hours and then at 6-hour intervals.** A rebound of bilirubin level is expected 2 to 4 hours after the ET and is more common in hemolytic disease of the newborn as the breakdown of the remaining innate sensitized RBCs will continue.
 4. **Re-medication.** Patients receiving antibiotics or anticonvulsants need to be re-medicated. Determination of drug levels after ET is advisable because the percentage of lost drug levels is variable.
 5. **Antibiotic prophylaxis after the transfusion should be considered on an individual basis.** Infection is uncommon but is the most frequent complication.
 6. **Delay feedings for at least 24 hours** after completion to observe the infant for the possibility of a post-ET ileus.
- VI. **Complications. Mortality risk is approximately 0.5%.**
- A. **Infection.** Bacteremia (usually caused by a *Staphylococcus* organism), hepatitis, CMV, malaria, and HIV have been reported.
 - B. **Vascular complications.** Clot or air embolism, vasospasm of the lower limbs, thrombosis, and infarction of major organs may occur. Portal vein thrombosis can occur.
 - C. **Cardiac arrhythmias,** arrest, and volume overload can occur.
 - D. **Coagulopathies** may result from thrombocytopenia or diminished coagulation factors. Platelets may decrease by >50% after a DVET. Disseminated intravascular coagulation and bleeding can occur.
 - E. **Electrolyte abnormalities.** Hyperkalemia, hypernatremia, hyperglycemia, hypercalcemia or hypocalcemia, and hypomagnesemia can occur. **Hypoglycemia** is especially likely in infants of diabetic mothers and in those with erythroblastosis fetalis because of islet cell hyperplasia and hyperinsulinism. Rebound hypoglycemia may result in these infants in response to the concentrated glucose (300 mg/dL) contained in CPD donor blood.
 - F. **Metabolic acidosis.** Metabolic acidosis from stored donor blood (secondary to the acid load) occurs less often in CPD blood.
 - G. **Metabolic alkalosis.** Metabolic alkalosis may occur as a result of delayed clearing of citrate preservative from the donated blood by the liver.
 - H. **Necrotizing enterocolitis.** An increased incidence of NEC after exchange transfusion has been reported. It is thought to occur from ischemic injury to the gastrointestinal tract possibly from larger aliquots of blood being used and how quickly the exchange of blood is. For this reason, the umbilical vein catheter should be removed after the procedure unless central venous pressure monitoring is required.
 - I. **Anemia or polycythemia can occur.**
 - J. **Feeding intolerance.**
 - K. **Mortality risk** is approximately 0.5%.
 - L. **Miscellaneous:** Hypothermia, hyperthermia, graft-versus-host disease, apnea and bradycardia, hypotension, hypertension.

35 Gastric and Postpyloric Tube Placement

Gastric tube placement involves placing a tube through the nose (nasogastric [NG]) or mouth (orogastric [OG]) into the stomach. In a **postpyloric (sometimes referred to as transpyloric) tube placement**, a tube is inserted through the nose or mouth through the pylorus into the small bowel (duodenum or jejunum).

GASTRIC TUBE PLACEMENT

I. Indications

A. To perform enteric feeding in the following situations:

- 1. High respiratory rate.** Enteric feedings are used at some centers if the respiratory rate is >60 breaths/min to reduce the risk of aspiration pneumonia (*controversial*).
- 2. Nutritional support in premature infants** who may have immature sucking and swallow mechanisms that normally develop after 32 weeks.
- 3. Neurologic disease** that impairs the sucking reflex or the infant's ability to feed. An abnormal gag reflex is also an indication for a gastric tube.
- 4. Insufficient oral intake.**

B. Gastric decompression in infants with necrotizing enterocolitis (NEC), bowel obstruction, congenital diaphragmatic hernia, intestinal malformations, or ileus.

C. Administration of medications. Consult a pharmacist for medications that are administered into the stomach.

D. When a postpyloric tube is placed, a gastric tube is needed to empty gastric contents and administer medications.

E. Analysis of gastric contents.

- #### II. Equipment.
- Infant feeding single-lumen tube (3.5 or 5F if <1000 g or 5–8F if ≥ 1000 g), dual-lumen vented Replogle tube for decompression (6, 8, or 10F; **Note:** tubes come with and without stylets; stylet use is **not recommended** in neonatal population), stethoscope, sterile water (to lubricate the tube), syringes (10–20 mL), 1/2-inch adhesive tape, benzoin, gloves, suctioning equipment, cardiac monitor, pulse oximeter, stethoscope, pH paper, and bag-and-mask ventilation with 100% oxygen (in case of emergency). Strongly recommended is a colorimetric device (eg, Kangaroo CO₂ Detector; Covidien, Mansfield, MA) or capnograph to help confirm the position of the tube by absence of carbon dioxide (CO₂) within the tube.

III. Procedure

A. Monitor heart rate and respiratory function throughout the procedure. Place the infant in the supine position, with the head of the bed elevated. The infant can be swaddled to provide comfort.

B. There are several methods of estimating gastric tube insertion length:

- 1. Orogastric tube insertion in very low birthweight infants.** Table 35–1 provides OG guidelines for infants <1500 g.
- 2. NEX method.** This method measures from the nose to the ear to the xiphoid (NEX) process. This method has been used for years but may misplace tubes, usually in the esophagus (up to 21%). This method is no longer recommended.
- 3. Age-related/height-based method.** In the age-related/height-based (ARHB) method, heights in age groups are used; this method requires multiple calculations that are time consuming and may lead to errors.

a. Less than 1 month of age: nasogastric only

- 1. Nasogastric tube insertion length (cm) = $1.950 \text{ cm} + 0.372 \times (\text{infant's length in centimeters})$**

Table 35–1. GUIDELINES FOR MINIMUM OROGASTRIC TUBE INSERTION LENGTH TO PROVIDE ADEQUATE INTRAGASTRIC POSITIONING IN VERY LOW BIRTHWEIGHT INFANTS

Weight (g)	Insertion Length (cm)
<750	13
750–999	15
1000–1249	16
1250–1500	17

Data from Gallaher KJ, Cashwell S, Hall V, Lowe W, et al: Orogastric tube insertion length in very low birth weight infants, *J Perinatol.* 1993 Mar-Apr;13(2):128-131.

- b. **Greater than 1 month of age (if >44.5 cm in length)**
 - i. **Orogastric tube** insertion distance = $13.3 \text{ cm} + 0.19 \times (\text{infant's length in centimeters})$
 - ii. **Nasogastric tube** insertion distance = $14.8 \text{ cm} + 0.19 \times (\text{infant's length in centimeters})$
4. **Nose/ear/mid-umbilicus for nasogastric/orogastric tubes.** In general, the nose/ear/mid-umbilicus (NEMU) method is considered to be the safest, most accurate, and most recommended method to use. Measure the distance from the tip of the nose (for nasogastric) or corner of the mouth (orogastric) to the bottom of the ear (earlobe) to the mid-umbilicus (distance halfway between the xiphoid process and umbilicus). This measurement, compared to measuring to the xiphoid process (NEX process) or umbilicus, has been shown to be the **most accurate**.
- C. **Mark the length on the tube.** Measure based on choice of the preceding calculations and lubricate the tube by moistening the end of the tube with sterile water. Note that smaller tubes (eg, 3.5F) clog easily.
- D. **Pain management.** Consider nonpharmacologic methods (see page 215).
- E. **The tube can be placed in 1 of 2 insertion points, oral or nasal.** There is controversy on whether the tubes should be placed orally or nasally. Nasal tubes are more secure and less prone to movement but may partially obstruct breathing. A Cochrane review (2013) states that there are insufficient data to support the use of one over the other in preterm or low birthweight infants.
 1. **Many centers preferentially use nasogastric tubes because they do not limit breast or bottle feeds. Do not use nasal insertion** with nasal trauma, recent esophageal surgery, choanal atresia, nasal prong continuous positive airway pressure, or significant respiratory distress. In these cases, the oral route is preferred.
 2. **Nasal insertion.** Avoid NG in very low birthweight infants because of increased incidence of respiratory compromise.
 - a. **Check nostrils for patency.** Moisten end of tube with sterile water.
 - b. **Flex the neck, push the nose up,** and insert the tube, directing it straight back (toward the occiput).
 - c. **Tilt head slightly forward.** Advance the tube to the desired distance.
 3. **Oral insertion is less traumatic and does not usually impact respiration.** Push the tongue down with a tongue depressor and pass the tube into the oropharynx. Slowly advance the tube the desired distance. It is easier for the infant to dislodge and may limit breast and bottle feeding.
- F. **Do not push against any resistance (perforation potential).**
- G. **Continue to observe the infant for respiratory distress and/or bradycardia.** A brief period of coughing or gagging and a decrease in heart rate are considered normal. Stop procedure immediately until the patient appears unstable.

H. Determine the location of the tube after placed and also before each use. Never instill materials into the tube until the position is verified. The optimum position for a gastric tube is within the body of the stomach. Error rates for malposition are common and can range from 21% to 56%. If misplaced in the esophagus or lungs, the infant can have aspiration, apnea, bradycardia, and desaturations. If placed near the pyloric junction and duodenum, the infant can manifest diarrhea, poor weight gain, or malabsorption. See Figure 35–1 for algorithm for performing and verifying optimal placement of gastric enteral tubes.

1. **Radiologic verification** is considered the **gold standard** and is recommended at the time of initial tube placement or tube change. It should provide 100% accuracy in determining the location. **Note:** An abnormally positioned NG/OG feeding tube on a radiograph may suggest an underlying serious condition that needs to be ruled out.
2. **Point-of-care ultrasound for verification.** This method to confirm correct placement of the gastric tube has been used in adults. A small study in neonates showed it is not a reliable technique. Further studies are needed to confirm the efficacy of using POCUS in neonates to verify GT positioning.
3. **Nonradiologic verification** can be done by the following methods. A recent study showed that for verification of tube placement, the most frequently used method was aspiration with inspection, followed by auscultation, assessment and verification of measurement marking, pH assessment, and, finally, radiographic study.
 - a. **Measurement marking.** Because the tube is commonly marked at the nose (NG tube) or lip (OG tube), check to see if the marking has moved as a way of verifying the tube is in the correct place. Unfortunately, this method is prone to error because the tube can migrate or coil.
 - b. **Auscultation** is not reliable as the only method to verify placement and should be used along with other assessment methods. While listening with the stethoscope over the stomach, inject 1 to 2 mL of air into the tube with a syringe and listen for a rush of air (swoosh sound) as the air enters the stomach (also known as the “whoosh test”). This may be unreliable because a rush of air can occur when the tip is in the distal esophagus and respiratory tract air can be heard by auscultation. It is difficult to distinguish from lung, esophageal, or abdominal sounds. This method is no longer recommended.
 - c. **Visual inspection of the aspirate** has not been reliable when used alone because gastric contents can vary in color. It can be affected by the time of the last feeding. Respiratory and gastric aspirates may be similar in color; therefore, the result may be misinterpreted. If used with pH assessment, it may be more beneficial.
 - i. **Normal gastric aspirate:** clear, tan, off white, pale yellow.
 - ii. **Intestinal aspirate:** green, greenish brown, golden yellow, bile stained.
 - iii. **Pleural space aspirate:** pale white or yellow
 - iv. **Tracheal aspirate:** clear, tan, off white, straw colored.
 - v. **Perforation of esophagus, stomach:** grossly bloody aspirate.
 - d. **Capnography and capnometry.** Both use CO₂ detection technology to determine if the tube is in the respiratory tract or anywhere in the gastrointestinal (GI) tract (note that the exact location in GI tract not known).
 - i. **Capnography** detects a CO₂ waveform that is emitted from the enteral tube. Absence of a CO₂ waveform suggests placement in the GI tract, and presence of a CO₂ waveform suggests placement in the trachea and distal airways.
 - ii. **Capnometry** uses an end-tidal CO₂ detecting device that is attached to the end of the tube. If there is CO₂, a color change occurs, indicating the tube is placed incorrectly in the respiratory tract.
 - e. **Gastric aspirate pH testing using pH paper or a pH meter** (pH paper is preferred and recommended (per National Patient Safety Agency) over litmus

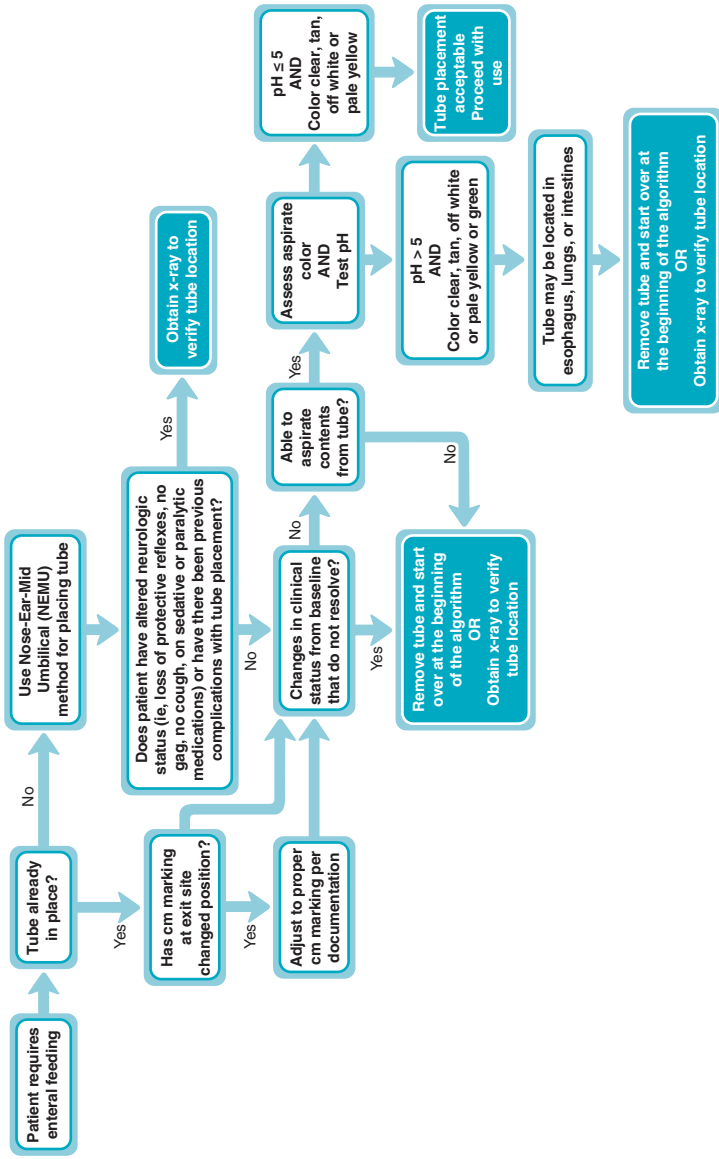

FIGURE 35-1. Algorithm for performing and verifying optimal placement of gastric enteral tubes. (Adapted with permission from Clifford P, Heimall L, Brittingham L, et al: *Following the Evidence Enteral Tube Placement and Verification in Neonates and Young Children*, J Perinat Neonatal Nurs, 2015 Apr-Jun;29(2):149-161.)

paper. Gastric fluid usually has a pH ≤ 5 to 5.55, and the intestine has a pH of ≥ 6 . A pH aspirate < 5 suggests gastric placement. If the pH is > 6 , then the placement of a gastric tube should be questioned. The mean values of pH may be affected by feeding status (pH of formula is 6.6 and pH of breast milk is 7–7.4), which may raise the pH, but studies found it was not statistically significant. Medications such as acid-blocking agents were not found to alter the pH aspirates. **Note:** Swallowed amniotic fluid may transiently raise gastric pH, and some preterm infants have a decreased ability to produce gastric hydrochloride. Gastric pH at birth is high (pH 6–8) because of alkaline amniotic fluid. Pulmonary and esophageal aspirates can have a high pH (tracheal fluid pH is usually 6 or higher). Gastric fluid has a much lower pH than respiratory or intestinal fluid. To differentiate intestinal and respiratory fluid, pH is less effective because both have a high pH.

f. Testing aspirate for bilirubin, pepsin, and trypsin can help identify site of tube placement but is usually not practical for routine procedures.

i. Gastric aspirate testing: bilirubin < 5 , high pepsin, low trypsin. A bilirubin < 5 mg/dL, pepsin ≥ 100 mcg/mL, and trypsin ≤ 30 mcg/mL indicate gastric placement.

ii. Intestinal aspirate testing: bilirubin > 5 , low pepsin, high trypsin.

iii. Respiratory aspirate: little or no trypsin or pepsin.

g. If the location is still in question, obtain a radiograph. However, this only verifies the location at the exact time of the radiograph. The tube tip should be below T12 for a gastric tube. See Figure 12–12, which demonstrates a nasogastric tube properly positioned in the stomach.

4. It is best to verify placement after insertion, once per shift, before each feeding, and with medication administration. Some recommend radiography to verify placement if planning to initiate enteral feeding or administering medication.

I. Once the tube is verified in the correct position, place that marked area at the lip or nares. Aspirate the gastric contents and secure the tube to the cheek with benzoin and 1/2-inch tape. Another effective method is to place a piece of tape on the upper lip (“moustache tape”) and secure the tube on the upper lip with a small loop and taping again to the moustache tape. For NG tubes, make certain the tube does not press on the nasal ala. For feeding, attach the tube to a syringe. For decompression, connect the tube (preferably a dual-lumen **Replogle tube**) to low continuous suction.

J. When not in use, the tube should be left open in a dependent drainage position below the level of the stomach.

IV. Removal of gastric tube. Disconnect suction (if attached) and pinch gastric tube closed when withdrawing the tube so contents will not spill into the pharynx.

V. Complications

A. Apnea and bradycardia. Usually mediated by a vagal response and resolve without specific treatment.

B. Hypoxia. Always have bag-and-mask ventilation with 100% oxygen available to treat this problem.

C. Misplaced tube. Incorrect placement in trachea, esophagus, eustachian tube, trachea, or oropharynx. Twisting, coiling, or knotting of the tube can occur.

D. Perforation of the esophagus, posterior pharynx, stomach, or duodenum. The tube should never be forced during insertion.

E. Aspiration. If feeding has been initiated in a tube that is accidentally inserted into the lung or if the GI tract is not passing the feedings out of the stomach. Periodically check the residual volumes in the stomach to prevent overdistention and aspiration (see Chapter 59). Any NG or OG tube may increase gastroesophageal reflux and risk of aspiration pneumonia.

F. Nasopharyngeal complications. Irritation, bleeding, infections. Grooved palate with prolonged OG placement.

POSTPYLORIC TUBE PLACEMENT

Postpyloric (transpyloric) tube placement requires a gastric tube for aspiration, drainage, and medication administration. A Cochrane review (2013) found that transpyloric tubes are not recommended in premature infants because there was no evidence of any benefit of transpyloric feeding in preterm infants, with increased adverse effects. Feedings with human milk via transpyloric tubes may reduce apnea and bradycardia in preterm infants with suspected gastroesophageal reflux.

I. Indications

A. Enteric feeding in the following conditions:

1. **Not tolerating gastric feeding** (eg, severe gastroesophageal reflux, persistent emesis).
2. **Infants at risk for aspiration.**
3. **Delayed gastric emptying and other motility disorders.**
4. **Severe gastric distension.**

B. To test duodenal and jejunal contents

C. Postoperative management of duodenal atresia

- ### II. Equipment.
- Weighted infant feeding tube (silastic tubes preferred with or without stylet; 6F <1500 g, 8F >1500 g), stethoscope, sterile water (to lubricate the tube), a syringe (20 mL), 1/2-inch adhesive tape, pH paper, continuous infusion pump and tubing, gloves, suctioning equipment, and bag-and-mask ventilation with 100% oxygen.

III. Procedure

- #### A. Determine insertion length.
- Measure using the ARHB or NEMU method noted for gastric intubation. Add the distance from the designated point to the right lateral costal margin. Mark the point on the tube with tape.
- #### B. Follow initial steps for gastric intubation as noted on page 357.
- Confirm the initial gastric position as previously described.
- #### C. Metoclopramide has been previously recommended to assist placement of the postpyloric feeding tubes.
- Based on reviews, it appears that metoclopramide enhances tube placement.
- #### D. Place infant into a right lateral position.
- With the patient on his or her right side, elevate the head of the bed 30 to 45 degrees. Distend the stomach by injecting 10 mL/kg of air into the gastric tube and close the tube.
- #### E. Insert the tube (lubricated at the tip with sterile water) to the desired length.
- Keep the infant in the right side down position for 1 to 2 hours to allow the weighted tube to migrate into the duodenum.
- #### F. It is essential to place an orogastric/nasogastric tube,
- as described earlier, for aspiration and medication delivery.
- #### G. Check postpyloric tube placement and patency.
1. **The “snap test.”** When air is aspirated, the plunger snaps right back to the tip of the syringe; if no air is aspirated, this means the tube is in the pylorus. Proper placement is characterized by high-pitched crackling sounds and the inability to withdraw air, but many providers consider this an unreliable test.
 2. **Checking the pH and color of the aspirate.** If pH >6 and the color of the aspirate is golden yellow, the tube is probably in the transpyloric position. To further confirm, **check bilirubin** level in the aspirate (a value >5 is seen if tube is in transpyloric position).
- #### H. Confirm placement with a radiograph.
- The tip of the tube should be just beyond the second portion of the duodenum. See Figure 12–13. **Aspirate contents** or initiate tube feeding. **Using bedside ultrasound** is a potential alternative to confirm placement of the transpyloric tube.
- #### I. Flushing the tube with 3 mL of water after each use will limit tube obstruction.
- Avoid flushing tubes with small-caliber syringes (1–5 mL) because they generate high pressure and may rupture tubing.
- #### J. If long-term use is anticipated, consider changing the tube every 2 to 4 weeks or per manufacturer’s recommendations.

- IV. **Removal of tube.** Discontinue the infusion, pinch off the tube, and withdraw slowly. Gastric tube can be left in place or removed as described earlier for gastric tubes.
- V. **Complications.** These are similar to NG/OG tube placement, as noted earlier. Other complications may include:
 - A. **Inability to pass tube beyond pylorus.** Fluoroscopic guidance may be necessary.
 - B. **Aspiration.**
 - C. **Infection.** Local infection or sepsis can occur. Enterocolitis can occur secondary to *Staphylococcus* or NEC.
 - D. **Malabsorption.** Enteral feeds bypass the stomach, leading to fat malabsorption and increased frequency of bowel movements; in addition, some medications may not be absorbed.
 - E. **Rare complications.** Intussusception, pyloric stenosis, enterocutaneous fistula, methemoglobinemia in very premature infants from intestinal obstruction and inflammation induced by the transpyloric tube, pyloric stenosis, bronchopleural fistula, and pneumothorax.

36 Heelstick (Capillary Blood Sampling)

I. Indications

A. **Blood collection,** when only a small sample (1 drop to <1 mL) is needed or when there is difficulty obtaining samples by venipuncture of other sources.

1. **Common capillary blood studies:** Complete blood count (CBC), general chemistry labs, bedside glucose estimation, liver function tests, thyroid levels, bilirubin levels, toxicology/therapeutic drug levels, and newborn metabolic screening.

2. **The following laboratory tests are not recommended by capillary blood sampling:** Coagulation studies, chromosomal analyses, erythrocyte sedimentation rate, immunoglobulin titers, some other, more sophisticated tests, any tests that require a lot of blood.

B. **Capillary blood gas determination** gives satisfactory pH and PCO₂, but not PO₂.

C. **Blood cultures** when venous access or other access is not possible. Sterile technique is required, but heel stick is not the preferred method.

D. **Not recommended for blood sampling in term infants.** Most sources confirm that **venipuncture, not capillary blood sampling,** by a skilled operator is the method of choice for blood sampling in term neonates. Lower pain scores are seen with venipuncture in infants.

II. **Equipment.** Automated self-shielding lancets are preferred in neonates (full-term neonate: incision depth of 1 mm and length of 2.5 mm; preterm neonate: incision depth of 0.85 mm and length of 1.75 mm; see Table 36-1); sterile manual lancets are not recommended but may be used in some units (sizes: 2 mm for <1500 g and 4 mm for >1500 g); capillary collection tube (for rapid hematocrit and bilirubin tests) or appropriate microcollection tubes (if more blood is needed [eg, for chemistry determinations]), preheparinized capillary tubes for blood gas analysis, filter paper card for newborn screening (if appropriate), clay or caps to seal the capillary tube, a warm washcloth with a diaper or heel warming device (eg, a chemically activated packet), antiseptic solution/swabs (alcohol/chlorhexidine swabs); non-sterile or sterile gloves.

Table 36–1. SOME COMMONLY USED AUTOMATED SELF-SHIELDING LANCETS FOR SAMPLE COLLECTION IN NEWBORNS

Device	Infant	Characteristics
Tenderfoot MicroPreemie ^a	<1000 g	Blue: depth 0.65 mm, length 1.40 mm Incision type
Tenderfoot Preemie ^a	Low birthweight, 1000–2500 g	White: depth 0.85 mm, length 1.75 mm Incision type
Tenderfoot Newborn ^a	Birth to 3–6 months, >2500 g	Pink/blue: depth 1.0 mm, length 2.5 mm Incision type
BD Microtainer Quikheel Preemie Lancet ^b	Low birthweight (>1.0 kg and <1.5 kg) premature infants or full term for lower blood volume	Pink: depth 0.85 mm, length 1.75 mm Incision type
BD Microtainer Genie Lancet ^{b,c}	Infant heel sticks for glucose testing	Purple: 1.25 mm × 28 g Puncture type
BD Microtainer Quikheel Infant Lancet ^b	Infants who need high flow, full term with high blood volume needed	Teal: depth 1.0 mm, length 2.5 mm Incision type
babyLance Preemie: BLP ^d	Preemie	Green: depth 0.85 mm Incision type
babyLance Newborn ^d	Newborn	Blue: depth 1.0 mm Incision type
Genteheel Micropreemie ^e	<1000 g	Yellow: depth 0.65 mm, length 1.4 mm Incision type
Genteheel Preemie ^e	Low birthweight, 1000–2500 g	Pink: depth 0.85 mm, length 1.75 mm Incision type
Genteheel Newborn ^e	>2500 g	Green: depth 1.0 mm, length 2.5 mm Incision type

Other devices include: Natus Medical NeatNick; Natus SugarPlum; Sarstedt Safety Heel; and Vitrex Steriheel Baby.

^aAccriva Diagnostics, Bedford, MA.

^bBD, Franklin Lakes, NJ.

^cBD Microtainer Genie Lancets (pink/green/blue) are for finger sticks and not for heel sticks in infants.

^dMediPurpose, Duluth, GA.

^eCardinal Health, Dublin, OH.

III. Procedure

A. Automated self-shielding lancets are preferred in neonates because they are more effective and associated with fewer complications, decreased tissue damage, and in infants with respiratory distress, decreased pain and enhanced cerebral oxygenation. Automated devices cause less hemolysis and less lab value error and provide an exact width and depth of incision. **Manual unshielded lancets** are no longer recommended (unless automated lancets are not available) because they cause more pain, may penetrate too deeply, and are more likely to injure healthcare providers.

Consider vascular puncture if an automatic lancet is not available. There are 2 types of lancet devices: **puncture** and **incision**.

1. **Puncture devices. Automated lancets** (eg, BD Microtainer contact-activated lancet; Becton, Dickinson and Company, Franklin Lakes, NJ) activate only when positioned and pressed against the skin. These puncture the skin by inserting a blade or needle vertically into the tissue. Puncture-style devices typically deliver a single drop of blood and are better for repeated punctures (eg, for glucose testing). SugarPlum glucose lancet is used to draw just one drop of blood to measure glucose.
 2. **Incision devices** (eg, BD Microtainer Quickheel Lancets, Tenderfoot, babyLance, gentleheel). These slice through the capillary beds. These are less painful and require fewer repeat incisions and shorter collection times and are recommended for infant heel sticks. Incision devices deliver a small flow of blood as opposed to a drop and are better to fill Microtainer tubes.
- B. Capillary blood sampling is considered the most common painful of blood drawing methods but the least invasive and safest of those done on neonates.** Sampling is done by puncturing the dermis layer of the skin to access capillaries running through the subcutaneous layer. The sample is a mixture of arterial and venous blood (from arterioles, venules, and capillaries) plus interstitial and intracellular fluids. The proportion of arterial blood is greater than that of venous, due to increased pressure in the arterioles leading into the capillaries. Warming of the puncture site further arterializes the blood. The areas on the bottom surface of the heel contain the best capillary bed. Infant heels are appropriate for blood collection until approximately 6 months to 1 year of age.
- C. Heel stick contraindications.** Local infection, poor perfusion, significant edema, injury of the foot, or any congenital anomaly of the foot.
- D. Infant should be supine.** Some advocate for infant to be on stomach with the limb lower than the level of the heart to increase blood flow.
- E. Warm the heel to increase arterial inflow (arterialization of the puncture site) (controversial).** Apply a heel warmer (specially designed heel pack for single use that is temperature controlled and safer) or warm washcloth with a diaper wrapped around it, or submerge the heel in warm water (need to control the temperature). This prewarming may increase the local blood flow in the capillaries (hyperemia) and reduce the difference between the arterial and venous gas pressures. It is often done when collecting a sample for a blood gas or pH determination. **Note:** Some feel if the heel is well perfused this step is not necessary, and 2 studies note that warming the heel does not increase blood flow or facilitate blood collection (studies not blinded). In another study, topical nitroglycerine did not facilitate blood collection in a heel stick study.
- F. Pain management. Heel sticks are very painful.** Factors that contribute to pain responses are size of needle, gestational age, repeated exposure, squeezing of the heel, severity of illness, and behavioral state of the infant. Pain from a heel stick cannot be completely eliminated. It is best not to squeeze the heel because this is very painful.
1. **The American Academy of Pediatrics recommends nonpharmacologic pain prevention** such as oral sucrose/glucose, breast feeding, kangaroo care, swaddling, rocking, nonnutritive sucking, facilitated tucking, gentle human touch (but no analgesic effects on very premature infants), or other methods. A combination of these methods seems to be more effective in controlling pain. **Multiple sensorial stimuli** (3 Ts: taste, touch, and talk) have been proven to be more effective than just oral sweet solution.
 2. **EMLA (eutectic mixture of lidocaine and prilocaine)** has not been found to be effective in heel stick pain reduction.
 3. **Systemic analgesia (acetaminophen)**, therapeutic touch, music therapy, co-bedding, heel warming, and noninvasive electrical stimulation at acupuncture points are not effective in relieving pain in neonates during a heel stick.

- 4. Automated devices, compared with conventional lancets,** reduce the duration of blood collection, thereby indirectly reducing the pain. Blade-shaped automatic lancets are recommended over needle-shaped lancets. It is preferable to have an automatic lancet with an arched cutting edge. Two studies assessed which automated lancet was the least painful (one study supported the Exxe Safe Blade and the other study found the Tenderfoot device to be superior).
- G. Choose the area of puncture** (Figure 36–1; red area is preferred). Always avoid the end (crown) of the heel (the posterior curvature where the calcaneus bone is close to the skin), as this area is associated with an increased incidence of osteomyelitis. Vary the sites to prevent bruising, tissue injury, and inflammation.
- 1. Recommended site.** There are 2 sites that are recommended based on a study by Blumenfeld et al. One site is medial to the visual line from the middle of the big toe to the posterior of the heel; the other is lateral to a line drawn between the fourth and fifth toes that extends posterior to the heel. These areas avoid the medial and lateral plantar nerve and artery and the medial calcaneal nerves.

FIGURE 36–1. Preferred sites and technique for heel stick in an infant. Use the red shaded area when performing a heel stick. (A) Use of an automated self-retracting lancet (BD Quikheel) for heel stick illustrated. (B) Standard lancet technique is shown. The automated lancet is held at 90 degrees to the axis of the foot and activated. (Reproduced with permission from Gomella LG, Haist SA: Clinician's Pocket Reference, 11th ed. New York, NY: McGraw-Hill Education; 2007.)

2. **Alternative site.** Based on a study by Jain and Rutter, a heel stick can also be safely done on any part of the plantar surface of the heel except the posterior aspect of the heel (standard lancet punctures 2.4 mm; shortest depth of perichondrium is in the center of the heel at 3 to 8 mm). Some sources recommend an alternative site (between the sides of the heel in the plantar area) to be used if the other areas have been used extensively because repeated heel sticks can cause tissue injury and inflammation. **Note:** Be aware of the nerves and arteries in this location. Always avoid the end (crown) of the heel (the posterior curvature where the calcaneus bone is close to the skin), as this area is associated with an increased incidence of osteomyelitis. Vary the sites to prevent bruising, tissue injury, and inflammation.
 3. **Fingertips and toes are not recommended in infants** and are only recommended in children >1 year old.
- H. Wash hands and wear gloves prior to procedure.** Wipe the proposed heel stick area with povidone-iodine, followed by a saline wipe, and let dry for approximately 30 seconds. Some sources advocate using only a 70% alcohol prep pad and letting it dry. Do not use cotton balls. (**Note:** Povidone-iodine can interfere with potassium, bilirubin, phosphorus, and uric acid. If the area is wet with alcohol, hemolysis may occur, altering the results.)
- I. As noted earlier, 2 general devices are available: automated and manual.** Automated devices (spring loaded) are recommended.
1. **Using an automated lancet (preferred method).** Prepare the unit and hold the device either perpendicularly to the skin or at 90 degrees to the long axis of the foot (see Figure 36–1A). Depress the trigger to activate the device and automatically make the puncture. Immediately discard the device.
 2. **Using a standard (not automated) lancet.** Encircle the heel with the palm of your hand and index finger (see Figure 36–1B). Make a quick puncture. Never puncture >2.4 mm to avoid complications. Incision depths recommended:
 - a. <1 kg: 0.65-mm incision depth.
 - b. >1 kg: 0.85-mm incision depth.
 - c. **Term infants:** 1-mm incision depth.
- J. Wipe off the first drop of blood with gauze,** as it is often contaminated with interstitial and intracellular fluid and may have a high potassium level, causing specimen dilution, hemolysis, and clotting. Wiping off the first drop also permits the sample to flow better as platelets may otherwise aggregate at the site. Gently apply pressure to the heel (“tennis racket grip”), hold heel in a dependent position, and place the collection tube at the site of the puncture. Capillary tubes will automatically fill by capillary action; gently “pump” the heel to continue the blood flow to collect drops in a larger tube. Allow time for capillary refill of the heel, and apply pressure so the incision is opened with each pumping maneuver. Do not squeeze, milk, scoop, scrape, or massage the area, as these actions may affect the test results and because squeezing the heel causes much pain.
- K. Seal the end of the capillary tube with clay** (if necessary).
- L. Order of collection/draw. Example using BD Microtainer blood collection tubes.** **Note that this differs from a venipuncture collection sequence.**
1. **Collect the blood gas sample first.** The blood becomes more venous if its collection is delayed. Run the sample promptly, making sure there are no air bubbles.
 2. **Hematology studies should be done next.** If the CBC is delayed, there is an increased chance of erroneous cell counts due to platelet clumping.
 3. **Lastly, take chemistry/toxicology samples.** Use the following order of draw for the specific color of microtainer tubes (minimizes the effect of platelet clumping):
 - a. **Blood gas always first.**
 - b. **Lavender (purple-topped) tubes** (additive: ethylenediaminetetraacetic acid (EDTA): For whole blood hematology (CBC with or without differential, erythrocyte sedimentation rate, reticulocyte count) and others.

- c. **Green-topped tubes** (additive: sodium or lithium heparin): For biochemistry tests that require a heparinized plasma sample such as ammonia, insulin, renin, or aldosterone.
 - d. **Gold-topped tubes** (additive: clot activator and gel for serum separation): For serum determinations in chemistry, such as bilirubin, creatinine, urea, calcium, sodium, potassium, chloride, chemistry panels (eg, liver function tests).
 - e. **Red-topped tube** (no additive): For chemistry testing, serology, blood bank tests, and therapeutic drug and antibiotic levels (eg, phenobarbital, theophylline).
- M. For filter paper newborn screening.** (See Chapter 16.) The paper can be directly applied to the heel, or the blood can be transferred from a capillary tube (without anticoagulants) to the filter paper.
- N. Maintain pressure on the site with a dry sterile gauze pad until the bleeding stops and elevate the foot.** Gauze can be wrapped around the heel and left on to provide hemostasis.
- O. Inaccurate laboratory results.** Relative to venous or arterial sampling, heel stick can alter results:
- 1. **Elevated:** Glucose, potassium, lactate, ionized calcium, hematocrit, white blood cell count, red blood cell count, mean corpuscular volume, mean corpuscular hemoglobin, lactate dehydrogenase, and aspartate aminotransferase.
 - 2. **Decreased:** Platelet counts, total protein, calcium, and electrolytes.
 - 3. **Blood gas values:** Slightly lower pH, slightly higher PCO_2 , and markedly lower PO_2 .
- IV. Complications**
- A. Infectious**
- 1. **Cellulitis.** Risk can be minimized with sterile technique. If present, a culture from the affected area should be obtained and the use of broad-spectrum antibiotics considered.
 - 2. **Osteomyelitis.** Usually occurs in the calcaneus bone. Avoid the posterior curvature of the heel, and do not puncture too deep. If osteomyelitis occurs, tissue should be obtained for culture, and broad-spectrum antibiotics should be started until a specific organism is identified. Infectious disease and orthopedic consultation is usually obtained.
 - 3. **Other infections.** Abscess and perichondritis have been reported.
- B. Scarring of the heel.** Occurs when there have been multiple punctures in the same area. If extensive scarring is present, consider another technique or site for blood collection.
- C. Pain and hypoxemia.** Heel stick related pain can cause declines in hemoglobin oxygen saturation as measured by pulse oximetry.
- D. Calcified nodules.** These can occur because of repetitive punctures but usually disappear by 30 months of age.
- E. Other complications.** Nerve damage, tibial artery laceration (medial aspect of heel), burning of the skin with too hot of water while warming the heel, bleeding, bruising, hematoma, and bone calcification.

37 Laryngeal Mask Airway

The **laryngeal mask airway (LMA)** is an alternative airway device that consists of a soft elliptical mask with an inflatable cuff that is attached to a flexible airway tube. The mask covers the glottis (laryngeal opening), and the inflatable cuff occludes the esophagus. Placement of the LMA is feasible in neonates. A study shows it was successfully placed in <35 seconds in most patients with only 1 attempt with minimal fluctuations in heart rate and oxygen saturation (SaO₂). It is intended for use in babies who weigh >2000 g. The seventh edition of the American Academy of Pediatrics/American Heart Association *Textbook of Neonatal Resuscitation* states: “When you ‘can’t ventilate and can’t intubate,’ a laryngeal mask may provide a successful rescue airway.” The International Liaison Committee on Resuscitation and the European Resuscitation Council recommend that LMA can be used as an alternative to intubation with an ETT in late preterm, term, and infants >2000 g when face mask ventilation is unsuccessful or intubation is not possible. A recent Cochrane review (2018) states: The LMA can achieve effective ventilation during neonatal resuscitation in a time frame consistent with current guidelines. It is more effective than bag-mask ventilation in terms of shorter resuscitation and ventilation times, and less need for endotracheal intubation. Bansal et al in a critical review of the LMA in neonatal resuscitation suggests that the use of the LMA is a feasible and safe alternative to mask ventilation of late preterm and term infants in the DR, but state it is not recommended as initial respiratory support since evidence is still insufficient.

I. Indications

A. Ineffective face mask ventilation in neonates with:

1. **Abnormal facial anatomy** (eg, cleft lip, cleft palate)
2. **Unstable cervical spine** (eg, osteogenesis imperfecta, arthrogyrosis, and trisomy 21)
3. **Upper airway obstruction** (eg, Pierre-Robin sequence, micrognathia, large tongue, redundant tissues, and oral, pharyngeal, or neck tumors)

B. Rescue procedure after failed intubation or intubation not feasible.

C. Short-term mechanical ventilation for procedures in the neonatal intensive care unit.

D. Resuscitation in delivery room.

Use of LMA was found to be a safe alternative to mask ventilation of late preterm and term infants in the delivery suite.

E. Administration of medications (*controversial*).

Medications may leak from the mask and not enter the lungs. The seventh edition American Academy of Pediatrics/American Heart Association *Textbook of Neonatal Resuscitation* states: “There is insufficient evidence to recommend using a laryngeal mask to administer intratracheal medications.” Recent studies have shown that surfactant therapy through the LMA may be effective (results showed a decreased rate of intubation and mechanical ventilation in premature infants with RDS), but since there is not enough sufficient evidence it is not recommended for routine use.

F. Fiberoptic-guided intubation.

LMA in infants undergoing minor elective procedures had clinically significantly fewer perioperative respiratory adverse events (PRAEs) and decreased incidence of major PRAEs than with endotracheal tubes.

- ### II. Equipment.
- There are various LMA devices for use in newborns (eg, LMA Classic, LMA ProSeal, LMA Supreme [LMA North America Inc, San Diego, CA], i-gel supraglottic airway [Intersurgical, Liverpool, NY], Ambu® AuraOnce [Ambu A/S, Ballerup, Denmark], Air-Q disposable laryngeal mask airway [Mercury Medical, Clearwater FL], Shiley™ LMA [Medtronic, USA]). For a basic laryngeal airway design, see Figure 37–1. Appropriate-size LMA: all neonatal LMA are size 1 for infants <5 kg, except Air-Q disposable LMA available size 0.5 for infants with BW <4 kg. Other equipment: water-soluble lubricant, 5-mL syringe, carbon dioxide (CO₂) detector, gloves. Optional: orogastric tube (5 to 6F).

FIGURE 37-1. Basic laryngeal mask airway design.

III. Procedure

- A. **Pain management/premedication.** Because this is usually an emergent procedure, premedication is not necessary in the delivery room or after an acute deterioration in the neonatal intensive care unit. In older children, propofol and midazolam have been used.
- B. **Use size 1 laryngeal mask airway.** Designed for infants >2000 g, but can be used for smaller infants (>1500 g) if needed.
- C. **Wash hands and put on gloves** following standard precautions.
- D. **Inspect the entire laryngeal mask airway device (airway connector, airway tube, inflatable cuff, aperture bar, inflation line, and inflation indication balloon)** to ensure there are no tears, cuts, or kinks.
- E. **Check cuff for leakage by inflating with 2 to 3 mL of air.** Be sure to fully deflate the cuff before insertion.
- F. **If the infant has a distended stomach and you are using a laryngeal mask airway that does not have a gastric port:** Prior to inserting the LMA, place an orogastric tube in the infant and aspirate any air in the stomach.
- G. **Lubricate the back of the mask with a water-soluble lubricant** if needed. Make sure the lubricant does not get near the openings on the inside of the mask.
- H. **Stand as if you were intubating the infant. Position patient on back in sniffing position.** Hold the LMA in the right or left hand.
- I. **With the aperture facing anteriorly, insert the laryngeal mask airway against hard palate and, using your index finger, guide the laryngeal mask airway.** The mask will follow the path of the mouth and palate, mimicking the swallowing of food. Insert until resistance is felt.
- J. **Inflate the mask with 2 to 4 mL of air (do not exceed maximum recommended by manufacturers)** to provide adequate seal (Figure 37-2). The mask will move slightly upward when it is inflated. Remove the syringe.
- K. **Attach a carbon dioxide detector** to airway tube
- L. **Connect the end of tube to bag, T-piece, or ventilator.**
- M. **Give 8 to 10 positive-pressure breaths.** Assess chest movement and breath sounds. One should notice an increase in heart rate, movement of the chest wall, increasing SpO₂, and equal breath sounds when listening to both sides of chest. Confirm the presence of CO₂ on the detector. All of these findings verify that the laryngeal mask is correctly placed.

FIGURE 37-2. Demonstration of correct anatomic positioning of the laryngeal mask airway cuff around laryngeal inlet.

- N. Secure laryngeal mask airway similar to an endotracheal tube.** Grunting and crying when the infant breathes spontaneously through the device is normal. A large leak of air or presence of a bulge in the neck could indicate that the LMA is not properly placed.
- O. Optional:** If there is a gastric drain tube, a size 5- or 6-F lubricated gastric tube can be inserted and the air aspirated out of the stomach. The syringe can be disconnected and left to air.

IV. Complications

- A. Air leak around LMA** may result in ineffective ventilation.
- B. Gastric distention and aspiration.**
- C. Malposition.**
- D. Laryngospasm and bronchospasm.**
- E. Soft tissue trauma of the uvula and epiglottis.**
- F. LMA obstruction of the laryngeal inlet** by a supraglottic mucus plug in a premature infant with tracheoesophageal fistula. Vomiting and regurgitation can occur.
- G. Partial airway obstruction secondary to an improperly placed LMA.**

V. Removal of the laryngeal mask airway

- A. Indications:** Infant has effective spontaneous respirations, or an endotracheal tube can be safely placed.
- B. Procedure:** Suction secretions around the mouth and throat, deflate the cuff, and remove the LMA.

38 Lumbar Puncture (Spinal Tap)

I. Indications

A. Obtain cerebrospinal fluid for the diagnosis of central nervous system disorders such as meningitis/encephalitis.

1. **Infections** that can be diagnosed are bacterial, viral, fungal, and TORCH (toxoplasmosis, other [usually syphilis], rubella, cytomegalovirus, and herpes simplex virus). Meningitis can be present in as many as 23% of cases of neonatal sepsis, and blood cultures can be negative in up to 38% of infants with meningitis.

2. **Initial sepsis workup (controversial)**. If central nervous system (CNS) involvement is suspected or blood cultures are positive, some sources recommend a lumbar puncture (LP). Because signs and symptoms of neonatal meningitis are vague and nonspecific, some clinicians advise that all infants with proven or suspected sepsis undergo LP. The American Academy of Pediatrics (AAP) recommends that an LP be performed in any infant with a positive blood culture, when clinical course or laboratory findings highly suggest sepsis, or in an infant with worsening clinical status on antibiotic therapy. Delay the LP in any infant who is critically ill who will not be able to tolerate the procedure. (Confirm that the antibiotic dosage will cover for meningitis.)

B. **Diagnose an inborn error of metabolism**. Multiple cerebrospinal fluid (CSF) studies exist that can help delineate different inborn errors of metabolism, including but not limited to amino acid analysis for nonketotic hyperglycinemia and CSF lactate-to-pyruvate ratio for mitochondrial disorders.

C. **Drainage of cerebrospinal fluid in communicating hydrocephalus associated with intraventricular hemorrhage**. (Serial LPs for this are *controversial*.) A Cochrane review (2017) found the following: “There was no evidence that repeated removal of CSF via LP, ventricular puncture or from a ventricular reservoir produces any benefit over conservative management in neonates with or at risk for developing post hemorrhagic hydrocephalus in terms of reduction of disability, death or need for placement of a permanent shunt.”

D. **Aid in the diagnosis of intracranial hemorrhage**. CSF studies are indicative but not diagnostic for intracranial hemorrhage. Signs include a large number of red blood cells (RBCs), xanthochromia, increased protein content, and hypoglycorrachia (abnormally low CSF glucose).

E. **Administration of intrathecal medications**. Chemotherapy, antibiotics, anesthetic agents, or contrast material.

F. **Evaluation of antibiotic efficacy in CNS infections by examining CSF fluid**.

G. **Diagnose CNS involvement with leukemia**.

II. **Equipment**. LP kit (usually contains 3–4 sterile specimen tubes; 4 are often necessary); sterile drapes; sterile gauze; 20-, 22-, or 24-gauge, 1.5-inch spinal needle with stylet (**do not use a butterfly needle** as it may introduce skin into the subarachnoid space and form a dermoid cyst); 1% buffered lidocaine and/or topical anesthetic (EMLA [eutectic mixture of lidocaine and prilocaine]); 25- to 27-gauge needle, 1-mL syringe; sterile gloves; mask; gown; hat; and skin disinfectant (10% povidone-iodine solution or other unit-approved type), point-of-care ultrasound.

III. Procedure

A. **Contraindications to lumbar puncture** include increased intracranial pressure (ICP) (risk of CNS herniation), uncorrected bleeding abnormality (thrombocytopenia or bleeding diathesis), overlying skin infection near puncture site, severe cardiorespiratory instability, and lumbosacral abnormalities that interfere with identification of key structures. If significant increased ICP is suspected, consider a magnetic resonance imaging (MRI) of the head. Herniation rarely occurs in the neonate with open cranial sutures but is reported.

B. Pain management

1. **The American Academy of Pediatrics recommends** that topical anesthetics (EMLA) be applied 30 minutes before the procedure. Cochrane review (2017) found 2 individual studies with a statistically significant reduction in pain using EMLA during an LP. An AAP update notes that EMLA may decrease pain during an LP, especially if the infant is given oral sucrose or glucose at the same time. Nonpharmacologic pain management alone, if appropriate, can be used (ie, sucrose with pacifier).
 2. **Lidocaine (buffered with bicarbonate)** 0.5% to 1% can be injected subcutaneously. Warming the lidocaine, using a small-gauge needle, and injecting slowly will help.
 3. **Systemic therapy.** Other recommendations include sedation with a slow intravenous opiate bolus if the infant is intubated; if not intubated, a bolus of midazolam in a term infant can be considered (see Chapter 81).
- C. Use of POCUS for lumbar puncture.** Typically done as a blind stick, with the added difficulty of the small interspinous spaces in neonates, use of bedside ultrasound is recommended since it can be used to identify key landmarks (spinous processes, interspinous spaces, and the terminal end of the conus medullaris). A static technique is used prior to the procedure to help determine the best location for needle insertion and maximum safe depth. Using dynamic guidance, one can see the passage of the needle into the skin. Of the few studies done in young infants, two-thirds showed an improved success rate using ultrasound. See Chapter 44 for technique.
- D. An assistant should restrain the infant in either a lateral decubitus position (Figure 38–1) with the knees and hip flexed toward the chest or in a sitting**

FIGURE 38–1. Positioning and landmarks used for lumbar puncture. The iliac crest (dashed line) marks the approximate level of L4.

position with the legs straightened depending on personal preference. The spine should be flexed to open the interlaminar spaces. The neck should not be flexed because of an increased incidence of airway compromise. An intubated infant must be placed in the lateral decubitus position. Some advocate that if CSF cannot be obtained in the lateral decubitus position, the sitting position should be used. Supplemental oxygen can help prevent hypoxemia. Monitor vital signs and pulse oximetry during the procedure. A recent study found that there was no difference in LP success between the lateral and sitting positions.

- E. **Once the infant is in position, check landmarks** (see Figure 38–1). Palpate the top of iliac crest. The intercrystal line/Tuffier’s line is the line across the top of the superior aspect of the iliac crests and is used to estimate the L4 vertebra. Just below the line is usually the L4–5 interspace. Slide your finger down to the L4 vertebral body. The L4–5 interspace is the preferred site of LP to avoid cord penetration because a neonate’s cord terminates lower than that of older patients. **Use of point-of-care ultrasound** is recommended if the health care provider is properly trained and the equipment is available.
- F. **Prepare materials.** Determine the amount of CSF needed based on the tests desired. Put sterile gloves on, open sterile containers, and have antiseptic solution poured into the plastic well located in the LP kit.
- G. **With sterile gloves on, clean the lumbar area with antiseptic solution, starting at the interspace selected.** Prep in a widening circle, up and over the iliac crest.
- H. **Drape the area with 1 towel under the infant and 1 towel covering everything but the selected interspace.** Keep the infant’s face exposed. Palpate again to find the selected intervertebral space. Keep a finger on the vertebral process above the selected space.
- I. **Insert the needle in the midline with steady pressure**, aiming toward the umbilicus.
 1. **Guidelines for spinal needle depth:** 1 to 1.5 cm in term infant and <1 cm in a preterm; or calculate depth of needle insertion: $0.03 \times$ body length (in centimeters). Advance the needle slowly and then remove the stylet to check for appearance of fluid. The fluid should be clear but may be slightly xanthochromic (common).
 2. **Remove the stylet frequently to keep from going too far and getting a bloody specimen.** Some studies suggest that early stylet removal—including not replacing the stylet after initial dermal penetration—can improve the success rate. Compared with older patients, a “pop” as the ligamentum flavum and dura are penetrated is not usually found. Rotate the needle if no fluid is seen, and **never aspirate with a syringe.**
- J. **Collect 0.5 to 1 mL of cerebrospinal fluid** in each of the necessary sterile specimen tubes by allowing the fluid to drip into the tubes. **CSF white blood cell (WBC) and glucose values can decrease over time after collection;** therefore, send these immediately. For routine CSF examination, send 3 to 4 tubes of CSF in the following recommended order:
 1. **Tube 1.** Gram stain, bacterial culture, and sensitivity testing.
 2. **Tube 2.** Glucose and protein levels. Other metabolic testing if desired.
 3. **Tube 3.** Cell count and differential.
 4. **Tube 4.** Optional/other studies. Rapid antigen tests for specific pathogens (eg, group B *Streptococcus*) or polymerase chain reaction (PCR) or reverse transcriptase PCR (eg, herpes, enterovirus), viral cultures, CSF metabolic studies.
- K. **If treating communicating hydrocephalus with intraventricular hemorrhage**, remove 10 to 15 mL/kg of CSF.
- L. **If a bloody specimen is obtained in the first tube:**
 1. **Observe for clearing in subsequent tubes.** An RBC count on the first and last tubes helps determine if the tap was traumatic (usually puncture of the epidural venous plexus on the posterior surface of the vertebral body) by comparing the difference in the number of RBCs/mm³. **Note:** Adjustment of WBC counts in a traumatic LP does not aid in the diagnosis of meningitis. A recent study found that for every 1000 CSF RBCs/mm³, the CSF protein increased by 1.1 mg/dL.

Table 38–1. NORMAL CEREBROSPINAL FLUID VALUES IN NEONATOLOGY

	WBC (mm ³)	Protein (mg/dL)	Glucose (mg/dL)
Term	0–32 (mean 61% PMN)	20–170	34–119
Preterm (970–2500 g)	0–29 (mean 57% PMN)	65–170	24–63
VLBW (550–1500 g)	0–44 (range 0%–66% PMN)	45–370	29–217

PMN, polymorphonuclear neutrophils; VLBW, very low birthweight.

Data from Rodriguez AF, Kaplan SL, Mason EO Jr. Cerebrospinal fluid values in the very low birth weight infant. *J Pediatr*. 1990;116(6):971–974; Sarff LD, Platt LH, McCracken GH Jr. Cerebrospinal fluid evaluation in neonates: comparison of high-risk infants with and without meningitis. *J Pediatr*. 1976;88(3):473–477; and Martin-Ancel A, Garcia-Alix A, Salas S, et al. Cerebrospinal fluid leucocyte counts in healthy neonates. *Arch Dis Child Fetal Neonatal Ed*. 2006;91(5):F357–F358.

2. If blood does not clear, but forms clots, a blood vessel was probably punctured.

3. If blood does not clear and does not clot and there are equal numbers of red blood cells in the first and last tubes, there could be intracranial bleeding.

M. Replace the stylet before removing the needle to prevent trapping the spinal nerve roots. Withdraw the needle. Maintain temporary pressure, and then clean and bandage the site.

N. A repeat tap in 24 to 48 hours may be recommended if the first tap is not diagnostic and the clinical picture is concerning.

IV. Interpretation of cerebrospinal fluid findings. Normal CSF values are listed in Table 38–1. Note that neonatal meningitis can occur with normal CSF values and no single value can exclude meningitis. Specific neonatal values that indicate meningitis are *controversial*. Use caution when interpreting results in the premature infant, because data suggest that results cannot be reliably used to exclude meningitis in this population.

A. Bloody cerebrospinal fluid. See Section III.L.

B. Cerebrospinal fluid protein and white blood cell count. Decreases with increasing postnatal age.

C. Elevated cerebrospinal fluid protein without increased cerebrospinal fluid white blood cell counts. Seen in congenital infections, intracranial hemorrhage, and parameningeal infections (eg, brain abscess).

D. Cerebrospinal fluid white blood cell count. Higher in gram-negative than gram-positive meningitis.

E. Number of bands in cerebrospinal fluid. Does not predict meningitis.

F. Cerebrospinal fluid glucose. A normal CSF value would be 80% of a term infant's blood glucose; 75% if preterm. **A low CSF glucose** has the greatest specificity for meningitis.

G. Generally, cerebrospinal fluid protein is higher in term infants with meningitis when compared to preterm infants. CSF glucose values are lower in term infants with meningitis when compared to preterm infants.

H. Other values suggestive of meningitis

1. Cerebrospinal fluid white blood cell count >20 to 30 cells with predominance of polymorphonuclear leukocytes (for infants >34 weeks with bacterial meningitis, the median WBC is 477/mm³; for infants <34 weeks, median WBC is 110/mm³).

2. Cerebrospinal fluid protein >150 mg/dL in preterm infants, >100 mg/dL in term (96% of infants with meningitis have a CSF protein >90 mg/dL).

3. **Cerebrospinal fluid glucose** <20 mg/dL in preterm infants, <30 mg/dL in term infants.
4. **Meningitis can be present** with normal CSF values.
- I. **Values suggesting meningitis is not present**
 1. **Cerebrospinal fluid white blood cell count (in any infant)** <10 cells/mm³.
 2. **Cerebrospinal fluid protein in term infants <100 mg/dL.** With preterm infants, it varies with gestational age.
 3. **Age-specific normal mean protein values:** 0–14 days, 79 mg/dL; 15–28 days, 69 mg/dL; 29–42 days, 58 mg/dL.
- V. **Complications.** There is no evidence that LP-related headache occurs in infants.
 - A. **Contamination of cerebrospinal fluid specimen with blood.** (See Section III.L.)
 - B. **Infection.** Sterile technique reduces risk. Bacteremia may result if a blood vessel is punctured after passage through contaminated CSF. Meningitis can occur if LP is performed during bacteremia. Abscesses (spinal and epidural) and vertebral osteomyelitis are rare.
 - C. **Intraspinal epidermoid tumor.** Results from LP with a needle without a stylet, causing the displacement of a “plug” of epithelial tissue into the dura. The incidence of traumatic LP is not reduced by the use of a needle without a stylet. Early stylet removal, however, can be recommended (see Section III.I.2).
 - D. **Herniation of cerebral tissue through the foramen magnum.** Uncommon in neonates because of the open fontanelle.
 - E. **Spinal cord and nerve damage.** To avoid this complication, use the L4–5 interspace. Between 25 and 40 weeks’ gestation, the spinal cord terminates between the second and fourth lumbar vertebrae. After 2 months postterm, the cord is in the normal adult position (T12–L3).
 - F. **Intramedullary hemorrhage/intratubular hemorrhage resulting in paraplegia.** It is important to consider the location of the conus medullaris in a preterm infant. An infant developed paraplegia following an LP because of an **intratumoral hemorrhage** from a congenital neuroblastoma.
 - G. **Bleeding/hematoma.** Spinal epidural hematoma, intracranial or spinal subdural hematoma, and intracranial or spinal subarachnoid hematoma have all been reported.
 - H. **Cerebrospinal fluid leakage into epidural space.**
 - I. **Apnea and bradycardia.** Can occur from respiratory compromise caused by the infant being held too tightly during the procedure.
 - J. **Hypoxemia.** Commonly seen; increasing oxygen before or during the procedure may help.
 - K. **Cardiopulmonary arrest** (rare).

39 Ostomy Care

- I. **Indications.** A variety of surgical procedures may require an **ostomy**, a **temporary or permanent artificial opening in the intestine (enterostomy)** or **urinary tract (urostomy)**. An ostomy is performed for gastrointestinal or urinary diversion. Ostomies in the neonatal intensive care unit are most commonly intestinal for the management of necrotizing enterocolitis (NEC), anorectal malformations, meconium ileus, Hirschsprung disease, volvulus, and intestinal atresias, and these disease entities are discussed elsewhere in this book. A **gastrostomy (surgical opening in the stomach)** may be necessary for feeding or decompression in a variety of conditions, such as the inability to swallow (neurologic or congenital anomalies), esophageal abnormalities,

and prolonged poor oral feeding. Urinary diversions are sometimes performed. This chapter will only discuss ostomy care in gastrointestinal diversions since they are the more common in neonates.

II. Ostomy classification

- A. **Ileostomy.** Stoma opening from the ileum used for NEC, intestinal malrotation or volvulus, and small bowel atresia or stenosis.
- B. **Colostomy.** Stoma opening from the colon used for NEC, Hirschsprung disease, malrotation or volvulus, imperforate anus, and colonic atresia.
- C. **Mucous fistula.** Distal nonfunctioning limb of intestine secured flush to skin with a mucocutaneous anastomosis.
- D. **Hartman pouch.** Distal intestine is left in the abdominal cavity rather than removed or secured as mucous fistula, allowing reconnection to stoma at later date.
- E. **Double-barrel stoma.** Loop of bowel is completely divided and 2 ends brought out as stomas to abdominal surface. Skin and fascia are closed between ends to provide separation of stomas.
- F. **End ostomy.** Intestine is completely divided. The functioning proximal end is everted, elevated above skin, and secured circumferentially.
- G. **Loop ostomy.** The intestine is incompletely divided with an opening at the antimesenteric side, while leaving the mesenteric side intact. This is used when temporary diversion or minimal surgical procedure is needed and not performed as often as end ostomy.
- H. **Gastrostomy.** Surgical opening into the stomach, where a gastrostomy tube is inserted into the opening for nutritional support, medications, or gastrointestinal decompression. It can also be placed by interventional radiology in a less invasive way.
- I. **Urostomy.** Opening made to divert urine from the urinary tract to the outside of the body through an intestinal stoma. Rare in the neonate.
- J. **Vesicostomy.** Surgical opening from the bladder to the skin for urinary diversion. More common in neonate (posterior urethral valves, neurogenic bladder).

III. Equipment

- A. **Ostomy.** Ostomy bag or pouch (1-piece or 2-piece system), skin barrier wafer, skin preparation agents, sterile water, gauze pads, petroleum gauze, and gloves. Products that improve security of pouch include plasticizing or liquid skin sealants (use on intact or damaged skin), skin barrier paste (protect exposed skin), adhesive agents (improve adherence), and skin barrier powder (dusted onto denuded skin to form protective crust).
- B. **Gastrostomy tube.** 12- to 14-F balloon or mushroom gastrostomy tube. Silicone is preferred over latex skin barrier.

IV. Procedures

A. Ileostomy and colostomy

1. Postoperative ileostomy and colostomy care

- a. **No bag is applied for first 24 to 48 hours postoperative** due to minimal stool production.
 - b. **Apply petrolatum gauze to stoma** to maintain moisture until first stool output appears. (When attaching pouch, remove residual petroleum because it will interfere with adherence.)
 - c. **Measure effluent output.** Volume >2 mL/kg/h should be replaced with $1/2$ normal saline. Some institutions add 10 to 20 mEq of potassium chloride per liter.
2. **Changing ostomy bags.** Not a sterile procedure, but regular hand washing and clean gloves are important. Goals are containment of stool/odor and protection of the peristomal skin. Minimize skin sealants, adhesives, and adhesive removers in premature infants due to more permeable skin.
 - a. **Empty bag** and carefully remove from skin.

- b. **Clean skin and stoma with warm water and dry thoroughly.** Inspect stoma and peristomal skin. Mild bleeding of the stoma is common with cleaning. Soap is not recommended.
- c. **Measure stoma at base using stoma-measuring guide or template.** Cut appropriate-size hole (usually 2–3 mm larger than stoma) in soft silicone-bordered dressing or wafer for bag; do not constrict stoma, but ensure that the skin is covered by the appliance.
- d. **Prepare skin for wafer application.** If there is no skin compromise, apply skin sealant to surface area. Apply stoma adhesive paste around stoma for better adherence. Apply skin barrier powder to denuded skin to form protective crust.
- e. **Position wafer on skin around stoma** and mold to contour of skin.
- f. **Adhere closed-ended ostomy bag** or pouch to wafer.
- g. **Position bag in lateral position** to allow for easy drainage.
- h. **Empty bag regularly** when one-third to one-half full. Change bag with any evidence of leaking.

B. Gastrostomy tubes

1. Types of gastrostomy tubes

- a. **Balloon tip.** Initial placement requires abdominal surgery. Tube has a retention balloon on distal end, similar to indwelling urinary catheter.
- b. **Mushroom tip** portion creates resistance to tube displacement.
- c. **Percutaneous endoscopic gastrostomy tube.** Placed by endoscopy. Tube has internal bumper secured against abdominal mucosa and external bumper to stabilize the tube.
- d. **Low-profile gastrostomy (“button”).** Replaces original gastrostomy tube once the stoma tract has matured 6 to 8 weeks. Access device is flush to the skin.

2. Care of all gastrostomy tubes

- a. **Flush tubing every 4 hours** during continuous feedings or before and after intermittent feedings with at least 3 mL of warm water.
- b. **Give only 1 medication at a time** and flush between medications.
- c. **Assess site daily** for breakdown, warmth, redness, edema, purulent drainage, leakage, foul odor, or pain.
- d. **Clean gastrostomy tube site** with warm water and mild soap to remove drainage or crusting. Dry skin thoroughly. Site should be kept clean and dry.
- e. **Do not use hydrogen peroxide** to clean site.

V. Complications

A. Ileostomy and colostomy.

Consider consultation with an ostomy nurse specialist for persistent dermatitis or ostomy issues.

1. **Peristomal skin breakdown.** Common problem as small bowel effluent contains a high concentration of digestive enzymes.
 - a. **Careful cleansing** of the stoma and surrounding skin requires gentle technique to avoid abrasions.
 - b. **To minimize contact dermatitis** from digestive fluids, fecal materials, or adhesives, select a correctly sized bagging system to minimize skin exposure.
 - c. **Use protective skin products** (see earlier) to further prevent contact between skin and ostomy output.
2. **Excessive output may cause dehydration and/or electrolyte imbalance.** Daily liquid output is normally 10 to 15 mL/kg; ileostomy output is usually greater than colostomy.
 - a. **Replace excessive output with appropriate fluids (1/2 normal saline).** Some institutions add 10 to 20 mEq of potassium chloride per liter to the replacement fluids or supplement potassium in the daily fluids.
 - b. **Malabsorption.** A risk with surgical loss of overall small intestine length.

- c. **Diarrhea** secondary to infectious agents or osmotic enteral loads is a constant threat. Replace fluid losses intravenously and evaluate electrolyte balance.
 - d. **Management.** May involve changes in enteral feeds such as continuous feeds or elemental formulas to improve absorption or tolerance. Probiotics (controversial) may improve gut flora. Cholestyramine may reduce diarrhea related to short gut and excessive bile acids.
 3. **If dermatitis is suspected (contact, fungal, or otherwise), change bag and barrier every 24 to 48 hours to reassess for further treatment.** Fungal skin infections may appear in the form of pustules or papules. Apply antifungal (eg, nystatin) powder to area before applying skin barrier wafer and bag.
 4. **Bleeding.** A small amount of blood from the stoma tissue itself after cleaning is normal. Notify pediatric surgeon about excessive bleeding or blood coming from lumen of the stoma.
 5. **Peristomal hernia.** A defect in abdominal fascia that allows intestine to bulge into peristomal area. Surgical intervention will be necessary if hernia is incarcerated.
 6. **Stomal stenosis.** An impairment of drainage due to narrowing or contraction of stoma tissue at the skin or subcutaneous fascial level; may require revision.
 7. **Retraction of a stoma.** Stoma tissue being pulled below skin level. Surgical reevaluation is suggested. Adequate bag adherence can be challenging if the stoma cannot be revised.
 8. **Necrosis of stoma tissue can occur from impaired blood flow.** Stomas are usually moist and pink-red in color. Color changes can occur when infant cries, but should return to normal when infant is calm. A dark maroon or black stoma may indicate necrosis.
 9. **Prolapse is a telescoping of intestine through the stoma beyond skin level.** This requires surgical assessment for perfusion, length, and stoma function. If ischemia or obstruction is suspected, then surgical intervention will be required.
- B. Gastrostomy**
1. **Leaking around tube.** This can result from tube displacement, improper balloon inflation, inadequate tube stabilization, or increased abdominal pressure.
 2. **Skin irritation.** Possible causes include leakage, sutures, and infection. Topical treatments include antifungal powder or ointment, zinc oxide, and skin barrier wafer. Cover site with dry gauze or foam dressing under stabilizer to pull drainage off skin.
 3. **Infection.** Most likely occurs within first 2 weeks after tube placement. Risk factors include skin breakdown, immunosuppressed patient, chronic corticosteroids, and excessive handling/manipulation of tube.
 4. **Granulation tissue formation.** A proliferation of capillaries that present as red, raw, beefy, painful, or bleeding tissue protruding from stoma. Possible causes include moisture, infection, tube not stabilized, and use of hydrogen peroxide. Treatment may include cauterization with silver nitrate. Surgery may also recommend steroid cream until resolved.
 5. **Tube occlusion.** May be caused by inadequate tube flushing, kink in tube, or formula or medication precipitation in tube.
 6. **Accidental removal.** Site can close within 1 to 4 hours. Immediately place appropriate-sized Foley catheter in stoma if tube is removed to maintain patency while the correct tube can be replaced.

40 Paracentesis (Abdominal)

I. Indications

- A. To obtain peritoneal fluid for diagnostic tests** to determine the cause of ascites. **Ascites is an excessive amount of fluid in the peritoneal cavity**, and in the neonate, it is usually urinary, biliary, or chylous. Other causes can occur but are less common.
- 1. Urinary ascites.** Due to perforation of the ureter, renal pelvis, or bladder (often caused by a distal urinary tract obstruction and proximal buildup of pressure). The most common neonatal cause is posterior urethral valves. Rare causes: ureterocele, ureteral or urethral stenosis, persistent cloaca, neurogenic bladder, urogenital sinus, congenital nephrotic syndrome, bladder neck obstruction, and renal vein thrombosis.
 - 2. Biliary ascites.** Due to perforation in the extrahepatic biliary tree (most common site is junction of common bile duct with cystic duct), injury to the bile ducts, or a choledochal cyst.
 - 3. Chylous ascites.** Usually idiopathic. Causes include: congenital chylous ascites (most commonly caused by a malformation of the lymphatic duct causing an obstruction or inadequate drainage of the intraabdominal lymphatic system), “leaky lymphatics,” lymphangiectasia, external compression (malrotation, intussusception, mesenteric cyst, incarcerated hernia), complication following neonatal surgery and others.
 - 4. Hepatocellular ascites.** Can be caused by neonatal hepatitis, viral hepatitis, α_1 -antitrypsin deficiency, congenital hepatic fibrosis, storage disorders, Budd-Chiari syndrome, or hepatic/portal vein thrombosis.
 - 5. Pancreatic ascites.** Usually caused by trauma, infection, anatomical lesions, congenital pancreatic pseudocyst.
 - 6. Gastrointestinal tract causes of ascites.** Any perforation of the gastrointestinal tract: necrotizing enterocolitis (NEC) with perforation/peritonitis, meconium peritonitis, perforation of the Meckel diverticulum, atresia, malrotation, volvulus, gastroschisis, omphalocele, post abdominal surgery, or intussusception. **Peritonitis** in neonates is most commonly associated with gastrointestinal perforations.
 - 7. Infections.** Most commonly congenital (cytomegalovirus [CMV], toxoplasmosis, syphilis, and others) but can also be from fungal (most common *Candida albicans*), viral (parvovirus, enterovirus), or bacterial infections (tuberculosis, salmonella).
 - 8. Inborn errors of metabolism.** Glycogen storage disorders, lysosomal storage disorders, and galactosemia can all cause ascites. Examples include infantile free sialic acid storage disorder (ISSD), Salla disease, GM1 gangliosidosis, Gaucher disease, and α_1 -antitrypsin deficiency.
 - 9. Cardiac abnormalities.** Congestive heart failure, arrhythmias, and right-sided heart obstruction.
 - 10. Chromosomal causes.** Turner syndrome and trisomy 21.
 - 11. Iatrogenic.** Can occur from fluid from central venous catheters or intraperitoneal extravasation of fluids from an umbilical vein catheterization–related perforation, gastric perforation from gastric tubes.
 - 12. Hemoperitoneum (bloody ascites).** Uncommon but can be nontraumatic (hepatoblastoma), secondary to birth trauma (hepatic, splenic, or adrenal), or secondary to a ruptured internal organ. Splenic trauma can be associated with consumptive coagulopathy.

- B. As a therapeutic procedure** to relieve pressure and aid in ventilation in a patient with cardiorespiratory compromise. **Examples include removal of peritoneal fluid from massive ascites or air from a pneumoperitoneum.**
- II. Equipment.** Sterile drapes, sterile gloves, topical disinfectant (eg, povidone-iodine solution), sterile gauze pads, tuberculin syringe, 1% lidocaine (see pain management options later in this chapter [Section III.G]), appropriate sterile collection tubes for fluid, a 5- to 20-mL syringe on a 3-way stopcock, 22- or 24-gauge catheter-over-needle assembly (24 gauge for <2000 g, 22–24 gauge for >2000 g); self-shielding device preferred. Consider the use of bedside ultrasound to guide needle placement.
- III. Procedure**
- A. Contraindications and precautions.** Paracentesis can be done with thrombocytopenia or coagulopathy if corrected before the procedure. Decompress bowel and empty bladder to minimize puncture of organs. Avoid surgical scar sites.
- B. Diagnosis of ascites** is usually done by clinical examination and ultrasound. Ascites is usually obvious on examination (abdominal distention, increasing abdominal girth, increased weight gain, bulging flanks, dullness to percussion, and dilated superficial veins). Most infants are also very edematous. Ascites obvious by clinical examination in a neonate usually indicates a fluid volume of ≥ 200 mL. Ascites not obvious on examination usually means the volume is <100 mL. Point-of-care ultrasound can be used for rapid diagnosis of ascites as it can identify small amounts of free fluid in the abdominal cavity.
- C. Position the infant supine with both legs restrained**, such as with a diaper wrapped around the legs. Slightly elevate the flank side you are not using, so the intestines float up to that side and the fluid becomes more dependent.
- D. Choose the site for paracentesis.** The area between the umbilicus and the pubic bone is not generally used because of the risk of bladder or intestinal perforation. The sites most frequently used are the right and left flanks. A good rule is to draw a line from the umbilicus to the anterior superior iliac spine and plan to use the area two-thirds of the way from the umbilicus to the anterior superior iliac spine (Figure 40–1).

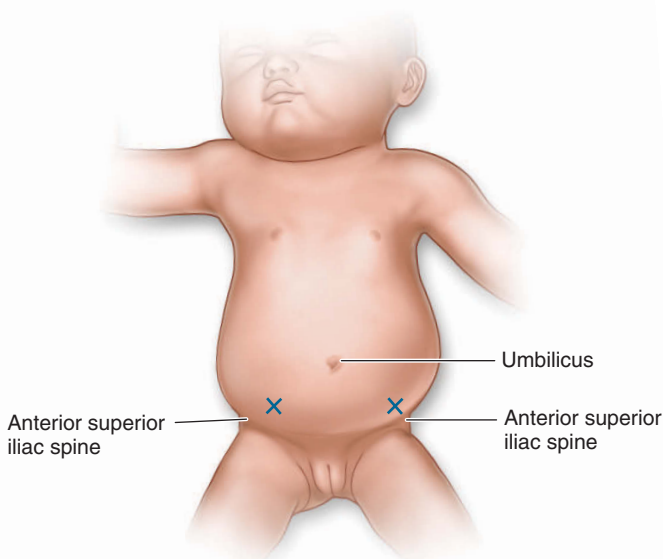

FIGURE 40–1. Recommended sites for abdominal paracentesis noted by the Xs.

- E. Point-of-care ultrasound.** Static technique can be used to localize the intraabdominal fluid and to identify landmarks to determine the optimal location of the needle. Dynamic technique uses real time imaging to show the direct trajectory of the needle to assist with fluid sampling. Use of POCUS in adults has not only helped with the decision for the need of procedure, but it also improves the success rate and lessens the adverse events. Studies evaluating POCUS for paracentesis in pediatrics are lacking (see Chapter 44).
- F. Prepare the area with povidone-iodine in a circular fashion,** starting at the puncture site. Put on sterile gloves, and drape the area. Perform a “time-out” per unit protocol.
- G. Pain management.** Topical anesthetic (eutectic mixture of lidocaine and prilocaine [EMLA]) can be used if the procedure is not emergent, or the area can be infiltrated with a tuberculin needle (skin to peritoneum) with lidocaine 0.5% to 1%. Use non-pharmacologic pain prevention (eg, oral sucrose or breastmilk) if possible.
- H. Connect the 10- to 20-mL syringe to the catheter and needle assembly.** If using an Angiocath with an auto-retractable needle, the syringe is connected to the catheter after the needle is retracted.
- I. Insert the needle at the selected site** (Section III.D). To minimize persistent fluid leak, aim the needle toward the back at a 45-degree angle and use a **Z-track technique**. Displace the cutaneous tissue 0.5 to 1 cm caudad from its original placement over the deeper tissues. Then insert the needle perpendicular to the skin; when the catheter is withdrawn at the end of the procedure, the cutaneous and peritoneal insertion sites will not align.
- J. Advance the needle, gently aspirating until fluid appears in the barrel of the syringe or until a flash is seen in the Angiocath.** Hold the assembly steady and remove the needle. Aspirate the contents slowly with the syringe and stopcock connected to the catheter. It may be necessary to reposition the catheter to obtain an adequate amount of fluid. Once the necessary amount of fluid is taken (usually 5–10 mL for tests and at least 10–15 mL if aiding ventilation), remove the catheter. **If too much fluid is removed, or it is removed too rapidly, hypotension may result.** If there is no fluid, the catheter could be attached to the intestine or in the retroperitoneum; reposition, withdraw, or remove the catheter and retry. If air is aspirated and there was no pneumoperitoneum, it usually means you have entered a hollow viscus and you need to withdraw the needle. If bright red blood is aspirated, it may mean an artery was punctured.
- K. Cover the site with a sterile gauze pad until leakage has stopped.**
- L. Distribute the fluid in containers as needed for testing.** Examples include complete blood count and differential, Gram stain and culture, protein, albumin, triglycerides, cholesterol, bilirubin, glucose, electrolytes, creatinine, inclusion bodies and treponemes, sialic acid, and amylase.
- M. Ascitic fluid analysis and appearance**
- 1. Gross appearance of the fluid.**
 - a. Translucent or straw colored sterile fluid:** Normal fluid.
 - b. Brown with debris:** Fecal matter, bacteria, and white blood cells suggests intestinal perforation. Dark brown fluid may indicate biliary ascites.
 - c. Bloody (hemorrhagic) fluid:** Organ trauma, a ruptured internal organ, or from a traumatic tap.
 - d. Milky appearance (if the infant is being orally fed); otherwise, it is usually straw colored or cloudy:** Suggests chylous ascites.
 - e. Cloudy, turbid color:** Suggests infection.
 - 2. Analysis of fluid:**
 - a. Gram stain positive for bacteria:** Suggests perforation or peritonitis.
 - b. Elevated creatinine level (ascites creatinine > serum creatinine):** Urinary ascites.
 - c. Elevated bilirubin:** Biliary or intestinal leak.

- d. **Elevated triglycerides and lymphocyte predominance (>75%)**: Suggests chylous ascites. Triglyceride levels may be low if the infant has never been fed.
- e. **Elevated amylase and lipase**: Suggests pancreatic ascites.
- f. **Elevated serum-to-ascites albumin gradient >1.1 g/dL**: Suggests hepatocellular disease (hepatitis, α_1 -antitrypsin deficiency).
- g. **Values consistent with infusate (check for glucose)**: Iatrogenic fluid or total parenteral nutrition ascites.
- h. **Inclusion bodies**: Congenital infections (CMV, tuberculosis, toxoplasmosis).
- i. **Treponemes**: Syphilis.
- j. **Sialic acid**: Infantile free sialic acid storage disease.

IV. Complications

- A. **Cardiovascular effects**. Hypotension, tachycardia, and decreased cardiac output can occur. Hypotension can be caused by removing too much fluid or removing fluid too rapidly.
- B. **Infection**. The risk of peritonitis is minimized by using strict sterile technique.
- C. **Perforation of a viscus**. To help prevent perforation, use the shortest needle possible and take careful note of landmarks (see Section III.D). If perforation occurs, broad-spectrum antibiotics may be indicated with close observation for signs of infection. Usually the puncture site heals spontaneously. **Perforation of the bladder** is normally self-limited and requires no specific treatment.
- D. **Persistent peritoneal fluid leak**. The Z-track technique (see Section III.I) helps prevent the persistent leakage of fluid. Leaks may have to be bagged to quantify the volume. Apply pressure over the site or apply a pressure dressing, and monitor the site.
- E. **Pneumoperitoneum**. Observation is usually required (see Figure 12–26 for a radiograph of a pneumoperitoneum).
- F. **Bleeding**. Severe bleeding from the liver or intra-abdominal vessels may require emergency surgery consultation. An **abdominal wall hematoma** can occur but is usually self-limiting. Correct abnormal clotting factors if necessary.
- G. **Scrotal swelling**. Occurs in males with extravasation of ascitic fluid between body wall layers and is usually self-limiting.

41 Pericardiocentesis

I. Indications

- A. **Emergency evacuation** of air or fluid from the pericardial space in the **treatment of cardiac tamponade** (inability of the heart to expand with decreased stroke volume and cardiac output) and hemodynamic instability caused by **pericardial effusion** (accumulation of excess fluid in the pericardial space) or **pneumopericardium** (accumulation of air in pericardial space). Early recognition and intervention are paramount and can be lifesaving because mortality can be high (up to 67%).
 - 1. **Cardiac tamponade secondary to a pericardial effusion**. A rare but life-threatening complication of central venous catheters, including PICC and UVC. Incidence is 1% to 3%. Etiology is unclear, but proposed causes include a direct puncture of a vessel or myocardium (areas of weakness and incomplete muscularization may occur in neonates) by the catheter tip during insertion or delayed perforation secondary to erosion of the cardiac or vascular wall. **Keep a high index of clinical suspicion in a neonate who has a central line and suddenly has**

cardiovascular collapse that does not respond to resuscitation or has resistance to external cardiac compressions and has no air leak by thoracic transillumination. Possible signs include hypotension, tachycardia, decreased/diminished heart signs, poor perfusion, decreasing arterial saturation, decreased heart sounds, increased jugular venous pressure (very difficult to assess in an infant), pulseless electrical activity with a central line, and pulsus paradoxus (a drop in systolic blood pressure >10 mm Hg during inspiration seen on blood pressure waveform and on echocardiography). The **Beck triad** (hypotension, increased jugular venous pressure, and distant heart sounds) is described in cardiac tamponade. Pericardial effusion is more common with lines in the right atrium; the median time to occurrence is 3 days after catheter insertion (range, 0–37 days). A chest radiograph may not be diagnostic; an echocardiogram is, but may delay treatment. **Note:** Pericardial effusion and cardiac tamponade can occur with a central venous catheter in the correct position. It is felt that total parenteral nutrition (especially intralipid) permeates into the interstitium and into the pericardial sac.

2. **Cardiac tamponade secondary to a pneumopericardium.** Rare but very dangerous, and usually occurs with other air leak syndromes, severe lung pathology, a history of vigorous resuscitation, and/or a history of assisted ventilation. **Early recognition (see signs above) and intervention are important. A chest radiograph can be diagnostic with lucency around the cardiac border.** (See Figure 12–22)
 - B. **To obtain pericardial fluid for diagnostic studies** in cases of **pericardial effusion.** Pericardial effusion is rare in neonates and most commonly occurs in a hydropic or septic infant. Other causes include thyroid dysfunction, cardiac and pericardial tumors (intrapericardial mixed germ cell tumor and intrapericardial teratoma have been reported in infants), congenital anomalies (diaphragmatic hernia/evagination, ruptured ventricular diverticulum), postoperative, and idiopathic.
- II. **Equipment.** Antiseptic solution (eg, povidone-iodine solution, chlorhexidine); sterile gloves; gown; sterile drapes; a safety-engineered, 22- or 24-gauge, 1-inch catheter-over-needle assembly; 21- or 23-gauge butterfly needles; extension tubing (if catheter to be left indwelling); 10-mL syringe; 3-way stopcock; lidocaine; underwater seal if the catheter is to be left indwelling; telemetry; fiberoptic light for transillumination (pneumopericardium); portable ultrasound device.
- III. **Procedure. Note:** If a central venous catheter is in place and a pericardial effusion is suspected, stop infusion of fluids into the catheter immediately.
 - A. **Contraindications.** There are no absolute contraindications for this procedure in the case of a cardiac tamponade. For a diagnostic pericardiocentesis, a coagulopathy may be a contraindication.
 - B. **This is a 2- or 3-person procedure.** Three people are preferred, but 2 are able to do it. One will insert the needle, 1 will operate the stopcock, and 1 will monitor telemetry for any changes in the cardiac rhythm during the procedure.
- IV. **Point-of-care ultrasound of the heart. (See Chapter 44.)** Ideally, pericardiocentesis is performed with the help of ultrasound because it can determine the site and angle of entry, allow an estimation of necessary needle depth, and can be used in real time imaging to aid in the procedure to reduce complications. Use of ultrasound for pericardiocentesis is supported by adult literature but use of POCUS for pericardiocentesis in pediatric literature is extremely limited and based on case reports. With a pneumopericardium, **thoracic transillumination** may be helpful to diagnose and monitor air evacuation while the procedure is done. **With sudden cardiovascular collapse, time does not allow these tests, and an immediate lifesaving aspiration is necessary.** In these cases, a quick betadine prep followed by a “blind” needle insertion with aspiration is necessary.
 - A. **Monitor electrocardiogram and vital signs.**
 - B. **Prep the area (xiphoid and precordium) with antiseptic solution.** Wash hands, put on sterile gloves and gown, and drape the area, leaving the xiphoid and a 2-cm circular area around it exposed.

FIGURE 41-1. Recommended sites for pericardiocentesis.

- C. Pain management.** If time permits, local anesthesia can be administered (0.25–1 mL of 1% lidocaine subcutaneously). A narcotic/analgesic drug can also be given.
- D. Prepare the needle assembly. There are 2 methods:**
- 1. Attach the catheter-over-needle** to a short piece of extension tubing that is attached to a 3-way stopcock. Attach a syringe to the stopcock. More common method used.
 - 2. Use a 22- to 24-gauge needle or butterfly attached directly to a syringe** (no cannula is placed; when fluid or air can no longer be aspirated, the needle is removed). Used in extreme emergencies when time does not permit other set up.
- E. Identify the site where the needle is to be inserted.** Most commonly, approximately 0.5 cm to the left of and just below the infant's xiphoid (left sternocostal margin) (Figure 41-1).
- F. Insert the needle at about a 30- to 45-degree angle (smaller degree angle for lower gestational age), aiming toward the midclavicular line on the left.** The 3-way stopcock is closed to the syringe and needle during the initial insertion. After insertion, the assistant should then open the 3-way stopcock to the needle and syringe. The needle should then be advanced toward the left shoulder while the assistant applies constant suction on the syringe until fluid or air is obtained.
- G. Monitor the infant with telemetry** to check for any changes in the cardiac rhythm while advancing the needle and during aspiration. If any ectopic beats occur, stop advancing or withdrawing air and retract the needle slightly. If ectopy continues, stop the procedure and remove the needle.
- H. Stop advancing once air or fluid is obtained (depending on which is to be evacuated).** Advance the cannula over the needle, remove the needle from the catheter, and reconnect the cannula to the extension tubing. If using a butterfly needle, connect the cannula to the extension tubing.
- I. Withdraw as much air or fluid as possible.** The goal is to relieve the symptoms or obtain sufficient fluid for laboratory studies. Once there is no more fluid or air that can be aspirated, the needle can be removed or an indwelling catheter can be left in place.

- J. **If an indwelling catheter is to be left in place (depends on the likelihood of reaccumulation)**, secure it with tape and attach the tubing to continuous suction (10–15 cm H₂O).
 - K. **Obtain a chest radiograph or echocardiogram/ultrasound.** Confirm the position of the catheter and/or the effectiveness of drainage. Transillumination can also be done.
- V. **Complications**
- A. **Cardiac puncture/perforation.** Grossly bloody fluid may indicate that the needle punctured the heart, which can be avoided by advancing the needle only far enough to obtain fluid or air. **Ultrasound guidance** is recommended if time permits. **Another technique to avoid puncturing the heart (if ultrasound is not available)** is to attach the electrocardiogram (ECG) anterior chest lead to the needle with an alligator clip. If changes are seen on the ECG (eg, ectopic beats, changes in the ST segment (elevation), increase in the QRS voltage), the needle has contacted the myocardium and should be withdrawn. Most needle perforations heal spontaneously. If cardiac perforation occurs, emergency intervention and cardiac surgeon consultation are needed.
 - B. **Pneumothorax or hemothorax.** Higher risk if landmarks are not used and “blind” punctures are done. If this complication occurs, a chest tube on the affected side is usually needed.
 - C. **Infection.** Strict sterile technique minimizes the risk of infection.
 - D. **Arrhythmias.** Usually transient. Repositioning the needle is usually effective, but with persistent arrhythmia, treatment may be necessary.
 - E. **Hemorrhage.** Bleeding is usually superficial and controlled with pressure. Hepatic puncture can occur.
 - F. **Hypotension.** May occur if a significant amount of fluid is drained. A fluid bolus may be necessary.
 - G. **Pneumomediastinum.** Only observation is required.
 - H. **Pneumopericardium.** Treat as above.

42 Peripheral Intravenous Extravasation and Infiltration: Initial Management

- I. **Indication.** To manage and minimize the initial injury resulting from infiltration of intravenous (IV) fluids or medications into tissue. Infiltration rates are high among neonates (up to 70%), with extravasation occurring in up to 23%. Risk factors associated with a higher risk of complications within 48 hours after puncture were: endotracheal intubation, total parenteral nutrition, blood transfusion, other medications, presence of infection, body weight at the day of insertion, and type of infusion (intermittent vs continuous).
- A. **Infiltration** refers to the leakage of **nonvesicant** (nonirritating) fluid from a catheter into the surrounding tissues. Infiltrates are usually benign unless a large amount of fluid causes compression of nerves or compartment syndrome. Typically involves routine IV solutions.
- B. **Extravasation** refers to the inadvertent leakage of **vesicants** (highly caustic fluid or medication that is capable of causing tissue necrosis) from a catheter into the surrounding tissues; this can occur from displacement of the catheter or increased vascular permeability. Common vesicants include total parenteral nutrition (TPN),

potassium, bicarbonate, and high-dextrose concentrates. Extravasation can cause a mild skin reaction, severe tissue necrosis, or an injury so severe it leads to surgical intervention, including amputation.

II. Procedures

- A. Prevention of extravasation and infiltration should be the goal.** This strategy includes frequent monitoring of puncture sites, appropriate infusion rates for the size of the catheter, and prompt evaluation if concerns of infiltration exist. Implementation of an IV infiltration management program or evidence-based guideline and checklist for IV infiltrate injuries was found to be effective in decreasing the IV infiltration rate and increasing the rate of early detection of infiltration. Cochrane review found insufficient evidence to recommend a single dressing or securement method over another for peripheral IVs and percutaneously inserted central catheters to prevent complications. Another consideration for prevention is to minimize vesicant administration through peripheral catheters as opposed to central lines.
- B. Initial treatment is determined by the stage of the infiltration/extravasation, the type of solution, and the availability of specific antidotes.** There is a lack of conclusive evidence regarding optimal care after IV extravasation in the newborn. Available literature is primarily anecdotal or descriptive case reports. A staging system has been proposed that provides guidance concerning the appropriate initial treatment options (Table 42–1). This chapter refers only to initial management and not to the management of long-term complications (scarring, tissue loss, vascular compromise).

Table 42–1. STAGING OF IV INFILTRATES^a

Stage	Description	Treatment Options ^a
I	Painful IV site No redness or swelling Catheter flushes with difficulty	1. Remove intravenous (IV) cannula. 2. Elevate extremity.
II	Painful IV site Redness and light swelling (0%–20%)	1. Remove IV cannula. 2. Elevate extremity.
III	Painful IV site Moderate swelling (30%–50%) Blanching Skin cool to touch, but with good pulse and brisk capillary refill below infiltration site	1. Leave IV cannula in place. Using 1-mL syringe, aspirate as much fluid as possible. 2. Remove cannula unless it is needed for administration of an antidote. 3. Elevate extremity. 4. Consider antidote (eg, hyaluronidase, phentolamine).
IV	Painful IV site Severe swelling (>50%) Blanching Skin cool to touch Decreased or absent pulse Delayed capillary refill >4 seconds Skin breakdown, blistering, or necrosis	1. Leave cannula in place. Using 1-mL syringe, aspirate as much fluid as possible. 2. Remove cannula unless needed for administration of antidote. 3. Elevate extremity. 4. Consider antidote. 5. If site is tense with swelling and skin is blanched, use multiple needle puncture technique (see Section II.D).

^aData from Millam D. Managing complications of IV therapy. *Nursing*. 1988;18:34-43; and Thigpen JL. Peripheral intravenous extravasation: nursing procedure for initial treatment. *Neonatal Netw*. 2007;26(6):379-384.

C. Specific antidotes

1. **Hyaluronidase.** Indicated for high osmotic solutions and drugs such as high-dextrose solutions, TPN, blood, calcium, penicillin, nafcillin, methicillin, potassium chloride, and vancomycin.

a. **Appropriate for stage III extravasation of IV fluids** except vasoconstrictors.

b. **Administer within 1 hour** after insult if possible, and no later than 3 hours.

c. **Clean area with antimicrobial agent** and maintain aseptic conditions.

d. **Inject 1 mL (150 U) as 5 separate 0.2-mL subcutaneous injections** around the periphery of the extravasation site. Change the needle after each injection.

e. **Cover with hydrogel dressing** (IntraSite; Smith and Nephew, Andover MA) and elevate for 48 hours.

2. **Saline irrigation is suggested to help prevent further damage in stage III or IV extravasation**, although no randomized control data exist on the intervention. When saline injection is performed, it can be done alone or following the injection of hyaluronidase. A Cochrane review (2017) states the following: "Saline irrigation is frequently reported in the literature as an intervention. No randomized controlled trials have examined the effects of saline irrigation with or without prior hyaluronidase infiltration for management of extravasation injury in neonates."

a. **If done in conjunction with hyaluronidase injection**, perform saline irrigation soon after hyaluronidase.

b. **Make 4 to 5 small stab incisions around the periphery**; if hyaluronidase was injected, these sites can serve as the stab incision sites.

c. **Infiltrate the subcutaneous tissue where extravasation occurred** with aliquots of up to 50 mL of normal saline. This allows saline and diluted extravasate to exit the stab incisions and flush out the area.

d. **Promote further fluid removal by massaging area**, followed by elevation for 24 to 48 hours.

3. **Phentolamine (Regitin)**

a. **The drug of choice for extravasation of dopamine and other vasoconstrictors** (eg, norepinephrine, epinephrine, dobutamine). It is an α -adrenergic blocking agent that decreases local vasoconstriction and ischemia (US Food and Drug Administration label for use as an antihypertensive).

b. **Clean area with antimicrobial agent** and maintain aseptic technique.

c. **Inject a 0.5-mg/mL solution subcutaneously into the affected area.** Usual amount needed is 1 to 5 mL, depending on size of infiltrate. May repeat if necessary.

4. **Topical nitroglycerin.** This agent promotes local vasodilation, which improves perfusion to the area.

a. **Effective treatment for extravasation of dopamine.**

b. **Clean area with antimicrobial agent** and maintain aseptic technique.

c. **Apply 2% nitroglycerine ointment** (4 mm/kg) to area. May repeat every 8 hours if necessary.

D. Multiple needle puncture technique

1. **May be used to create an avenue for fluid to escape** and help to minimize tissue damage.

2. **Clean with antimicrobial agent** and maintain aseptic technique.

3. **Using a 20-gauge needle, puncture the skin subcutaneously** multiple times in the affected area. Change the needle after each puncture.

4. **Cover with saline-soaked gauze** to absorb the fluid, and elevate the extremity.

5. **Evaluate** every 1 to 2 hours for 48 hours.

III. Complications.

Initial management may cause the following:

A. **Infection.** Use strict aseptic technique during injections.

B. **Trauma to site.** Handle skin gently; remove skin disinfectant with sterile saline pad.

C. **Hypotension.** Could potentially occur with a large dose of phentolamine or with absorption of topical nitroglycerin.

43 Therapeutic Hypothermia

Therapeutic hypothermia (TH) is now the gold standard treatment for infants with moderate to severe hypoxic ischemic encephalopathy, whereby the infant's core body temperature is decreased within 6 hours after birth followed by slow rewarming for neuroprotection. This treatment slows the metabolic rate so cells can recover and prevent further damage. Neonatal encephalopathy can be due to different causes; care providers should take careful assessment of possible etiologies because this could lead to specific therapy that may improve prognosis. When a clear diagnosis of hypoxia-ischemia is known to be the reason for moderate to severe encephalopathy, TH is implemented if the infant meets the criteria. It has been shown to improve survival and outcome and reduce the risk of death or major neurodevelopmental disability at 18 months of age with data suggesting that the long term benefits resulted in improved neurocognitive outcomes persisting into middle childhood. The benefits of cooling outweigh the short-term risks related to hypothermia. Published hypothermia protocols have consistently used gestational age of at least ≥ 36 weeks at birth to qualify for TH and starting treatment within the first 6 hours after birth with systemic temperatures between 33°C and 35°C and continuing treatment for a total of 72 hours. Deviating from this protocol is not recommended as it may result in an increase in adverse outcomes; longer or deeper hypothermia showed an increase in mortality. **Cooling infants who are <36 weeks' gestation is not recommended because of insufficient evidence to evaluate risks and benefit in this patient population.** The best benefit of TH is when it is started before 6 hours of life, but there may be a small benefit and low risk for infants with moderate HIE who have it started between 6 and 24 hours of life. A Cochrane review provided evidence from 11 randomized controlled trials ($n = 1505$ infants) that TH is beneficial in term and late preterm newborns with moderate to severe HIE.

There are 2 types of cooling, **selective head cooling (SHC)** and **whole-body cooling (WBC)**, which is more common. **Selective head cooling** is done by using a cooling cap that circulates cold water that is placed on the infant's head to lower the core temperature. **Whole body cooling** is done by using a cooling blanket or different types of wraps or mattresses that circulate cold water that is placed under the baby to lower the total body temperature. Both methods have been shown to be effective, and several recent studies showed no significant differences in adverse effects, neuromotor development at 12 months, or mortality rate between SHC and WBC when treating HIE. Further trials to determine the appropriate cooling technique are necessary to better understand the advantage of WBC versus SHC. Some neonatal intensive care units (NICUs) prefer using WBC because it is easier to administer and allows one to perform electroencephalogram monitoring on the infant. It is recommended that application of TH should only be done by following published guidelines. **The protocol discussed in this chapter is based on WBC published by Shankaran et al (*New England Journal of Medicine*, 2005).**

- I. **Indication.** Treatment of newborn infants who fulfill the criteria for diagnosis of moderate to severe HIE (see Chapter 110).
- II. **Eligibility for therapeutic hypothermia.** Newborn infants ≥ 36 weeks' gestation admitted to NICU for perinatal depression should be sequentially evaluated for eligibility for TH by clinical and physiologic criteria followed by complete neurologic examination.
 - A. **Clinical and physiologic criteria**
 1. **Blood gas pH of ≤ 7.0 or base deficit of ≥ 16 mmol/L** in a sample of umbilical cord blood or any blood during the first hour after birth; proceed to step B.
 2. **Blood pH of 7.0 to 7.15 or base deficit of 10 to 15.9 mmol/L plus history of an acute perinatal event* and Apgar score of <5 at 10 minutes or continued need for assisted ventilation for at least 10 minutes; proceed to step B.** (*Examples of acute perinatal event include abruption placenta, cord prolapse, severe fetal heart rate abnormality, variable or late decelerations, maternal trauma, hemorrhage, or cardiorespiratory arrest.)

Table 43–1. SIGNS OF MODERATE OR SEVERE ENCEPHALOPATHY

Category	Moderate Encephalopathy	Severe Encephalopathy
Level of consciousness	Lethargic	Stupor/coma
Spontaneous activity	Decreased activity	No activity
Posture	Distal flexion, full extension	Decerebrate
Tone	Hypotonia (focal, general)	Flaccid
Primitive reflexes		
Suck	Weak	Absent
Moro	Incomplete	Absent
Autonomic system		
Pupils	Constricted	Skew deviation/dilated/nonreactive
Heart rate	Bradycardia	Variable heart rate
Respirations	Periodic breathing	Apnea

B. Complete neurologic examination. Once infant meets clinical and physiologic criteria, a **complete standardized neurologic examination is to be performed.** Moderate to severe encephalopathy is defined as seizures or presence of 1 or more signs in 3 of the 6 categories in staging of HIE. The number of moderate or severe signs will determine the extent of encephalopathy; if signs were equally distributed, the designation is based on the level of consciousness.

- 1. If seizure is documented or reported, infant is automatically eligible for cooling.**
- 2. If no seizure is documented or reported,** infant has to have at least 3 of 6 signs of moderate or severe encephalopathy to be eligible for cooling (Table 43–1).

III. Equipment (Whole-Body Cooling)

- A. Hyper-hypothermia machine** used to raise or lower a patient's temperature to a target level through conductive heat transfer. Use 2 to 3 gallons of distilled water for initial setup.
- B. Infant-size hyper-hypothermia blanket.** A single-patient use blanket to provide both heating and cooling to maintain patient's target temperature. (**Note:** Low cost alternatives such as ice packs, frozen gel packs, and phase changing materials can be used in resource limited settings and is beneficial, but require careful monitoring to avoid temperatures outside the therapeutic range.)
- C. Infant esophageal probe and cable.** Allows continuous monitoring of patient's core temperature while on the hyper-hypothermia machine. (Some centers use rectal temperature probes.)
- D. Drainage hose.** Use to drain water from the hyper-hypothermia machine.
- E. Available open infant radiant warmer bed with warming capability** at the conclusion of the TH period.

IV. Procedure

- A. Confirm eligibility** for hypothermia therapy, per Section II.
- B. Pain management.** There is no specific recommendation for sedation and pain control during cooling; however, based on the author's experience, low-dose morphine or fentanyl drip has been effective in keeping the infant comfortable during the cooling process. Close monitoring for evidence of respiratory depression in patients who are not intubated is recommended.
- C. Gather equipment.** Follow preparation instructions of the hyper-hypothermia machine per operation manual.

FIGURE 43-1. Whole-body cooling hypothermia patient setup.

- D. Precool the blanket to 5°C for whole-body cooling to maintain an esophageal temperature of 33.5°C ± 5°C.** Lay infant supine on the precooled blanket with occiput resting on the blanket. A single-layer thin blanket may be placed between the infant and the cooling blanket to prevent soiling of equipment (Figure 43-1).
- E. Insert the esophageal temperature probe into an external naris.** Probe may be softened by placing in warm water for a few minutes. The probe should be positioned in the lower third of the esophagus (desired length = distance from nares to ear to the mid-sternum minus 2 cm). Secure the probe by taping with adhesive to the side of the infant's nose. Connect the probe to the cooling unit. Confirm probe placement with a radiograph. However, do not wait for a radiograph; connect the probe to the cooling unit and begin temperature monitoring straight away. Some recommend a **rectal temperature sensor**. Measure and mark the sensor, lubricate the tip, insert the rectal probe 5 to 6 cm into the rectum, and secure to the buttocks with tape.
- F. Use an open radiant warmer bed for optimal monitoring.** Skin temperature will be monitored by skin temperature probe on the lower abdomen attached to the radiant warmer. The radiant warmer is set to "manual mode" with the heat turned off (allows for continuous skin temperature monitoring without any heat output from the warmer). Do not use any other source of exogenous heat.
- G. Operate the cooling unit in automatic mode** with a core temperature goal of 33.5°C ± 0.5°C (follow your NICU-specific cooling unit instruction manual).
- H. The infant's esophageal temperature will begin to decrease soon after the initiation of the cooling therapy.** The cooling blanket system adjusts automatically to achieve 33.5°C by approximately 90 to 120 minutes. Once stable at 33.5°C, some esophageal temperature fluctuation around the setpoint is to be expected, but should not be greater than ± 0.5°C. Monitor and record esophageal, skin, and water temperatures, as well as all vital signs at 15-minute intervals during cooling (or follow unit-specific policy). **Total period of cooling is 72 hours.**
- I. Gradual rewarming is done over 6 hours after completion of 72-hour cooling period.** The automatic cooling unit setpoint temperature is increased by 0.5°C every hour to maximum setpoint of 36.5°C. The goal is to slowly increase the temperature by 0.5°C per hour to reach normothermia by the end of 6 hours. Smaller or sicker infants may require a longer period to reach normothermia. Monitor vital signs (especially temperature) throughout the rewarming period. **Hyperthermia must be avoided.** New-onset or rebound seizures have been reported during and after rewarming.

- J. When normothermia is achieved, turn off hyper-hypothermia unit and remove cooling blanket and esophageal probe.** Return to temperature maintenance per local NICU protocol.
- K. During the cooling and rewarming process,** infant should receive routine clinical care appropriate for the level of acuity, including laboratory blood studies for surveillance of respiratory, cardiovascular, hematologic, and renal dysfunction. Blood gas measurements must be corrected for body temperature during hypothermia.
- L. Adjuvant therapies.** The incidence of death and disability with therapeutic hypothermia is approximately 40%. Promising adjunctive therapies to augment therapeutic hypothermia include erythropoietin, melatonin, xenon, 2-iminobiotin, stem cells, and antiepileptic medications. Erythropoietin has shown promise in preliminary studies.
- V. Complications.** The following is a list of potential complications of systemic hypothermia; note that all complications may not be included.
- A. Cardiovascular and respiratory**
- 1. Arrhythmia.** Hypothermia can decrease depolarization of cardiac pacemaker cells, causing bradycardia (most common cardiovascular complication). Maintain infant's temperature within the target range of $33.5^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$ to prevent more severe arrhythmias.
 - 2. Hypotension.** Decreases in stroke volume and heart rate may contribute to the decrease in cardiac output, leading to hypotension.
 - 3. Pulmonary hypertension.** Increased pulmonary vascular resistance has been reported in hypothermic infants; however, the number of hypoxic-ischemic infants with persistent pulmonary hypertension in large clinical trials was similar between cooled and noncooled infants.
 - 4. Blood gases.** Hypothermia decreases oxygen consumption and carbon dioxide production; therefore, ventilator settings need to be monitored and adjusted to avoid hyperventilation that can cause cerebral vasoconstriction. **Blood gas values are temperature dependent,** and if blood samples are warmed to 37°C before analysis (as is common in most laboratories), PO_2 and PCO_2 will be overestimated and pH underestimated in hypothermic patients. For accurate blood gas interpretation, blood samples should be analyzed at the patient's real temperature. If this is not possible, the blood gas values assayed at 37°C can be estimated in the following way, as described by Polderman (2009):
 - a. Subtract 5 mm Hg PO_2 per 1°C** that the patient's temperature is $<37^{\circ}\text{C}$.
 - b. Subtract 2 mm Hg PCO_2 per 1°C** that the patient's temperature is $<37^{\circ}\text{C}$.
 - c. Add 0.012 pH units per 1°C** that the patient's temperature is $<37^{\circ}\text{C}$.
- B. Dermatologic**
- 1. Skin breakdown.** Vasoconstriction during extreme cold can lead to decreased blood flow and localized damage to skin and other tissues. Regular inspection of the infant's skin is part of routine care during cooling.
 - 2. Subcutaneous fat necrosis.** The cause of subcutaneous fat necrosis is unknown. It has been associated with perinatal asphyxia. Hypothermia causes vasoconstriction that worsens skin perfusion that has already been compromised by asphyxia, thereby leading to fat necrosis. Most of the reported cases occurred after completion of cooling. Serum calcium levels have to be monitored in affected infants due to risk of hypercalcemia.
- C. Hematologic.** Serial follow-up of hematologic parameters is an important part of surveillance during hypothermia therapy.
- 1. Hypothermia-induced thrombocytopenia** is due to **increased platelet destruction** (platelet sequestration in the liver and spleen) and **disseminated intravascular coagulopathy** resulting in early thrombocytopenia and bone marrow suppression.
 - 2. Coagulopathy induced by mild hypothermia** with the risk of severe bleeding associated with TH is small.

D. Metabolic

1. **Metabolic acidosis.** Decreased cardiac output leading to reduced clearance of lactic acid.
 2. **Altered glucose metabolism.** Hypothermia decreases insulin sensitivity and secretion, leading to hyperglycemia; higher doses of insulin maybe needed. During rewarming, infants treated with insulin for hyperglycemia may be at risk for hypoglycemia as sensitivity to insulin is restored.
 3. **Drug metabolism and excretion of drugs and metabolites might be modified by cooling,** as well as the presence of hepatocellular and renal impairment complicating HIE. Metabolism of drugs such as phenobarbital, morphine, and vecuronium is slowed by effects of the temperature-dependent hepatic cytochrome P450 enzyme system. **Potentially toxic levels of drugs can accumulate in the system if metabolism and excretion are impaired.** Check antibiotic levels if being used.
- E. **Infections.** Cooling has immunosuppressive and anti-inflammatory effects. Meta-analysis of large trials did not show any increase in incidence of infection in cooled infants.

44 Transillumination and Point-of-Care Ultrasound

Transillumination and point-of-care ultrasound (POCUS) are techniques that can be used as an aid in performing procedures, to diagnose specific conditions, and to help in clinical decision making. Both **transillumination and POCUS** can be performed at the bedside, require no sedation, and have no significant complications. Although transillumination has been around since 1831 (Richard Bright's first description using a candlelight to shine through the head of a macrocephalic adult and diagnose hydrocephalus), it has only been used in neonatology since the 1970s. The first ultrasound studies can be traced back to 1794, but diagnostic ultrasound did not enter medicine until the 1950s. The first portable ultrasound unit was initially developed in 1988 to help identify and diagnose serious injuries in troops in the field. POCUS was used in the late 1990s by emergency room physicians as a trauma screening tool and is now gaining popularity in other medical disciplines.

I. Transillumination

- A. **Indications.** Transillumination is the use of a strong light source as a noninvasive tool for bedside diagnosis and to aid in procedures. By shining a bright light through an area of the body or an organ, abnormal air, fluid, or a nonsolid mass can be potentially diagnosed. One of the best uses of transillumination in the neonatal care unit is that it can provide a rapid diagnosis in an unstable infant with a tension pneumothorax, pneumopericardium, or abdominal perforation and allow for immediate intervention if necessary. Individuals with deutan color vision (red-green blindness) may have difficulty with transillumination techniques.

1. Procedures

- a. **Localize an artery or vein for vessel cannulation** or blood sampling.
- b. **Bladder aspiration.** Verify the presence of urine in the bladder and show the size and location of the bladder.
- c. **Cannulation of umbilical vessels.** Identify the path of vessels and identify a false passage of an umbilical catheter.

2. **False-positive and false-negative results for pneumothorax.** Limit these by using a sufficiently bright light source and dimming the room lights.
 - a. **False positive.** Pneumothorax example: subcutaneous air or edema, pulmonary interstitial emphysema, pneumomediastinum, large stomach air bubble. Very premature infants with thin skin can appear to have a pneumothorax when it is not present (ie, the chest lights up).
 - b. **False negative.** Pneumothorax example: small air leak, increased skin thickness, thick/edematous chest wall, darkly pigmented skin, light not bright enough, room not dark enough.

II. Point-of-care ultrasound (POCUS) is also called **bedside ultrasound imaging (BUSI)**, **clinical ultrasound (CUS)**, or **focused ultrasound**. POCUS in the neonatal intensive care unit (NICU) or newborn nursery is done with a portable ultrasound device to perform a focused ultrasound exam at the bedside to help with a procedure or answer a specific clinical question by a nonradiologist imager (eg, neonatologist). The Society of Point of Care Ultrasound considers it complementary (not adjunctive) to the physical examination because it adds anatomic, functional, and physiologic information. Historically ultrasound use in the NICU has only been done by cardiologists or radiologists. An increasing number of NICUs and providers are becoming familiar with the benefits of POCUS but it still remains underused. Some clinicians have even recommended that it become part of the routine physical examination, with the handheld ultrasound acting as a “visual stethoscope.” The American Academy of Pediatrics has already published a policy statement for POCUS for pediatric emergency physicians.

Premature infants are perfect POCUS candidates because they have less subcutaneous fat and muscle. Providers in certain countries (eg, Canada, United Kingdom, Australia, New Zealand) are already using POCUS in their NICUs. A recent survey validated that neonatal perinatal fellowship programs agree that POCUS is beneficial and neonatology fellows should receive necessary training.

Advantages of POCUS include timely and accurate diagnosis at the bedside, aid in procedures, acceleration of clinical decisions, and no ionizing radiation exposure; in addition, it is ideal for the nonmobile patient who cannot be transported, can be performed and repeated any time, may decrease unnecessary testing, and also decreases costs compared to other diagnostic modalities.

Disadvantages of POCUS include lack of training, length of training involved (targeted neonatal echocardiography recommendation is a minimum of 4–6 months), lack of knowledge of ultrasound anatomy, limited penetration through air and bones so deeper structures cannot be seen well, loss of control by radiology, lack of access to ultrasound equipment, paucity of positive impact studies, and medicolegal implications. The potential utility of POCUS in the NICU or newborn nursery includes use in certain procedures and clinical applications. **The majority of these applications and techniques have been based on experience with pediatric emergency POCUS and use in adults, some with very limited studies.** Integration of POCUS into neonatology practice will ultimately depend on multiple factors, including sufficient training and experience and access to ultrasound equipment.

A. Point-of-care ultrasound indications: Procedure Applications

1. **Central and peripheral catheters.** The majority of catheters placed in the NICU are done “blindly.” POCUS allows for direct visualization and localization of the vessel and can help guide catheter placement. It can also more accurately confirm the position of the catheter and its tip when compared to radiography. It can result in faster placement, fewer manipulations, decreased complications, and fewer radiographs ordered.
 - a. **Umbilical venous catheter.** Umbilical venous catheter (UVC) tip placement is not precise in a typical radiograph. With ultrasound, the UVC can be placed in a perfect position (UVC beyond the inferior vena cava [IVC]–right atrium [RA] junction). Look at subxiphoid long axis below and above the diaphragm and identify location of the hepatic segment of the IVC, hepatic vein, and ductus venosus. Hepatic veins and IVC should not be obstructed.

7. **Thoracentesis.** POCUS can detect air or fluid in the pleural space and may help with removal (ultrasound-guided thoracentesis). There has been a case report of an ultrasound used to assist with needle aspiration of a spontaneous pneumothorax in a preemie.
 8. **Pericardiocentesis.** POCUS can detect the presence of pericardial fluid, assess its significance, and help guide pericardiocentesis. **Static:** identify the location of the effusion and mark area of needle insertion. **Dynamic:** direct visualization of the needle into the pericardial space.
 9. **Extracorporeal life support.** Evaluate cannula position and function with ultrasound methods more accurate than chest radiograph. Assess cardiac function, ductal shunting, and presence of atrial communication.
- B. Point-of-care ultrasound indications: Clinical Applications.** To aid in diagnosis and clinical decision making. POCUS should always be combined with a detailed clinical examination.
1. **Head/neck.** Emergency assessment of an intracranial hemorrhage (infant deteriorates and hemorrhage suspected), hydrocephalus, ventriculomegaly, asymmetry of the ventricles, calcifications, early ischemia, periventricular leukomalacia, Doppler assessment of cerebral arteries, determination of change in resistive index in intracranial pressure in infants with hydrocephalus and posthemorrhagic hydrocephalus, and laryngeal ultrasound to assess vocal cord palsy and paralysis.
 2. **Heart. Focused cardiac ultrasound (FOCUS)/point-of-care echocardiography** is the greatest indication for ultrasound in the NICU. **Functional echocardiography** describes the use in the clinical assessment of the hemodynamic status in neonates. **Targeted neonatal echocardiography** is the term used for focused studies. These studies enable monitoring of cardiac function, evaluating murmurs, and obtaining cardiac and hemodynamic information. The following can be evaluated: left ventricular systolic and diastolic function, right ventricular systolic pressure and pulmonary artery pressure, atrial-level shunt, presence of physiologically significant patent ductus arteriosus (hemodynamic significance and effect of treatment), need for and response to inotropic agents, systemic and pulmonary blood flow, organ perfusion, pericardial fluid, left ventricular preload/volume depletion for oliguria, pulmonary hypertension, and coarctation of the aorta. (See consensus statement Targeted Neonatal Echocardiography in the Neonatal Intensive Care Unit: Practice Guidelines and Recommendations for Training in Selected References).
 3. **Persistent pulmonary hypertension of the newborn.** Targeted neonatal echocardiography allows assessment of effect of treatment on right ventricular function, pulmonary artery pressures, and shunt directions at atrial and ductal level.
 4. **Hypotension not related to structural heart disease.** May help determine the cause and direct management. Evaluate IVC to estimate intravascular volume status; gauge response to fluid boluses and inotropic support.
 5. **Abdomen.** Bowel viability assessment: Ultrasound is limited in GI pathology because gas-filled bowel reflects the ultrasound beam.
 - a. **Necrotizing enterocolitis.** US can detect a small amount of intramural gas or changes in bowel wall thickness or peristalsis. Able to better detect pneumatosis intestinalis (see small echogenic dots within the bowel wall) and portal venous gas than with x-ray. Can also see intestinal ischemia, bowel wall thickening, abnormal bowel wall perfusion, and reduced peristalsis. US may also aid in diagnosis of perforation and abscess formation (see loculated right lower quadrant mass and intra-abdominal fluid containing debris). Color Doppler can estimate bowel wall perfusion and show loss of blood flow with nonviable bowel.

- b. **Intussusception and volvulus.** Ultrasound is the first-choice test for intussusception. In ileocolic intussusception (most common type), one sees a peripheral hypoechoic ring with a central echogenicity (pseudokidney sign). In volvulus, ultrasound can visualize the twisting of the mesenteric vessels.
 - c. **Hypertrophic pyloric stenosis.** Ultrasound is the gold standard for diagnosis. Diagnosis is based on elongation of pyloric channel >17 mm, anteroposterior diameter of pylorus >12 mm, and wall thickness >2 mm.
 - d. **Kidney/ureter/bladder.** Evaluate hydronephrosis, calyceal dilatation, renal abnormalities, distended bladder from outlet obstruction, and ascites.
6. **Lung ultrasound** can be used to differentiate normal lung from lung diseases and disorders. Studies suggest lung ultrasound has better sensitivity and specificity than chest x-ray in diagnosing a pneumothorax. It has also been used as a predictor of the need for intubation by seeing a persistence of a white lung in 1 small study. Lung ultrasound is based on the presence or absence of lung sliding, A lines, B lines, lung consolidation, shred sign, B profile lung point, dynamic air/fluid bronchograms, anechoic zone, jellyfish sign, sinusoid sign, or quad sign (see descriptions of these findings in Section II.D.4). **A recent article has published algorithms for lung ultrasound for immediate postnatal respiratory distress and for late-onset neonatal respiratory distress (Kurepa et al, 2018).** Some lung ultrasound examples include the following:
- a. **Normal lung findings:** Well-defined A lines, regular pleural line and presence of lung sliding, rare or absent B lines.
 - b. **Transient tachypnea of the newborn:** Regular pleural line and presence of lung sliding, absent A lines, present B profile with double lung point.
 - c. **Meconium aspiration syndrome:** Present lung sliding, absent A lines, absent B profile with double lung point.
 - d. **Pneumothorax (confirmed):** Absent lung sliding, present A lines, present lung point (specific sign of pneumothorax).
 - e. **Pneumothorax (possible):** Absent lung sliding, present A lines, absent lung point, presence of **stratosphere sign** (barcode sign). Presence of B lines has almost 100% negative predictive value for pneumothorax.
 - f. **Respiratory distress syndrome:** Absent lung sliding, absent A lines, absent anechoic zone with or without jellyfish sign, sinusoid sign, quad sign, present bilateral/uniform consolidation.
 - g. **Pneumonia:** Absent lung sliding (25% have this), absent A lines, absent anechoic zone with or without jellyfish sign, sinusoid sign, quad sign, absent bilateral/uniform consolidation, present shred sign and/or dynamic air/fluid bronchograms.
 - h. **Atelectasis:** Absent lung sliding, absent A lines, absent anechoic zone with or without jellyfish sign, sinusoid sign, quad sign, absent bilateral/uniform consolidation, absent shred sign and/or dynamic air/fluid bronchograms.
 - i. **Lung edema:** Present lung sliding, absent A lines, present bilateral uniform B profile.
 - j. **Pleural effusion:** Absent lung sliding, absent A lines, present anechoic zone with or without jellyfish sign, sinusoid sign, quad sign.
 - k. **Pulmonary hemorrhage:** Lung consolidation with air bronchograms, shred sign, pleural effusion, disappearing A lines.
 - l. **Bronchopulmonary dysplasia:** Present lung sliding, thick pleural line with scattered small consolidations, possible white lung to coalescent B lines, absent A lines, absent bilateral/uniform B profile.
 - m. **Amniotic fluid aspiration:** Homogenous pattern of B lines and variable subpleural consolidation alternating with spared areas.
7. **Use in neonatal peripheral intravenous extravasation injuries.** POCUS can provide direct visualization of the skin tissue and therefore may provide a better objective staging of peripheral intravenous extravasation injuries.

8. **Use of cardiopulmonary point-of-care ultrasound in neonatal transport.** Use of cardiopulmonary POCUS before transport helped improve diagnostic accuracy in determining cardiac or respiratory failure in 1 study of critically ill neonates.
- C. Equipment.** Portable ultrasound equipment (SonoSite [FUJIFILM SonoSite, Bothell, WA], Mindray [Mindray North America, Mahwah, NJ], others), ultrasound gel, transducers (also known as probes) or specific neonatal transducers available for specific body areas (eg, neonatal abdominal, neonatal head), high-frequency probes (8–12 MHz; should be available for use in neonates). For imaging neonatal hearts, use an ultrasound system that is two dimensional with M-mode and full Doppler with electrocardiogram tracing.
1. **Ultrasound terms: Echogenicity** is the ability of a tissue to reflect or transmit an ultrasound wave. **Anechoic** (absence of echoes) appears black on screen. **Hypoechoic** (less echogenicity) appears gray on the screen. **Hyperechoic** (more echogenic) appears white on the screen.
 2. **Types of transducers/probes:** High-frequency probes penetrate less and produce high-resolution images. Low-frequency probes penetrate more and produce lower resolution images.
 - a. **Linear transducers** use high frequency (5–15 MHz) to produce a high-resolution image and are the most commonly used transducers in neonates; they are also used for blood vessel visualization.
 - b. **Convex/curved/curvilinear transducers** use low to midrange frequency (2–5 MHz) to visualize deep structures such as transabdominal imaging.
 - c. **Phased array transducers** use a low frequency (1–5 MHz) and can be used for cardiac/brain imaging. Phased arrays and 3-dimensional transducers are used for cardiac imaging.
 3. **Scanning modes:** Imaging modes commonly used in ultrasound include:
 - a. **B or brightness mode(now known as 2D mode):** Most commonly used ultrasound mode; a transducer scans a plane through the body that can be viewed as a two dimensional image on the screen.
 - b. **M or motion mode:** A rapid sequence of B mode scans that are in sequence, allowing one to see and measure range of motion. Used for cardiac scanning and lung sliding.
 - c. **Doppler mode**
 - i. **Color Doppler:** Most common Doppler type; measures mean velocity and direction of flow (most often blood flow) on B-mode image.
 - ii. **Power Doppler:** Displays intensity of the Doppler signal by a variation in color; averages flow over multiple frames.
 - iii. **Spectral Doppler:** Distinguishes arterial versus venous waveforms.
 4. **Knobs on point-of-care ultrasound**
 - a. **Gain knob:** Increases or decreases the brightness of returning echoes on the screen. It changes the amount of black, white, or gray on the screen.
 - b. **Depth knob:** Adjusts the field of view. Higher depth will get a bigger picture; use lower depth for a more focused picture.
- D. Procedure.** Perform in incubator or radiant warmer. Consider warming the gel. Apply gel to the probe. **Static technique is the use of ultrasound prior to a procedure** to identify anatomy, locate vessels, determine needle placement, determine catheter tips, and help decide if a procedure should be done, but the procedure is performed without the use of ultrasound. **Dynamic technique is the use of ultrasound during the procedure**, where the ultrasound provides direct visualization of the procedure (eg, observe the passage of needle from skin into spinal canal). Most of these procedure techniques have been based on pediatric and adult literature.
1. **Cranial ultrasound.** Look at coronal (front to back), sagittal (left to right), and axial views (posterior fossa). Place a linear transducer over the anterior fontanelle, and visualize the brain in a coronal (sweep beam from anterior to posterior

aspect of head) and sagittal plane (sweep beam from left to right direction). Look at 2 ventricles, and evaluate for hemorrhage, calcifications, or early ischemia. Look at the superior sagittal sinus above the interhemispheric fissure and examine for signs of extra-axial fluid; rule out a subdural hematoma here. For color Doppler: evaluate flow velocities in cerebral arteries and veins.

2. **Cardiac ultrasound.** FOCUS includes evaluation of the heart and IVC. Standard assessment includes views in parasternal short axis, apical 4-chamber windows, subxiphoid, and parasternal short and long axis. Assess the IVC in subxiphoid longitudinal plane. **Dynamic:** use M-mode and measure vessel diameter during inspiration and expiration, view aorta in subxiphoid location, and measure size of aorta during systole.
3. **Abdominal ultrasound.** Use linear probe of 8 to 15 MHz. Look for bowel wall thickening >2.6 mm, portal venous air, pneumatosis intestinalis, free air, intra-abdominal fluid, and an increase in bowel wall echogenicity. Color Doppler can estimate bowel wall perfusion.
4. **Lung ultrasound.** Use high-frequency (≥ 10 MHz) linear transducer set to lung preset. Orient transducer in a sagittal plane. Examine in supine, lateral, or prone position and examine anterior, lateral, and posterior areas. Scan each lung in the longitudinal and transverse orientation. Scan from clavicles to the diaphragm; use M-mode to confirm the presence or absence of lung sliding. Note that all signs of lung ultrasound arise from the pleural line.
 - a. **Normal lung findings.** Air completely scatters the ultrasound waves, and parietal and visceral pleura slide against each other with every respiration. Presence of A lines and lung sliding indicates normal lung with no lung pathology.
 - i. **Pleural line** is a curvilinear smooth echogenic line that comes from the reflection of the pleural surface.
 - ii. **Lung sliding** is the movement of the parietal against the visceral pleura during respiration. It creates a “**seashore sign**,” indicating a healthy lung.
 - iii. **A lines** are horizontal hyperechogenic lines distal to the pleural line that are a demonstration of air below the pleura. They are present in normal lungs and also in a pneumothorax.
 - iv. **Bat sign** appears when there are 2 adjacent ribs with shadowing (looks like wings of bat) on top of the pleural line (looks like body of bat).
 - b. **Abnormal lung ultrasound findings**
 - i. **B lines/B line artifacts** are either unilateral or bilateral vertical lines that are hyperechoic and extend from the pleura to the edge of the screen and do not fade. They erase A lines. They indicate lung fluid. May be normal in infants during the first 48 hours of life, or longer in premature infants, until fluid reabsorbs. The appearance of compact B lines indicates white lung.
 - ii. **Lung point** represents the zone between normal (lung sliding) and abnormal (no lung sliding) lung.
 - iii. **Double lung point:** The difference in lung echogenicity between the upper lung fields that are improved and the lower lung fields that are still wet.
 - iv. **Barcode or stratosphere sign:** The absence of lung sliding in a pneumothorax. There is free air that separates the lung from the pleura that looks like a barcode.
 - v. **Lung consolidation:** Appears as a tissue-like density like the liver. It erases both A lines and pleural line. The **shred sign**, an irregular shredded image, is specific for lung consolidation.
 - vi. **Air bronchograms** appear as tiny hyperechoic lines.
 - vii. **Jellyfish sign:** Seen with pleural effusion when the lung is partially collapsed from fluid; the lung tip flaps freely in the effusion.

- viii. **Sinusoid sign** occurs when the lung moves toward and away from the pleural line with inspiration and expiration and is seen in pleural effusion.
 - ix. **Curtain sign** occurs in a pleural effusion during inspiration when the image appears to vanish when the lung expands and is interposed between the probe and the effusion.
 - x. **Quad sign** occurs with a pleural effusion; 4 boundaries are as follows: pleural line forms the upper border, lung surface line forms the lower border, and the side borders are shadowing of the ribs.
5. **Vascular access ultrasound:** For peripheral intravenous access, peripheral arterial access, central venous access, umbilical artery and vein placement, and intraosseous placement. Using the linear high-frequency transducer, scan in longitudinal and transverse planes to identify structures, anatomic anomalies, and optimal site of cannulation. Vessels can be cannulated in the short (out of plane; image is perpendicular to the course of vessel) or long (in the plane; image is parallel to the course of the vessel) axis. Differentiates nerves from arteries from veins. Both arteries and veins have an echoic (black) lumen, but arteries have thicker walls that are brighter than veins. Veins are collapsible with compression; arteries are not. Nerves will show internal echoes when the scanning plane is perpendicular to the nerve, and arteries will show arterial pulsations. **Doppler color flow** can also distinguish arteries from veins. **For UAC placement**, flow in aorta should be unobstructed and the antegrade systolic peak pulse wave of velocity should be <1 per second on pulsed Doppler. **For UVC placement**, the UVC is seen passing down the umbilicus recess (echolucent large vessel) and through the ductus venosus. If the UVC is not in the ductus venosus, it is not in the correct position. **For intraosseous placement**, scan distal to the insertion site of the intraosseous needle, and angle it slightly cephalad to intercept the plane of the intraosseous needle.
6. **Bladder ultrasound:** For suprapubic aspiration or urethral catheterization. Use a high-frequency linear-array transducer and apply it in the transverse position in the midline of the abdomen. Image the bladder in the sagittal plane. Note that the bladder is an anechoic structure when filled with urine with the wall appearing as a thin echogenic line. To visualize the entire needle length, introduce the needle into the plane of the ultrasound beam.
- a. **Calculate the urinary bladder index** by measuring the transverse and anteroposterior measurements of the bladder in the transverse plane. Note that the bladder is anechoic, fluid filled, and extends above the pubic symphysis when full.
 - b. **Measure the cephalocaudal and anteroposterior diameter of the bladder.** If the cephalocaudal diameter is >20 mm and the anteroposterior diameter is >15 mm, bladder aspiration success rate is near 100%.
7. **Thoracentesis.** Perform static and dynamic technique. Use a linear probe and apply it parallel to the spine on the affected hemithorax. Start at the lower ribs and move the probe toward the head, while looking for the pleural effusion. The pleural effusion will appear dark, whereas the lung tissue will be bright. Verify the pleural effusion by moving the probe parallel inside the intercostal space. Mark the site for needle/chest tube insertion. Site should be on the posterior axillary line. Alternatively, one can scan the hemithorax from the inferior border of the scapula to the upper lumbar region. Evaluate the costophrenic sulcus from the paravertebral region posteriorly to the parasternal region anteriorly. Identify pertinent structures prior to the procedure.
8. **Lumbar puncture.** Estimate landmarks by palpation first. Use a 7- to 15-MHz hockey stick (linear array transducer). Use either the transverse or longitudinal approach. Move the probe up and down the spine. Perform static technique to identify the spinous processes (most superficial bony prominence that is

visualized on ultrasound), interspinous spaces, epidural space, subarachnoid space, and level of conus medullaris. The cerebrospinal fluid is anechoic, and the strands of the cauda equine are hyperechoic, and the conus is a hypoechoic tapering structure. Dynamic technique is not well studied in neonates but can help guide the needle into the interspace.

9. **Paracentesis.** Use an 8- to 15-MHz linear probe. Do static and dynamic technique. Examine bilateral upper and lower quadrants, splenorenal and hepatorenal spaces, and pelvis. Note that the pockets of fluid are anechoic or hyperechoic and the peritoneal lining is hyperechoic. Identify largest pocket of fluid and intra-abdominal structures (urinary bladder, bowel, and inferior epigastric vessels) to avoid. Set color Doppler threshold low and identify the inferior epigastric vessels.
 10. **Pericardiocentesis.** Do static and dynamic technique. Obtain images in the parasternal long, apical, or subxiphoid view. Note the pericardial effusion will be an anechoic (black) space surrounding the bright echogenic pericardium. Measure from the epicardial surface of the heart to its maximum dimension on 2-dimensional imaging at end diastole. Identify right and left ventricle, liver, pericardium, and pericardial space. Identify the internal mammary artery (note that it is 3–5 cm lateral to the lower sternal border) and neurovascular bundles so these may be avoided. Note that the pericardial effusion will be an anechoic space surrounding the bright echogenic pericardium. A pneumopericardium will show bright spots/echogenic bubbles moving along the pericardial layer during diastole. A tamponade will show poor filling and/or diastolic collapse of the right side of the heart (right atria or right ventricle).
 11. **Urinary tract ultrasound.** Scan each kidney in the longitudinal and transverse orientation. Evaluate kidneys, collecting system, and bladder. Normal bladder: see earlier in chapter (Section II.A.3).
 12. **Endotracheal tube ultrasound.** Using high parasternal view or suprasternal approach, ultrasound exam can be done to confirm the ETT tip. Studies used either a 13-MHz linear transducer or a probe with a 5- to 8-MHz frequency. Correct ETT placement was 0.5 to 1.0 cm from the upper border of arch of aorta, between the thoracic inlet and the carina. The distance of the tip of the ETT from the carina can be measured. Tip of the probe is seen as a white or hyperechoic line that can help identify the tip of the ETT.
- E. Complications.** Although the safety profile of ultrasound is excellent, POCUS should only be performed by those healthcare workers who are fully trained. Knowledge of equipment settings and potential thermal and other bioeffects is essential.
1. **Maintain body temperature.** Monitor the infant's temperature and keep the infant warm during the scan. Warm the gel and open the incubators as few times as possible.
 2. **Attention to immature skin and prevention of infection.** Minimize skin trauma and use infection prevention protocols per specific NICU.
 3. **Cardiorespiratory monitoring.** Minimize the duration of the scan, and monitor cardiorespiratory status during the procedure.
 4. **Prolonged duration of scanning may cause small risk of cell damage.** Use of the "as low as reasonably achievable" principle is recommended. Examination times should be as short as possible. Output levels should be as low as possible.
 5. **Incorrect interpretation ("misreadings").** Following is a partial listing of errors that can be made on POCUS interpretation:
 - a. **Confusing vein for artery or nerve.**
 - b. **Misinterpreting pericardial fat for pericardial effusion.**
 - c. **Mistaking inferior vena cava for aorta.**
 - d. **Reversing right and left heart chamber.**
 - e. **Mistaking other fluid-filled structures for the bladder.**
 - f. **Combination of spleen and air in stomach can look like pneumonia.**

45 Venous Access: Intraosseous Infusion

- I. Indications.** **Intraosseous (IO) infusion** is the infusion of fluids or medications into the bone marrow cavity of a large bone. It is used for emergency vascular access (fluids and medications) when other access methods have been attempted and cannot be quickly established or have failed. In neonates during resuscitation, it is difficult to give medications through a peripheral vein because of insufficient perfusion. The bone medullary cavity does not collapse during circulatory failure or hypovolemia. Some recommend IO access if venous access is not established within 3 attempts or within 90 seconds. The **umbilical vein is the preferred route in the delivery room in a hospital setting**, but IO access can be considered if rapid intravenous (IV) access is essential and the operator is not experienced in umbilical vein catheter placement. IO access is an acceptable alternative in prehospital settings and emergency rooms. IO infusion of medications and fluids has the same hemodynamic effect as medications and fluids infused by the IV route.
- II. Equipment.** Antiseptic solution, 4 × 4 sterile gauze pads, sterile towels, gloves, IO device (devices approved for newborns are available; Table 45–1), syringe with saline flush, IV fluid, and infusion setup (Luer lock catheter with a 3-way stopcock).
- III. Procedure**
- A. Contraindications** include prior unsuccessful attempt in the same bone, bone diseases (eg, osteogenesis imperfecta, osteopetrosis, osteomyelitis), infection of the overlying skin, presence of a fracture, hemophilia or other coagulopathies, and thermal injury to the overlying skin. There are limited data, but IO seems safe in preterm infants.

Table 45–1. COMPARISON OF SOME INTRAOSSEOUS (IO) DEVICES USED IN NEONATOLOGY

IO Device	Features
Butterfly needles or short hypodermic needles	18–20 gauge (<i>Note:</i> needles without stylet usually not recommended but have been used in preterm infants; absence of stylet may increase incidence of obstruction of needle by bony spicules)
Spinal/lumbar puncture needle ^a	Straight needle with stylet, 18–20 gauge
Bone marrow biopsy needle ^a	Hollow needle with handle and stylet, 18 gauge
IO infusion needle (eg, Sussmane-Raszynski IO infusion needle; Jamshidi Illinois IO infusion needle)	Specialized handles and stylets with short needle shafts, 15.5 and 18 gauge
EZ-IO Pediatric (Teleflex, Morrisville, NC)	Reusable lithium-powered drill that drills the IO needle into the IO space; 15-gauge needle; length 15 mm for infants 3–39 kg
Bone Injection Gun, Pediatric (B.I.G., WaisMed, Houston, TX)	Automatic impact driven (spring-loaded) device; uses the “position and press” mechanism; 18 gauge <12 years; dial in age for needle depth

^aBest for emergency use where specifically designed IO device is not available.

Data from Tobias JD, Ross AK: Intraosseous infusions: a review for the anesthesiologist with a focus on pediatric use, *Anesth Analg*. 2010 Feb 1;110(2):391-401.

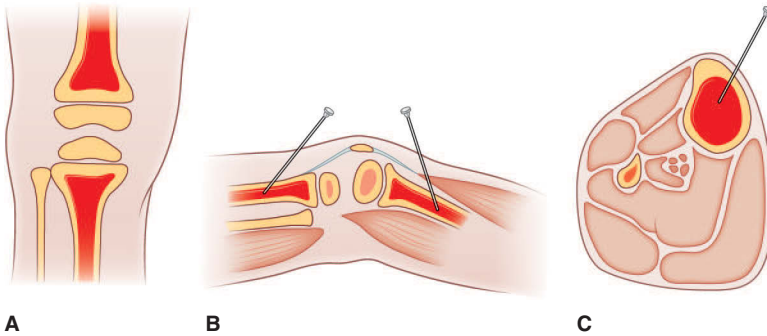

FIGURE 45-1. Technique of intraosseous infusion. (A) Anterior view of sites on the tibia and the fibula. (B) Sagittal view. (C) Cross-section through the tibia. (Reproduced with permission from Hodge D: *Intraosseous infusions: a review*, *Pediatr Emerg Care*. 1985 Dec;1(4):215-218.)

- B. The proximal tibia (anteromedial surface) is the preferred site in the infant** (vs the sternum in adults) and is described here (Figure 45-1). Benefits include a flat wide surface, less amount of soft tissue to obscure the bony landmark, and that it does not interfere with airway management or chest compressions, if needed. The intramedullary vessel in the tibial marrow empties into the popliteal vein and into the femoral vein. The preferred second site in the infant is the **distal femur**. Both sites avoid the epiphyseal plates of the bone. In some references the distal tibia is mentioned as an alternative site for infants but in other references it is recommended only for children >1 year. A theoretical alternative intraosseous infusion site that has been suggested is the greater tubercle of the humerus 9.5 to 11.1 mm from the acromion.
- C. Select the area in the midline on the flat surface of the anterior tibia, approximately 2 cm below and 1 to 2 cm medial to the tibial tuberosity (bony bulge below knee cap).** This area avoids the epiphyseal growth plate injury, and the thinner cortex here ensures an easier insertion. The mean medullary diameter of the proximal tibia at the site that is recommended is only 7 mm in the neonate and 10 mm in a 1- to 12-month-old infant.
- D. Restrain the patient's lower leg,** and place a small sandbag/rolled towel or IV bag behind the knee for support.
- E. Wash hands and put on gloves.** Clean the area with antiseptic solution. Sterile drapes can be placed around the area.
- F. Pain management.** Lidocaine (0.5%–1%) can be injected into the skin, soft tissue, and periosteum, but this is optional because this is usually an emergency procedure.
- G. Intraosseous needle insertion.** (See specific devices in Table 45-1.) Insertion site should be at least 10 mm distal to tibial tuberosity to avoid epiphyseal growth plate. Preference depends upon the study, some health care providers recommend manual needles or power driven devices over impact driven devices in infants. One study compared different devices and techniques and found that intraosseous access for premature and neonatal infants was best achieved by using a manually twisted butterfly needle.
- 1. Manual technique (butterfly or short hypodermic needle, spinal, bone marrow biopsy, or intraosseous needles).** Stabilize the limb above and lateral to the insertion site with the nondominant hand. Insert the needle perpendicular to the skin to avoid the growth plate. Advance the needle firmly, using hand-delivered steady force with a twisting and rotating, not rocking, motion until a

lack of resistance is felt, a “pop” usually no more than 1 cm is necessary, at which point entry into the marrow space should have occurred. The needle will stand up without support, and it will feel firm in the bone, although it may not be as firm in a neonate with a thin cortex. **Note** that it is best not to place the other hand under the tibia for stabilization, as excessive force may cause the needle to pass through the bone and exit on the other side.

2. **Impact driven or spring loaded device technique (eg, B.I.G. Pediatric device** [Bone Injection Gun; WaisMed Medical, Houston, TX]). Dial the age to get the appropriate needle depth. Position device at 90 degrees to the skin and hold firmly with one hand while the other hand pulls out the safety latch. It uses a “position and press” mechanism with a spring-loaded device that penetrates the cortex when the button is pushed. No additional force is needed other than holding the device firmly against the skin. Manufacturer-recommended site for infants is 0.5 inches medial and distal to the tibial tuberosity.
 3. **Drill assisted technique (eg, EZ-IO Pediatric** [Teleflex, Morrisville, NC]; only recommended for infants >3 kg). Device operates like a power drill. It has a tip that rotates into the IO space at a preset depth. Once the needle enters the space, the stylet is withdrawn, and a metal catheter remains with a Luer lock attachment. Manufacturer recommends removal within 24 hours.
- H. Once the catheter is in place, remove the stylet and tape needle in place.**
- I. **Confirm appropriate IO needle placement.** Some healthcare providers will aspirate blood or bone marrow, but the recommendations from the American Heart Association *Textbook of Neonatal Resuscitation* state that this is not a reliable indicator of correct needle placement. They feel if the needle is in the correct place it will stand and feel firm in the bone and not wiggle because it is supported by bony cortex. One recommendation to make sure the IO needle is in the correct place is to slowly infuse 2 to 3 mL of a saline flush solution. There should be no extravasation or swelling with correct placement **POCUS using color Doppler** can assess correct and incorrect placement (extravasation of fluid) of an intraosseous needle, but there is limited experience in pediatrics. Usually a plain radiograph is obtained to confirm position and rule out a fracture.
 - J. **Bone marrow aspiration for laboratory studies** can be done, if needed. Bone marrow aspirates can be sent for bedside glucose testing, electrolyte concentrations, pH, PCO₂, hemoglobin, culture and sensitivity, blood type and crossmatch, and drug levels. CBC is not recommended because of immature cells found in the bone marrow. Even if marrow cannot be aspirated, the IO needle can be used if it flushes without extravasation. If appropriate, secure the needle to the skin with tape to prevent it from dislodging.
 - K. **Attach the needle to intravenous infusion set (Luer lock with 3-way stopcock) and infuse at same rate used for intravenous route.** Hypertonic and alkaline solutions should be diluted 1:2 with normal saline. Administer at the same rate as that for an IV infusion. Any fluid or medication that can be used via an umbilical venous catheter can be used via the IO route (Table 45–2).
 - L. **Secure the needle and catheter with tape and an arm board,** allowing one to be able to visualize the area. Secure IV tubing with tape to the leg.
 - M. **Intraosseous vascular access should optimally be used for <2 hours** to minimize the risk of infectious complications, with some devices approved by the US Food and Drug Administration for longer use. When completed, withdraw the needle, apply pressure, and dress the site. Use for >24 hours is not recommended.
 - N. **With unsuccessful intraosseous placement,** do not repeat attempts at the same site or use the same site for 1 to 2 days.
 - O. **Monitor the site frequently for redness, bruising, inflammation, swelling, or any fluid extravasation.** Monitor limb circulation. Measuring the leg circumference hourly is recommended.
 - P. **It is important to note that the needle should be removed as soon as the infant has stabilized** or an alternative access has been successful.

Table 45–2. FLUIDS AND MEDICATIONS THAT HAVE BEEN ADMINISTERED BY THE INTRAOSSEOUS ROUTE

Intravenous Fluids			
Blood and blood products (eg, fresh frozen plasma, whole blood)	Crystalloids (lactated Ringer's, sodium chloride solutions [0.9% and hypertonic])	Dextrose solutions (D50 should be diluted)	Colloids
Medications			
Adenosine	Digoxin	Lorazepam	Prostaglandin
Amikacin	Dobutamine	Magnesium sulfate	Rocuronium
Aminophylline	Dopamine	Methylene blue	Sodium bicarbonate
Amiodarone	Ephedrine	Methylprednisolone	(diluted)
Ampicillin	Epinephrine	Midazolam	Succinylcholine
Atracurium	Fentanyl	Morphine	Sulfadiazine
Atropine	Furosemide	Naloxone	Thiamine
Calcium chloride and gluconate	Gentamicin	Pancuronium	Thiopental
Cefotaxime	Heparin	Pentothal	Vancomycin
Ceftriaxone	Isoproterenol	Phenobarbital	Vasopressin
Clindamycin	Insulin	Phenytoin	Vecuronium
Contrast media (dilute if possible)	Ketamine	Potassium chloride	Vitamins
Dexamethasone	Labetalol	Propofol	
Dextrose (D50; dilute)	Levarterenol	Propranolol	
Diazepam	Lidocaine		
Diazoxide			

Data Dubick MA, Holcomb JB. A review of intraosseous vascular access: current status and military application. *Mil Med.* 2000 Jul;165(7):552-559 and MacDonald M, Ramasetu J, Rais-Bahrami K: *Atlas of Procedures in Neonatology*, 5th ed. Philadelphia, PA: Wolters Kluwer; 2012.

IV. Removal

- A. **Remove any dressing or tape.** Stabilize the extremity.
- B. **Use aseptic technique.** Gently rotate the needle while withdrawing it.
- C. **Apply pressure to the site for a minimum of 5 minutes** and cover with sterile dressing.
- D. **Continue to observe the limb for 24 hours.**

V. Complications

- A. **Extravasation.** (Most common complication.) If giving caustic/vasoactive medications, such as dopamine, and extravasation occurs, tissue damage is possible. Subperiosteal infiltration of fluid can also occur.
- B. **Infections.** Introduction of pathogens during needle insertion can occur and lead to an infection. Localized cellulitis, subcutaneous abscess, periostitis, and sepsis have all been reported. Osteomyelitis is rare (<0.6%). To prevent osteomyelitis, hypertonic and alkaline solutions and all medications should be diluted. Sterile technique is important, and if compromised, consider antibiotic coverage.
- C. **Clotting of bone marrow.** Results in loss of vascular access.
- D. **Iatrogenic bone fracture.** Fractures can occur in infants secondary to the increased force required to penetrate the bone and also are increased in infants with osteopenia. Radiograph confirmation of the needle should be done to confirm position and rule out fracture (tibial fracture is most common).

- E. **Compartment syndrome.** Due to prolonged infusion and extravasation. The leaking fluid collects in the spaces between the muscles of the leg.
- F. **Blasts in the peripheral blood.** These have been noted after IO infusions.
- G. **Fat embolism.** Much less likely in infants than adults. Before the age of 5 years, the intramedullary space consists mainly of red marrow, which is more vascular and has a lower fat component. No adverse outcomes have been related to embolic events.
- H. **Bone growth concerns have been ruled out.** Studies have shown there is no long-term effect on tibial growth after IO infusion with a properly placed IO needle trocar. At the tibia, IO blood transfusions may result in transient radiologic changes but do not impact bone growth. If the catheter is placed in the growth plate, an injury may occur, but has not been reported in pediatric literature.
- I. **Needle dislodgement.**
- J. **Amputation of the leg.** Rare case reports (one that was treated with therapeutic hypothermia).

46 Venous Access: Peripherally Inserted Central Catheter

- I. **Indications.** Peripherally inserted central catheter (PICC) or percutaneous central venous catheterization (PCVC) involves inserting a long small-gauge catheter into a peripheral vein and threading it into a central venous location. The catheter can be placed in large vessels such as the temporal vein in the scalp, cephalic and basilic veins in the arm, or the saphenous vein in the leg.
 - A. **When intravenous access is anticipated for an extended period.** The Centers for Disease Control and Prevention (CDC) recommends placing PICC access if therapy is needed for >6 days.
 - B. **High-risk patient populations (surgical).**
 - C. **In low birthweight infants when it is anticipated that full enteral feedings will not be achieved within a short period.** Cochrane review found in one small study that the use of percutaneous central venous catheters increases nutrient output. Three trials suggested that the use of percutaneous central venous catheters decreased the number of catheters needed to deliver nutrition.
 - D. **Fluid delivery, nutritional solutions, and medications when other venous access is not acceptable or able to be obtained** (eg, hypertonic intravenous [IV] solutions).
- II. **Equipment**
 - A. **Basic supplies.** Cap, mask, sterile gloves, sterile gown, transparent dressing, sterile tape strips, a sterile tray, locally approved bactericidal skin prep, a sterile tourniquet, sterile transilluminator cover (optional), saline flush solution, sterile saline wipes, sterile gauge, and a T-connector.
 - B. **Percutaneous catheter device.** Silicone catheters and polyurethane catheters (typically with guidewire) are available. Some infants may benefit from dual lumen catheters due to multiple infusions or medication incompatibility. Ensure careful consideration when using dual lumen catheters due to increased associated risks, including catheter thrombosis and infection. According to the National Association

of Neonatal Nurses (NANN) guidelines, the most commonly used PICC catheters are 1.1 to 2F (28- to 23-gauge) catheter. Use the smallest catheter possible to accommodate the vein. Choose proper-sized catheters because a catheter too large for a vessel may cause the vessel to spasm.

1. Specialty antibiotic-coated catheters. Cochrane review (2015) found that although data from one trial did indicate that antimicrobial-impregnated central venous catheters might prevent catheter-related bloodstream infection in newborns, the available evidence is insufficient to guide clinical practice.

2. Specialty heparin-bonded catheters. Cochrane review (2014) found 2 studies on heparin-bonded catheters that revealed no decrease in catheter-related thrombosis; 1 study did report a decrease in catheter-related bloodstream infections and colonization with the use of heparin-bonded catheters.

III. Procedure. If a guidewire is present, it needs to be removed before blood is withdrawn or the catheter is flushed. Providers placing lines need to be trained with competency check off, to maintain skills with a designated minimum number of insertions per year, and to be comfortable with manufacturer guidelines specific to catheter devices. A review of the NANN Guideline for Peripherally Inserted Central Catheters (see Selected References) is suggested.

A. Obtain informed consent and perform a time-out. Gather the equipment and assemble the tray with the catheter using sterile technique.

B. Consider utilization of available technology including transillumination or ultrasound-guided insertion techniques. These techniques have been shown to improve success rates. **Ultrasound-guided PICC line placement** is very effective in very low and extremely low birthweight infants. The inserter should be proficient with associated technology. See Chapter 44.

C. Select a suitable large vessel. The right saphenous vein is an ideal site associated with lower complication rates (Figure 47–1). Position the infant with the selected vessel accessible. An assistant is helpful to maintain sterility and provide nonpharmacologic pain management (see Section III.G).

D. Determine the length of the catheter. Measure the distance between the insertion site and the desired catheter tip location.

1. Upper extremity position: Measure to the level of the superior vena cava (SVC).

2. Lower extremity position: Measure to the inferior vena cava (IVC).

E. Put on the cap and mask, wash your hands, and then put on the sterile gown and gloves (provider placing line). Anyone within about 3 feet of the bedside should have a cap and mask on and observe maximal sterile barrier precautions.

F. Prepare the area of insertion using a unit-approved bactericidal agent and allow the solution to dry. Avoid alcohol because it can cause degradation of some catheters. Tourniquet proximal to the insertion site.

FIGURE 46–1. Technique for insertion of the introducer needle into the vein.

- G. Pain.** The American Academy of Pediatrics policy statement indicates that the goal for pediatricians is to prevent or minimize pain in the neonate.
- 1. Guidelines should be written by the local unit** to address pharmacologic and nonpharmacologic pain management strategies for PICC insertion.
 - 2. Pharmacologic pain management** may include topical anesthesia (EMLA [eutectic mixture of lidocaine and prilocaine]) or systemic opiate-based anesthesia. Sucrose pacifier may provide sufficient analgesia.
- H. Place sterile drapes over the patient.** Use maximal sterile barrier precautions with a large sterile field around the area of insertion that covers most of the infant.
- I. Remove the plastic protector from the introducer needle.**
- J. Insert the introducer and needle into the vein.** Confirm entry into the vein by observing for a flashback of blood in the needle. Do not advance the introducer and needle once the flashback has been noted due to risk for puncturing through the opposite side of the vessel (see Figure 46-1).
- K. Release the tourniquet.**
- L. Hold the introducer and needle to maintain the position in the vein and withdraw the needle.** Slowly advance the catheter through the introducer with a pair of smooth forceps or fingers into the vein. **Ridged forceps may damage the catheter** (Figure 46-2).
- M. Once the catheter has been advanced to the premeasured location, stabilize the catheter by placing a finger 1 to 2 cm above the tip of the introducer.** Carefully withdraw the introducer completely out of the skin. Hold sterile gauze to the area until hemostasis is achieved (Figure 46-3).
- N. Separate the introducer from the catheter.** Grasp the opposite halves of the introducer, and carefully peel each half apart until the needle splits completely (Figure 46-4).
- O. During removal of the introducer needle, the catheter may partially withdraw.** Readvance to the desired location.
- P. If a guidewire is present, remove the wire slowly and steadily from the catheter.** Do not attempt to reintroduce the wire once it has been removed from the catheter.
- Q. As the introducer wire is withdrawn, blood return may or may not be observed in the catheter.** Smaller catheters are less likely to have blood return. Using a 3-mL syringe, aspirate blood through the catheter until blood reaches the hub. (Slightly more

FIGURE 46-2. The catheter is inserted through the introducer needle with forceps.

FIGURE 46-3. The catheter is stabilized while withdrawing the needle.

pressure is necessary to withdraw blood through the very small diameter of the catheter. If you achieve blood return, the catheter is patent and in the intravascular system.) Once blood has been aspirated back to the catheter hub, place a T-connector and flush the catheter with normal saline. Avoid excessive pressure when flushing the catheter as it can result in catheter rupture or fragmentation with possible embolization.

- R. Secure the catheter to the extremity by placing a sterile tape strip over the disc to anchor the catheter** (damage may occur if placed directly on the catheter). Coil the external catheter, making sure there are no kinks, and cover with a sterile transparent dressing. **Do not suture the catheter in place.**
- S. Connect the intravenous fluid.** New fresh sterile IV fluids should be connected to the new catheter. The necessary use of heparin for patency is *controversial*. The lowest PICC maintenance infusion rate has been widely reported as 1 mL/h. Cochrane review (2014) recommends prophylactic use of **heparin** in PICC lines because it allows a higher number of infants to complete their therapy and reduces the risk of catheter occlusion. The American College of Chest Physicians Evidence-Based Clinical Guidelines (2012) recommends continuous infusion of unfractionated heparin 0.5 U/kg/h to maintain patency in neonates with central venous access devices.

FIGURE 46-4. Technique for removing the needle wing assembly of most catheters.

- T. Obtain a radiograph to verify the central catheter tip location.** Most catheters are radiopaque. Occasionally, they are too small to visualize the catheter tip location. In some instances, 0.3 to 1 mL of contrast is used prior to radiograph to assess tip location. The position of the catheter tip should be in a central location such as the SVC or IVC because these locations are associated with a lower risk of complications. If unable to advance to a central location, the line may be used as a midline catheter with the tip in the proximal portion of the extremity (avoid placing the tip in a flexed position). Hypertonic solutions should not be infused through a midline catheter. Midline catheters are typically used for a shorter duration (<1 week). **Sonography** has been used in a pilot study to localize the position of the catheter.
- U. Lower extremity peripherally inserted central catheter.** A cross-table lateral x-ray should be done to assess the proper placement of the catheter in the IVC (risk for spinal vein insertion).
- V. Chart the size and the length of catheter that has been inserted** and the position of the catheter on radiograph.
- W. Precautions**
- 1. Avoid blood pressure measurements on the extremity containing the catheter.**
 - 2. Only trim catheters prior to placement if directed by manufacturer.** A rough-cut end may increase thrombus formation.
 - 3. During insertion through the introducer needle, avoid pulling the catheter back through the introducer needle.** Risk for the catheter to sever.
 - 4. Do not suture the catheter.**
 - 5. Blood product administration is controversial.** In general, try to avoid due to the risk of catheter occlusion.
 - 6. Avoid excessive pressure when flushing the line due to risk of rupture** (do not use syringe <3 mL).
- X. Maintenance of the catheter**
- 1. Prevention of central line-associated bloodstream infection.** Line insertion bundles, care guidelines, and specially trained insertion teams have been associated with decreased incidence of infection.
 - 2. The transparent dressing should remain in place over the catheter.** Routine dressing changes are not recommended. The dressing should be changed using sterile technique if the current dressing is soiled or is no longer occlusive.
 - 3. Examine the site for inflammation or tenderness.**
 - 4. Fluids and medications** running through the catheter should be prepared using sterile conditions and heparinized according to hospital or unit protocol.
 - 5. Limit the number of times the catheter is accessed to decrease infection.** Research suggests that the hub is a common site of contamination and subsequent infection. Clean hubs with antiseptic each time the line is entered.
 - 6. Use the exchange technique for occluded or malpositioned catheters in limited circumstances** because it has been associated with a higher risk of central line-associated bloodstream infection (CLABSI).
- Y. Removal of the catheter.** The catheter can remain in place for several weeks. Several studies have shown an increase in the infection rate after 2 weeks.
- 1. The use of antibiotic administration prior to removal is controversial** and has been studied on a limited scale. A small trial suggests that antibiotics given 12 hours prior to removal, whether for treatment or prophylaxis, has been associated with a decreased incidence of late-onset sepsis after catheter removal. The theory is that this reduces the risk of bacterial showering with line removal. Prophylactic antibiotic administration has not yet been introduced widely into practice and needs to be studied on a larger scale.
 - 2. Gently remove the occlusive dressing** from the extremity and the catheter.
 - 3. Grasp the catheter tubing near the insertion site** and gently pull the catheter in a continuous movement. If resistance is met, do not apply force and do not stretch the catheter. Doing so could cause the catheter to rupture.

4. **Apply a moist, warm compress to the area above the catheter tract for several minutes, and then reattempt removal of the catheter.** If the catheter is still resistant, it may take several hours to days to remove some catheters.
5. **Once the catheter is removed, inspect and measure it to make sure the entire catheter was removed from the vein.** Compare this to the initial insertion note.
6. **Cover the site with petroleum-based gauze and occlusive dressing for 24 to 48 hours.** This technique reduces the risk of air embolism. A Cochrane review found the following: “Chlorhexidine dressing/alcohol skin cleansing reduced catheter colonization, but had a risk of contact dermatitis in preterm infants and did not affect major outcomes like sepsis and CLABSI compared to polyurethane dressing/povidone iodine cleansing. Silver alginate patch appears safe but cannot be recommended because of insufficient evidence.”

IV. Complications. Common complications are listed.

- A. Infiltration.** Assess for swelling at the insertion site up to the catheter tip location.
- B. Catheter occlusion.** PICCs are at risk for occlusion due to the size, fragility of the catheter, and the potential for neonatal flexion of extremities. Take care to avoid kinking the catheter during securement because it could lead to catheter occlusion. If resistance is met when flushing the catheter, do not attempt to flush it any further because it could result in catheter rupture and ultimately possible embolization. Tissue plasminogen activator/alteplase therapy may be indicated in certain clinical situations (refer to your local unit protocol).
- C. Infection or sepsis. A catheter-associated bloodstream infection is the most common healthcare-associated infection in the neonatal intensive care unit.** Each unit should develop a strategy to track CLABSI and develop strategies for prevention. Refer to NANN guidelines (see Selected References) and CDC guidelines for risk reduction strategies. Infants requiring a PICC are at an increased risk for nosocomial infections (poor skin integrity, immature immune system, multiple invasive procedures, exposure to multiple pieces of equipment). Coagulase-negative staphylococci account for >50% of infections. Other pathogens include gram-negative organisms (20%), *Staphylococcus aureus* (4%–9%), *Enterococcus* (3%–5%), and *Candida* (10%). Paired samples should be drawn (catheter and a peripheral vein) from neonates with suspected sepsis to isolate a potentially infected catheter. Neonates with suspected CLABSI should be treated with broad-spectrum antibiotics to cover both gram-positive and gram-negative organisms. Line stewardship focuses on daily review of the need for central access.
- D. Air embolism.** Special precautions should be taken to avoid air in the line.
- E. Catheter embolus.** Risk for catheter shearing if the catheter is pulled back through the introducer needle.
- F. Catheter migration/malposition.** Catheters can move after initial placement. Assess the catheter position with an x-ray the first 2 to 3 days after insertion and at minimum weekly.
- G. Pericardial effusions are a rare but life-threatening complication of percutaneous central venous catheters.** Keep a high index of clinical suspicion in a neonate who has a central line and suddenly has cardiovascular collapse that does not respond to resuscitation, resistance to external cardiac compressions, and no transilluminated air leak. It is more common with lines in the right atrium, and the median time to occurrence is 3 days after percutaneous central catheter insertion. Chest radiograph may not be diagnostic; echocardiography is diagnostic but may delay treatment, and mortality is high.

47 Venous Access: Peripheral Intravenous Catheterization

- I. **Indications.** Peripheral intravenous (IV) catheterization involves inserting an IV catheter into a peripheral vein.
 - A. **Vascular access in nonemergent and emergent situations** for the administration of IV fluids and medications.
 - B. **Administration of parenteral nutrition.**
 - C. **Administration of blood and blood products.**
 - D. **Blood sampling only if associated with initial intravenous placement.**
- II. **Equipment**
 - A. **Basic.** Armboard, adhesive tape, tourniquet, alcohol swabs, normal saline for flush (0.5% normal saline if hypernatremia is a concern), povidone-iodine solution/swabs, transparent dressing material, appropriate IV fluid, and connecting tubing. For difficult venous access, transillumination, near-infrared light, or ultrasound can be used, and these are considered optional. In-line filters are sometimes used; however, a Cochrane review (2015) found that there was insufficient evidence to recommend the use of IV in-line filters to prevent morbidity and mortality in neonates.
 - B. **Intravenous catheter.** Safety-engineered/self-shielding devices preferred: 23- to 25-gauge scalp vein (“butterfly”) needle or a 22- to 24-gauge catheter-over-needle. Use at least 24 gauge for blood transfusion.
- III. **Procedure**
 - A. **Catheter-over-needle assembly**
 1. **Select the vein.** Common neonatal IV insertion sites are shown in Figure 47–1. Several techniques have been described based on personal preference.
 - a. **The vessel can be entered directly after puncture of the skin on the top of the vein.**
 - b. **Enter the vein at the “crotch” or “Y region,” the location where 2 veins join together** (Figure 47–2A).
 - c. **Insert alongside the vein and advance approximately 0.5 cm before entry into the side of the vessel** (Figure 47–2B).
 2. **To help identify the vein, use visualization, palpation, near infrared spectroscopy imaging, transillumination, or point-of-care ultrasound using static technique (see Chapters 25 and 44).** The dorsum of the hand is the best choice to preserve the sites for potential central venous catheters (cephalic, brachial, greater saphenous veins) if needed. Avoid areas of flexion.
 - a. **Scalp.** Supratrochlear (frontal), superficial temporal, or posterior auricular vein (last resort).
 - b. **Back of the hand.** Preferred site using the dorsal venous network.
 - c. **Forearm.** At the wrist area is the cephalic and basilic vein. Median antebrachial vein and accessory cephalic vein are higher up on the forearm.
 - d. **Foot.** Dorsal venous arch.
 - e. **Antecubital fossa.** Basilic or cubital veins.
 - f. **Ankle.** Greater and small saphenous veins.
 3. **Use of point-of-care ultrasound for peripheral intravenous catheterization.** One can use real time imaging to help guide the peripheral IV placement. Benefits include less time for placement, better success, decreased attempts and needle redirections, and less complications. See Chapter 44 for technique.
 4. **Shave the area if a scalp vein is to be used.** Try to place needle behind the hair line in the event of cosmetic scarring.

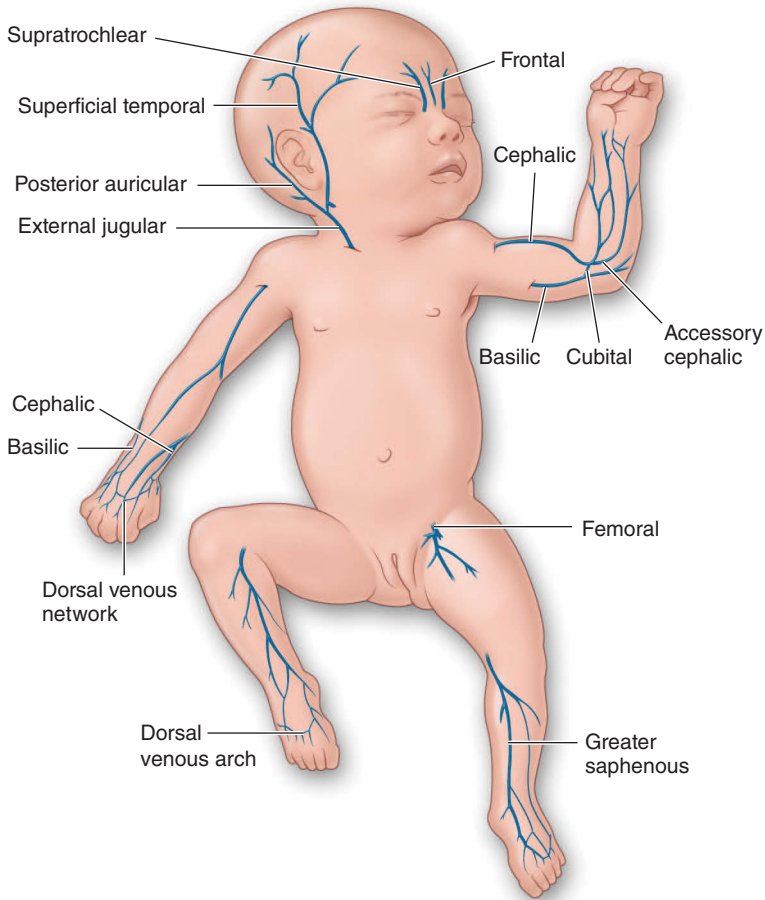

FIGURE 47-1. Frequently used sites for venous access in the neonate.

5. **Restrain the extremity on an armboard** or have an assistant help hold the extremity or the head.
6. **Pain management.** Oral sucrose/glucose, pacifier, swaddling, and other non-pharmacologic methods can be used for pain reduction. The American Academy of Pediatrics recommends eutectic mixture of lidocaine and prilocaine (EMLA) applied 30 minutes before the procedure.
7. **Apply a tourniquet proximal to the puncture site.** If a scalp vein is to be used, a rubber band can be placed around the head, just above the eyebrows.
8. **Wash hands and put on nonsterile gloves.** Glove use after hand hygiene prior to patient and line contact is associated with a decreased incidence of gram-positive infections in preterm infants.
9. **Clean the area with antiseptic solution.** Allow to dry and wipe off with sterile water or saline.

FIGURE 47-2. Two commonly used techniques for entering the vein for intravenous access in the neonate (see text). (A) Enter vein at the “crotch” or “Y region” where 2 veins come together. (B) Side entry technique where the needle is inserted into the skin and then advanced 0.5 cm before puncturing the vein on the side. Some providers will enter the vein from the top as well.

10. **Fill the needle and the hub with flush via syringe (if possible)**, and then remove the syringe.
11. **Pull the skin taut** to stabilize the vein.
12. **Puncture the skin** and then enter the side of the vein in a separate motion. Alternately, the skin and the vein can be entered in one motion.
13. **Carefully advance the needle** until a flash of blood appears in the hub.
14. **Activate the shield** to safely sheath the needle and advance the catheter. Injecting a small amount of flush solution into the vein before advancing the catheter may help.
15. **Remove the tourniquet** and gently inject some normal saline into the catheter to verify patency and position.
16. **Connect the intravenous tubing and fluid** and tape securely in place using transparent dressing.
17. **Heparin for peripheral intravenous lines (controversial)**. Heparin is usually not recommended for peripheral IV lines. A 2013 review found that low-dose heparin in peripheral IV catheters prolonged the catheter life with a decrease in infusion failure rates when a continuous infusion was used. Cochrane review states that there are insufficient data concerning the effect of heparin for prolonging IV use in neonates and that recommendations cannot be made.

One study found that heparinized saline flushes increased the functional duration of peripheral IV catheters.

- B. Scalp vein or butterfly needle.** Used for short-term therapy, for small scalp veins, or for smaller veins in which a catheter-over-needle assembly cannot be used. Scalp veins provide an option for IV access in infants because of limited subcutaneous fat and less movement. The needles are often easier to insert but do not have much durability.

1. **Follow steps 1 to 9 for catheter-over-needle procedure (see Section III.A).**
2. **Foot.** Dorsal arch veins are very small but are very good to use. A vein that runs behind the malleolus on the lateral aspect of the foot is easy to access.
3. **Antecubital fossa.** The median antecubital, cephalic, and basilic veins are excellent veins but need to be splinted well for them to maintain the site.
4. **Grasp the plastic wings.** Using your free index finger, **pull the skin taut** to help stabilize the vein.
5. **Insert the needle through the skin in the direction of the blood flow.**
6. **Advance the needle when blood appears in the flash chamber or tubing.** Gently inject some of the flush to ensure patency and proper positioning of the needle.
7. **Connect the intravenous tubing and fluid, and tape the needle into position.**

- IV. Complications.** In one study, the incidence of IV complications was up to 63%.

- A. Hematoma** at the site can often be managed effectively by gentle pressure.
- B. Phlebitis (inflammation of the vein) risk** increases the longer a catheter is left in place, especially if >72 to 96 hours. Sites are rotated at 72- to 96-hour intervals to decrease phlebitis and infection.
- C. Occlusion/obstruction** is a common complication.
- D. Vasospasm** rarely occurs when veins are accessed and usually resolves spontaneously.
- E. Infection risk** can be minimized by using sterile technique, including antiseptic preparation. The risk of infection increases after 72 hours. Peripheral IV catheterization is rarely associated with bloodstream infection. Presence of blood in the hub is universal and may facilitate infection.
- F. Embolus (air or clot).** Never allow the end of the catheter to be open to the air, and make sure that the IV catheter is flushed free of air bubbles before it is connected. Do not use excessive force when flushing.
- G. Infiltration/extravasation injury** results from the leakage of fluid from a vein into the surrounding tissue, usually due to improper catheter placement or damage to the vessel. See Chapter 42 for details on management of infiltration and extravasation.
 1. **Infiltration of nonvesicant fluid** does not cause tissue loss, but a large volume can cause compression of the neurovascular structures, leading to compartment syndrome.
 2. **Extravasation can cause a mild injury or severe necrosis** (blisters, tissue injury, and necrosis) and may result in the need for skin grafting. To limit this, confirm intravascular placement of the catheter with the flush solution before the catheter is connected to the IV tubing. Infiltration often means that the catheter needs to be removed. Avoid hyperosmolar solutions for peripheral infusion, and use caution with dopamine, which can cause constriction. Vialon catheter material was found to reduce the risk of infiltration (35% in infants <1500 g) as compared to Teflon in one study.
- H. Calcification of subcutaneous tissue** secondary to infusion of a calcium-containing solution.
- I. Fluid overload,** electrolyte problems (hypernatremia).

48 Venous Access: Umbilical Vein Catheterization

I. Indications

- A. **Immediate, postnatal access** for intravenous (IV) fluids or emergency medications.
- B. **Long-term central venous access** in low birthweight (BW) infants or sick infants for administration of IV fluids, total parenteral nutrition, other hypertonic or hyperosmotic solutions, and medications.
- C. **Exchange or partial exchange transfusion.**
- D. **Delivery of blood and blood products.**
- E. **Central venous pressure monitoring** (if umbilical venous catheter [UVC] passes through the ductus venosus).
- F. **Secondary aid** in the diagnosis of cardiovascular or other anomalies by an unusual course of the UVC or the blood gas values are suspicious.
 1. **Congenital diaphragmatic hernia.** UVC is left of the midline because of the anomalous positioning of the liver in the chest.
 2. **Persistent left superior vena cava.** UVC extends beyond the lung (it enters the persistent left superior vena cava and then the left jugular vein).
 3. **Congenital absence of the ductus venosus.** This can cause an abnormal path of UVC (caudal loop is seen on radiograph).
 4. **Infradiaphragmatic total anomalous pulmonary venous return.** Diagnosed by high partial pressure of oxygen in an infradiaphragmatic UVC.

II. Equipment

- A. **Basic.** Identical to umbilical artery catheterization (see Chapter 28).
- B. **Umbilical venous catheters**
 1. **Types. Single lumen:** 2.5, 3.5, or 5F; **dual lumen:** 3.5 or 5F; **triple lumen:** 5 or 8F.
 2. **Size guideline.** Preterm: 3.5 or 5F; term and late preterm: 5F. Other guidelines: 3.5 or 5F catheter <3.5 kg, 5 or 8F >3.5 kg. An 8F catheter is recommended for exchange transfusion or large-volume replacement. **American Academy of Pediatrics (AAP) Perinatal Continuing Education Program recommendations:** 5F for all infants for emergency medications, 8F for exchange transfusions for large infants. **Dual (double-lumen) catheters** are sometimes recommended in infants <28 weeks and <1000 g, in infants who need several different medications, in infants who need inotropes or insulin, and in critically ill infants such as those with severe cases of persistent pulmonary hypertension or meconium aspiration syndrome.

III. Procedure

A. Important umbilical vein catheter tips

1. **There is only 1 umbilical vein, and it remains a viable option for cannulation up to 1 week after birth.** The umbilical vein carries oxygenated blood from the placenta to the fetus. The UVC passes into the umbilical vein through the umbilicus and follows this path: junction of the right and left portal vein in the liver, across the ductus venosus, across the level of the right and left hepatic vein, and into the inferior vena cava (IVC) to the junction of the IVC and right atrium.
2. **In an emergency postnatal situation (eg, delivery room),** a UVC can be rapidly inserted until blood return is obtained (usually 2–4 cm in a term infant; some sources insert 5 cm plus cord length with less distance in preterm) as emergency venous access. Resuscitation medications, volume, and blood can be given.

3. **Single- versus multiple-lumen catheters.** **Cochrane review** (2005) makes no recommendation on using single- versus multiple-lumen catheters. Double-lumen catheters decreased the number of additional venous lines during the first week of life, but they broke, leaked, and clogged more (smaller diameter). No differences in UVC placement difficulty, misplacement, catheter-related infections or blood clots, or rate of infant mortality were noted. Consider using the least number of lumens required.
 4. **Suspect cardiac tamponade in a neonate with an umbilical vein catheter (even if properly placed) who develops a sudden unexplained clinical deterioration in cardiopulmonary status.** Urgent echocardiography or pericardiocentesis should be considered. Routine radiography/ultrasound to verify placement is recommended by some to check for tip migration. Positional changes in the upper extremity may cause migration of the catheter tip. When obtaining a chest radiograph, note arm position. Minimize infant mobilization while the catheter is in place to prevent the catheter from migrating to the right atrium.
 5. **Catheter duration recommendations** from the Centers for Disease Control and Prevention (CDC), 14 days; other sources, 7 days, up to 28 days if absolutely necessary. The AAP notes catheters can be used up to 14 days if used aseptically. A Cochrane review (2017) analyzed whether early planned removal of UVCs would decrease the chance of an infection in newborn infants but found the following: “There was only one RCT [randomized controlled trial] and it did not show that early planned removal could reduce the chance of developing a bloodstream infection.”
 6. **Heparin use in umbilical vein catheters is controversial.** Literature is conflicting; there are recommendations for and against its use. The majority of neonatal intensive care units use heparin in UVCs. A common practice is as follows: heparin (typical range, 0.5–1 U/mL) in all fluids via the UVC. Use of heparin flushes alone is not effective in maintaining patency. The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend heparin in central venous access devices at a continuous infusion at 0.5 U/kg/h; the AAP recommends a starting dose of 0.12 U/kg/h.
 7. **Blood cultures** can be obtained from a UVC right after placement; otherwise, venipuncture is preferred.
 8. **Point-of-care ultrasound (POCUS) during placement of UVC.** Ultrasound guidance can help guide the catheter and allow for faster placement and results in fewer manipulations and x-rays compared with conventional placement. See Chapter 44.
- B. Estimate the depth of insertion for umbilical vein catheter.** Multiple methods have been reported; refer to institutional guidelines if possible. It is important to standardize the calculation method, since this improves the accuracy of placement. Some recommendations are to insert it 2 cm longer than the recommended length, since it is easier to withdraw the catheter than to insert it deeper. Remember to add the umbilical stump length to the calculation.
1. **Dunn method (early method).** Measures the shoulder-umbilicus length and uses a nomogram to determine the insertion length. Do not measure the shoulder diagonally to the umbilicus (it needs to be a straight line from the shoulder to the level of the umbilicus). This method was more accurate than the Shukla-Ferrara method (see below) in 1 study. **The catheter tip should be placed between the level of the diaphragm and the left atrium on the graph (see Figure 48–1).**
 2. **Shukla-Ferrara method.** Based on BW, may lead to overinsertion in very low BW infants.

$$(3 \times \text{BW in kg} + 9)/2 + 1 \text{ cm}$$

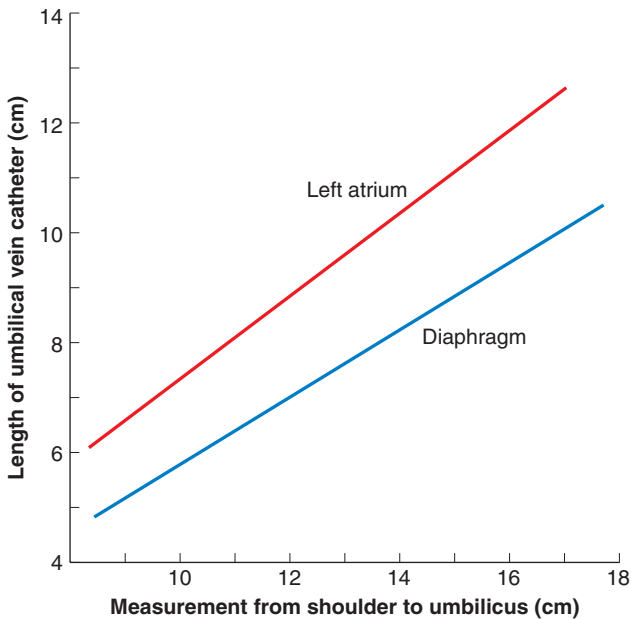

FIGURE 48-1. The umbilical venous catheter is placed above the level of the diaphragm and below the left atrium. Determine the shoulder-umbilical length as for the umbilical artery catheter. Use this number and determine the catheter length using the graph. Add the length of the umbilical stump to the length of the catheter. The catheter length should be between the diaphragm and left atrium on the graph. (Data from Dunn PM. *Localization of the umbilical catheter by post-mortem measurement.* Arch Dis Child. 1966;41:69.)

If the umbilical artery length has been previously calculated (page 315), use the following formula:

$$\text{UVC length: } \frac{1}{2} \times \text{umbilical artery line calculation} + 1$$

- a. **Modified (revised) Shukla (birthweight) equation.** May reduce the rate of overinsertion.

$$(3 \times \text{BW in kg} + 9)/2 \text{ cm}$$

3. **Another method relies on external anatomic landmarks to determine the appropriate insertion length.** It can be used in infants with all BWs. The measurement “UN” was found to be more accurate in infants with all BWs than any BW-based formula in one study.

$$\begin{aligned} \text{UN (distance in cm from the umbilicus to the nipple)} - 1 \text{ cm} \\ = \text{distance to place the UVC} \end{aligned}$$

4. **Other measurements used:**

- a. **Xiphoid to umbilicus length:** Measure from the xiphoid to the umbilicus and add 0.5 to 1 cm.
- b. **Shoulder to umbilicus length:** Measure the shoulder (end of clavicle) to umbilicus length and then multiply by 0.66.

C. Pain management. Since the umbilical cord is denervated, pain may be minimal. No formal anesthesia is usually needed if you avoid traumatizing the skin. Use non-pharmacologic pain prevention and relief techniques if possible.

D. Technique

1. **Place the infant supine with a diaper wrapped around both legs for stabilization.**
2. **Prepare the tray as you would for the umbilical artery catheterization.** (See Chapter 28.) Fill the lumen with infusion solution so it is air free. Don a gown, mask, and sterile gloves.
3. **Prepare the area around the umbilicus with antiseptic solution per local policy.**
4. **Place sterile drapes, leaving the umbilical area exposed.**
5. **Tie a piece of umbilical tape** or a purse string suture around the base of the umbilicus.
6. **Cleanly cut the excess umbilical cord with a knife blade (scalpel), leaving a stump of about 0.5 cm.** Scissors are not recommended because they can crush the vessels. If bleeding occurs, tighten the umbilical tape, or press downward just above the umbilicus on the infant's abdomen (since the umbilical vein travels toward the head). Identify the umbilical vein; it is thin walled, larger than the arteries, and close to the periphery of the stump (see Figure 28–3B). Normally one can determine the vessels by visual observation. If not, rub the flat side of the instrument across the stump; the arteries can be felt with resistance, but the vein will not.
7. **Grasp the end of the umbilicus with the curved hemostat to hold it upright and steady** (Figure 48–2A).
8. **Open and dilate the umbilical vein with the forceps.** If any clots are visible in the lumen, remove them with forceps. **Insert the flushed catheter** (Figure 48–2B) the desired length. Direct the UVC toward the head/cephalad with a hand providing liver immobilization (this improves the rate of insertion into the IVC). Some units use **ultrasound to help guide the catheter**, and this has been found to reduce complications during UVC insertion.
9. **Occasionally, a catheter enters the portal vein** (Figure 48–3). Suspect portal vein entry if you meet resistance and cannot advance the catheter the desired

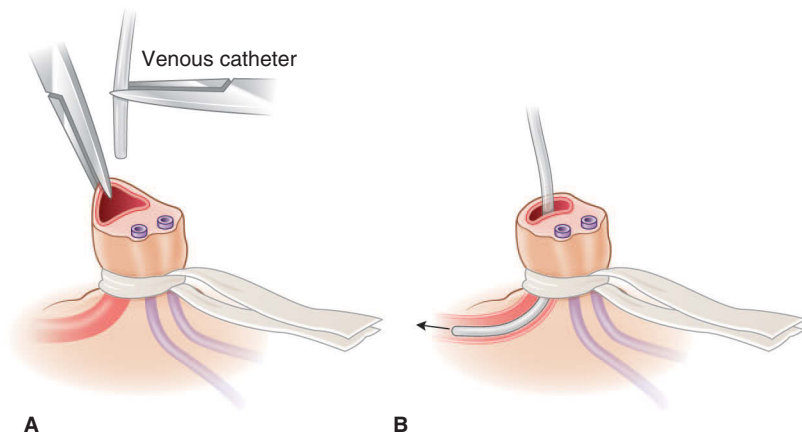

FIGURE 48–2. Umbilical vein catheterization. (A) The umbilical stump is held upright before the catheter is inserted. (B) The catheter is passed into the umbilical vein.

FIGURE 48-3. Anatomic relationships used in the placement of an umbilical venous catheter.

distance or if you detect a “bobbing” motion of the catheter. Several options are available to correct this:

- a. **Withdraw the catheter 2 to 3 cm**, rotate it, and try to reinsert it.
 - b. **Try injecting flush as you advance the catheter.** Sometimes this makes it easier to pass the catheter through the ductus venosus.
 - c. **Double-catheter technique** is based on the concept that if the first catheter occupies the wrong vessel (portal system), the second catheter will enter the correct vessel (and pass through the ductus venosus) because the wrong one is blocked. Leave the misplaced catheter in place and pass another catheter through the vein; the misplaced one can then be removed (reported 50% success rate). This technique increases the risk of perforation.
10. **Connect the catheter to the fluid and tubing.**
 11. **Secure the catheter similar to an umbilical artery catheter** (see Figures 28–4 and 28–5). Never advance a catheter once it is secured in place.
 12. **Minimize infant mobilization while the catheter is in place to prevent the catheter from migrating to the right atrium.**
 13. **Confirm placement.** Incorrect placement is associated with higher complication rates. The UVC should be at the junction of the inferior vena cava and the right atrium (in the inferior vena cava, below the level of the right atrium and above the level of the ductus venosus). Incorrect placement is associated with higher complication rates (pericardial or peritoneal effusion,

cardiac tamponade, arrhythmia, thrombosis, liver tissue necrosis, intracardiac thrombosis, death).

a. Anteroposterior and lateral radiographs that include abdomen and chest are the radiographs of choice to confirm catheter position (see Figure 12–14). The UVC should be just **above the diaphragm** but below the right atrium. The UVC tip should be 0.5 to 1.0 cm (reported range, 0–2 cm) above the right diaphragm (UVC tip at thoracic vertebrae 8–9 usually corresponding to the right cavoatrial junction). **The lateral image is necessary to show the exact location and will show the course of the umbilical vein and ductus venosus in relation to the liver.** *Note:* Air can sometimes be seen in the portal venous branches immediately after UVC insertion. As an isolated transient finding, it should not be confused with portal air due to necrotizing enterocolitis.

i. Thoracic level on x-ray does not accurately predict catheter position. UVCs were found to be located at a wide range of vertebral bodies (T6–11) by echocardiogram. Recommendations vary on what thoracic level the UVC line should be at (T8–9, T9, or T9–10).

ii. Some clinicians suggest radiography is unreliable and very imprecise in confirming catheter tip position. Lateral radiographs do not always accurately predict catheter placement. Anteroposterior radiographs underestimate the incidence of left atrial placement, and lateral radiographs overestimate left atrial placement.

b. POCUS. Present evidence supports the use of ultrasound for localization of the UVC. It has been suggested as the best modality since it more accurately confirms the position of the catheter tip and resulted in decreased radiation exposure than x-ray. Some also recommend the routine use of POCUS screening at regular intervals in all newborns with a UVC to make sure the catheter is in the proper position, and to follow any migration of the catheter and detect any complications.

c. Blood gas determining partial pressure of oxygen and saturation can be obtained to confirm venous sampling (sensitivity 45% and specificity 95%).

d. Gold standard is considered echocardiography with saline contrast injection to document distal catheter location.

e. If bright red (arterial) blood is obtained, the UVC has either crossed the foramen ovale and needs to be pulled back, or the catheter is in an artery.

f. If the catheter needs to be repositioned, you can withdraw (whether the sterile field is intact or not) if necessary. If you need to insert it further, you can only do this if the sterile field was kept intact. If the sterile field is not intact, you will have to remove and repeat with a clean setup.

14. There is insufficient evidence to support or refute the routine use of prophylactic antibiotics with umbilical vein catheterization (Cochrane review, 2005).

Do not use topical antibiotic ointments or creams at umbilical insertion sites because these will promote fungal infections and antimicrobial resistance.

IV. Umbilical vein catheter removal. UVC removal should be done as soon as possible because of the higher risk of colonization and infection with longer indwelling times.

A. Make sure the umbilical tie is loose and cut and remove any sutures or tape that would hinder removal.

B. Withdraw the catheter slowly 1 to 2 cm at a time over a few minutes until about 2 to 5 cm remain.

C. Tighten the umbilical tie and stop any infusions.

D. Pull the rest of the catheter out slowly (rate of 1 cm/min).

E. Apply gentle pressure above the umbilicus until bleeding has stopped; loosen the umbilical tie.

F. Send tip for culture if infection is suspected. Observe for excessive oozing or hemorrhage.

- V. Complications.** Risk of complication is high (10%–50%). Keep the catheter tip in the IVC and not at the foramen ovale, portal vein, or hepatic vein. Remember, complications can occur even with appropriately placed UVCs.
- A. Infection.** Most commonly reported adverse effect. Minimize the risk by strict sterile technique, never advancing a secured catheter, and limiting indwelling time. Sepsis is most common, but cellulitis, omphalitis, endocarditis, septic emboli, liver abscess, and lung abscess can also occur. The AAP and CDC recommend to remove and not replace the line if any signs of a central line–associated bloodstream infection are present.
- B. Cardiac complications.** Pericardial effusion is the second most common complication. It can be asymptomatic; suspect in infants with a UVC and progressive cardiomegaly. Right atrial arrhythmias can be caused by a UVC inserted too far that irritates the heart. Cardiac tamponade, cardiac perforation, pneumopericardium, and thrombotic endocarditis have also been reported.
- C. Thrombotic or embolic phenomenon.** Largest risk factor is placement of central catheters. Make sure to flush catheters prior to insertion and never allow air to enter the end of the catheter. Nonfunctioning catheters should be removed. Never try to flush clots from the end of the catheter. Emboli can be in the lungs, liver, or anywhere in systemic circulation. Careful monitoring is indicated in very low BW infants who have a hematocrit >55% because they have an increase in UVC-associated thrombosis. The AAP and CDC recommend removing the line if thrombosis is present.
- D. Blood loss/hemorrhage** can occur if tubing becomes disconnected.
- E. Retroperitoneal fluid extravasation** (genital, buttocks, thigh, abdominal), ascites, hemoperitoneum.
- F. Necrotizing enterocolitis** is thought to be a complication of UVCs, especially if in place for >24 hours. Studies suggest a higher cumulative risk in premature infants, especially if the UVC migrates to the portal vein or ductus venosus.
- G. Fungal infections of the right atrium.** Reported complication rate of 13%.
- H. Pulmonary edema, hemorrhage, infarction, and hydrothorax** can occur from a catheter that has lodged in or has perforated a pulmonary vein.
- I. Portal vein hypertension.** Caused by a catheter positioned in the portal system.
- J. Hepatic complications** include necrosis, calcification, laceration, abscess, biliary venous fistula formation, hematoma, infusate ascites, and portal venous air/hematoma/erosion. Do not allow a catheter to remain in the portal system. In case of emergency placement, the catheter should be advanced only 2 to 5 cm (just until blood returns) to avoid hepatic infusion.
- K. Other rare complications reported.** Creation of a false luminal tract, vessel perforation, hepatic cyst, digital ischemia, perforation of the peritoneum, hemorrhagic infarction of the lungs, colon perforation, perforation of a Meckel diverticulum, persistent neonatal hypoglycemia, Wharton jelly embolism, and gangrene of an extremity.

49 Venous Access: Venipuncture (Phlebotomy)

- I. Indications.** Cochrane review states that **venipuncture**, by a skilled operator, is the **method of choice for blood sampling** in term infants. It was found to be less painful than heel stick sampling and a more effective sampling method.
- A. Blood sampling for routine analysis or blood culture.** Venipuncture typically allows a larger volume of blood (recommended if ≥ 1 mL is needed) to be collected

and is the method of choice for obtaining **blood cultures**. It is preferred over capillary blood sampling for certain tests (drug levels, hemoglobin/hematocrit, karyotype, coagulation studies, and cross-matching blood). Arterial blood sampling is preferred for lactate, pyruvate, and ammonia.

B. Central hematocrit. Venipuncture hematocrit is more reliable than heel stick hematocrit.

C. Venous blood gas. This can be used in some diseases (neonatal sepsis/respiratory distress syndrome) to diagnose acid-base imbalance if an arterial blood gas cannot be obtained. Venous samples show good validity in terms of pH, PCO_2 , and HCO_3^- .

D. Administration of medications (infrequent application of venipuncture).

II. Equipment. Whenever possible, use safety needles that are self-shielding; 23- or 25-gauge syringe-mounted needles or 23- to 25-gauge winged infusion needles (butterfly needles; 23 gauge preferred to reduce risk of hemolysis or clotting), gloves (sterile for blood culture), 1- to 5-mL syringe, alcohol swabs, 3 povidone-iodine swabs (for blood culture), appropriate specimen containers (eg, red-topped tube, blood culture bottle[s]), a tourniquet or rubber band (for the scalp), 4×4 sterile gauze pads, optional localization devices if available (transilluminator, near-infrared visualization unit; eg, AccuVein, Palatine, IL, ultrasound).

III. Procedure

A. Use distal venous sites first to preserve venous access. Decide which vein to use. Use Figure 47–1 as a guide. Veins to use commonly include basilic, cephalic, or cubital veins in the antecubital fossa, veins on the dorsum of the hand (dorsal venous network) or foot (dorsal venous arch), wrist, greater saphenous vein at the ankle, scalp vein. Blood sampling proximal to intravenous sites should not be done.

B. In cases of difficult vein localization. Transillumination (see Chapter 44), near-infrared spectroscopy vein imaging (eg, AccuVein AV300; see Chapter 25), or possible bedside ultrasound (more commonly used for peripheral intravenous IV access) can be used (see Chapter 44).

C. Restrain the infant as appropriate.

D. Pain management. The American Academy of Pediatrics (AAP) recommends topical anesthesia (eg, eutectic mixture of lidocaine and prilocaine [EMLA], applied 30 minutes prior to procedure), oral sucrose or glucose, and nonpharmacologic pain prevention and relief techniques, with a combination of sucrose or glucose and nonpharmacologic techniques considered more effective.

1. Topical local anesthetics. AAP reports that topical anesthesia did decrease measures of pain during venipuncture. Cochrane review found there was not enough quality evidence to determine whether topical local anesthetics applied to the skin help relieve pain during needle-related procedures in newborn infants.

2. Sucrose/glucose. Sucrose is more commonly used, but glucose can be used as an alternative. Cochrane review states the following: “Sucrose is effective for reducing procedural pain from single events such as venipuncture. Optimal dose could not be identified and use in extremely preterm, unstable or ventilated neonates and needs to be addressed.” AAP recommends an oral dose of 0.1 to 1 mL of 24% sucrose (or 0.2–0.5 mL/kg) 2 minutes before a painful procedure.

3. Nonpharmacologic pain prevention during venipuncture

a. Breast feeding. Cochrane review found that breast feeding during venipuncture was associated with lower pain responses in term infants compared with other nonpharmacologic interventions. The effect of breast feeding was similar to oral sucrose or glucose. Giving human milk via a pacifier or syringe seems to be as effective as giving sucrose or glucose for pain in term infants.

b. Massage. A recent review found that, when comparing massage to breast feeding during venipuncture, massage caused the lowest pain score followed by breast feeding. Another study found that upper limb massage may be effective in decreasing the infants' venipuncture pain perceptions.

- c. **Maternal milk odor** (through a diffuser) was found to have an analgesic effect and to decrease the variability of the infant's heart rate and blood oxygen saturation in preterm infants during a venipuncture.
 - d. **Maternal voice** is effective in decreasing physiologic parameters during and after the painful procedure of venipuncture.
 - e. **Swaddling and skin-to-skin care.** There was no difference between swaddling and skin-to-skin kangaroo care on physiologic pain and other indices in neonatal premature infants during venipuncture.
 - f. **Sensorial stimulation** was found to be effective at decreasing pain during minor procedures, and 1 review found it to be more effective than sucrose.
4. **Combination of methods.** When using a combination of oral sucrose with non-pharmacologic measures, there is added analgesic effect.
- E. **“Tourniquet” the extremity to occlude the vein.** Use a rubber band (for the head), a tourniquet, or an assistant's hand to encircle the area proximal to the vein. Removing and reapplying may optimize the distension of the vein.
 - F. **Prepare the site with antiseptic solution.** For blood cultures, wipe at least 3 times in concentric circles starting at the puncture site.
 - G. **Attach syringe (1–5 mL) to needle.**
 - H. **Puncture the skin with the bevel up** (for optimal blood flow and less chance of occlusion by vein wall). Direct the needle into the vein at a 15- to 30-degree angle. Use the vessel bifurcation if possible.
 - I. **Once blood enters the tubing,** collect the blood slowly with gentle suction to avoid hemolysis or vein wall occlusion (or administer the medication).
 - J. **Remove the tourniquet.** Remove and press the button to shield the needle. Apply gentle pressure on the area until hemostasis has occurred (usually 2–3 minutes). Distribute blood samples to the appropriate containers and invert or store as indicated.
- IV. **Complications**
- A. **Infection is a rare complication,** minimized by sterile technique. Septic arthritis of the hip has been reported from femoral venipuncture.
 - B. **Venous thrombosis/embolus** is often unavoidable, especially when multiple punctures are performed on the same vein and the vein is large.
 - C. **Hematoma or hemorrhage** is avoided by applying pressure to the site after the needle is removed to ensure hemostasis. If a coagulation defect is present, hemorrhage can occur.
 - D. **Scarring of the dorsum of the hand** from multiple venipunctures can occur in very low birthweight neonates.
 - E. **Cervical dural puncture can occur** from internal jugular venipuncture in an infant secondary to insertion of the needle at excessive depth.
 - F. **Laceration of artery** near the vein.

50 Abdominal Distension

- I. Problem.** The nurse calls you to the bedside to assess a newborn infant with abdominal distention. How is abdominal distension defined? There is no statistical definition of abdominal distension. Some reported definitions include: actual increase in abdominal size, measurable change in abdominal circumference, or “when the abdominal wall is on a higher plane than the xiphisternum in an infant lying on their back on a flat surface.” Abdominal distension will frequently be evaluated as increased girth in comparison to the neonate’s baseline. This can be associated with other concerning symptoms or be an isolated finding.
- II. Immediate questions**
- A. Are there additional gastrointestinal symptoms?** Bilious emesis is an emergent condition that suggests intestinal malrotation with volvulus until proven otherwise. Perform a physical exam to determine whether the abdomen is firm or soft and whether bowel sounds are present. A distended abdomen that is soft with normal bowel sounds is usually benign. In contrast, a firm abdomen with no bowel sounds and taut and discolored skin is significantly more concerning and will likely require immediate intervention. Presence of bilious or nonbilious emesis, increased gastric residuals, and bloody stools will also help guide acuity and the differential.
- B. Are there concerning systemic symptoms?** If the distention is associated with tachycardia, tachypnea, apnea, temperature instability, and irritability, the etiology of the distention becomes more concerning for infection, and the evaluation should include a sepsis workup in addition to further evaluation of the gastrointestinal (GI) system. The neonate’s state (comfortable vs distressed) will also guide the differential diagnosis.
- C. Was the baby feeding and how?** Neonates can present with abdominal distention during a feed advance or a change in type of feed. Neonates may be receiving large quantities of feeds or feeds via a nasogastric (NG) or orogastric (OG) tube faster than they can digest them.
- D. Has the neonate stoolled recently?** If the baby has not stoolled in >12 to 24 hours, consider constipation. If the neonate is only a few days old and has never stoolled, consider an intestinal obstruction. If there has been a recent stool, quality of stool and presence of blood should be assessed. See also Chapter 72.
- E. Is the neonate on continuous positive airway pressure?** If the neonate is receiving continuous positive airway pressure (CPAP) or other noninvasive ventilation, the abdomen can become distended because positive pressure will push air through the esophagus and subsequently the stomach and intestines.
- F. Is the stomach being vented?** If the neonate is receiving CPAP, it is important that the stomach be vented to relieve the abdomen of increased air pressure. If there is concern for abdominal distention, an OG or NG tube should be passed for decompression. If it cannot be passed or loops within the esophagus, this is concerning for esophageal atresia with a distal tracheoesophageal fistula. Continuing with CPAP in this situation will fill the stomach and intestines with air without an outlet. In this case, CPAP should be minimized and discontinued if possible.
- G. Does the neonate look edematous?** Abdominal distention could be secondary to third spacing from ascites or other fluid. Palpation of the abdomen and other signs of edema elsewhere in the body should help identify whether the distention is secondary to air or fluid.

III. Differential diagnosis. (See Figure 50–1.) The differential includes acute emergent concerns and benign causes. It is important to rule out the etiologies that need immediate intervention first because abdominal distention can be the first presenting sign of conditions that will have significant adverse outcomes if not treated immediately.

A. Obstruction. A small bowel obstruction with intestinal malrotation/volvulus typically occurs with bilious emesis. Large bowel obstructions typically present with no stooling and distension.

1. Small bowel obstruction

a. Malrotation with volvulus. This is an emergent concern for which a surgical consultation is required. One-third of infants with malrotation present with volvulus before 1 month of age.

b. Intestinal atresias. Occur in the ileum > duodenum > jejunum > colon. May have bilious or nonbilious emesis with a failure to pass stool.

c. Meconium ileus. Meconium obstructs the terminal ileum, leading to distension. Approximately 90% of patients with meconium ileus have cystic fibrosis.

2. Large bowel obstruction

a. Hirschsprung disease. Aganglionosis of distal colon/rectum leading to delayed passage of stool. Approximately 75% of infants with Hirschsprung disease fail to pass meconium in the first 48 hours after birth. More common in males.

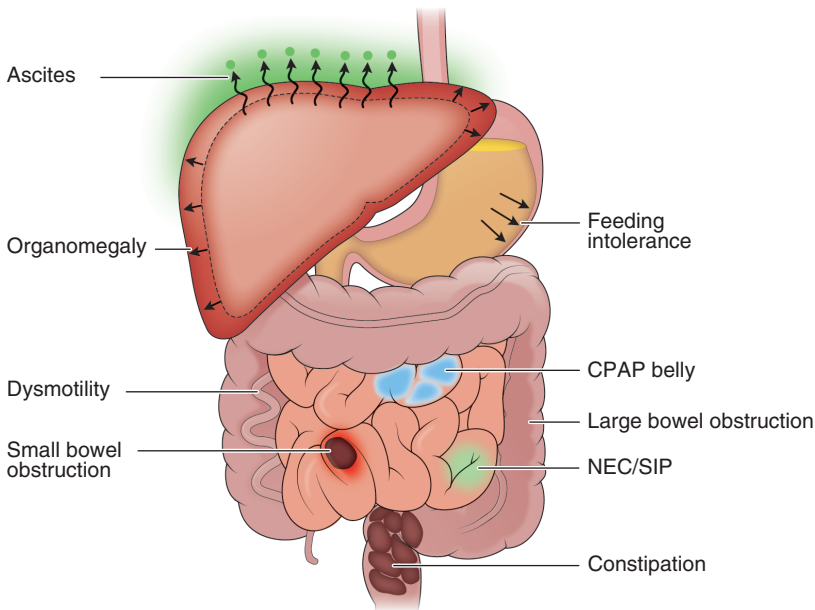

FIGURE 50–1. Causes of abdominal distention in a neonate. CPAP, continuous positive airway pressure; NEC, necrotizing enterocolitis; SIP, spontaneous intestinal perforation. (Used with permission from Namrita Odackal, DO.)

- b. **Small left colon.** Typically seen in term infants born to mothers with a history of diabetes. Fail to pass stool in the first 48 hours. Transient disease that usually resolves spontaneously.
 - c. **Anorectal malformation.** May be imperforate anus with or without a fistula or simply anal stenosis. Anal atresia is highly associated with other anomalies including VATER/VACTERL (vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia/vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and radial abnormalities, and limb abnormalities).
 - d. **Meconium plug.** Meconium obstructs the rectum and/or lower colon. Increased incidence of Hirschsprung disease. More commonly seen in infants of diabetic mothers.
- B. **Perforation.** Perforation of the bowel (pneumoperitoneum) can occur from congenital defects or secondary to acquired intestinal diseases. Plain radiographs will indicate free air lying over the liver. (See Figure 12–26.) Surgical evaluation is required.
 1. **Congenital.** More likely to occur secondary to bowel obstructions or atresias. Bowel perforation in utero may lead to meconium peritonitis and secondary abdominal distension.
 2. **Acquired**
 - a. **Necrotizing enterocolitis.** Perforation occurs in approximately 30% of necrotizing enterocolitis (NEC) cases. Terminal ileum and ascending colon are the most common locations.
 - b. **Spontaneous intestinal perforation.** Isolated perforation, typically in the ileum, that occurs most commonly in extremely low birthweight infants with an incidence of 5%. Risk factors include concomitant use of steroids and indomethacin and extreme prematurity. Presents in the first 2 weeks, often with a bluish discoloration of the abdomen and abdominal distension.
 3. **Other.** Traumatic perforations of the stomach may occur from NG/OG tube misplacement or excessive positive-pressure ventilation.
 - C. **Necrotizing enterocolitis.** NEC can present with isolated GI symptoms, including abdominal distention and bloody stools, and also with systemic symptoms of sepsis, such as apnea and temperature instability. Concern for NEC is greater with a history of prematurity, hypoxemia, and formula feeds. NEC occurs in approximately 6% of infants <1500 g. Red blood cell transfusion (controversial) or significant anemia in the prior 48 hours may also be a risk factor. Overall mortality is between 10% and 15%, with an increase to 30% if intestinal perforation occurs. Pneumatosis intestinalis is the classic sign on abdominal radiograph, and thrombocytopenia is also classically seen.
 - D. **Sepsis.** Abdominal distention and other signs of feeding intolerance can be clinical signs of sepsis, particularly in premature patients who may not mount a fever. This should be considered with or without NEC based on the entire clinical picture. Sepsis occurs in approximately one-third of very low birthweight infants, and incidence is indirectly related to gestational age.
 - E. **Anatomic abnormality or organomegaly.** If the baby is 1 to 2 days old, has been in the well-baby nursery where close monitoring is less likely, or has received late prenatal care, consider an undiagnosed anatomic abnormality that is presenting with abdominal distention (eg, a tracheoesophageal fistula, abdominal mass, or hepatosplenomegaly associated with an inborn error of metabolism).
 - F. **Dysmotility/gastroparesis.** It may take several days for premature neonates to have normal gut motility, and they may present with abdominal distention if feeds are relatively larger or faster than they can handle. Alternatively, the neonate could have pathologic dysmotility secondary to Hirschsprung disease, cystic fibrosis, or other genetic disorders.
 - G. **Constipation.** If the neonate has yet to stool or is stooling infrequently, abdominal distention may present secondary to backup of GI contents.

- H. Ascites.** If the patient is septic or has leaky capillaries secondary to extracorporeal membrane oxygenation or some other systemic or local source of inflammation, a loss of protein or other liver function, hydrops, impaired right ventricular function, or high-output cardiac failure, the neonate could have fluid collecting into the abdominal interstitial space, causing abdominal distention.
- I. Continuous positive airway pressure belly.** When receiving positive pressure through a noninvasive route (ie, no endotracheal tube), the air cannot differentiate between passing through the esophagus or trachea. This can cause inflation within the GI tract, leading to abdominal distention. This is more likely if the stomach is not being intermittently vented. This occurs in >75% of infants <1000 g and less frequently in larger infants.
- J. Feeding intolerance.** Some neonates will not tolerate specific types of formula or may have a milk protein allergy. This can present with malabsorption, bloating, and abdominal distention, with or without bloody stools.

IV. Database

A. Physical examination. Examination of the abdomen should include auscultation and palpation of the abdomen. Examine for discoloration of the abdominal skin. Look for systemic signs of distress such as increased work of breathing from increased abdominal girth; edema in the face, hands, or feet; and hypotonia. Some neonatal intensive care units measure abdominal girth, although this is *controversial* because it can be affected by many variables such as time since last feed/stool and amount of body fat/edema. If performed, measurements should be taken 1 cm above the umbilicus in a supine position. A change of up to 1.5 cm suggests normal variability.

- 1. If the examination is abnormal beyond abdominal distention,** place the infant on nothing by mouth (NPO) while continuing the evaluation. Abdominal radiographs and gastric decompression are indicated, and consider a sepsis evaluation and surgical consultation.
- 2. If the examination is normal beyond abdominal distention** and the infant is tolerating feeds, continue close examination and consider a baseline radiograph.

B. Laboratory studies

- 1. Complete blood count and/or C-reactive protein.** Thrombocytopenia and other complete blood count abnormalities may indicate sepsis. Some institutions use C-reactive protein to help guide sepsis evaluations.
- 2. Blood and urine cultures.** If concerned for sepsis, a blood and urine culture should be obtained to assess for both aerobic and anaerobic bacteria.
- 3. Liver function tests.** Liver function tests can help evaluate when concerned for hepatomegaly or ascites secondary to liver pathology. If abnormal, coagulation studies may be indicated.

C. Imaging and other studies

- 1. Abdominal radiograph.** The abdominal radiograph is a good screening study that may reveal ileus, distended loops of intestine, pneumoperitoneum (Figure 12–26), or pneumatosis intestinalis (Figure 12–27). This can be followed by serial imaging depending on severity and level of concern. If free air is suspected, a lateral decubitus film should be done in addition. Alternatively, an abdominal x-ray can confirm that there is air passing through to the rectum, indicating less concern for obstruction.
- 2. Abdominal ultrasound.** Ultrasound can be used for diagnosing masses, ascites, or debris indicating perforation. May also be used to assess for pneumatosis intestinalis (NEC).
- 3. Fluoroscopy.** If obstruction is suspected, a fluoroscopic upper GI study should be conducted emergently. Immediate evaluation to look for flow of contrast from the esophagus, through the stomach, and through the duodenum and remainder of the intestinal tract is indicated.

V. Plan

- A. **Rule out emergent conditions.** Intestinal obstruction and infection (either systemic or NEC) are the most serious pathologies associated with abdominal distention.
- B. **Decide whether to stop or continue feeds.** Enteric feeds may or may not be a contributing factor to abdominal distention. If the etiology is considered to be benign, continuing feeds is reasonable. If imaging is concerning for ileus or slow motility through the GI tract, slowing feeds or holding a feed advance at the current volume of feeds may be appropriate. If there is concern for significant illness, NEC, spontaneous intestinal perforation, or sepsis, stopping feeds is appropriate to avoid ischemia to the GI tract, which would potentially cause further damage. The duration of holding feeds depends on clinical improvement. Intravenous fluid hydration or nutrition should be started if feeds are held.
- C. **Treat the symptoms.** Acutely, venting the abdomen via an NG or OG tube and helping the baby stool with glycerin suppositories can relieve abdominal pressure, which may be affecting respiratory status. If there is ascites causing distention, diuretics or a peritoneal tap may be indicated. If treating the neonate for pain, careful thought should be given to treating with opiates as this will further delay gut motility.
- D. **Treat the underlying cause.** Once the etiology has been established, ultimately symptoms will resolve when the underlying cause is treated. In severe cases, treatment may require surgical intervention, antibiotics, and long-term parenteral nutrition.
- E. **Monitor for worsening abdominal distention.** Routine measuring of abdominal girth once a shift (center dependent) or with serial x-rays (to continue to monitor for ileus, ascites, or free air) may be indicated to monitor for worsening abdominal distention.

51 Abnormal Blood Gas

- I. **Problem.** An abnormal blood gas value for a neonate is reported by the laboratory. Blood gas measures pH, PCO_2 , and oxygen (O_2), and all the other components (base excess, bicarbonate concentration, and oxygen saturation) are calculated based on the 3 levels measured. Accepted normal values for an arterial blood gas on room air are pH 7.35 to 7.45 (pH varies with age; a pH >7.30 is generally acceptable), PaCO_2 35 to 45 mm Hg (slightly higher accepted if the blood pH remains normal), and PaO_2 50 to 95 mm Hg (based on gestational age). (See Table 9–1, page 98, for normal range of arterial blood gas values for term and preterm infants.)

II. Immediate questions

A. What component of the blood gas is abnormal?

1. **What is the pH?** The pH determines the presence of acidemia or alkalemia. Is it acidic (pH <7.35) or alkalotic (pH >7.45)?
 - a. **pH is proportional to HCO_3^- (base excess)**
 - i. **Metabolic acidosis.** Abnormal \downarrow in HCO_3^- \downarrow pH.
 - ii. **Metabolic alkalosis.** Abnormal \uparrow HCO_3^- \uparrow pH.
 - b. **pH is inversely proportional to PCO_2**
 - i. **Respiratory acidosis.** Abnormal \uparrow PCO_2 \downarrow pH.
 - ii. **Respiratory alkalosis.** Abnormal \downarrow PCO_2 \uparrow pH.
2. **What is the PCO_2 ?** Is it increased or decreased? PCO_2 reflects alveolar ventilation and is mediated by the respiratory system, and the only way to remove it is through the lungs. If it is abnormal, it suggests a respiratory disorder.

3. **What is the PaO_2 ? Is it increased or decreased?** Hypoxia (inadequate oxygenation) or hyperoxia (excess supply of oxygen) can occur.
 4. **What is the HCO_3^- ? Is it increased or decreased?** Bicarbonate is a weak base that is mediated by the renal system as part of the acid-base homeostasis. It is retained or excreted by the kidney to regulate acid-base balance. If bicarbonate is abnormal, it is a metabolic disorder.
- B. Is this blood gas value very different from the patient's previous blood gas determination?** If the patient has had metabolic acidosis on the last 5 blood gas measurements and now has metabolic alkalosis, it might be best to repeat the blood gas measurements before initiating treatment. **Do not treat the infant based on 1 abnormal gas value**, especially if the infant's clinical status has not changed.
- C. How was the sample collected?** Blood gas measurements can be reported on **arterial, venous, or capillary (heel stick)** blood samples.
1. **Arterial blood samples. Best indicator of pH, PaCO_2 , and PaO_2 .** The **gold standard** of obtaining a blood gas is to obtain one from an indwelling arterial catheter (peripheral or umbilical). Blood gases by **intermittent arterial punctures** may not accurately reflect the infant's respiratory status. A sudden decrease in the PaCO_2 and PaO_2 can occur during the puncture. Crying can decrease the PaCO_2 , HCO_3^- , and oxygen saturation. Arterial blood gas reference values per the Perinatal Continuing Education Program (PCEP) are as follows: pH, 7.30 to 7.40; PaCO_2 , 40 to 50 mm Hg; and PaO_2 , 45 to 65 mm Hg.
 2. **Venous blood samples.** Gives a lower pH value, a significantly lower PO_2 , and a higher PCO_2 than arterial samples. It is good for HCO_3^- estimation. Venous blood gas reference values per PCEP are as follows: pH, 7.25 to 7.35; PCO_2 , 45 to 55 mm Hg; and PO_2 , unreliable.
 3. **Capillary (heel stick) samples.** Gives a satisfactory assessment of the infant's pH and PCO_2 but does not give an accurate PaO_2 . Capillary blood gases (CBG) give a similar or lower pH value (not as low as venous pH), similar or slightly higher PCO_2 , and lower PO_2 than arterial samples; capillary blood gas measurements are not reliable in an infant who is cold or has decreased perfusion (hypotensive or in shock). CBG reference values with proper technique per PCEP are as follows: pH, 7.25 to 7.35; PCO_2 , 45 to 55 mm Hg; and PO_2 , unreliable.
- D. Is the infant on ventilatory support?** Management of abnormal blood gas levels is approached differently in an intubated infant than in a patient breathing room air.
- E. Is there a sudden change in the blood gas or a gradual change over several blood gases? A sudden change in a blood gas accompanied by a sudden deterioration in the infant's clinical status is an emergency situation and is more urgent than a gradual change in a blood gas.** The differential of the 2 conditions is also different.
1. **A sudden change in the blood gas (a sudden decrease in PaO_2 and an increase in PaCO_2) with a sudden clinical deterioration in the infant** can be a result of a blocked or displaced endotracheal tube, a pneumothorax (tension or unilateral), the endotracheal tube in the mainstem bronchus, or a malfunctioning ventilator.
 2. **A gradual change in the blood gas with a gradual deterioration in the infant.** Gradual changes can reflect that there is increasing respiratory failure or inadequate ventilation requiring that the settings be changed. Examples include:
 - a. **Gradual decrease in PaO_2 , gradual increase in PaCO_2 :** Inappropriate ventilator settings, atelectasis that is causing increased intrapulmonary shunting.
 - b. **Gradual increase in PaCO_2 , no changes in PaO_2 :** Inadequate alveolar ventilation or an increased dead space (from tubing or airway issues).
- F. Is there a nonrespiratory cause of the change in blood gas in an infant on a ventilator?** Nonrespiratory causes can result in changes in blood gases. These include intraventricular hemorrhage, seizures, hypoglycemia, overwhelming sepsis, pneumopericardium, patent ductus arteriosus (PDA), and hypotension. **Note that any severe illness can cause a metabolic acidosis.**

III. Differential diagnosis

A. Metabolic acidosis (pH <7.30–7.35 with a normal to low carbon dioxide). After birth, it is normal for an infant to have a mild metabolic acidosis. Metabolic acidosis is very common in the neonatal intensive care unit (NICU), especially in the very sick neonate. The **3 main causes of metabolic acidosis are loss of base (mainly bicarbonate) from renal or gastrointestinal causes, decreased renal excretion of acid, or an increased production of acid.** Metabolic acidosis is classified as increased anion gap, normal or nonanion gap, or low anion gap acidosis. **Determining the anion gap will help decide the cause of the acidosis.**

1. **Anion gap.** Difference in measured cations and anions in serum or plasma. Calculated by:

$$\text{Anion gap (mEq/L)} = \text{sodium (mEq/L)} - [\text{chloride (mEq/L)} + \text{bicarbonate (mEq/L)}]$$

- a. **Normal range.** 8 to 16 mEq/L (up to 18 mEq/L in premature infants <1000 g).
 - b. **Increased.** >16 mEq/L in infants (>18 mEq/L in premature infants <1000 g).
2. **Common causes of metabolic acidosis in the newborn**
 - a. **Increased anion gap metabolic acidosis (normal chloride)** implies presence of other acids.
 - i. **Lactic acidosis associated with clinical evidence of decreased tissue perfusion is common in the neonate.** A serum anion gap >16 mEq/L is highly predictive of lactic acidosis (<8 mEq/L lactic acidosis is highly unlikely). Some infants may not have an increased anion gap with lactic acidosis. **Causes:** asphyxia, hypoxia, respiratory distress syndrome (RDS), sepsis, compromised cardiac output (cardiogenic, septic, and hypovolemic shock), circulatory or respiratory failure, massive hemorrhage/severe anemia, periventricular hemorrhage (PVH)/intraventricular hemorrhage (IVH), hypothermia/cold stress, hypotension, PDA, necrotizing enterocolitis (NEC) or any intestinal ischemia, excessive ventilator pressures with decreased cardiac output, seizures, and ascites/third spacing of fluids.
 - ii. **Inborn errors of metabolism.** Inborn errors have lactic acidosis not associated with clinical evidence of poor tissue perfusion. An anion gap of >16 is seen in many inborn errors of metabolism secondary to accumulation of fixed acids. Examples include: **organic acidemias** (most common), galactosemia, hereditary fructose intolerance, maple syrup disease, congenital/primary lactic acidosis, type I glycogen storage disease and pyruvate dehydrogenase/carboxylase deficiency, mitochondrial respiratory chain defects, multiple carboxylase deficiency, and fatty acid oxidation defects. In an infant with persistent metabolic acidosis with increased anion gap, negative urine ketones, whose mother had HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, think fatty acid oxidation defects.
 - iii. **Acute kidney injury and chronic kidney disease.** Results in failure of excretion of hydrogen ions and other unmeasured acid anions.
 - iv. **Late metabolic acidosis of prematurity (first to third week of life)** occurs in healthy premature infants who have a mild to moderate metabolic acidosis and decreased growth. It is caused by an excessive acid load from high-protein formula (casein-based formulas), amino acid intake, or intravenous (IV) alimentation on the premature kidney with decreased renal clearance.
 - v. **Toxins and medications.** Maternal use of salicylates and maternal acidosis. Benzyl alcohol in doxapram. Others: alcohols and glycols, acetaminophen, α -adrenergic agents, cocaine, nitroprusside, ibuprofen, iron, isoniazid, paraldehyde, sulfasalazine, valproic acid.

- b. Normal or non-anion gap metabolic acidosis (normal anion gap, elevated serum chloride, hyperchloremic acidosis).** A low serum potassium indicates loss of base; a high serum potassium suggests renal tubular acidosis (RTA). Most common causes are RTA and diarrhea.
- i. Renal loss of bicarbonate**
 - (a) **Immature kidneys.** Bicarbonate wasting.
 - (b) **Renal tubular acidosis.** Defect in either the reabsorption of bicarbonate or the secretion of the hydrogen ion. (Most common cause in preterm infants is proximal RTA.) Check urine pH; <7 suggests proximal RTA, whereas >5.5 suggests distal RTA.
 - (c) **Acute kidney injury.**
 - (d) **Renal dysplasia.**
 - (e) **Medications. Carbonic anhydrase inhibitors** can cause reduced uptake of bicarbonate ions (acetazolamide, dorzolamide, methazolamide, hydroxyurea). Aldosterone inhibitors: spironolactone and eplerenone.
 - (f) **Hypoaldosteronism.** Low Na⁺, elevated K⁺.
 - (g) **Hyperparathyroidism.**
 - ii. Gastrointestinal loss of bicarbonate**
 - (a) **Diarrhea (usually secretory).**
 - (b) **Urologic and gastrointestinal procedures.** Surgery for NEC, ileostomy, enterocutaneous or bowel fistula, small bowel or pancreatic drainage, any bowel diversion in contact with urine.
 - (c) **Medications.** Ion exchange resins, cholestyramine, calcium chloride, magnesium sulfate.
 - iii. Dilutional acidosis.** Rapid volume expansion with lactated Ringer's solution, saline, or dextrose with dilution of bicarbonate.
 - iv. Factitious acidosis.** Due to excessive heparin in the syringe. Air contamination can give a large base deficit.
 - v. Excessive chloride in intravenous fluids.**
 - vi. Hyperalimentation acidosis** caused by the acid load.
 - vii. Potassium-sparing diuretics and hyperkalemia.**
- c. Low anion gap metabolic acidosis.** (Low or negative anion gap.) Rare; usually caused by laboratory error or hypoalbuminemia.
- B. Metabolic alkalosis (pH >7.45 with base excess of >5). First clue is often an elevated bicarbonate.** It is usually iatrogenic and uncommon in the neonatal period and due to an excess of base (HCO₃⁻) or loss of acid H⁺. In the neonatal period, the most common causes of an excess of base is chronic administration of alkali administration. In the neonate, the most common cause of loss of acid is continuous nasogastric suction, diuretic treatment, and persistent vomiting. There are 2 types: chloride resistant (high urinary chloride) and chloride responsive (low urinary chloride). **Obtain a spot urinary chloride** to help determine the etiology.
- 1. High urinary chloride >20 mEq/L (chloride-resistant metabolic alkalosis; increased extracellular fluid volume).** Excess alkali administration (acetate, citrate, bicarbonate, lactate); early diuretic therapy (especially furosemide); hypokalemia; large blood product transfusion; Bartter syndrome (mineralocorticoid administration); exogenous steroid therapy; Cushing, Conn, or Liddle syndrome; primary aldosteronism, congenital adrenal hyperplasia variant (deoxycorticosterone excess syndrome); milk-alkali syndrome; neonatal pseudo-Bartter syndrome (secondary to maternal eating disorder).
 - 2. Low urinary chloride <10 mEq/L (chloride-responsive metabolic alkalosis; low serum chloride and decreased extracellular fluid volume).** Loss of gastric secretions (persistent vomiting, continuous nasogastric/orogastric suction), secretory diarrhea (congenital chloride-wasting diarrhea), acute correction of chronically compensated respiratory acidosis, late diuretic therapy, post hypercapnia syndrome.

3. **Common causes of metabolic alkalosis in the newborn**
 - a. **Prolonged nasogastric/orogastric suction.**
 - b. **Diuretic therapy** (especially furosemide in patients with bronchopulmonary dysplasia/chronic lung disease [BPD/CLD]).
 - c. **Excess alkali administration** (eg, sodium bicarbonate, citrate, acetate, or lactate infusion) as in parenteral nutrition or increased alkali load from feedings.
 - d. **Potassium depletion.**
 - e. **Compensation for respiratory acidosis** (eg, infant with BPD/CLD/chronic ventilation).
4. **Less common causes.** Pyloric stenosis (persistent vomiting), Bartter syndrome (rare), pseudo-Bartter syndrome due to maternal eating disorder, primary hyperaldosteronism, congenital chloride-wasting diarrhea, congenital adrenal hyperplasia (certain types).
- C. **Respiratory alkalosis (a decrease in carbon dioxide with an increase in pH).** Alkalosis can be associated with decreased cerebral blood flow and a decrease in tissue oxygen delivery. Hypocarbica is associated with periventricular leukomalacia and deafness.
 1. **Overventilation by the ventilator.** Most common cause in NICU.
 2. **Air bubble in the blood gas collection syringe.** This can falsely lower the PaO₂ and PaCO₂.
 3. **Heparin can falsely lower the PaCO₂.** Make sure minimal heparin remains in the syringe.
 4. **Hyperventilation therapy.** Used to be a treatment of persistent pulmonary hypertension but is no longer recommended.
 5. **Central hyperventilation.** Central nervous system (CNS) stimulation of the respiratory drive caused by a CNS disorder or transient hyperammonemia (ammonia stimulates the respiratory center, resulting in hyperventilation).
 6. **Hypoxemia can cause a low carbon dioxide.** Respiratory centers are stimulated through chemoreceptors.
 7. **Hyperventilation.** Seen in a spontaneously breathing infant secondary to sepsis, fever, aspiration pneumonia, or retained fluid.
 8. **Compensation for a primary metabolic acidosis.**
- D. **Respiratory acidosis (increase in PaCO₂ with decrease in pH).** A gradual increase in PCO₂ is usually secondary to insufficient alveolar ventilation.
 1. **Obstructed endotracheal tube (eg, mucus plug).** Tube blockage can occur after a few days of ventilation because of increased secretions.
 2. **Improper endotracheal tube position.** An endotracheal tube positioned in the oropharynx, down the right mainstem bronchus, or at the carina.
 3. **Ventilator malfunction or insufficient respiratory support.** Disconnect the ventilator and manually inflate the infant's lungs; if the condition improves, then the problem is with the ventilator. There can be a mechanical failure, tubing can be disconnected, leak may be present, or there can be electrical failure.
 4. **Ventilator strategy that allows permissive hypercapnia (controlled mechanical hypoventilation) is controversial.** Use caution with permissive hypercapnia until further studies are done. Severe hypercapnia or hypocapnia should be avoided. In infants with BPD/CLD, higher carbon dioxide (CO₂) is sometimes tolerated to wean them from mechanical ventilation.
 5. **Increasing respiratory failure.** Lung diseases such as RDS, pneumonia, transient tachypnea, BPD/CLD, pleural effusion, pulmonary hypoplasia, atelectasis.
 6. **Pneumothorax.**
 7. **Hypoventilation or poor respiratory effort** from maternal anesthesia, medications, neuromuscular disorders, congenital central hypoventilation syndrome, sepsis, intracranial hemorrhage, or hypoglycemia.

8. **Patent ductus arteriosus with pulmonary edema.** Suspect a PDA if the infant has a systolic murmur, active precordium, bounding pulses, and increased pulse pressure. Other clinical signs and symptoms may include congestive heart failure, deteriorating blood gases with an increase in the ventilator settings, and cardiomegaly with increased pulmonary vascularity on chest radiograph.
9. **Others.** Congenital diaphragmatic hernia, phrenic nerve paralysis, and other causes.

E. Low oxygen (hypoxia)

1. **Agitation**
2. **Improper endotracheal tube position**
3. **Inadequate ventilatory support**
4. **Congenital heart disease (cyanotic);** see Chapter 56
5. **Respiratory diseases**
 - a. **Primary lung disease.** Respiratory distress syndrome, transient tachypnea of the newborn, BPD/CLD, and others.
 - b. **Airway obstruction.** Mucus plug, choanal atresia, other congenital malformations (eg, macroglossia, cystic hygroma).
 - c. **External compression of the lungs.** Air leak syndrome (eg, pneumothorax) or congenital defects (eg, congenital diaphragmatic hernia).
6. **Apnea of prematurity**
7. **Persistent pulmonary hypertension**
8. **Central nervous system/neuromuscular disorders**
9. **Metabolic abnormalities**
10. **Hematologic disorders**
11. **Sepsis/hypotension**

- F. **High oxygen (hyperoxia).** Hyperoxia can cause severe retinopathy of prematurity, CLD, and brain injury in preterm infants. Overventilation (high FiO_2 , high positive end-expiratory pressure (PEEP), high peak inspiratory pressure (PIP) or tidal volume, high inspiratory time, high flow, high rate) can cause a high PaO_2 . Nitrogen washout therapy using 100% oxygen to rapidly resolve a pneumothorax can cause hyperoxia but is no longer recommended. Decrease the oxygenation first before reducing any of the other ventilator parameters.

IV. Database

- A. **Physical examination.** Evaluate for signs of sepsis (eg, hypotension or poor perfusion). Check for equal breath sounds; asymmetric breath sounds suggest pneumothorax or incorrect endotracheal tube (ETT) placement. Observe for chest wall movement. Listen for breath sounds over the chest versus the epigastric region, which may help determine whether the ETT is malpositioned. Listen to the heart for any murmur, and palpate for cardiac displacement.
- B. **Laboratory studies**
 1. **Repeat blood gas measurement if the result is unexpected.** Do not make a major clinical decision based on a venous or capillary blood gas values or on just 1 arterial blood gas result.
 2. **Serum electrolytes.** To include blood urea nitrogen, creatinine, glucose, and potassium (severe metabolic alkalosis can cause hypokalemia). Serum Na^+ , K^+ , Cl^- , and bicarbonate (from arterial blood gas) to determine anion gap.
 3. **Urine chloride.** To evaluate metabolic alkalosis. May not be valid in the setting of diuretic use.
 4. **Urinary ketones.** If absent or small, consider lactic acidosis; if moderate or large, suspect organic acidemias (maple syrup urine disease, glycogen storage disease, disorders of pyruvate metabolism, others).
 5. **Plasma ammonia level.** If normal, may be RTA; may be increased in urea cycle defects and in some organic acidemias (acidosis and hyperammonemia).
 6. **Serum potassium level.** Severe metabolic alkalosis can cause hypokalemia.

7. **Measure the anion gap.** Correct for hypoalbuminemia by adding 2.5 mEq/L to the anion gap for every gram per deciliter that the concentration of serum albumin is reduced below the normal value of 3.5 g/dL.
8. **Plasma lactate is increased in lactic acidosis.** Measure lactate in infants who have a normal anion gap but in whom lactic acidosis is suspected. Normal and elevated lactate can be seen in organic acidemias; lactate is elevated in sepsis (predictor of mortality) and hypoperfusion.
9. **Complete blood count with differential.** If sepsis is being considered.
10. **Further sepsis workup if indicated.** Blood culture, urinalysis and culture, and lumbar puncture if indicated.
11. **Metabolic screen if indicated.** Urine and plasma for amino acids and organic acids.

C. Imaging and other studies

1. **Pulmonary mechanics.** Check the tidal volume (VT) delivered on the ventilator. The normal VT is 5 to 6 mL/kg. If the VT is low, it could mean that not enough pressure is given or there is an obstruction in the ETT.
2. **Transillumination of the chest.** If pneumothorax is suspected (see Chapter 44).
3. **Chest radiograph.** Should be performed if an abnormal blood gas value is reported, unless there is an obvious cause. An anteroposterior view should be obtained to check ETT placement (see Figure 12–11), rule out air leak (eg, pneumothorax; see Figure 12–24), check heart size and pulmonary vascularity (increased or decreased), and determine whether the infant is being hypoventilated or hyperventilated.
4. **Abdominal radiograph.** If NEC is suspected in a patient with **severe metabolic acidosis**. See Figure 12–27.
5. **Ultrasonography of the head.** To diagnose IVH. See Figures 12–1 through 12–4 for examples of IVH.
6. **Echocardiography.** May detect PDA or other cardiac abnormality and can be used to diagnose low cardiac output.
7. **Ultrasonography of the abdomen with color Doppler studies.** To evaluate for NEC and bowel necrosis.

V. Plan

- A. **Overall plan.** Verify the blood gas result, determine the cause of the problem, and provide specific treatment. First, examine the infant. If the infant's clinical status has not changed, repeat a blood gas to verify the report. If the clinical status has changed, the abnormal report is probably correct; repeat the blood gas and begin further evaluation of the infant.
- B. **Specific management of blood gas abnormalities**
 1. **Metabolic acidosis**
 - a. **Understand and treat** the underlying cause of the acidosis.
 - b. **Correct any treatable causes** such as hypoxia, hypovolemia, sepsis, hemorrhage, low cardiac output, or severe anemia.
 - c. **Do not treat metabolic acidosis** with hyperventilation.
 - d. **Volume expansion should not be used to treat acidosis** unless there are signs of hypovolemia. Severe acidosis causes a decrease in myocardial contractility. **Cochrane review** states that there is insufficient evidence to state that a fluid bolus reduces morbidity and mortality in preterm infants with metabolic acidosis.
 - e. **Watch for hypokalemia** as metabolic acidosis is corrected.
 - f. **If metabolic acidosis is persistent and the infant does not respond to treatment**, consider an inborn error of metabolism.
 - g. **Controversy over sodium bicarbonate use in metabolic acidosis.** Treatment with sodium bicarbonate is no longer routinely recommended as supportive therapy in metabolic acidosis. It has been quoted as being “basically useless therapy” and is associated with adverse sequelae, such as hyponatremia,

intracranial hemorrhage (increases IVH), transient fluctuations in the cerebral blood flow and cardiovascular hemodynamics in extremely premature infants, decreased oxygen delivery to tissues, aggravated myocardial injury and cardiac function deterioration, worsening intracellular acidosis, and increased risk of death. **It is no longer recommended in the following situations:**

- i. **Sodium bicarbonate in the delivery room.** The American Academy of Pediatrics (AAP) and American Heart Association (AHA) guidelines do not recommend the use of sodium bicarbonate in the delivery room.
 - ii. **Sodium bicarbonate in postresuscitation care.** AAP and AHA do not recommend giving sodium bicarbonate to an infant with metabolic acidosis after resuscitation. They state it might be helpful early on and might actually improve the acid pH, but if the infant's lungs cannot exhale the CO₂ that is formed, the acidosis will worsen.
 - iii. **Sodium bicarbonate in a newborn** with perinatal asphyxia, ischemia (NEC), or prolonged hypoxia (persistent pulmonary hypertension) is not recommended.
 - iv. **Sodium bicarbonate in preterm or extremely premature infants.** No evidence of benefit. Cochrane review states there is insufficient evidence to state that use of sodium bicarbonate in preterm infants with metabolic acidosis reduces mortality and morbidity.
 - v. **Sodium bicarbonate in a cardiac arrest.** Sodium bicarbonate infusion during a cardiac arrest is not recommended in neonatal patients. May cause harm as noted earlier.
 - vi. **Sodium bicarbonate in sepsis.** Sodium bicarbonate in sepsis is accepted in adults with a pH <7.15. Limited data in neonates.
- h. Some other less controversial recommendations** concerning sodium bicarbonate use in metabolic acidosis.
- i. **Sodium bicarbonate is part of the European and United Kingdom neonatal resuscitation guidelines** because there is some evidence that using alkali to reverse intracardiac acidosis may sometimes restore the heart rate when all else fails.
 - ii. **Sodium bicarbonate use in an infant with severe metabolic acidosis (pH <7.15)** with certain life-threatening conditions (eg, cardiac dysfunction, ventricular tachycardia requiring cardioversion, severe hyperkalemia with electrocardiogram changes, certain inborn errors of metabolism with acute metabolic decompensation). Use of sodium bicarbonate in each individual patient must be evaluated and the potential risks and benefits considered.
 - iii. **Sodium bicarbonate use in replacement of base for ongoing gastrointestinal and renal losses.** Not proven but is often accepted as reasonable therapy. Bicarbonate therapy has been used for conditions such as diarrhea and proximal RTA type 2.
 - iv. **Sodium bicarbonate use in inborn errors of metabolism.** Sodium bicarbonate has been used to correct metabolic acidosis in some inborn errors of metabolism (eg, organic acidemia) and is used if the infant has an acute metabolic decompensation with metabolic acidosis (pH 7.0–7.2).
 - v. **Sodium bicarbonate use in hyperkalemia.** Sodium bicarbonate decreases the serum potassium level by moving potassium into the cells. It accepted in the emergent treatment of hyperkalemia. See Chapter 65.
- i. Medications for metabolic acidosis**
- i. **Sodium bicarbonate administration.** As reviewed earlier, administration of sodium bicarbonate has very limited use. However, if there are specific indications for its use, it should be a diluted formulation and

a slow correction. Verify there is adequate ventilation and circulation to prevent an increase in CO_2 retention. Give in a large vein because it is hypertonic and can be caustic. Initial dose is 1 to 2 mEq/kg/dose IV administered slowly over 30 minutes. Use a 0.5-mEq/mL solution or dilute the 1-mEq/mL solution 1:1 with sterile water for injection; maximum rate in neonates and infants is 10 mEq/min. (See also Chapter 155.)

- ii. **Tromethamine (tromethamine acetate) is no longer available in the United States.** It has been used in infants who have metabolic acidosis with significant hypercarbia (high PCO_2 of >65 mm Hg) or significant hypernatremia (serum sodium >150 mEq/L) despite aggressive assisted ventilation.
 - iii. **Sodium or potassium acetate (intravenous preparations)** can be used to treat metabolic acidosis through the conversion of acetate to bicarbonate at a 1:1 ratio. It is used in hyperalimentation or IV fluids for bicarbonate replacement as part of urinary losses in preterm infants and treatment of chronic metabolic acidosis. The dosing for sodium or potassium acetate is similar to sodium bicarbonate. See dosing in Chapter 155.
 - iv. **Citrate and citric acid solutions (oral medications).** Used in the treatment of chronic metabolic acidosis, as in RTA or chronic kidney disease, because sodium and potassium citrate salts have the ability to buffer gastric acidity and are metabolized to bicarbonate. See Chapter 155 for dosing information.
- j. **Conditions with metabolic acidosis and their specific treatments**
- i. **Sepsis.** Initiate a septic workup and consider broad-spectrum antibiotics. (See Chapter 146.)
 - ii. **Necrotizing enterocolitis.** See Chapter 109.
 - iii. **Hypothermia or cold stress.** See Chapter 8.
 - iv. **Periventricular/intraventricular hemorrhage.** Weekly ultrasonographic examinations of the head and daily head circumferences are indicated. Monitor the infant for signs of increased intracranial pressure (convulsions, vomiting, and/or hypotension). (See Chapter 103.)
 - v. **Patent ductus arteriosus.** If hemodynamically significant, PDA should be treated. (See Chapter 114.)
 - vi. **Shock/low cardiac output.** Give volume expansion if hypovolemic or vasoactive medications based on cardiac function. (See Chapter 70.)
 - vii. **Renal tubular acidosis.** Treat with alkaline therapy such as sodium bicarbonate or citrate or citric acid solution.
 - viii. **Inborn errors of metabolism.** Rare cause (see Chapter 100).
 - ix. **Maternal use of salicylates.** Acidosis usually resolves without treatment.
 - x. **Acute kidney injury.** See Chapter 86.
 - xi. **Congenital lactic acidosis.** Supportive care, correction of the metabolic acidosis with sodium bicarbonate.
 - xii. **Parenteral hyperalimentation.** Preterm infants usually need acetate supplementation in hyperalimentation to correct for ongoing bicarbonate losses. It should be given to infants with a base deficit >-5 . The use of acetate in total parenteral nutrition reduces the severity of the acidosis and the incidence of hyperchloremia.
 - xiii. **Late metabolic acidosis of prematurity.** Use a low casein formula; this may alleviate the acidosis. In some cases, giving a base such as sodium acetate may be necessary.
2. **Metabolic alkalosis.** Mild or moderate alkalosis may not require correction. Severe metabolic alkalosis is associated with increased mortality, and chronic metabolic acidosis may increase the risk of sensorineural hearing loss. **First**

treat any underlying cause. Volume replacement can be used in cases of volume contraction and chloride depletion. If hypokalemia is present, that should be treated. Chloride replacement as potassium chloride (KCl) can be used, but infusion rate may have to be limited. Dilute hydrochloric acid or ammonium hydrochloride can be considered in severe persistent cases but must be given carefully and can be associated with serious complications. **Acetazolamide** may be effective in decreasing serum bicarbonate and has been used in pediatric cardiac patients with congenital heart disease with chloride-resistant metabolic alkalosis and in some carefully selected infants with chronic metabolic alkalosis with chronic respiratory insufficiency.

- a. **Reduce excess administered alkali.** Adjust or discontinue the dose of sodium bicarbonate or potassium citrate and citric acid solutions; reduce acetate in hyperalimentation.
 - b. **Hypokalemia.** This can cause a shift of hydrogen ions into cells as potassium is lost. The infant's potassium level should be corrected (see Chapter 68).
 - c. **Prolonged nasogastric suction.** Treated with IV fluid replacement, usually with 1/2 normal saline with 10 to 20 mEq KCl/L, replaced mL/mL each shift.
 - d. **Vomiting and loss of chloride from diarrhea.** Give IV fluids and replace deficits, as described earlier.
 - e. **Compensation for respiratory acidosis.** Correct ventilation.
 - f. **Diuretics.** These can cause mild alkalosis; no specific treatment is usually necessary. Stop the dose temporarily, decrease the diuretic dose if necessary, or add a potassium-sparing diuretic such as spironolactone.
 - g. **Barter syndrome.** Correct dehydration and electrolyte imbalance (replace electrolyte losses). Treatment includes potassium supplements, and after 6 to 12 weeks, indomethacin is given.
 - h. **Primary hyperaldosteronism.** Treatment depends on the cause. Acute therapies include diuretics, angiotensin-converting enzyme inhibitors, and steroids.
3. **Other causes of abnormal blood gases**
- a. **Endotracheal tube problems.** Determine whether there are any changes in the pulmonary function test measurements on the ventilator that may indicate a problem with the ETT. **Colorimetric CO₂ detectors** can be used to determine airway patency, with a color change from purple to yellow if there is exhaled CO₂ gas. If there is no color change, there is airway obstruction and a possible ETT problem. Mark position on the ETT when it is correctly placed to note whether the tube is out of position.
 - i. **Mucus plug.** With decreased bilateral breath sounds and retractions, a plugged ETT is possible. Pulmonary function measurements on specific ventilators may also define this if the VT is low. The infant can be suctioned, and if clinically stable, repeat blood gas measurements can be obtained. If the infant is in extreme distress, replace the tube.
 - ii. **Endotracheal tube placement problems.** An infant with a tube placed down the **right mainstem bronchus** has breath sounds on the right only and decreased breath sounds on the left. Withdraw the tube 0.5 to 1 cm. Listen for equal breath sounds and check an x-ray. An infant with a **tube that has dislodged or is in the nasopharynx** has decreased or no breath sounds on chest auscultation. Listen from breath sounds over the stomach or see if air is escaping from the mouth. Need to replace the tube.
 - b. **Ventilator issues.** Changes in blood gas levels based on changes in routine ventilator settings can be found in Table 51-1. Advanced ventilator management for high-frequency devices can be found in Chapter 9.
 - i. **Overventilation.** If the blood gas levels reveal overventilation, the ventilation parameters need to be adjusted. Deciding which parameter to adjust depends on the patient's lung disease and the disease course.

Table 51–1. CHANGES IN BLOOD GAS LEVELS CAUSED BY CHANGES IN VENTILATOR SETTINGS

Variable	Rate	PIP	PEEP	IT	FiO ₂
To increase PaCO ₂	↓	↓	NA	NA	NA
To decrease PaCO ₂	↑	↑	NA ^a	NA ^b	NA
To increase PaO ₂	↑	↑	↑	↑	↑
To decrease PaO ₂	NA	↓	↓	NA	↓

FiO₂, fraction of inspired oxygen; IT, inspiratory time; NA, not applicable; PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure.

^aIn severe pulmonary edema and pulmonary hemorrhage, increased PEEP can decrease PaCO₂.

^bNot applicable unless the inspiratory-to-expiratory ratio is excessive.

- (a) **If the oxygen level is high.** Easiest solution is to decrease the FiO₂. Other options include decreasing the PEEP, PIP, VT, inspiratory time, rate, and flow.
- (b) **If the carbon dioxide level is low.** Decrease the rate. Other options include decreasing the PIP or VT, expiratory time, or flow.
- ii. **Insufficient respiratory support.** If the infant's chest is not moving, the PIP is not high enough; an adjustment of the ventilator setting is needed. Also check the VT; if it is low, it could mean not enough pressure is given.
 - (a) **If the oxygen is low, with increase in PaCO₂ and gradual deterioration in the infant.** One or more of the following can be increased: FiO₂, PIP, PEEP, inspiratory time, or VT. Increase FiO₂ by 5% to 10%, and increase PIP and PEEP by increments of 1 to 2 cm H₂O. Increase inspiratory time (preterm infants not >0.4 seconds; term infants not >0.5 seconds). Increase the VT by 1 to 2 mL/kg (volume ventilator).
 - (b) **If the CO₂ is high and no changes in PaO₂.** One or more of the following can be increased: ventilator rate by increments of 5 to 10 breaths/min, PIP by 2 to 5 cm H₂O (pressure ventilator), VT by 1 to 2 mL/kg (volume ventilator), flow rate, or expiratory time. Decreasing PEEP will increase VT and decrease CO₂. **Increased dead space from tubing can cause this;** cut the endotracheal tube to make it shorter.
- iii. **Ventilator malfunction. This can cause an acute change in the blood gas.** To check to see if there is ventilator malfunction, disconnect the ventilator from the infant and manually inflate the infant's lung. If the infant improves, then it is the ventilator. Ventilator problems include the following: the concentration of O₂ going to the ventilator may be wrong, there may be a leak, the tubing may be disconnected, or there may be electrical or mechanical failure. Notify respiratory therapy to check the ventilator and replace it if necessary.
- iv. **Agitation.** May cause oxygenation to drop in the infant; sedation may be needed (*controversial*) or ventilator settings may need to be adjusted.
 - (a) **Note: Agitation can be a sign of hypoxia, so a blood gas level should be obtained before ordering sedation.** If there is documented hypoxia, attempt to increase oxygenation.

- (b) **Sit by the bedside and try different ventilator rates** to see whether the infant fights less.
 - (c) **Routine sedation.** Usually not recommended because in very low birthweight infants and premature infants, it is associated with an increase in severe IVH, delay in diuresis, and ileus. **If sedation is used**, use the preferred agent at your institution (see Chapter 81 for agents used: diazepam, lorazepam, midazolam, fentanyl, chloral hydrate, morphine).
- c. Acute change in clinical pulmonary status**
- i. **Pneumothorax.** See Chapter 75.
 - ii. **Endotracheal tube problems, ventilator malfunction.** See Sections V.B.3.a.i and ii, and V.B.3.b.iii.
 - iii. **Atelectasis.** Treatment consists of percussion and postural drainage and possibly increased PIP or PEEP. Avoid percussion in small preterm infants; a study showed a strong link between IVH and porencephaly with chest physiotherapy in extremely premature infants.
 - iv. **Pulmonary edema.** Diuretics (eg, furosemide) are the primary treatment with mechanical ventilation as indicated.
 - v. **Persistent pulmonary hypertension.** See Chapter 115.

52 Apnea and Bradycardia (A's and B's): On Call

I. Problem. An infant has just had an apneic episode with bradycardia (often referred to as “A’s and B’s”). American Academy of Pediatrics (AAP) has defined apnea as follows: “**Apnea** is the absence of breathing for 20 seconds or longer or a shorter pause associated with bradycardia (<100 beats per minute), cyanosis, or pallor.” Shorter apnea <10 seconds without hypoxemia or bradycardia is usually due to immaturity and is not clinically important. (See also Chapter 89.)

A. The 3 types of apnea with approximate incidence are:

1. **Central apnea.** Complete absence of the brainstem stimulus to breathe, resulting in no respiratory effort (10%–25%). Preterm infants can have central apnea due to their immature brains. Other causes include: inborn errors of metabolism, metabolic issues (hypoglycemia, hypocalcemia, acidosis), congenital anomalies, CNS infections, birth asphyxia, head trauma, toxin exposure.
2. **Obstructive apnea.** Infant breathes but no airflow is present because of an obstruction usually at the pharyngeal level by mucus or airway collapse (10%–20%). Preterm infants have an increase in obstructive apnea due to difficulty maintaining their airway as a result of positioning.
3. **Mixed apnea.** Elements of both central and obstructive apnea. Mixed apnea involves a period of central apnea usually followed by airway obstruction or vice versa. This is the **most common type found in most premature infants** (50%–75%). Other causes include gastroesophageal reflux, pertussis, and bronchiolitis.

B. Definitions

1. **Apnea of infancy.** The AAP definition of apnea of infancy (AOI) is as follows: “an unexplained episode of cessation of breathing for 20 seconds or longer or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia” in an infant >37 weeks’ gestational age at the onset of the apnea. It

occurs in 1 per 1000 infants. AOI and **apnea in term infants** are interchangeable terms. **Apnea in a term infant** is not common and is usually pathologic and secondary to a long list of causes (eg, infection, seizure disorder, severe birth asphyxia, stroke, drug depression, intracranial hemorrhage, cerebral infarction, polycythemia, micrognathia).

2. **Apnea of prematurity.** AAP defines apnea of prematurity (AOP) as follows: "Sudden cessation of breathing that lasts for at least 20 seconds or is associated with bradycardia or oxygen desaturation (cyanosis) in an infant <37 weeks' gestational age." It may start as obstructive or central but involves elements of both and is most commonly mixed apnea. AOP is a developmental disorder usually of **physiologic immaturity of respiratory control**, but other diseases may contribute. Factors found in the pathogenesis of AOP include central mechanisms and peripheral reflex pathways. **Central mechanisms** include decreased central chemosensitivity, hypoxic ventilatory depression, upregulated inhibitory neurotransmitters, and delayed central nervous system development. **Peripheral reflex pathways** include decreased or increased carotid body activity, laryngeal chemoreflex, and excessive bradycardic response. The incidence of AOP is inversely correlated with gestational age and birthweight. It affects almost all infants born ≤ 28 weeks of gestation or with a birthweight <1000 g. AOP may be hereditary. AOP usually presents on days 2 to 7. It usually resolves by 36 to 37 weeks of postmenstrual age (PMA) in 92% of infants born at ≥ 28 weeks' gestation and by 40 weeks of PMA in >98% of infants. Infants born at <28 weeks' gestation can have apnea to or beyond term gestation. **If apnea presents in the first 24 hours of life or after day 7, it is very unlikely to be AOP. Note: AOP is a diagnosis of exclusion.**
 3. **Persistent apnea.** Apnea that persists in a neonate ≥ 37 weeks of PMA. It usually occurs in infants born at <28 weeks' gestation.
 4. **Extreme apnea event.** AAP defines this as apnea >30 seconds and/or heart rate <60 beats/min for >10 seconds.
 5. **Periodic breathing.** Periodic breathing is a normal variation of breathing found in premature and full-term infants. There are pauses of breathing for no more than 5 to 10 seconds at a time (may have minor oxygen desaturation and bradycardia) followed by a series of rapid breathing episodes and then a return to normal breathing without stimulation. It occurs mainly during quiet sleep. It is absent the first few days of life, is more frequent at 2 to 4 weeks of age, and is usually gone by 6 months.
 6. **Brief resolved unexplained event (BRUE),** formerly known as apparent life threatening event (ALTE), is not synonymous with apnea and has specific defining criteria. It applies to a well-appearing infant (no underlying health problems) <1 year old who has a brief, <1-minute (usually <20–30 seconds) event that resolves, is unexplained after a history and physical examination, and includes 1 or more of the following: cyanosis or pallor; decreased, absent, or irregular breathing; altered level of responsiveness; or marked change in tone (hypertonia or hypotonia).
- C. **Secondary causes of apnea (apnea with identified causes).** Apnea that results from an underlying disorder (eg, sepsis, anemia, asphyxia, temperature instability, pneumonia, others). Some will classify this as **pathologic apnea** (apnea from pathologic causes such as sepsis or pneumonia). Note that **immaturity** can worsen any apnea that is associated with a specific cause.

II. Immediate questions

- A. **Did you observe the apnea? What was going on when the apnea occurred? Do you know what type of apnea it is?** Try to distinguish the type; **obstructive apnea** is the easiest to detect visually, whereas central and mixed are more difficult. A thorough history of the event may help differentiate the type of apnea. **If it occurred during feeding with a nasogastric/rogastic tube, is the tube in proper position?** (Stimulation of laryngeal receptors causes **central apnea**.) **Did it occur with insertion of a nasogastric/rogastic tube?** Consider a vagal response (vagal nerve stimulation

resulting in **central apnea**.) If the infant has no respiratory effort on the monitor or on physical examination (absent breath sounds, chest wall not moving), think **central apnea**. **What position was the infant in when it occurred?** Neck flexion can obstruct the airway and cause **obstructive apnea**. **Was the infant just suctioned when the apnea occurred?** Aggressive pharyngeal suctioning can cause **central apnea**. **Does the infant have excessive secretions?** If so, this suggests **obstructive apnea**.

- B. What is the gestational age of the infant? The incidence of apnea is inversely related to gestational age.** A's and B's are common in **premature infants** (all infants <28 weeks' gestation have apnea; 80% of infants at 30 weeks and 20% of infants at 34 weeks have apnea) and uncommon in **term infants**. In **term infants**, the incidence is 0.8 to 1.0 per 1000 term births. Apnea in term infants is usually associated with a serious disorder or related to a maternal condition (magnesium treatment or maternal exposure to narcotics). **Apnea in a term infant is usually never physiologic; it requires a full workup to determine the cause.**
- C. What is the birthweight of the infant?** Apnea increases as birthweight decreases. All babies <1000 g will have at least 1 apneic spell. Thirty percent of all babies weighing <1800 g will have at least 1 apneic spell.
- D. Was significant stimulation needed to return the heart rate to normal?** An infant requiring significant stimulation (eg, oxygen by bag-and-mask ventilation) usually needs an immediate evaluation. An infant who has had 1 episode of apnea and bradycardia not requiring oxygen supplementation may not need a full evaluation unless the infant is term.
- E. If the patient is already receiving medication (eg, methylxanthine) for apnea and bradycardia, is the dosage adequate?** Determine the serum drug level.
- F. Did the episode occur during or after feeding?**

1. Feeding hypoxemia is more common in premature infants and can be seen in term infants. When infants start oral feedings, they can experience hypoxemia, cyanosis, and bradycardia. Apnea occurs more commonly during feeding due to the following reasons: obvious increased work of breathing, diaphragmatic fatigue, abdominal distension causing a decrease in lung volume, and immaturity of coordination of sucking, swallowing, and breathing such that ventilation is impaired during sucking and swallowing. Feeding hypoxemia resolves with maturation.

2. Gastroesophageal reflux. It has been stated that **gastroesophageal reflux (GER) causes apnea and bradycardia** because it was observed when regurgitation of formula into the pharynx occurred after feeding. This has been a source of much debate, with recent studies showing no relationship between the 2 conditions. Evidence now shows that apnea is rarely temporally related to GER episodes and GER does not make apnea worse.

3. Insertion of a nasogastric tube may cause a **vagal reflex**, resulting in apnea and bradycardia.

- G. How old is the infant? Apnea in the first 24 hours is usually pathologic.** The peak incidence of AOP occurs between 5 and 7 days of postnatal age.
- H. Is there a change in the frequency or an increase in severity of episodes? Is this the first episode, or has the pattern changed?** If the pattern changes or the amount and severity of each episode increase, then something new may be going on and a workup should be done.
- I. What is the temperature of the infant and the environment?** Hyperthermia and hypothermia can cause apnea. Overwarming an infant can cause apnea, and cold-stressed infants being warmed can have apnea.

III. Differential diagnosis. Causes of A's and B's can be classified according to diseases and disorders of various organ systems, gestational age, or postnatal age. **AOP is a diagnosis of exclusion; therefore, it is important to diagnose and treat any secondary cause.**

A. Diseases and disorders of various organ systems

1. Head and central nervous system

a. Perinatal asphyxia

- b. **Intraventricular/intracranial or subarachnoid hemorrhage**
 - c. **Meningitis**
 - d. **Hydrocephalus with increased intracranial pressure**
 - e. **Cerebral infarct with seizures**
 - f. **Seizures (apnea is an uncommon presentation of a subtle seizure).** Consider a seizure if apnea occurs without bradycardia; tachycardia can be seen before or during the apneic attack.
 - g. **Birth trauma**
 - h. **Congenital myopathies or neuropathies**
 - i. **Congenital malformations**
 - j. **Congenital central hypoventilation syndrome**
 - k. **Encephalopathy**
2. **Respiratory system**
- a. **Hypoxia, hypercarbia**
 - b. **Upper airway obstruction/malformation** (eg, Pierre Robin sequence), nasal obstruction
 - c. **Lung disease/pneumonia/respiratory distress syndrome/aspiration/bronchopulmonary dysplasia**
 - d. **Hypercarbia, inadequate ventilatory support, or performing extubation too early**
 - e. **Surfactant deficiency**
 - f. **Pulmonary hemorrhage**
 - g. **Pneumothorax**
 - h. **Respiratory syncytial virus**
 - i. **Vocal cord paralysis**
3. **Cardiovascular system**
- a. **Congestive heart failure**
 - b. **Patent ductus arteriosus**
 - c. **Cardiac disorders** such as cyanotic congenital heart disease, congenital heart block, hypoplastic left heart syndrome, and transposition of the great vessels.
 - d. **Severe hypovolemia/hypotension/hypertension**
 - e. **Increased vagal tone.** There is increased vagal tone in newborns, especially in the postdelivery period. Vagal hyperreactivity has been described in sudden infant death syndrome (SIDS).
4. **Gastrointestinal tract**
- a. **Necrotizing enterocolitis.** Apnea is associated with the onset of necrotizing enterocolitis (NEC).
 - b. **Gastroesophageal reflux disease.** All preterm infants and many term infants have GER. GER disease (GERD) is when GER occurs with many of the symptoms or complications associated with it. Some of the signs attributed to GERD in infants include apnea, desaturation, and bradycardia. Studies have shown that in premature infants the timing of reflux episodes to apnea is rarely related. In full-term infants, GER is an infrequent cause of apnea.
 - c. **Feeding intolerance**
 - d. **Oral feeding.** Introduction of oral feeding in premature infants can cause changes in color and heart rate due to ineffective feeding (sucking, swallowing, and breathing).
 - e. **Abdominal distension** (decreases lung volume and increases vagal stimulation).
 - f. **Bowel movement**
 - g. **Nonrotavirus infection; esophageal hematoma.** Both rare.
5. **Hematologic system**
- a. **Severe anemia** has been implicated in the pathophysiology of AOP. There is no specific hematocrit at which apnea and bradycardia occur, and they

can be seen in infants with anemia of prematurity. Although it makes sense that giving blood transfusions would increase the respiratory drive and decrease AOP, studies on this are conflicting. One study showed decreased apnea 3 days after blood transfusions were given in preterm infants when compared to 3 days before, but there are no data on long-term reduction in apnea after a blood transfusion. It has been shown that liberal blood transfusion may reduce apnea compared with more restrictive blood transfusion.

b. **Polycythemia.** More common in term infants.

6. **Other diseases and disorders**

a. **Temperature instability.** Most often hyperthermia, but also hypothermia, can cause apnea and bradycardia. Note the incubator temperature; the infant may have a normal body temperature but may have a rise in incubator temperature (the infant is hypothermic) or may require a lower incubator temperature (the infant is hyperthermic). Any rapid fluctuation of temperature can cause apnea. Cold stress can occur after birth or during transport or a procedure, and it may produce apnea.

b. **Infection (sepsis).** Check for bacterial, fungal, and viral infections. Respiratory syncytial virus, *Ureaplasma urealyticum*, and botulism can all cause apnea in preterm infants. Human *Parechovirus* type 3 causes apnea in premature infants.

c. **Metabolic/electrolyte imbalance and inborn errors of metabolism.** Hypoglycemia, hypo-/hypernatremia, hypermagnesemia (during parenteral nutrition), hyperkalemia, hyperammonemia, and hypo-/hypercalcemia can cause apnea and bradycardia. Hypothyroidism and inborn errors of metabolism can also cause apnea and bradycardia. Magnesium given to the mother for preeclampsia has been associated with apnea and hypoventilation in the newborn.

d. **Vagal reflex** secondary to nasogastric tube insertion, feeding, and suctioning.

e. **Acute/chronic pain.**

f. **Head/body position (neck flexion).** Improper neck positioning (especially hyperextension and hyperflexion of the neck) can cause tracheal occlusion and obstructive apnea.

g. **Drugs/drug withdrawal.** Oversedation from **maternal drugs** such as magnesium sulfate, opiates, and general anesthesia can cause apnea in the newborn. Apnea can be seen in drug withdrawal of infants born to drug-addicted mothers. In the infant, high levels of phenobarbital or other narcotics or sedatives, such as diazepam and chloral hydrate, may cause apnea and bradycardia. Topical eye drops for routine eye examinations can sometimes cause changes in apnea pattern. Prostaglandin E₁, γ -aminobutyric acid (GABA), and adenosine therapy can cause apnea.

h. **Immunization.** Apnea (with or without bradycardia) is reported in extremely low birthweight (ELBW) infants (<1000 g) after the use of DTwP (diphtheria and tetanus toxoids with the whole-cell pertussis vaccine), but more recent reports did not support this in ELBW with DTaP (diphtheria and tetanus toxoids with acellular pertussis). Apnea and bradycardia with oxygen desaturation are increased in very low birthweight infants when they are given the combination DTaP, inactivated poliovirus, hepatitis B, and *Haemophilus influenzae* b (Hib) conjugate vaccines. Postimmunization apnea has been seen in the following circumstances: infants with apnea within 24 hours prior to immunization, younger age, or weight <2000 g at the time of immunization and a 12-hour Score for Neonatal Acute Physiology II (SNAP II) (illness severity score) <10. If these infants at risk are still in the hospital when they get an immunization, some feel they should be monitored for 48 hours after immunization. One strategy for infants at risk

is to vaccinate in the hospital so they can be observed. These postimmunization events do not appear to have a detrimental effect on the clinical course of immunized infants.

- i. **Kangaroo care.** Studies are conflicting as to whether kangaroo care (KC) increases or decreases apnea. Recently it was found that the effect of KC on apnea rates was the same as that seen with prone positioning. Infants in the neonatal intensive care unit (NICU) should have continuous cardiovascular monitoring. Make sure there is correct head positioning for patency of the airway, and make sure the endotracheal tube, arterial and venous lines, and any other equipment are not compromised. Cochrane review found that KC is an effective and safe alternative to conventional neonatal care for low birth-weight infants in resource-limited countries but did not specifically evaluate the effects of KC on apnea and bradycardia.
- j. **Surgery.** This can cause postoperative apnea in premature infants.
- k. **Ophthalmologic examinations.** Retinopathy of prematurity (ROP) examination has been reported as a cause of apnea and bradycardia. From 19% to 25% of infants (usually younger gestational age and lower birthweight) experienced an increase in cardiorespiratory events in the 24 hours after eye exams.
- l. **Jaundice (unconjugated hyperbilirubinemia)** is associated with central apnea in premature infants.
- m. **Genetic basis of apnea of prematurity.** Recent studies have suggested a genetic basis to AOP because it has a higher incidence in first-degree relatives. A study showed a higher rate of AOP among monozygotic twins compared to dizygotic twins of the same sex. Single nucleotide polymorphisms of genes encoding for adenosine receptors A1 and A2A are linked to the highest risk of having apnea. Certain gene polymorphisms of A2A and A2B receptors are associated with a lower incidence of apnea. Central infantile apnea may be familial.

B. Gestational age. See Table 52-1.

1. **Full-term infants.** Term infants rarely have apnea; the incidence is low, and it is usually not due to physiologic causes as in premature infants. The cause is usually serious and pathologic, and the disease or disorder must be identified. The onset of apnea in a term infant at any time is a **critical event** that requires immediate investigation. The causes of apnea in a term infant can be quite different depending on the age when the infant presents.

Table 52-1. SOME COMMON CAUSES OF APNEA AND BRADYCARDIA ACCORDING TO GESTATIONAL AGE

Premature Infant	Full-Term Infant	All Ages
Apnea of prematurity	Seizure disorder	Sepsis
Patent ductus arteriosus	Infection	Necrotizing enterocolitis
Respiratory distress syndrome	Severe birth asphyxia	Meningitis
Periventricular-intraventricular hemorrhage	Intracranial hemorrhage	Aspiration
Anemia of prematurity	Stroke	Gastroesophageal reflux
Posthemorrhagic hydrocephalus	Drug depression	Pneumonia
	Cerebral infarction	Cardiac disorder
	Polycythemia	Postextubation atelectasis
		Seizures
		Cold stress
		Asphyxia

- a. **Apnea in a term infant <3 days old**
 - i. **Apnea in the delivery room:** Intrapartum maternal drugs (narcotics, anesthetic agents, magnesium sulfate), brain injury secondary to hypoxia and ischemia (with hypotension, hypoxemia, and metabolic acidosis), general anesthesia, early onset sepsis.
 - ii. **Other conditions presenting with central apnea early on:** Infections (early-onset sepsis, pneumonia, meningitis), congenital central nervous system malformations (Dandy-Walker syndrome, Arnold-Chiari malformation), seizures (stroke or infarction), metabolic causes (abnormal glucose, calcium, electrolytes), traumatic brain injury, spinal cord transection, intracranial hemorrhage, temporal lobe lesions, feeding-related hypoventilation/apnea (infants suck vigorously up to 30–60 times per minute; since there is a protective upper airway closure with each swallow, infants can have apnea), upper airway obstruction (anomalies, craniofacial abnormalities, choanal atresia, Pierre Robin sequence, Treacher Collins syndrome, Goldenhar syndrome, Crouzon disease, Down syndrome, airway mass lesions, tracheal web/stenosis, vocal cord paralysis, and others), positional (asphyxiating position after delivery during KC), congenital central hypoventilation syndrome (healthy newborn with apnea and cyanosis), phrenic nerve palsy, and unexplained causes.
 - b. **Apnea in a term infant >3 days old.** The focus is on GER, respiratory syncytial virus, seizures, central nervous system disorder, cardiac disease (arrhythmias, structural, cardiomyopathies, conduction defects), metabolic/inborn errors of metabolism (mitochondrial disease, Pompe disease, Leigh syndrome, mucopolysaccharidoses), anaphylaxis, bacterial infections (eg, urinary tract infection), anemia, upper airway obstruction, and bilirubin encephalopathy. Beyond the neonatal period, the presumed apnea may be a **brief resolved unexplained event (BRUE)** (see page 443).
 - c. **Apnea of immaturity in a term infant.** There are some term infants in whom the **workup is negative** and no cause can be found. Some term infants may not have a fully mature respiratory control network and may have changes in the brain and peripheral chemoreceptor systems that could put them at risk for apnea. This apnea is considered secondary to physiologic immaturity in a term infant.
2. **Preterm infants.** The most common cause is AOP, usually presenting between days 2 and 7 of life (usually <34 weeks' gestation, <1800 g, and no other identifiable cause). It is a diagnosis of exclusion **and other causes need to be considered and ruled out before this diagnosis can be made.** AOP is related to immaturity of the central and autonomic nervous and neurotransmitter systems.
- C. **Postnatal age can be a clue to the cause of apnea with common causes noted:**
1. **Apnea onset within hours after birth.** Oversedation from maternal drugs, birth asphyxia, seizures, hypermagnesemia.
 2. **Apnea on day 1.** Usually pathologic; consider sepsis or respiratory failure.
 3. **Apnea on day 1 or 2.** Sepsis, hypoglycemia, respiratory failure, polycythemia.
 4. **Apnea onset <1 week.** Patent ductus arteriosus, periventricular-intraventricular hemorrhage, sepsis, respiratory failure, AOP.
 5. **Apnea onset >1 week of age.** Posthemorrhagic hydrocephalus with increased intracranial pressure or seizures, postextubation atelectasis, outgrown dose of caffeine or theophylline.
 6. **Apnea onset after 2 weeks in a previously well premature infant.** This requires immediate evaluation because it is usually indicative of a serious illness such as sepsis, meningitis, or other condition.
 7. **Apnea onset at 4 to 6 weeks.** Respiratory syncytial virus infection.
 8. **Variable onset of apnea.** Sepsis, NEC, meningitis, aspiration, GER, cardiac disorder, pneumonia, cold stress, fluctuations in temperature.

IV. Database. Complete history and review of maternal, prenatal, intrapartum, resuscitation, and postpartum history. Determine any prenatal risk of sepsis. A thorough history of any feeding problems is important. A history of feeding intolerance increases the suspicion of NEC. Was the mother on magnesium or opioids? Did the infant receive opioids? Was there any perinatal asphyxia? Is the infant jittery or lethargic? Is there any evidence of temperature instability?

A. Complete physical examination. Overall, does the infant appear sick or well? Pay particular attention to the following signs:

1. **Head.** Signs of increased intracranial pressure, central nervous system depression, or irritability.
2. **Nares.** Pass a small-diameter feeding tube through the nares to rule out choanal atresia.
3. **Heart.** Listen for a murmur or gallop.
4. **Lungs.** Check for adequate movement of the chest if mechanical ventilation is being used; otherwise, note signs of respiratory distress.
5. **Abdomen.** Check for abdominal distention (early sign of NEC). Other signs of NEC are decreased bowel sounds and visible bowel loops. Note any bloody stools.
6. **Skin.** An infant with polycythemia has a ruddy appearance; pallor is associated with anemia.
7. **Neurologic examination.** Do a complete neurologic examination and observe for seizure activity. Is there hypotonia?

B. Laboratory studies

1. Immediate studies

- a. **Arterial blood gas.** To rule out hypoxia and acidosis.
- b. **Complete blood count with differential.** May suggest infection, anemia, or polycythemia.
- c. **Cultures of the blood, urine, and cerebrospinal fluid.** If infection is suspected and these specific tests are indicated. **C-reactive protein** at 36 to 48 hours after birth may be useful as an infection screen. Polymerase chain reaction analyses and viral cultures are appropriate if a viral infection is suspected. **Lumbar puncture and cerebrospinal fluid (CSF) analysis** are appropriate if meningitis is suspected or if increased intracranial pressure from hydrocephalus is causing apnea and bradycardia.
- d. **Serum electrolyte, calcium, magnesium, and glucose levels.** To rule out metabolic abnormality.
- e. **Serum phenobarbital and methylxanthine levels.** To check levels if indicated.

2. Additional studies

- a. **If an inborn error of metabolism is suspected.** Test for organic acid levels, amino acid profiles, ammonia, pyruvate, and lactate. Ketones in the urine may indicate an organic acidemia.
- b. **Stool analysis.** To rule out infectious organisms.

C. Imaging and other studies may be needed depending on the differential

1. Immediate studies

- a. **Chest radiograph.** Should be performed immediately if there is any suspicion of heart or lung disease.
- b. **Electrocardiogram.** If cardiac disease is suspected. Electrocardiogram changes in the R-wave amplitude and QRS duration appear at the onset and termination of apnea and bradycardia episodes. Also rules out prolonged QT syndrome.
- c. **Abdominal radiograph.** Should be performed immediately if indicated. It may detect signs of NEC (see Figure 12–27).
- d. **Ultrasonography of the head.** To rule out periventricular-intraventricular hemorrhage, hydrocephalus, or any congenital abnormalities. To screen for any abnormal findings.

2. Additional studies

- a. **Echocardiography.** To rule out congenital heart disease.

- b. **Electroencephalography.** Apnea and bradycardia may be manifestations of seizure activity.
- c. **Computed tomography of the head.** To detect cerebral infarction and subarachnoid hemorrhage. Use adjusted scanning protocol to limit radiation exposure. The AAP recommends early noncontrast computed tomography (CT) in term encephalopathic infants to rule out hemorrhage.
- d. **Magnetic resonance imaging (MRI)** may be used because of the concern for radiation exposure. Term infants may require an MRI for a more extensive workup; sedation may be necessary for the study.
- e. **If concerned about gastroesophageal reflux:** Upper gastrointestinal (GI) series is no longer recommended.
 - i. **Contrast fluoroscopy** can show episodes of reflux but cannot determine if it is significant GER or if it correlates with symptoms.
 - ii. **Gastroesophageal reflux scintigraphy (termed milk scan if used with milk or formula)** is used to document GER. It is comparable to the pH probe and superior to the barium swallow. Technetium-99m-sulfur colloid is put in a water-based solution or milk (milk scan) and is instilled in the stomach. The patient is scanned in the supine position for 1 to 2 hours with the gamma camera. Positive scintigraphy has no correlation with clinical signs.
 - iii. **Esophageal pH probe monitoring.** A small-caliber tube with a pH electrode is passed into the distal esophagus. Continuous monitoring can be carried out over 4 to 24 hours. This can determine the number of reflux episodes, the duration of the longest episode, and the reflux index (RI; percentage of total recording time of esophageal pH <4). RI >7% is abnormal, RI <3% is normal, and RI of 3% to 7% is indeterminate. If abnormal, it still does not verify that reflux is causing the symptoms. Most reflux in infants is not acidic. pH monitoring is of limited use in preemies because their gastric pH is >4 approximately 90% of the time.
 - iv. **Multichannel intraluminal impedance.** Most accurate method of detecting GER. It is often combined with pH measurement to determine acidity. It detects the bolus movement of liquid and air in the esophagus via a catheter with electrodes and can determine if there is reflux in the esophagus and the height of the reflux.
- f. **Lateral neck radiography, head and neck tomography (3-dimensional), and otolaryngology evaluation** to evaluate the upper airway in obstructive apnea.
- g. **Polygraphic recording.** Can be done but may not be useful in infants near discharge. Usually multichannel, which can include many physiologic parameters such as heart rate, nasal thermistor detection of airflow, and impedance pneumography. Continuous recordings for up to 24 hours may help in the differential diagnosis of apnea. There are many different types of devices used.
 - i. **Polysomnography.** This is the collective process of monitoring and recording physiologic data during sleep. It includes respiration, perioral electromyography, oxygen saturation, heart rate, electroencephalography, electrocardiography, and electrooculography.
 - ii. **Thermistor pneumocardiogram.** This incorporates a thermistor, which detects changes in nasal and mouth airflow. It incorporates a pH probe to study the acidity in the esophagus.
 - iii. **Impedance pneumography.** This measures chest wall movements, oronasal flow, heart rate, and oxygen saturation by a multichannel recorder to help identify different types of apnea.

V. Plan. See also Chapter 89.

A. Prophylactic therapy and recommended monitoring

1. **At-risk infants.** In the Caffeine for Apnea of Prematurity (CAP) study where the inclusion criterion was documented apnea, to facilitate extubation or prophylaxis

(only 20%), the infants who did the best (survival without neurodevelopmental disability at 18–21 months) were the very low birthweight infants (<1250 g) who were treated early with caffeine (<3 days compared to >3 days). Rates of bronchopulmonary dysplasia (BPD) were also decreased. In a Canadian study on infants <31 weeks' gestation, prophylactic caffeine was associated with decreased rates of death, BPD, and patent ductus arteriosus (PDA). Even though the use of prophylactic caffeine in the CAP trial was only 20% and there are limited data stating that prophylactic caffeine is beneficial, **the majority of NICUs routinely give prophylactic caffeine to infants <1000 g (or some <1250 g) soon after birth to avoid intubation and mechanical ventilation.** Some recommend caffeine for infants ≤28 weeks' gestation. It is also given prophylactically in preterm infants on mechanical ventilation getting ready to be extubated to enhance extubation. The AAP states that further trials are needed to study the safety and benefits of prophylactic caffeine in regard to potential neurobehavioral benefits and in infants who require mechanical ventilation. A recent follow-up of infants in the CAP trial found no adverse effects of caffeine on attention, executive function, intelligence, and behavior when compared to controls. At 11 years of age, the caffeine group performed better on certain tests (visual perception, fine motor coordination, and others). Cochrane review does not support the use of prophylactic caffeine for preterm infants at risk of apnea. It is best to follow your institution's protocol.

2. **Prophylactic use of kinesthetic stimulation (oscillating mattresses) to prevent apnea in preterm infants** is not recommended, and a Cochrane review found it to be ineffective.
3. **Postoperative apnea/bradycardia.** Caffeine can be used to prevent postoperative apnea/bradycardia and oxygen desaturation in preterm infants. Infants <46 weeks' postconceptional age should be monitored for a minimum of 12 hours postoperatively. Cochrane review indicates the following: "After general anesthesia, caffeine can be used to prevent postoperative apnea/bradycardia and episodes of oxygen desaturation in growing preterm infants if this is deemed clinically necessary."
4. **Postimmunization of preemies.** Infants who had apnea after their first immunization should receive cardiorespiratory monitoring for a minimum of 24 hours after immunization.
5. **Postretinopathy of prematurity exams.** As noted, ROP exams may increase the risk of a cardiorespiratory event for 24 hours after the exam (similar to the incidence after immunization). Monitor these infants for 24 hours after the exam.
6. **Co-bedding of preterm twins.** Cochrane review found no difference between the co-bedded group and the group receiving care separately in terms of apnea, bradycardia, or desaturation episodes.

B. General plan

1. Assess the infant first.

- a. **Is the infant blue?** Use tactile stimulation (gently stroking or rubbing baby's back or extremities; sometimes, more vigorous rubbing is necessary to resume breathing). If the infant does not respond, do not continue the tactile stimulation.
 - i. **Bag-and-mask ventilation** until heart rate and respirations normalize.
 - ii. **Supplemental oxygen** if cyanosis persists.
 - iii. **Intubation** may be necessary if the infant is not responding.
 - iv. **Send stat labs, and obtain a chest x-ray and possible abdominal radiograph.**
 - v. **Rule out simple causes:** Is temperature okay in isolette? Is the nasogastric or endotracheal tube in the correct position? Is the position of the infant okay?
- b. **Is the infant pink and breathing, and is the heart rate acceptable?** The infant may have had a true apneic spell with spontaneous remission of breathing by the infant. Malfunction of the monitor could also have been the cause.

- c. **Apnea in the delivery room.** Apnea is an indication for positive-pressure ventilation in the delivery room per the *Textbook of Neonatal Resuscitation*, seventh edition.
2. **Determine the cause of apnea and bradycardia and treat if possible.** Sepsis is a cause that cannot be overlooked because antibiotics need to be started. Rule out sepsis/infection and other treatable causes (eg, intraventricular hemorrhage [IVH], seizures, PDA, anemia, NEC) before diagnosing and treating the infant with AOP.
3. **Apnea in a term infant** is approached differently because it is more likely to be pathologic and is usually secondary to an underlying known cause. Term infants require a detailed evaluation (thorough maternal, prenatal, intrapartum, resuscitation, postpartum, and feeding history and physical examination) to identify the cause (a long differential) and treat it accordingly. These infants should be admitted and observed with cardiorespiratory and pulse oximetry monitoring. A full workup depending on the specific history is necessary. Minimal laboratory studies to be ordered include complete blood count, electrolytes, calcium blood glucose, and arterial blood gas. Other studies (CT scan, radiographs, electroencephalogram, otorhinolaryngology consult, genetics consult, MRI, pneumogram, polysomnogram) may be necessary depending on the history and findings on the physical examination. Management and guidelines are lacking for this group. Caffeine is not recommended in this group of infants. It is best to identify the cause and target treatment based on that. If no cause can be found, a pneumogram or polysomnogram may be helpful. If a BRUE event is being considered, review BRUE clinical guidelines.
4. **Apnea of prematurity**
 - a. **Nonpharmacologic treatments**
 - i. **Environmental temperature.** Because overheating may play a role in apnea, keep the environmental thermostat neutral or at the lower end of the range; a specific environmental temperature cannot be recommended. Some recommend humidification of warm gas. Body temperature between 36.5°C and 37°C seems to be effective in decreasing apnea episodes.
 - ii. **Infant body positioning.** Often used as a first-line intervention in infants with AOP. Studies are conflicting on whether different body positions decrease apnea in the premature infant. Several studies have shown that certain positions can decrease AOP; decrease episodes of oxygen desaturation; or improve apnea, bradycardia, and desaturation. A recent Cochrane review (2017) found insufficient evidence to determine effects of body positioning on apnea, bradycardia, and oxygen saturation in preterm infants and do not recommend the use of one position over another for premature infants with apnea. **It is important to avoid extreme flexion or extension, which decreases the patency of the airway** and may cause obstruction and apnea. Three positions (prone position, head elevated tilt position [HETP], and 3-stair position [TSP]) are used in the NICU.
 - (a) **Prone position (body lying face down).** Avoid neck flexion or extension, which can decrease the patency of the airway. Several studies show that the prone position stabilizes the chest wall and decreases AOP. It also increases ventilation, and reduces GER and energy expenditure in respiration. Only recommended for infants with apnea with NICU monitoring.
 - (b) **Head elevated tilt position.** The bed is tilted in an inclined position of 15 degrees so the head and neck are elevated 15 degrees from the prone position; this position reduces episodes of oxygen desaturation. It does not improve AOP in an infant receiving aminophylline treatment.

- (c) **Three-stair position.** The head and abdomen are maintained at horizontal position. The head is on 3 blankets, the thorax is on 2 blankets, and the pelvis is on 1 blanket. Airway obstruction and neck inclination do not occur. This position was shown to improve apnea, bradycardia, and desaturation. It does not improve AOP in an infant receiving aminophylline treatment.

iii. Stimulation

- (a) **Tactile stimulation** provides excitatory activity in the brainstem to stimulate respiratory activity and represents the most common intervention. Tactile stimulation includes rubbing the skin, stroking the back, patting the infant, and tapping or tickling the feet.
- (b) **Olfactory stimulation.** Introducing a pleasant odor (vanillin) into the incubator (15 drops of saturated vanillin solution to the infant's pillow at the periphery) decreased the frequency of apnea by 45% in one 24-hour study in infants who were unresponsive to caffeine or doxapram (see Chapter 22).
- (c) **Kangaroo care for the treatment of AOP** is controversial, with conflicting studies on whether it increased or decreased apnea and bradycardia events. It was found to have the same effect as prone positioning. Cochrane review states that evidence supports KC in low birthweight infants as an alternative to conventional neonatal care, especially in resource-limited settings.
- (d) **Kinesthetic stimulation (oscillating mattress).** Not effective in clinically significant apnea. Use of stochastic mechanosensory stimulation (mattress with embedded actuators that delivers subarousal vibration to infants) stabilized breathing during sleep and helped to decrease the incidence of AOP, oxygen desaturation, and some aspects of bradycardia.

iv. Maintain nasal patency. Because nasogastric tubes increase nasal airway resistance and an increase in upper airway resistance may increase AOP, **orogastric tubes** have been preferred in premature infants with apnea. Cochrane review indicates that there is insufficient evidence that the route of feeding tube placement affects the incidence or frequency of apnea or bradycardia. Tube placement should be based on clinician preference.

- v. Feeding.** One observational study found that transpyloric feeding (especially with human milk) may decrease the frequency or degree of apnea and bradycardia in preemies with GER. A Cochrane review of transpyloric versus gastric feeding for preterm infants found no trials that addressed the issue of whether transpyloric versus gastric feeding affected the incidence of GER-related apnea or bradycardia. They found that transpyloric feedings do not have benefits for preterm infants and there is a higher risk of adverse effects (GI disturbance and mortality).

C. Specific management. Deciding on which infants to treat usually depends on how many episodes of apnea are occurring, the severity of each episode, and the required intervention to stop the episode of apnea. If there are multiple or severe apneic episodes, medical treatment may be necessary. Different institutions have varying guidelines on when to start medical treatment. **Some recommendations** include the following: >6 apneic episodes every 12 hours requiring only minimal stimulation; >2 apneic episodes per hour requiring minimal stimulation over a couple of hours; >1 to 2 apneic episodes in 24 hours requiring vigorous stimulation; any episode during which the infant does not respond to tactile stimulation; or when the infant requires bag-and-mask ventilation with oxygen. These infants are usually managed with noninvasive respiratory support, with medications added as needed. It is best to follow your institution's guidelines. **Combination therapy** (nasal continuous positive airway pressure [nCPAP] in conjunction with xanthine therapy) is very effective.

1. **Respiratory support.** Maintain adequate oxygen saturation with supplemental oxygen (indicated if there is desaturation or bradycardia). Avoid vigorous suctioning.
 - a. **Low-flow oxygen** may decrease the rate of intermittent hypoxia and apnea. Avoid hyperoxia.
 - b. **Nasal cannula oxygen.** This is a small, tapered cannula that is used to deliver oxygen or blended oxygen. It can cause nasal irritation, causing arousal, and may help to prevent apnea.
 - i. **Low-flow nasal cannula (<1 L/min)** can be used as an adjunct for apnea. Low-flow oxygen decreases the rate of intermittent hypoxia and apnea.
 - ii. **High-flow nasal cannula** can provide high concentrations of oxygen and also deliver a positive end-expiratory pressure and can be used as an alternative to nCPAP. The rates are 1 to 6 L/min. One study showed that nasal cannula oxygen was just as effective as nCPAP. Heated humidified high-flow nasal cannula is preferred over high-flow nasal cannula.
 - c. **Nasal continuous positive airway pressure.** Continuous positive airway pressure (CPAP) via nasal prongs reduces the frequency and severity of apneic spells. It decreases the risk of obstructive apnea. (**Note:** Different sources cite different CPAP parameters. Variable-flow CPAP may be better than ventilator or bubble CPAP. Ranges reported: 2–4, 3–6, 4–6, and 5–8 cm H₂O.) **A range of 4 to 6 cm H₂O seems to be cited frequently and is considered safe.** Use the settings recommended by your institution. It can be used in conjunction with medication (after a therapeutic level has been obtained). Side effects of CPAP include bowel distension, nasal trauma, barotrauma, and pneumothorax.
 - d. **Noninvasive ventilation.** Noninvasive ventilation is a method of ventilation without tracheal intubation that uses constant or variable pressure to provide ventilatory support. It is often used with CPAP. **Nasal intermittent positive-pressure ventilation (NIPPV)** is a type of noninvasive ventilation that combines nCPAP with superimposed positive-pressure breaths. Cochrane review states that NIPPV reduced the frequency of apneas more effectively than nCPAP. NIPPV via nasal prongs is more effective than nCPAP alone in AOP. NIPPV also reduces the incidence of extubation failure more effectively when compared with nCPAP.
 - e. **Mechanical ventilation.** Should only be used if apnea and bradycardia cannot be controlled by other less invasive interventions (drug therapy, nCPAP, or NIPPV). Low pressures (minimal peak inspiratory pressure) are used at the rate necessary to prevent apnea.
2. **Pharmacotherapy.** See detailed dosing information in Chapter 155.
 - a. **Caffeine is the drug of choice for apnea.** Theophylline and caffeine seem to have equal efficacy (both reduce apnea and the use of mechanical ventilation within 2–7 days of beginning treatment), but **caffeine** offers multiple benefits over theophylline (ie, longer half-life, fewer side effects, lower toxicity, once-daily dosing, increased CSF penetration, better longer term outcomes, and no drug level monitoring required). Some authors have called caffeine the “**silver bullet**” or “**magic bullet**” in neonatology. **Long-term dose is 20 mg/kg loading dose and 5 to 10 mg/kg/d for maintenance.** Caffeine therapy reduces the rate of severe retinopathy, BPD, and neurodevelopmental disability at 18 months. Long-term follow-up at 11 years showed benefit of a reduced risk of motor impairment in children who were very low birthweight. It is associated with improved neurodevelopmental outcome at 18 months, improved survival at 18 to 21 months in infants 500 to 1250 g, a reduction in death, decreased incidence of BPD, less time on mechanical ventilation, and a decreased incidence of cerebral palsy, cognitive delay, and severe ROP. A recent follow-up study of infants in the CAP trial found no adverse effects of caffeine on attention, executive function, or behavior and found that the

caffeine group performed better on tests for visual perception, visuospatial organization, and visuomotor integration at the age of 11 years.

- i. **When to start caffeine therapy?** The optimal time to start therapy is not known. Early caffeine therapy (<3 days) is associated with a decreased incidence of BPD and a shorter course of mechanical ventilation. The AAP states that it would be reasonable to start caffeine therapy in infants >28 weeks' gestation who are not on positive-pressure support once they have their first apnea episode.
 - ii. **When to discontinue caffeine therapy?** The optimal time to stop therapy is not known, and no trials have addressed this. The AAP suggests considering a trial off caffeine when the infant is no longer on positive-pressure ventilation and the infant has either been free of apnea for 5 to 7 days or is 33 to 34 weeks of PMA.
- b. **If apnea persists, begin doxapram hydrochloride.** (*Controversial*, not recommended as routine therapy.) The package insert notes it should not be used in neonates due to the benzyl alcohol component. Doxapram appears to be efficacious when theophylline, caffeine, and CPAP have failed; it can reduce apnea within 48 hours after other methods have failed. A recent article stated that both oral and intravenous (IV) doxapram treated most cases of apnea in preterm infants, avoiding the need for endotracheal intubation and invasive ventilation. There are concerns regarding side effects: risk of reduced cerebral blood flow with mental delay later; increased QTc interval, second-degree heart block, severe hypokalemia, and lower mental developmental index at 18 months; irritability, gastric retention, electroencephalogram changes in preterm infants, hypertension, seizures, and GI disturbance; and metabolic acidosis (has benzyl alcohol preservative). If acidosis occurs, consider stopping doxapram. A recent review concluded that the routine use of doxapram could not be recommended because there were no conclusions on safety and efficacy as a result of the limited studies and low level of evidence. Cochrane review states the following: "IV doxapram might reduce apnea within the first 48 hours of treatment; further studies are needed to determine the role of it in clinical practice."

D. Cause-specific treatment of apnea and bradycardia

1. Anemia

- a. **Transfusion is not routinely recommended** because data are conflicting and evidence is insufficient. The rationale is that if you give red blood cells to an infant, you increase the total content of oxygen in the blood, increase tissue oxygenation, and increase oxygen-carrying capacity, thereby increasing the respiratory drive and decreasing the episodes of apnea. Most institutions do not treat anemia if the infant is asymptomatic, the infant is feeding and growing, and the reticulocyte count is >5% to 6%. If the hematocrit (Hct) is very low (<25% based on institutional guidelines), transfusion may be indicated. If the infant is symptomatic (significant apnea and bradycardia, defined as >9 episodes in 12 hours or >2 episodes in 24 hours requiring bag-and-mask ventilation), on therapeutic doses of methylxanthines, not feeding well, or on oxygen or respiratory support and the reticulocyte count is not appropriate for the low hematocrit (ie, reticulocyte count <2%–3%), transfusion may be indicated to an Hct level of $\geq 30\%$ (*controversial*). Note that **transfusion-associated NEC** (ie, NEC that appears 48 hours after a blood transfusion) is a concern and has been associated with approximately 25% to 35% of NEC cases. One survey showed that the majority of neonatologists support the following guidelines for transfusion:
 - i. Without symptoms but Hct is 20% to 25%.
 - ii. Symptomatic (ie, $\text{FiO}_2 > 40\%$ per nasal cannula) with Hct of 25% to 30%.
 - iii. Require ventilator assistance with $\text{FiO}_2 > 40\%$ and have an Hct of 30% to 35%.

- b. Erythropoiesis-stimulating agents such as recombinant human erythropoietin and darbepoetin.** The use of recombinant human erythropoietin (EPO) with iron for anemia of prematurity, decreasing the need for transfusions, is **controversial**, with early studies showing an increase in the risk of development and progression of ROP, although later studies showed no difference in stage 3 or greater ROP in EPO versus placebo groups. **Early and late recombinant human EPO treatment is not recommended.** There may be benefit in infants <1000 g, in whom a significant reduction in transfusions was found at 1 month.
- 2. Gastroesophageal reflux.** There is normal physiologic GER (no signs other than spitting up) and pathologic GER or GERD (acidic reflux that causes injury to the lower esophageal mucosa and complications such as respiratory problems and poor growth). Signs of pathologic GER/GERD include frequent regurgitation, apnea, bradycardia, desaturation, poor weight gain, feeding aversion, irritability, and discomfort. The majority of signs of pathologic GER/GERD do not correlate with multichannel intraluminal impedance or pH measurements (see page 450). Physiologic GER is considered a normal developmental process that will resolve with maturation. In the majority of infants with apnea, GER is not the cause. Furthermore, research has not shown a relationship between GER and AOP. Nonpharmacologic therapy does not seem to decrease signs of GER in preterm infants, and medications are not recommended in this group. **This guideline is only included here for the uncommon circumstance where there is a definitive relationship between symptoms and GER or in a term infant with apnea with severe GER.**
- a. Feeding modifications**
- i. Breast-fed infants.** Modify maternal diet if breast fed. Restrict maternal cow's milk and eggs for 2 to 4 weeks for any infant with GERD who is breast feeding (to rule out milk protein allergy in the infant, which can mimic GERD).
 - ii. Formula-fed infants.** Milk protein sensitivity may cause vomiting and crying in infants. Infants with recurrent vomiting may benefit from a 2- to 4-week trial of an extensively hydrolyzed protein formula. Hydrolyzed protein formulas decrease reflux and symptoms of GER in term infants but only decrease reflux episodes in preterm infants, not symptoms. Hydrolyzed protein formula can be tried in term infants and in preterm infants with severe reflux.
 - iii. Small-volume feeds or hourly feeding.** No randomized trials have been done studying different feedings (bolus intragastric tube vs transpyloric vs continuous intragastric) on symptoms and severity of GER. Overfeeding can aggravate reflux, so decreasing the volume of feeds while increasing the frequency is recommended. Hourly feedings decreased the total GER episodes but increased the acidic reflux episodes in premature infants. Another study found that longer feeding duration and slower milk flow rates were associated with decreased GER events.
 - iv. Thickened feedings.** Thickening feeds decreases GER in term infants but does not decrease the acidic GER. North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) states that thickening feeds decreases visible regurgitation but does not cause a measurable decrease in the frequency of episodes. For **term infants** with GER and GERD, add 1 Tbsp of dry rice cereal per 1 oz of formula. For **preterm** infants, the US Food and Drug Administration and AAP issued a warning about thickened feedings and NEC in premature infants. **The following should not be used in infants <37 weeks:** pectin-based thickeners, carob bean gum–based products, SimplyThick, and xanthan gum–based products. Commercial anti-regurgitant formulas decrease overt regurgitation and frequency of

vomiting compared with formula with rice or unthickened formula. Cochrane review found with moderate certainty evidence that feed thickeners should be considered if regurgitation symptoms persist in term bottle-fed infants. The reduction of 2 episodes of regurgitation per day is likely to be of clinical significance.

- v. **Continuous or transpyloric feedings.** Transpyloric feedings (especially with human milk) may reduce apnea and bradycardia in preterm infants with GER. Cochrane review on transpyloric versus gastric feeding in preterm infants showed that transpyloric enteral feeding did not improve feeding tolerance, had an increased risk of stopping feeds, and increased mortality. There is no evidence to support the use of continuous feedings or transpyloric feeding for the treatment of GER.
 - b. **Position. Head up angle is ineffective in decreasing acid reflux in older infants; this position has not been studied in preterm infants.** Left lateral and prone positioning after feeding may decrease reflux episodes but showed no decrease in behavioral manifestations of reflux in one small study. Right lateral positioning may increase reflux episodes but was also found to enhance gastric emptying. Therefore, it is uncertain whether positioning techniques actually decrease signs of GER in infants with reflux. One group recommended to place infants in the right lateral position right after feeding for 1 hour and then place them in the left lateral position. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition states that prone positioning is acceptable if the infant is awake and being observed, especially right after feeding. Because of the increased risk of SIDS with the lateral and prone positioning, the AAP and NASPGHAN have stated the following: "All infants with GER should be placed for sleep in the supine position with the exception of the rare infants for whom the risk of death from GER is greater than the risk of SIDS." An example of an exception is infants with upper airway disorders with an impaired airway protective mechanism such as type 3 or 4 laryngeal clefts who have not had surgery yet.
3. **Medications.** The **Choosing Wisely campaign** states to avoid routine use of acid blockers and motility agents for physiologic GER that is effortless, painless, and not affecting growth. If GER is associated with poor growth or significant respiratory symptoms, the infant needs further evaluation. Avoid routine use of antireflux medications for treatment of symptomatic GERD or for the treatment of apnea and desaturation in preterm infants because there is no evidence that pharmacologic treatment of GER with medications that either decrease acidity or increase motility decrease the risk of apnea and bradycardia in preterm infants. These medications should be used sparingly or not at all in preterm infants (see Chapter 155 for details).
- a. **Prokinetic, promotility agents (metoclopramide, domperidone, and erythromycin).** These agents increase the muscle tone of the digestive tract and should decrease the volume of the refluxate. In older infants, these agents improve gastric emptying, decrease regurgitation, and enhance lower esophageal sphincter tone. These medications have not been shown to decrease GER symptoms in preterm infants. These medications all have significant side effects and are not recommended in preterm infants if the only indication is GER. Side effects include increased risk of infantile pyloric stenosis and increased risk of cardiac arrhythmia (erythromycin) and neurologic side effects (domperidone, metoclopramide). Metoclopramide now has a black box warning for tardive dyskinesia.
 - b. **Antacids (Maalox and Mylanta).** Antacids neutralize and buffer the gastric acid, raise the pH of the gastric refluxate, and may improve the symptoms and signs of GER. Their use increases the risk of infection and feeding intolerance in infants receiving gavage feedings, and there is a risk of concretion

formation. Side effects include diarrhea or constipation. If used, the dosage is 0.5 to 1 mL/kg by mouth every 4 hours by nasogastric tube.

- c. **Sodium alginate with sodium bicarbonate (Gaviscon).** These medications work by protecting the esophagus from acidification. They may decrease the signs of GER in older infants. In preterm infants, these medications decreased the frequency of regurgitation, decreased the number of acidic GER episodes, and decreased the total esophageal acid exposure. The long-term safety has not been evaluated in preterm infants. Side effects have included bezoar formation and adverse effects from the aluminum content. (**Note:** Gaviscon is now aluminum free.) None of these agents are recommended as the only treatment. Further studies need to be done.
 - d. **Histamine (H₂) receptor blockers (ranitidine, famotidine)** inhibit histamine-stimulated acid secretion by the gastric parietal cells, decrease hydrochloric acid secretion, and increase intragastric pH. Of the 4 H₂ blockers available, **ranitidine and famotidine are most commonly used in infants** and are preferred because of fewer side effects. No studies of these medications have been done in preterm infants. Use of these medications in preterm infants is associated with an increased incidence of NEC, late-onset infections (*Candida* and gram-negative sepsis), possibly IVH, and death in some studies.
 - e. **Proton pump inhibitors (omeprazole, lansoprazole)** block the proton pump in the gastric parietal cell, which is the last step in the acid secretory pathway, and decrease both basal and stimulated parietal cell acid secretion. Proton pump inhibitors in preterm infants will maintain the stomach pH >4 but do not relieve the clinical signs of GER in clinical trials. Like the H₂ blockers, they also increase the risk of *Candida* infections. There is also increased risk of gram-negative sepsis. Lansoprazole was associated with a higher rate of adverse events.
- E. Persistent apnea.** AOP usually resolves by 37 weeks. Persistent apnea is apnea that persists ≥37 weeks of PMA. It usually occurs in infants born at ≤28 weeks' (24–26 weeks) gestation. These infants can have apnea that persists to term gestation or after. These infants are usually ready to go home except they continue to have apnea. These infants can be at risk for serious episodes of apnea, bradycardia, and cyanosis for several months. How to manage these infants at home is not well studied, and recommendations are lacking. Sometimes a comprehensive polygraphic recording (pneumogram) is done prior to discharge to give a more detailed explanation of the apnea and help in the decision process, but studies have shown it is not useful. The **Choosing Wisely campaign** states the following “Avoid routine use of pneumograms for pre-discharge assessment of ongoing or prolonged apnea of prematurity.” A pneumogram does not predict the risk of SIDS or recurrence of a significant event, a severe cardiopulmonary event, or the need for readmission. Medication is usually continued in these infants after discharge. There is no evidence that AOP increases the risk of SIDS. Cardiorespiratory monitoring at home with an event recorder can be recommended. Parents should be told that home monitoring does not prevent SIDS. Parents need to be instructed in the use of the monitor and be trained in cardiopulmonary resuscitation. **AAP recommendations for home monitoring** may be justified in some premature infants with an unusually prolonged course of recurrent extreme apnea. It can be discontinued at 44 weeks of PMA unless there is a significant medical condition that necessitates that it be continued. Use is limited after episodes stop or at approximately 43 weeks of PMA. It is not recommended in preterm infants with resolved AOP. After 43 weeks, extreme apnea events (apnea >30 seconds and/or heart rate <60 beats/min for >10 seconds) are very rare.
- F. Discharge considerations for apnea of prematurity**
1. **Discontinue caffeine therapy (see page 455).**
 2. **Observe the infant for apnea and bradycardia for a few days after caffeine has been stopped since the half-life of caffeine is 50 to 100 hours.** Most physicians

agree that the infant needs to be apnea free for a period of time before discharge. The period of time that most neonatologists recommend before discharge is 5 to 7 days of being apnea free after caffeine therapy has been discontinued. Based on studies, this period of time should be customized for the individual newborn (shorter duration for older gestational ages and longer duration for younger gestational ages, especially <26 weeks).

3. **Bradycardic episodes that are brief and isolated** and resolve on their own or are feeding related that resolve with stopping feeding do not need to delay discharge.
- G. **Close monitoring with readmission may be indicated in certain situations** (general anesthesia, viral illnesses, immunizations) in preterm infants until 44 weeks of PMA. Preterm infants who have had immunizations or ROP exam may need to be observed and monitored for 24 hours because there have been reports of apnea in these situations.

53 Arrhythmia

- I. **Problem.** An infant has an abnormal tracing on the heart rate monitor. Arrhythmias in neonates can be classified as benign or pathologic. They can be found in 1% to 5% of all neonates.
- II. **Immediate questions**
 - A. **What is the heart rate?** The heart rate in newborns varies from 70 to 190 beats/min (normally 120–140 beats/min; may decrease to 70–90 beats/min during sleep and increase to 170–190 beats/min with increased activity such as crying). See Table 53–1 for normal heart rate values.
 - B. **Is the abnormality continuous or transient?** Transient episodes of sinus bradycardia, tachycardia, or arrhythmias (usually lasting <15 seconds) are benign and do not require further workup. Episodes lasting >15 seconds usually require full electrocardiogram (ECG) assessment.
 - C. **Is the infant symptomatic?** A symptomatic infant may need immediate treatment. Signs of some pathologic arrhythmias include tachypnea, poor skin perfusion, lethargy, hepatomegaly, and rales on pulmonary examination. All of these signs and symptoms may signify congestive heart failure (CHF), which may accompany arrhythmias. If an infant shows clinical signs of heart failure that are believed to have been caused by an arrhythmia, then this suggests the infant was in an abnormal rhythm for a significant period of time (hours to days). CHF resulting from rapid cardiac rhythms is unusual with heart rates <240 beats/min.
- III. **Differential diagnosis**
 - A. **Heart rate abnormalities.** Heart rates in the normal newborn vary dramatically. Some evidence, using computer programs to assess heart rate variability in the neonatal period, suggests that the lower heart rates early on are due to the inability of the infant's sympathetic system to inhibit the parasympathetic (or vagal) response.
 1. **Tachycardia.** Heart rate >2 standard deviations (SDs) above the mean for age (see Table 53–1).
 - a. **Benign causes.** Postdelivery, heat or cold stress, painful stimuli, medications (eg, atropine, caffeine, epinephrine, intravenous glucagon, pancuronium bromide, tolazoline, and isoproterenol).

Table 53–1. HEART RATES IN NEWBORNS

Age	Term Infants		Preterm Infants	
	Mean HR	Range HR	Mean HR	Range HR
1 minute	80	20–140	100	50–145
2 minutes	140	80–200	120	80–160
3 minutes	150	100–200	140	105–175
4 minutes	160	120–195	155	120–183
5 minutes	160	120–190	160	120–180
10 minutes	160	110–185	160	129–195
Normal Newborns				
Up to 24 hours	119	84–145		
1–7 days	133	100–175		
8–30 days	163	115–190		

HR, heart rate.

Data from Hastreiter AR, et al. The electrocardiogram in the newborn period: I. The normal infant, *J Pediatr* 1971 Jan;78(1):146–156; Dawson JA, et al. Changes in heart rate in the first minutes after birth. *Arch Dis Child Fetal Neonat Ed.* 2010;95:F177–F181; Brady JP, et al. Heart rate changes in the fetus and newborn infant during labor, delivery and immediate neonatal period. *Am J Obstet Gynecol.* 1962;84:1–12; Davidson S, et al. Spectral analysis of heart rate fluctuations and optimal thermal management for low birth weight infants. *Med Biol Eng Comput.* 1997;35:619–625.

b. Pathologic causes

- i. **Common.** Fever, shock, hypoxia, anemia, sepsis, patent ductus arteriosus, and CHF.
 - ii. **Uncommon.** Hyperthyroidism, metabolic disorders, cardiac arrhythmias, and hyperammonemia.
2. **Bradycardia.** Bradycardia is a heart rate >2 SDs below the mean for age (see Table 53–1). Transient bradycardia is fairly common in newborns (particularly premature infants); rates range from 60 to 70 beats/min.
- a. **Benign causes.** During defecation, vomiting or micturition, gavage feedings, suctioning, medications (eg, propranolol, digitalis, atropine, and infusion of calcium; maternal long-acting β -blockers to treat hypertension given within 24 hours of delivery).

b. Pathologic causes

- i. **Common.** Hypoxia, apnea, convulsions, airway obstruction, air leak (eg, pneumothorax), CHF, intracranial bleeding, severe acidosis, and severe hypothermia.
- ii. **Uncommon.** Hyperkalemia, cardiac arrhythmias, pulmonary hemorrhage, diaphragmatic hernia, hypothyroidism, and hydrocephalus.

B. Arrhythmias

1. **Benign arrhythmias.** Includes any transient episode (<15 seconds) of sinus bradycardia and tachycardia and any of the benign causes of sinus tachycardia and bradycardia noted in Section III.A.1 and III.A.2. Sinus arrhythmia, a phasic variation in the heart rate often associated with respiration, is also benign.

- a. **Premature atrial beats.** These can occur in the newborn and are usually benign. The QRS is narrow, and the T waves are often discordant. (See the example in Figure 53–1A.) They tend to decrease in number or resolve entirely in the first few months of life. If the premature atrial contraction (PACs), premature beats that occur in the upper chambers of the heart, are frequent or occur at a particular time in the cardiac cycle (during ventricular repolarization, when the lower chambers are refractory), they can cause paradoxical bradycardia from “blocked” PACs. A workup is usually not indicated unless the infant has the premature atrial beats in association with structural cardiac disease or if there is significant bradycardia. The most common cause of PACs in the neonatal intensive care unit setting is usually a deep central line in the right atrium.
- b. **Unifocal premature ventricular beats.** Fairly frequent in the newborn. The QRS is wide, and the T wave is discordant with the sinus T wave. (See Figure 53–1B.) If seen in a newborn, obtain a 12-lead ECG. Do not treat unless the infant is symptomatic. Sometimes premature ventricular contractions (PVCs), premature beats that occur in the lower chambers of the heart, become less frequent when the sinus rate increases. PVCs tend to decrease in number or go away entirely in the first few months of life. If the PVC burden is frequent (usually assessed by review of telemetry), the mother’s perinatal history should be pursued to rule out the possibility of myocarditis from a perinatal infection. If myocarditis is suspected, an echocardiogram with a pediatric cardiology consult should be part of the diagnostic evaluation.
- c. **Sinus bradycardia.** Usually benign but is a diagnosis of exclusion after review of telemetry, a 12-lead ECG, echocardiogram, and evaluation of any clinical symptoms that may be related to the bradycardia. It is important to correlate clinical symptoms with heart rate and rhythm. Consider a head ultrasound to ensure no neurologic injury, because increased intracranial pressure can be missed and is a common etiology of low heart rates.

2. Pathologic arrhythmias

- a. **Reentry supraventricular tachycardia.** Most common type of cardiac arrhythmia seen in the neonate (Figure 53–1D). Supraventricular tachycardia (SVT) is usually due to an accessory connection between the atria and ventricles and creates the substrate for paroxysms of tachycardia; it requires vagal maneuvers and other measures to terminate (adenosine, antiarrhythmics, direct current cardioversion).
- b. **Atrial flutter.** Difficult to distinguish from other SVTs, unless the block is >2:1. Administration of adenosine may increase the block to 3:1 or 4:1, allowing the flutter waves to become more visible on the ECG tracing. The typical finding is “saw-tooth” P waves in the inferior leads; usually the P waves do not return to baseline (no isoelectric segment, Figure 53–1E).
- c. **Atrial fibrillation.** Less common than SVT or atrial flutter. Defined by an irregular ventricular rate with no discernible P waves.
- d. **Wolff-Parkinson-White pattern/ventricular preexcitation.** A short PR interval and delta wave and slow upstroke of the QRS complex with a wider than normal QRS. Difficult to identify when the rate is fast (Figure 53–1C) or if in SVT.
- e. **Ectopic beats.** These are beats that start from anywhere outside the sinus node. Figure 53–1A shows an ectopic atrial beat (the P wave of the fourth beat is different in morphology than the preceding beats) and Figure 53–1B shows a premature ventricular complex/beat. The term “premature” is used when the ectopic beat comes in earlier than when one would expect the sinus node to initiate a beat.
- f. **Ventricular tachycardia.** Usually a wide QRS complex rhythm (with more QRS complexes than P waves) in an infant who may or may not be hemodynamically stable. Treatment depends on the etiology and workup (Figure 53–1F).

FIGURE 53-1. (A) A **premature atrial beat** that is blocked (blocked premature atrial contraction). Note the deformation of the T wave in the last beat; this is the ectopic P wave, and if early enough, it will block and there will be a pause afterward until the sinus node conducts. (B) A **premature ventricular beat**. The QRS is wide, and the T wave is discordant with the sinus T wave. (C) **Sinus rhythm with ventricular preexcitation** (Wolf-Parkinson-White pattern); note the short PR and delta wave with no appreciable flat PR segment between the P wave and onset of delta wave. (D) **Supraventricular tachycardia**, a narrow-complex QRS tachycardia with a rate of almost 300 beats/min. The P waves are retrograde following the QRS before the T wave, likely atrioventricular reentrant tachycardia. (E) **Atrial flutter**, a narrow QRS tachycardia with flutter waves in between; there is variable conduction to the ventricles. (F) **Ventricular tachycardia**, a wide QRS tachycardia (rate 160–185 beats/min) that starts with a wide QRS complex; there is no relationship between the P waves and QRS. (G) **Complete heart block** with more P waves than QRS complexes and no relationship between top and bottom chambers; ventricular rate is 52 beats/min, and atrial rate is 125 beats/min.

g. Atrioventricular block with symptoms. Occurs in newborns with complete block and ventricular rates <55 beats/min (Figure 53–1G). Premature infants may even require a higher rate. Because cardiac output in premature and young term babies can increase only by rate increase (their stroke volume is fixed by the small size of the ventricles), fevers, sepsis, and other stressors are tolerated poorly by babies with complete heart block.

3. Arrhythmias secondary to extracardiac disease

- a. **Sepsis (usually tachycardia).**
- b. **Diseases of the central nervous system (usually bradycardia).**
- c. **Hypoglycemia.**
- d. **Drug toxicity.** Digoxin dysrhythmias, such as PACs or PVCs and atrioventricular (AV) blocks (potentiated by hypokalemia, alkalosis, hypercalcemia, and hypomagnesemia); theophylline (less frequently used in neonatal intensive care units).
- e. **Electrolyte abnormalities** such as potassium, sodium, magnesium, or calcium abnormalities.
- f. **Other.** Metabolic acidosis or alkalosis, adrenal insufficiency.

IV. Database

A. History and physical examination. Assess whether the mother was ill during the pregnancy because neonatal myocarditis can occur from certain maternal viral illnesses. Also assess whether the mother had taken medications during the pregnancy or has connective tissue disease or hyperthyroidism. Check for signs of CHF (ie, tachypnea, rales on pulmonary examination, enlarged liver, and cardiomegaly). Vomiting and lethargy may be seen in patients with digoxin toxicity. Hypokalemia can cause ileus.

B. Laboratory studies

1. **Electrolyte, calcium, and magnesium levels**
2. **Blood gas may reveal acidosis or hypoxia**
3. **Drug levels to evaluate for toxicity**
 - a. **Digoxin.** Normal 0.5 to 2.0 mcg/mL (some assays up to 4 mcg/mL). Elevated levels of digoxin alone are not diagnostic of toxicity; clinical and ECG findings consistent with toxicity are also needed, and many neonates have naturally occurring substances that interfere with the radioimmunoassay test for digoxin.
 - b. **Caffeine.** Toxicity is manifested by tachycardia and feeding intolerance. Reduce dose or skip dose.

C. Imaging and other studies

1. **Electrocardiogram.** Should be performed in all infants who have an abnormal rhythm that lasts >15 seconds or is not related to a benign condition. Diagnostic features of the common arrhythmias are listed next. Although PR interval varies with heart rate, a **PR interval of >160 milliseconds** is abnormal in any newborn.
 - a. **Supraventricular tachycardia** (see Figure 53–1A)
 - i. Ventricular rate of 180 to 300 beats/min
 - ii. No change in heart rate with activity or crying
 - iii. An abnormal P wave (maybe retrograde) or PR interval
 - iv. A fixed R-R interval
 - b. **Atrial flutter**
 - i. Atrial rate is 220 to 400 beats/min.
 - ii. A saw-tooth configuration seen best in leads V_1 to V_3 or the inferior leads (II, III, and aVF) but often difficult to identify when a 2:1 block or rapid ventricular rate is present (see Figure 53–1E).
 - iii. The QRS complex is usually normal.
 - c. **Atrial fibrillation**
 - i. Irregular atrial waves that vary in size and shape from beat to beat.
 - ii. The atrial rate is 350 to 600 beats/min.
 - iii. The QRS complex is normal, but ventricular response is irregular.

- d. **Wolff-Parkinson-White pattern/ventricular preexcitation** (see Figure 53-1C)
 - i. A short PR interval
 - ii. A widened QRS complex
 - iii. Presence of a delta wave
- e. **Ventricular tachycardia**
 - i. Ventricular beats at a rate of 120 to 200 beats/min and a widened QRS complex (see Figure 53-1F). Can be difficult to differentiate from SVT with aberrancy and should mandate involvement by pediatric cardiology.
- f. **Ectopic beats (supraventricular or ventricular)**
 - i. Abnormal P wave and may have a widened QRS if conducts to ventricles due to aberrant conduction
 - ii. Wide QRS without a preceding P wave
- g. **Atrioventricular block**
 - i. **First-degree AV block** (Figure 53-2A)
 - (a) A prolonged PR interval (normal range, 0.08–0.12 seconds)
 - (b) Normal sinus rhythm
 - (c) A normal QRS complex
 - ii. **Second-degree AV block**
 - (a) Mobitz type I (Figure 53-2B)
 - (i) A progressively prolonged PR interval until a ventricular beat is dropped (Wenckebach)
 - (ii) A normal QRS complex
 - (b) Mobitz type II (Figure 53-2C). A constant PR interval with dropped ventricular beats or nonconducted P waves.
 - iii. **Third-degree AV block** (Figure 53-2D)
 - (a) Regular atrial beat.
 - (b) Slower ventricular rate.
 - (c) Independent atrial and ventricular beats.
 - (d) Atrial rate increases with crying and level of activity. The ventricular rate usually stays the same.
- h. **Hyperkalemia**
 - i. Tall, tented T waves
 - ii. A widened QRS complex
 - iii. A flat and wide P wave
 - iv. Ventricular fibrillation and late asystole
- i. **Hypokalemia**
 - i. Prolonged QT and PR intervals
 - ii. Depressed ST segment
 - iii. Flat T wave
- j. **Hypocalcemia.** A prolonged corrected QT interval. QTc interval prolongation may also be due to myocardial stress at the time of delivery and may resolve. Persistent prolongation of the QTc interval with normocalcemia mandates questions about family history of arrhythmia or sudden death. An ECG on the parents may be indicated.
- k. **Hypercalcemia.** Shortened corrected QT interval.
- l. **Hypomagnesemia.** Same as for hyperkalemia.
- m. **Hyponatremia.** Increased duration of the QRS complex.
- n. **Hypertnatremia.** Decreased duration of the QRS complex.
- o. **Metabolic acidosis**
 - i. Prolonged PR and QRS intervals
 - ii. Increased amplitude of the P wave
 - iii. Tall, peaked T waves
- p. **Metabolic alkalosis.** Inverted T wave.
- q. **Digoxin**

FIGURE 53-2. Types of atrioventricular (AV) block. (A) **First-degree AV block:** PR interval is long. (B) **Mobitz type I second-degree AV block (Wenckebach):** progressive lengthening of PR interval until ventricular beat is blocked. (C) **Mobitz type II second-degree AV block:** PR interval is constant; ventricular beat is blocked. (D₁) **Infant with complete or third-degree AV block:** atrial rate is 175 beats/min, ventricular rate is 62 beats/min; no relationship between P waves and QRS complexes. (D₂) **Same infant at 2 months of age:** atrial rate is 119 beats/min, ventricular rate is 54 beats/min; still no relationship between P waves and QRS complexes.

- i. **Therapeutic levels.** Prolonged PR interval and a short QT interval.
 - ii. **Toxic levels.** Most common are sinoatrial block, second-degree AV block, and multiple ectopic beats; also seen are AV block and bradycardia.
- r. **Caffeine**
- i. **Therapeutic levels.** Desired effect is decreased frequency and duration of apneic spells; no significant changes on ECG.
 - ii. **Toxic levels.** Tachycardia with feeding intolerance.
2. **Chest radiograph.** Perform in all infants with suspected heart failure or air leak. Ensure proper central line placement and position.
3. **Echocardiogram**
- a. **Certain deficits in atrioventricular conduction** (higher grade heart block or complete heart block) can be a manifestation of certain forms of congenital heart disease or cardiomyopathy.
 - b. **Supraventricular tachycardia or ventricular tachycardia** almost always requires an echocardiogram to evaluate ventricular function and to ensure no coincident congenital heart disease.

V. Plan

- A. **General management.** Decide whether the arrhythmia is benign or pathologic, as noted. If it is pathologic, full ECG evaluation must be performed. Any acid-base disorder, hypoxia, or electrolyte abnormality needs to be corrected.
- B. **Specific management**
1. **Heart rate abnormalities**
- a. **Sinus tachycardia**
 - i. **Benign.** No treatment is necessary because the tachycardia is usually secondary to a self-limited event.
 - ii. **Medications.** With certain medications, such as caffeine, observe infant for other signs of toxicity and decrease or skip the next dose.
 - iii. **Pathologic conditions.** The underlying disease should be treated.
 - b. **Sinus bradycardia.** Confirm it is sinus bradycardia and not complete heart block.
 - i. **Benign.** No treatment is usually necessary.
 - ii. **Drug related.** Check the serum drug level if possible and then consider lowering the dosage or discontinuing the drug unless it is necessary.
 - iii. **Pathologic.** Treat the underlying disease.
 - (a) **In severe hypotension or cardiac arrest,** check the airway and initiate breathing and cardiac compressions.
 - (b) **Administer atropine, epinephrine, or isoproterenol** to restore normal rhythm. (See Chapter 155 for detailed dosing.)
2. **Arrhythmias.** For dosages and other pharmacologic information, see Chapter 155; for details on cardioversion, see Chapter 32.
- a. **Benign.** Observation.
 - b. **Pathologic.** Treat any underlying acid-base disorders, hypoxia, or electrolyte abnormalities. Note position of umbilical lines, which might be triggering arrhythmias if deep in the right atrium.
 - i. **Supraventricular tachycardia**
 - (a) **If the infant's condition is critical.** Electrical cardioversion is indicated, with an antiarrhythmic medication started for maintenance therapy. Digoxin is contraindicated if the patient has Wolff-Parkinson-White (WPW)/preexcitation.
 - (b) **If the infant's condition is stable.** Vagal stimulation (ice or an ice-cold washcloth applied to the infant's face for a few seconds) can be tried. Adenosine, 100 mcg/kg intravenous push into a central vein, converts SVT to sinus rhythm. It may be necessary to double the dose to 200 mcg/kg (300 mcg/kg maximum). **Never use verapamil in infants.** An antiarrhythmic is started for maintenance therapy

(usually digoxin or propranolol, depending on the presence of WPW). SVT refractory to digoxin and propranolol may be treated with other antiarrhythmic medications (flecainide, sotalol, or amiodarone).

ii. **Atrial flutter**

- (a) **If the infant's condition is critical (severe congestive heart failure or unstable hemodynamic state).** Perform synchronized electrical cardioversion.
- (b) **If the infant is stable.** Start digoxin, which slows the ventricular rate. A combination of digoxin and propranolol may be used instead of digoxin alone. If the infant spontaneously converts, medication may be discontinued. This plan should be made in concert with a pediatric cardiologist.
- (c) **If rate is rapid and 2:1 block is present.** Atrial flutter may be hard to identify on ECG. May give adenosine (see earlier) to increase block to 3 or 4:1.

iii. **Recurrent atrial flutter management.** Same as that for atrial flutter.

iv. **Atrial fibrillation (unusual in infants).** Management is the same as for atrial flutter.

v. **Wolff-Parkinson-White pattern/ventricular preexcitation.** Often accompanied by SVT. β -Blockers are preferred because digoxin may promote 1:1 conduction during rapidly conducted atrial fibrillation and demise.

vi. **Ventricular tachycardia.** Perform electrical cardioversion (except in digitalis toxicity) if unstable. Drugs that may be used include lidocaine, esmolol, procainamide, phenytoin, or amiodarone. The choice is usually determined by the cause of the ventricular tachycardia and the hemodynamic status of the patient.

3. **Ectopic beats**

- a. **Asymptomatic.** No treatment is necessary.
- b. **Symptomatic.** With underlying heart disease, in the unlikely event that ectopic beats compromise cardiac output, suppress with phenytoin, propranolol, or amiodarone.

4. **Atrioventricular block**

- a. **First degree.** No specific treatment necessary.
- b. **Second degree.** Treat the underlying cause. Consider congenital long QT syndrome because neonates with this syndrome can present with 2:1 heart block in the neonatal period.
- c. **Third degree (complete heart block)**
 - i. **Rate >70 beats/min.** If the infant is asymptomatic, observe and evaluate for congenital/structural heart disease or autoimmune causes (see later in chapter). Generally at this rate, no problems develop.
 - ii. **Rate <55 beats/min.** The patient usually needs emergency pacing if hemodynamically unstable, with the need for subsequent permanent pacing. The decision for permanent pacing also depends on the presence of coincident congenital heart disease, ventricular function, and the type of escape rhythm.
 - iii. **Rate between 55 and 70 beats/min.** Gray zone. Monitor urine output as an index of end-organ perfusion and measure serum lactate. Check the mother for SAA or SSA antinuclear antibodies (associated with complete heart block and cardiomyopathy). Infants with nonimmune complete heart block generally fare better than those whose heart block is caused by maternal antibodies. Mothers who have given birth to an infant with complete heart block because of autoimmune-related SSA or SAA antibodies have a 50% to 69% chance of subsequent infants having complete heart block. Standard of care for these mothers' subsequent pregnancies

includes maternal treatment with hydroxychloroquine (Plaquenil) and following PR interval of the fetus weekly starting at 12 weeks. In an effort to increase fetal heart rate, maternal terbutaline is sometimes used if the infant's heart rate is slow enough to worry about fetal demise.

5. Arrhythmias secondary to an extracardiac cause

- a. **Pathologic conditions.** Treat the underlying disease.
- b. **Digoxin toxicity.** Check the PR interval before each dose, obtain a stat serum digoxin level, and hold the dose. Consider digoxin immune Fab (Digibind).
- c. **Theophylline toxicity.** Reduce the dosage or discontinue medication.

6. Electrolyte abnormalities

- a. **Check serum electrolyte levels with repeat determinations.**
- b. **Treat electrolyte abnormalities accordingly.**

- VI. Technique of defibrillation/cardioversion** is discussed in Chapter 32. Defibrillation and cardioversion are used for rapid termination of a tachyarrhythmia from the atrium or ventricle that is unresponsive to basic treatment or is causing the patient to have cardiovascular compromise.
- VII. Fetal considerations.** A multidisciplinary approach in any fetus with any arrhythmia serious enough to cause fetal hydrops is mandatory. Perinatologists, neonatologists, and cardiologists must be prepared to exert efforts in concert if such infants are to survive. Usually there is at least some warning that such an infant is being delivered, but in the event that specialists are not all in attendance, the physician assuming responsibility for care must be ready to intubate, perform pleural and pericardial taps and a paracentesis if necessary, and treat the arrhythmia responsible for fetal CHF.

54 Bloody Stool

- I. Problem.** A newborn infant has passed a bloody stool. A bloody stool in a neonate can represent a spectrum of conditions from benign (eg, anal fissure, swallowed maternal blood, cows' milk protein sensitivity) to life threatening (eg, necrotizing enterocolitis [NEC], malrotation with volvulus). It is critical to detect the cases that have significant underlying pathology, especially those that require emergent operative care.

II. Immediate questions

- A. Is the stool grossly bloody? Hematochezia** is passage of fresh blood through the anus. It can be pure blood, bright red or maroon colored, or blood mixed with stool. A grossly bloody stool usually signifies **lower gastrointestinal (GI) bleeding** (typically below the ligament of Treitz, the anatomic landmark of the duodenojejunal junction), which includes the jejunum, ileum, cecum, colon, rectum, and anus. Hematochezia can occur rarely with massive upper GI tract bleeding with a rapid transit time. **Necrotizing enterocolitis (NEC)** is the most common cause of bloody stool in premature infants and is critical to identify.
- B. Is the stool otherwise normal in color but with streaks of blood?** This is more characteristic of a lesion in the anal canal, such as an anal fissure. **Anal fissure** is the **most common cause of rectal bleeding** in the first 2 years of life and is the most common cause in well-appearing infants.
- C. What is the consistency of the stool?** A hard stool usually signifies constipation, which can cause a fissure, whereas a loose or diarrheal stool usually signifies colitis.
- D. Is the stool black and tarry looking? Melena** is the passage of black or tarry stools through the anus. Melena usually suggests the blood is from the upper GI tract (proximal to the ligament of Treitz which includes the esophagus, stomach, or duodenum).

Melena can also be from bleeding from the small bowel or proximal ascending colon if transit time is slow enough to allow bacteria to denature the hemoglobin. Nasogastric trauma and swallowed maternal blood are common causes.

- E. Is the stool occult blood (fecal occult blood testing) positive only?** Microscopic blood as an isolated finding is usually not significant in the neonate. Tests for occult blood are very sensitive and can be positive with conditions such as repeated rectal temperature measurements or perianal dermatitis.
- F. How old is the infant?** The age of the infant is important as it can give clues to the diagnosis. **For the first week of life consider:** swallowed maternal blood syndrome, vitamin K deficiency bleeding (early or classic onset), Hirshsprung disease, malrotation with midgut volvulus, term infant with NEC. **For infants less than 1 month of age, consider:** anal fissure, malrotation with midgut volvulus, NEC, colitis, and milk allergy. **For infants usually 1 month or older consider:** lymphonodular/nodular lymphoid hyperplasia, milk protein allergy, late onset VKDB, intussusception.
- G. Was the infant given vitamin K at birth? What were the maternal medications during her pregnancy?** This should be asked of all parents especially if the infant is breast fed (breast milk has less vitamin K than cow's milk formula) or was born out of the hospital (did not receive vitamin K). An infant with **vitamin K deficiency bleeding (VKDB)** may present with hematemesis, melena, or blood flecks/streaks in the stool. If the mother was on certain medications that can cross the placenta and interfere with vitamin K metabolism (eg, phenobarbital, phenytoin, carbamazepine, primidone, warfarin, aspirin, cephalosporins, rifampin, isoniazid, anticoagulants), these may cause early-onset VKDB.
- H. What medications is the infant on?** Certain medications can cause bleeding in the newborn. If the infant has been given nonsteroidal anti-inflammatory drugs, heparin, indomethacin, or dexamethasone, these are all associated with bleeding.
- I. Does the infant appear well, or is the infant ill and toxic appearing? Are there other significant clinical findings?** Infants with NEC, Hirschsprung enterocolitis, bleeding disorders, intussusception, or malrotation with volvulus are typically ill appearing. Infants with an anal fissure, swallowed maternal blood, milk protein allergy, or nodular lymphoid hyperplasia usually appear well. Remember that a **bloody stool with other significant clinical findings is worrisome.**
- J. Was there any recent surgery?** Circumcision can cause blood staining, and any GI surgery may cause bloody stools as a routine consequence or potential complication.
- III. Differential diagnosis.** The most common reasons are swallowed maternal blood from delivery and anal fissures. Significant hemorrhages are often caused by a duodenal or gastric ulcer. Etiology can often be based on the color or type of stool. The common causes are listed in Table 54–1. Verify non-GI causes before starting an entire GI evaluation (see Section III.F).
- A. Melena (black tarry stools).** Usually from the upper GI tract but can be from the small bowel or proximal colon, as noted previously. The appearance of the black tarry stool is because of the oxidation by intestinal bacteria that convert hemoglobin to hematin. **Emergent considerations** include coagulopathies, hemorrhagic gastritis, stress ulcer with massive bleed, and congenital GI tract malformations.
- 1. Maternal blood.** Swallowing of maternal blood during delivery, called **melena neonatorum**, accounts for 30% of infant "GI bleeding." In infants with normal meconium, swallowed blood usually appears in the stool on the second or third day of life (or second or third stool has blood). **Swallowing of blood during breast feeding** (secondary to cracked and bleeding nipples, case reports of fibrocystic breast disease) can also be a cause. **Swallowing of bloody amniotic fluid** from antepartum hemorrhage associated with bleeding into the amniotic fluid for several hours before birth is rare. This usually presents in the first stool.
 - 2. Trauma** from nasogastric tube, suctioning, or intubation.
 - 3. Coagulopathies.** **VKDB** occurs from a deficiency in vitamin K–dependent coagulation factors and can be prevented if vitamin K is administered at birth.

Table 54–1. CAUSES OF BLOODY STOOL IN A NEONATE

Exogenous (External Source)	Gastrointestinal
Swallowed maternal blood syndrome	Anal fissure
Swallowed blood during breast feeding (cracked/bleeding nipples), fibrocystic disease	Stress gastritis/erosions
Swallowed bloody amniotic fluid	Ulcer (gastric/duodenal ulcer)
	Necrotizing enterocolitis
Trauma	Malrotation with volvulus
Nasogastric tube	Meckel diverticulum
Suctioning	Hirschsprung disease with enterocolitis
Intubation	Intussusception
Rectal (temperature probes, rectal thermometer)	Atrioventricular malformation
	Hemangioma
Hematologic Disorders	Gastrointestinal duplication cyst
Vitamin K deficiency bleeding	Incarcerated hernia
Thrombocytopenia	Rectal prolapse
Disseminated intravascular coagulation	Lymphonodular hyperplasia
Liver failure	Prolapsed rectal polyp
Inherited coagulation disorder	Vascular malformations
	Infectious
Maternal Medications	Sepsis (bacterial): group B <i>Streptococcus</i> , <i>Escherichia coli</i> , <i>Listeria</i>
Thiazides	Sepsis (viral): Cytomegalovirus (CMV), herpes
Phenobarbital	Infectious enterocolitis:
Oral anticoagulants	<i>Salmonella</i> , <i>Shigella</i> , <i>E coli</i>
Anticonvulsants	CMV, rotavirus
	Allergy
Infant Medications	Milk protein allergy
Nonsteroidal anti-inflammatory drugs	Eosinophilic gastrointestinal disorders
Heparin	Food protein–induced enterocolitis syndrome
Indomethacin	Allergic proctocolitis
Dexamethasone	Perianal dermatitis

It is categorized based on timing of symptoms: early onset (within 24 hours), classic onset (2–7 days), or late onset (rare; 2 weeks to 6 months). Infants can have hematemesis, melena, petechiae, oozing from the umbilicus, and retinal hemorrhages. Severe hemorrhage occurs in about 0.25% to 0.50% of neonates. **Other coagulopathies to consider** include the following: thrombocytopenia, disseminated intravascular coagulation (DIC), inherited clotting factor deficiency, liver failure found in some metabolic disorders (iron storage disorder), ischemic injuries, and infections (sepsis).

4. **Formula intolerance/dietary protein intolerance.** Milk protein sensitivity is secondary to cow's milk or soybean formula, and symptoms of blood in the stool usually occur in the second or third week of life. Infants usually have a mucoid bloody diarrhea and rarely melena.
5. **Eosinophilic gastrointestinal disorders (eosinophilic esophagitis, gastroenteritis, and colitis)** can present with melena.
6. **Other gastrointestinal causes**
 - a. **Gastritis/stress ulcer/esophagitis/erosions.** Occurs in up to 20% of infants in the neonatal intensive care unit (NICU). Prematurity, stress, and mechanical ventilation are associated with stress gastritis. **Hemorrhagic gastritis** can occur from NSAIDs, steroids, and theophylline therapy. Indomethacin is

associated with gastric mucosal injury. **Stress ulcer** is a common cause and can occur in the stomach or duodenum and is associated with prolonged severe illness or steroid therapy. Stress-induced gastric ulcers should be suspected in any infant presenting with massive GI bleeding after birth asphyxia and difficult delivery. Maternal stress in the third trimester may increase maternal gastrin secretion and contribute to a peptic ulcer in the newborn. **Esophagitis** can occur from trauma from pharyngeal, esophageal, or gastric suction at birth. A gastric and esophageal lesion together is unique to neonates. **Erosions** of the esophageal, duodenal, and gastric mucosa are a common cause of bloody stool. **Mallory-Weiss syndrome** is a tear in the distal esophagus and proximal stomach that is an unusual cause of upper GI bleeding in an infant.

b. Congenital gastrointestinal tract malformations

- i. Anatomic.** Intestinal malrotation, duplication cysts, anatomic duplications, Meckel diverticulum, Hirschsprung disease. Meckel diverticulum is the most common congenital abnormality of the small intestine.
- ii. Vascular.** GI infantile hemangiomas can present with GI bleeding (melen and hematochezia), often with profound anemia. AV malformations or venous malformations are rare causes. **Associated syndromes with vascular malformations** of the GI tract are Down syndrome, Klippel-Trenaunay syndrome, Osler-Weber-Rendu disease, and blue rubber bleb nevus syndrome.

- 7. Isolated rectal bleeding in preterm and term infants.** Many cases of bloody stool in an infant with no other clinical signs of illness have no identifiable cause. Fortunately most resolve in several days. Controversial whether to stop feedings or give antibiotics. Breast feeding should be encouraged.
- 8. Rare causes.** Gastric teratoma, gastric Dieulafoy lesion, GI tract telangiectasia, heterotopic pancreatic tissue in the stomach, pyloroduodenal intestinal duplication, and dengue shock syndrome.

B. Grossly bloody stool (hematochezia). Usually from lower GI tract (jejunum, ileum, colon) but can be from the upper GI tract with rapid transit time (rare). **Emergent considerations** include NEC, coagulopathies, malrotation with volvulus, Hirschsprung disease, infectious colitis, and incarcerated hernia.

- 1. Swallowing of maternal blood** with rapid transit time.
- 2. Necrotizing enterocolitis.** NEC is usually seen in premature infants but can be seen in term infants. Term infants usually present within the first week of life and account for less than 10% of all NEC cases, preterm infants present later. It should be ruled out in any infant who presents with a grossly bloody stool.
- 3. Coagulopathies.** DIC is usually associated with bleeding from other sites and may be secondary to an infection.
- 4. Bleeding diathesis** (eg, platelet abnormalities and clotting factor deficiencies) can cause bloody stools. Hemophilia can present as GI hemorrhage. **Severe liver disease** can cause coagulopathy.
- 5. Surgical diseases**
 - a. Malrotation with midgut volvulus.** Obstruction after birth can cause bleeding with ischemic damage or other causes of volvulus. Classically presents with bilious emesis and abdominal distension.
 - b. Meckel diverticulum** is the vestigial remnant of the vitelline duct, which contains mainly gastric mucosa that can secrete acid and cause ulceration of tissue, which in turn causes **rectal bleeding**. (Meckel diverticulum rule of 2s: 2% of population, length 2 inches, within 2 ft of ileocecal valve, 2 times as common in males, diagnosed in the first 2 years of life, 2 types of tissue present).
 - c. Hirschsprung enterocolitis.** Ten to 30% of patients present with GI bleeding and abdominal distension; failure to pass meconium and feeding intolerance are typical.

- d. **Intussusception.** Rare in the neonatal period; incidence is greatest in infants 3 months to 1 year of age. Most present with typical symptoms: bloody stool (“currant jelly” stool), abdominal mass, vomiting, and intermittent screaming. Intrauterine intussusception presents with a complete ileus.
 - e. **Gastrointestinal tract duplications (duplication cysts).** Rare, abnormal extra portions of the intestine that are congenital anomalies of unknown etiology. They are called duplication cysts because they are attached to the normal intestine and share its blood supply. **Colonic and tubular** are least common but do occur; presents with intestinal obstruction, abdominal mass, and bleeding. Bleeding occurs due to presence of ectopic gastric mucosa or stasis.
 - f. **Hernias.** An incarcerated inguinal hernia typically presents with a very irritable infant who refuses to eat and, on physical examination, has a tender firm mass in the inguinal region. An infant with an **internal hernia** caused by a congenital defect in the mesentery can present with bilious vomiting, grossly bloody stool, and abdominal distension. An internal hernia secondary to a congenital defect in the mesentery can mimic NEC but requires emergency operative care.
 - g. **Rare causes.** Rectal polyp (more common in toddlers but can occur in newborns); acute appendicitis
6. **Colitis** can be secondary to the following:
- a. **Intestinal infections (bacterial enteritis).** Rare in the neonatal period and more common in older children and adults. Pathogens that can cause lower GI bleeding include **bacterial:** *Salmonella*, *Shigella*, *Campylobacter*, *Clostridium difficile*, *Escherichia coli*, *Yersinia enterocolitica*; **viral:** cytomegalovirus, herpes simplex; or **parasitic:** *Entamoeba histolytica*. **Dysbiosis (low numbers of normal flora)** may play a role in grossly bloody stools in preterm infants. Microbiota composition differs in infants who have a bloody stool and those who do not.
 - b. **Food allergy** is a common cause of GI bleeding due to colitis in newborns and is less common in preterm infants or those who are breast fed. Food allergy is a clinical diagnosis. The mechanism is a hypersensitivity reaction of the bowel mucosa to digested antigens with resulting enterocolitis. It can occur in breast-fed infants exposed to cow’s milk proteins in human breast milk. Dietary formula-related intolerance factors include allergic and dietary protein-induced colitis. The top ingested allergens are cow’s milk products (most common, 76%) and soy protein. The most common clinical sign of cow’s milk protein allergy is a bloody stool in a well-appearing infant. **There are multiple types of food-related GI disorders:**
 - i. **Allergic enterocolitis** can present with massive bloody stool, and routine lab data show no eosinophilia. However, rectal mucosal biopsy shows eosinophilic infiltration.
 - ii. **Eosinophilic gastrointestinal disorders** (mixed immunoglobulin E [IgE] and non-IgE cell mediated) are noted by the overproduction of eosinophils. The primary eosinophil inflammation can be anywhere in the GI tract (esophagitis, gastroenteritis, colitis). A new disease that is part of eosinophilic gastrointestinal disorders is called **neonatal transient eosinophilic colitis (NTEC)** and occurs in infants with lower GI bleeding with no known allergic component involved (no prior feeding had occurred). It may start in the fetal stage.
 - iii. **Food protein-induced enterocolitis syndrome/dietary protein-induced enterocolitis syndrome** is non-IgE cell mediated. The entire GI tract is affected, and the symptoms can be severe (vomiting, diarrhea, lethargy, metabolic acidosis, shock). Acute food protein-induced enterocolitis syndrome (FPIES) can have frank or occult blood in the stool.

Cow's milk and soy protein in formula are the most common triggers; therefore, it is rare in breast-fed infants.

- iv. **Hematochezia in exclusively breast-fed infants** presents at an average age of 7.4 weeks. Diarrhea is the most common symptom (other symptoms include mild anemia, red and white blood cells in stool, negative culture, or colitis on colonoscopy) and may represent sensitivity to protein eaten by the mother. The hematochezia disappears after the mother is on a protein-free diet.

C. Streaks of bright red blood coating a normal or hard formed stool. Most commonly associated with a perianal disorder.

1. **Anal fissure** can be secondary to constipation and straining. This is the **most common cause of bleeding in infants**: spots of blood in the diaper or a strip of blood on the outside of one side of the stool. Etiology is a tear of the anal canal at the mucocutaneous line from a hard stool. Deeper rectal fissures can also occur.
2. **Rectal trauma** may be secondary to temperature probes or thermometer.
3. **Perianal irritation and excoriations** can cause small amounts of blood. This can be from a diaper rash.
4. **Rare causes.** Rectal prolapse is reported with chronic constipation, cow's milk allergy, *Shigella* diarrhea, rectal ulcer, β -hemolytic streptococcal cryptitis, ulcerative proctitis, rectal parasite infections, Hirschsprung disease, high anorectal malformations, and cystic fibrosis. **Perianal abscess/fistula in ano** is common in infants <1 year of age. It can originate from anal cryptitis, which then forms a perianal abscess.

D. Bright red blood with moderately loose/frothy/mucus-laden stools

1. **Food protein-induced (allergic) proctocolitis** (non-IgE cell mediated) presents with bright red rectal bleeding with mucus in a healthy infant. (See page 472.)
2. **Lymphonodular/nodular lymphoid hyperplasia (of the rectosigmoid area).** Usually presents in infants age 1 month or older. Characterized by multiple masses of lymphoid nodules that are usually present in the terminal ileum or colon. It disrupts the normal mucosa and leads to thinning of the mucosa and bleeding. Etiology is unknown. It can occur from cow's milk allergy or an immunologic response.

E. Occult gastrointestinal blood by fecal occult blood testing/Hemoccult test. Occult blood in the stool is very common, with up to 60% of neonates <1800 g having at least 1 occult blood-positive stool in the first 6 weeks of life. Stools may be heme positive after indomethacin for patent ductus arteriosus. It is transient and not clinically significant.

1. **Positive fecal occult blood test/Hemoccult test.** As an isolated finding, it is usually not significant. Tests for occult blood are very sensitive and can be positive with **repeated rectal temperatures or any perianal dermatitis.**
2. **A positive fecal occult blood test can be a finding in exclusively breast-fed infants (secondary to cow milk soy protein induced allergic colitis) and an early finding** with more significant diseases such as NEC, esophagitis, gastritis, Meckel diverticulum, acid peptic disease, polyposis, vascular malformations, eosinophilic gastroenteritis, polyps, vascular malformation, eosinophilic colitis, and others such as food protein-induced allergic proctocolitis (FPIES).
3. **Necrotizing enterocolitis.** Presence of occult blood does not directly correlate with the development of NEC.

F. Blood spots in a diaper (nongastrointestinal causes). This can be from other etiologies besides the GI tract: hematuria, severe diaper rash with excoriation, blood from a circumcision, or vaginal bleeding in a female infant (also called **pseudomenses**; withdrawal of maternal hormones). Reddish-orange spots ("brick stain") in the diaper are from uric acid crystals in the urine and are usually benign but may

indicate concentrated urine. A red-stained diaper can also be from bile pigments or porphyrins.

- IV. Database.** The age of the infant is important. If the infant is <7 days old, swallowed maternal blood is a likely cause; in older infants, this is unlikely. Cow's milk protein allergy usually presents in the first few months of life. NEC is unlikely in the first few days of life. Lymphonodular/nodular lymphoid hyperplasia presents in infants age 1 month or older. Ask the mother about medications taken during pregnancy. Is the infant breast feeding? Get a detailed description of the stool because type of stool and color of blood can help to differentiate the bleeding source (see Section III). Some advocate using a grading system (grade 1, 1 to 3 specks of blood; grade 2, 4 to 20 specks; grade 3, distinct blotch of blood staining the diaper; grade 4, gross blood with occasional blood clumps; and grade 5, all gross blood, no stool) to assess the severity of visible blood in the stool.

A. Physical examination

- 1. Evaluate the infant's peripheral perfusion.** An infant with NEC can be poorly perfused and may appear to be in early or impending shock. Bruising may suggest a coagulopathy.
- 2. Examine naso-/oropharyngeal area** for a source of bleeding.
- 3. Abdominal examination.** Check for bowel sounds and tenderness. Hyperactive bowel sounds are more common in upper GI bleeding. If the abdomen is soft and nontender and there is no erythema, a major intra-abdominal process is unlikely. If the abdomen is distended, rigid, or tender, an intra-abdominal pathologic process is likely. Abdominal distention is the most common sign of NEC. Abdominal distention may also suggest intussusception or midgut volvulus. If there are red streaks and erythema on the abdominal wall, suspect NEC with peritonitis. Malrotation with ischemic bowel can also present with peritonitis. If there is an abdominal mass, consider duplication. Consider Hirschsprung disease or malrotation if there is obstruction. Hepatomegaly, splenomegaly, or jaundice may indicate liver disease.
- 4. Genitourinary/anal examination.** Does the infant have a rash? If the infant's condition is stable, perform a visual examination of the anus to check for anal fissure or tear. Look for polyps, masses, or fistulas. Gentle digital rectal examination with a lubricated fifth digit may reveal fissures or polyps. Bedside "anoscopy" can be done by placing a well-lubricated blood collection tube into the anus.

B. Laboratory studies

1. Initial studies

- a. Fecal occult blood testing.** Hemocult or other test should be obtained to confirm the presence of blood in the stool.
- b. Apt test.** To differentiate maternal from fetal blood if swallowed maternal blood is suspected. A positive Apt test indicates that the blood is due to either GI or pulmonary bleeding from the neonate. A negative test would indicate that the blood is of maternal origin suggesting that the infant swallowed or aspirated maternal blood.
- c. Complete blood count with differential.** If a large amount of blood is lost acutely, it takes time for it to be evident on hemoglobin results; therefore, initial hemoglobin values may be unreliable. An increased white blood cell count suggests infection or thrombocytopenia (can be associated with NEC or sepsis). Eosinophilia can be present in the serum with allergic enterocolitis, but it is not a uniform finding.
- d. Chemistry panel.** High blood urea nitrogen can be seen in upper GI bleeding due to resorption of blood in GI tract.
- e. Coagulation studies** rule out DIC or a bleeding diathesis. The usual studies are partial thromboplastin time (PTT), prothrombin time (PT), fibrinogen level, and platelet count. Thrombocytopenia can also be seen with cow's

milk–protein allergy. An elevated PT can indicate a coagulopathy, and a prolonged PTT may indicate hemophilia.

- f. **Suspected NEC.** If NEC is suspected, the following studies should be performed:
 - i. **Complete blood count with differential.** To establish an inflammatory response and to check for thrombocytopenia and anemia.
 - ii. **Serum potassium levels.** Hyperkalemia secondary to hemolysis may occur.
 - iii. **Serum sodium levels.** Hyponatremia can be seen secondary to third spacing of fluids.
 - iv. **Blood gas levels.** To rule out metabolic acidosis, often associated with sepsis or NEC.

2. Further studies

- a. **Stool studies.** Certain pathogens cause bloody stools, but they are rare in the neonatal nursery. Obtain **stool cultures** for common pathogens, ova, and parasites. **Stool smear** for white blood cells (elevated with colitis) and eosinophils (suggests allergic type of colitis).
- b. **Rectal biopsy.** A **rectal mucosal biopsy** can show eosinophilic infiltration suggestive of an allergic origin.
- c. **Serum radioallergosorbent test for cow's milk protein** with a specific IgE for whole cow's milk.

C. Imaging and other studies

1. Immediate study

- a. **Abdominal radiograph.** A plain radiograph of the abdomen is useful if NEC or a surgical abdomen is suspected. Look for an abnormal gas pattern, a thickened bowel wall, pneumatosis intestinalis, or perforation. Pneumatosis can appear as a “soap bubble” area (see Figure 12–27). If a suspicious area appears on the abdominal radiograph in the right upper quadrant, it is usually not stool. A left lateral decubitus view of the abdomen may show free air if perforation has occurred and it cannot be seen on a routine anteroposterior film. Surgical conditions usually show signs of intestinal obstruction. Most common sign in intussusception in premature infants is dilated bowel loops.
- b. **Ultrasound** can detect most of the common abdominal masses. It is the diagnostic modality of choice for suspected ileocolic intussusception. The “pseudokidney of intussusception” which is the longitudinal appearance of the intussuscepted segment of bowel which looks like a kidney is seen. Ultrasound can also be used to aid in the diagnosis of necrotizing enterocolitis.
- c. **Contrast studies** can be done for diagnosis of obstruction. An upper GI study can diagnose malrotation; the “bird beak” sign (contrast in the dilated proximal duodenum) can be seen.
- d. **Endoscopy of upper gastrointestinal tract** allows visualization of the esophagus, stomach, and duodenum and helps to identify the site of bleeding in the upper tract.
- e. **Meckel scan** (technetium-99m pertechnetate nuclear scan) can help diagnose Meckel diverticulum.
- f. **Radioactive tagged red blood cell scan** can localize the site of lower GI bleeding if the source is unknown.
- g. **Colonoscopy/flexible sigmoidoscopy** can be done to rule out colitis, polyps, or other masses. It can reveal nodular lymphoid hyperplasia. Can be done on infants who do not respond to elimination of formula for food protein–induced proctocolitis.
- h. **Rectal mucosal biopsy** can show eosinophilia in the lamina propria in cases of allergic enterocolitis.

55 Counseling Parents Before High-Risk Delivery

- I. **Problem.** The nurse calls to notify you of a pending high-risk delivery. You are on delivery room duty, and you are asked to counsel the parents before their infant is delivered.
- II. **Immediate questions**
 - A. **Are both parents and other important family members available? What language do they speak? Is an interpreter needed?** Discuss the situation with the obstetric staff, and call for an interpreter if needed. Avoid using family members to translate because they need to be listening, may not have the expertise to provide appropriate translation of medical details, and may at times dominate questioning during the counseling session.
 - B. **Is the mother too sick or uncomfortable to be able to adequately participate in the discussion?** In this situation, time is critical; be sure to include other family members.
 - C. **How well do the parents understand their current situation?** Discuss the circumstances with the obstetric staff, and ask the parents what they understand. Some practitioners ask parents to repeat what they have heard at the end of the session.
 - D. **What do they know about neonatal intensive care units (NICUs), pregnancy and neonatal complications, chronic health problems, and neurodevelopmental disability?** This helps you in beginning and planning the discussion.
- III. **Differential diagnosis.** Neonatologists are called to counsel expectant parents in a wide variety of circumstances. These generally include:
 - A. **Preterm birth**
 - B. **Fetal growth restriction (FGR) (also known as intrauterine growth restriction [IUGR])**
 - C. **Maternal substance use disorder (SUDS)**
 - D. **Signs of fetal distress**
 - E. **Congenital anomalies**
- IV. **Database**
 - A. **Maternal/paternal data.** Obtain information regarding the age of both parents; mother's obstetric, past medical, and social history; history of the pregnancy, medications, and pertinent laboratory data; and family history.
 - B. **Fetal data.** Review fetal information with the obstetric staff, including accuracy of pregnancy dating, findings on prenatal ultrasounds, and signs of fetal distress.
- V. **Plan**
 - A. **General approach to parent counseling.** Although circumstances are often less than ideal, it is important to communicate as effectively and empathetically as possible. Sit down, communicate at eye level, take time to introduce yourself and your role, and talk in a clear and unhurried manner. Explain all medical terms, avoid using abbreviations, keep in mind that most people cannot think in percentages, acknowledge uncertainties, and try to give the parents an idea of what to expect. Ask if they understand, and summarize the most important points. Ask if they have any questions and offer to follow-up with them if they have more questions.
 - B. **Goal of counseling session.** Because a complete discussion is often unrealistic, your goal is to help parents anticipate and to provide a framework for understanding what happens during delivery and in the neonatal intensive care unit (NICU).
 - C. **Content of discussion.** As appropriate, discuss the infant's chances of survival, possible complications, and the range of long-term outcomes. (In preparation for counseling the parents, review appropriate references, other chapters in this book, and other textbooks for more information.) Describe anticipated activity during delivery

and transition to the NICU. Giving the parents the opportunity to tour the NICU allows them to see the monitoring and life support equipment, so that they can better see their own baby attached to it all.

- D. Bedside manner.** For many, the shock and anxiety of facing difficult circumstances challenge their ability to process information, especially when a lot of medical and technical terms are used. Avoid overloading the family with information. Your communication is most effective if conveyed in a caring, empathetic, and unhurried manner. *Understand that hope helps people get through the most dire situations.*

VI. Specific counseling issues. Although medical terms are used in this section, use simple language when counseling parents. Stress influences the ability to process information in even the most medically sophisticated parents.

- A. Preterm delivery.** The more immature the infant, the greater are the risks of death, complications, health sequelae, and neurodevelopmental disability (see Table 55-1 for **estimate only** of survival by gestational age and birthweight [Mednax, 2015], and Table 55-2 for **estimates** of morbidity based on gestational age). Gestational age serves as a proxy for maturity when counseling parents before delivery.

1. Immediate questions. Why is the mother delivering preterm? What is the gestational age of the fetus? Are there concerns about fetal growth, fetal distress, infection, or anomalies that may influence fetal outcome?

2. Specific issues to address with the parents

a. Mortality. Even with aggressive intervention, the lower limit of viability is 23 to 24 weeks' gestation, with occasional survival reported at 22 weeks' gestation.

b. Complications of prematurity. Complications of prematurity include respiratory distress syndrome (RDS); electrolyte and metabolic problems; infection; necrotizing enterocolitis (NEC); patent ductus arteriosus (PDA); apnea and bradycardia; anemia; and intraventricular hemorrhage (IVH) and other signs of brain injury. Chronic complications include bronchopulmonary dysplasia/chronic lung disease (BPD/CLD); retinopathy of prematurity (ROP) with subsequent visual problems, hearing impairment, and neurodevelopmental impairment. Complication rates increase with decreasing gestational age.

c. Long-term neurodevelopmental outcome. Rates of neurodevelopmental disabilities increase with decreasing gestational age at birth, with the highest rates in those born before 25 weeks' gestation (see Table 55-2). Even late preterm children (born at 34-36 weeks' gestation) have higher rates of cerebral palsy and school problems than do infants born full term. Learning disability, language delays, visual perceptual deficits, minor neuromotor dysfunction, executive dysfunction, attention deficits, and behavior problems are more frequent in school-age children born preterm than in controls born full term. Nonetheless, the majority of preterm survivors have normal intelligence, graduate from high school, and become functioning adults in their communities.

B. Fetal growth restriction. See also Chapter 104.

1. Immediate questions. What is the cause of the FGR and when was it detected? Does the fetus have anomalies? Are there signs of fetal decompensation?

2. Specific issues to address with parents

a. Prediction of outcome. The most important determinant of FGR outcome is its cause. Infants with chromosomal disorders and congenital infections (eg, toxoplasmosis, cytomegalovirus) experience early FGR, often do not tolerate labor and delivery well, and commonly have a disability. When there is fetal deprivation of uterine supply, the fetus initially compensates by reducing weight and length before head growth and, after 30 weeks' gestation, may accelerate fetal maturation. Although accelerated maturation improves fetal survival if delivered preterm, there is a cost in terms of cognitive development. Adverse intrauterine circumstances that overwhelm compensatory mechanisms lead to progressive damage to fetal organs (eg, liver, gut, brain) and may result in fetal death.

Table 55–1 SURVIVAL BY ESTIMATED GESTATIONAL AGE AND BIRTH WEIGHT^a

Weight Group (gm)	Estimated Gestational Age (wks)										Overall	
	22	23	24	25	26	27	28	29	30	31		
250 to 500	15.6%	28.1%	40.4%	46.3%	50.0%							37.5%
501 to 750	28.8%	46.8%	65.6%	77.2%	87.1%	85.1%	92.6%	87.1%				69.8%
751 to 1000			77.1%	84.6%	90.5%	95.8%	98.0%	97.2%	97.9%	93.4%		92.3%
1001 to 1250				91.3%	90.6%	95.9%	97.5%	98.5%	98.7%	99.7%		97.7%
1251 to 1500					95.9%	95.9%	96.4%	98.8%	98.9%	99.9%		99.0%
1501 to 1750						97.3%	97.3%	99.5%	99.5%	99.4%		99.7%
1751 to 2000							95.5%	95.5%	99.0%	99.6%		99.8%
2001 to 2250									93.3%	98.3%		99.9%
Overall for EGA	22.9%	43.3%	65.1%	78.8%	88.7%	94.0%	97.2%	98.2%	98.9%	99.4%		
Total Patient Count	131	467	814	904	1195	1442	1797	2089	2893	3752		

^aThe outcomes of 119,139 non-anomalous neonates born at, cared for in, and discharged from 272 hospitals in 34 states from 2016 to 2017. Estimated gestational age range was 22 to 42 weeks. Birth weight range was 0.3 to 6.0 kg. For calculations the minimum cell sample size was 20 patients. Data on outcome of infants more than 31 weeks is not presented as their percent survival and percent survival without morbidity approached 100%. These numbers represent an estimate. The likelihood of a good outcome is influenced by many variables, only two of which are estimated gestational age and birth weight. Table 55–2. ESTIMATES OF MORBIDITY USEFUL IN COUNSELING PARENTS

Risk Factor	Cerebral Palsy (%)	Intellectual Disability (%)	Sensory Impairment (%)
None	0.1	1–2	0.1–0.2
Prematurity			
GA 33–36 weeks	0.3–0.7	1–2	0.1–0.2
GA 29–32 weeks	2–5	2–3	0.4–2
GA ≤28 weeks	6–15	3–8	2–4
GA ≤25 weeks	7–25	27–35	3–5

GA, completed weeks of gestation at birth (birthweight data are difficult to accurately determine for prenatal counseling).

- b. Complications of fetal growth restriction.** IUGR infants are vulnerable to postnatal complications, including perinatal asphyxia, cold stress, polycythemia, hypoglycemia, and feeding problems.
- c. Long-term outcome.** Full-term FGR infants with fetal deprivation of supply have an increased risk of motor and cognitive impairments (eg, cerebral palsy, minor neuromotor dysfunction, learning disability, attention deficits, behavior problems) and, as adults, cardiovascular disease, obesity, and diabetes. Preterm FGR infants are vulnerable to the complications of both preterm delivery and FGR.
- C. Maternal substance use disorder**
- 1. Immediate questions.** Which drugs did the mother use? When and how much?
 - 2. Specific issues to address with parents**
 - a. Fetal growth restriction.** Infants with intrauterine exposure to opiates, cocaine, alcohol, cigarettes, and some prescription drugs may have FGR (see preceding Section VI.B).
 - b. Specific syndromes and risks.** Fetal alcohol and fetal hydantoin syndromes are well defined but often difficult to diagnose in the neonatal period. Both carry an increased risk of intellectual disability. (See Chapter 93.)
 - c. Neonatal abstinence syndrome (NAS).** Infants with intrauterine exposure to opiates, cocaine, alcohol, or some prescription medications may demonstrate signs of neonatal withdrawal (see Chapter 102). These infants require close observation after delivery and may require medications to help them through the withdrawal period. Later, these infants have an increased incidence of school and behavior problems.
 - d. Maternal cocaine use** is associated with increased rates of miscarriage, stillbirth, abruption, preterm labor, and FGR. Infants with central nervous system infarctions resulting from intrauterine cocaine exposure are at high risk for cerebral palsy, especially hemiplegia, as well as cognitive and sensory impairments.
- D. Signs of fetal distress**
- 1. Immediate questions.** Which signs of fetal distress are evident and for how long?
 - 2. Specific issues to address.** Fetal distress is a risk factor for respiratory distress at birth requiring resuscitation, persistent pulmonary hypertension, neonatal encephalopathy, and metabolic problems (eg, hypoglycemia). The type of fetal distress and perinatal and postnatal complications, especially neonatal encephalopathy and brain injury on neuroimaging, electroencephalogram, and neurodevelopmental examination (see Chapter 18), are prognostic indicators. Nonetheless,

the majority of infants with fetal distress who recover quickly after birth have a good prognosis.

E. Congenital anomalies

1. **Immediate questions.** What anomalies have been detected, and how were they noted? Is the anomaly life threatening? What workup and/or fetal therapy has been done? Have any other anomalies been detected?
2. **Specific issues to address with the parents.** See also Chapter 93.
 - a. **Diagnosis.** The type of congenital anomaly, its severity, and whether further evaluation has identified other anomalies or etiology determine how you should counsel the parents. Identification of an anomaly should trigger a search for other anomalies.
 - b. **Prognosis.** Clinical courses and outcomes have been well described for most chromosomal disorders (eg, trisomy 21, 22q11 deletion), many multiple congenital anomaly syndromes (eg, VATER/VACTERL [vertebral defects, *a*nal atresia, *t*racheo*e*sophageal fistula, and *r*adial or *r*enal dysplasia/vertebral defects, *a*nal atresia, cardiac malformations, *t*racheo*e*sophageal fistula, *r*enal dysplasia, and *l*imb abnormalities] association, arthrogryposis), and some specific single anomalies (eg, meningomyelocele, congenital heart disease). The presence of a congenital anomaly increases an infant's risks of FGR, preterm birth, and neurodevelopmental disability.
 - c. **Counseling parents.** A study of mothers who were counseled after prenatal diagnosis of a congenital anomaly who were interviewed a week after delivery found that the consultation helped to prepare them. They authors concluded that "parents want realistic medical information, specific to their situation, provided in an empathetic manner and want to be allowed to hope for the best possible outcome."

56 Cyanosis

- I. **Problem.** During a physical examination, an infant appears blue. Cyanosis is a physical sign indicating a bluish/purplish discoloration of the skin and/or mucous membranes. There are many different types of cyanosis, and it is important to differentiate physiologic versus pathologic cyanosis. **This chapter will focus mainly on central cyanosis because it is a potentially serious condition that requires an immediate evaluation.** The differential diagnosis of central cyanosis includes disorders involving an increase in deoxygenated hemoglobin (respiratory, cardiovascular, neurologic, or other) or hematologic disorders involving abnormal hemoglobin (methemoglobinemia/sulfhemoglobinemia). **Early diagnosis and treatment for any cyanotic infant is essential.**

II. Immediate questions

- A. **What type of cyanosis does the infant have?** Some types of cyanosis are not considered pathologic and require no workup; others such as central cyanosis can be associated with a life-threatening disease. Differentiate the type of cyanosis to help guide the workup and treatment.
 1. **Central cyanosis: bluish skin, including the tongue, mucosal membranes, and lips.** This is caused by lack of oxygen in the blood (low PaO₂ and low SaO₂). While this can occur immediately after birth, persistent central cyanosis is never normal and needs to be evaluated to rule out major cardiac, lung, central nervous system (CNS), metabolic, or hematologic diseases.

2. **Peripheral cyanosis: bluish skin with pink lips, mucous membranes, and tongue.** Associated with normal PaO₂ and normal (or falsely low if sensor wrapped around a cold blue finger or toe) arterial oxygen saturation. It is caused by decreased/sluggish local circulation leading to an increase in deoxygenated blood on the venous side. This is a consequence of increased oxygen extraction by the tissues and may be a physiologic response. Peripheral cyanosis can be a normal finding; can be associated with causes of central cyanosis; or can be caused by vasomotor instability, venous obstruction (venous thrombosis), polycythemia, low cardiac output (cardiomyopathies, hypocalcemia), shock, sepsis, hypothermia, hypoadrenalism, hypoglycemia, vasoconstriction secondary to cold exposure, and elevated venous pressure. Peripheral cyanosis is common in Down syndrome (vasomotor instability).
 3. **Acrocyanosis (bluish hands and feet only).** There is normal oxygen saturation in the blood. A type of peripheral cyanosis, it is cyanosis of the extremities and around the mouth and may be considered a normal finding immediately after birth, within the first 1 to 2 days, or with cold stress. Spasm of smaller arterioles is the cause. In a normothermic older infant, consider hypovolemia as the main cause.
 4. **Perioral/cirumoral cyanosis (bluish color around the lips and philtrum [nose to upper lip]).** There is normal oxygen saturation in the blood. It is common after birth and is due to the close proximity of the blood vessels to the skin. Infants have a prominent superficial perioral venous plexus that can engorge with feeding, and this is not a sign of peripheral or central cyanosis and usually resolves after 48 hours.
 5. **Traumatic cyanosis.** There is normal oxygen saturation in the blood. This is cyanosis of the head and face usually found with petechiae. This is a result of venous congestion during delivery caused by a face presentation or nuchal cord.
 6. **Pseudo-cyanosis.** Bluish color of the skin without hypoxemia, hemoglobin abnormality, or peripheral vasoconstriction. The mucous membranes of the mouth are pink, and with pressure on the skin, the color does not blanch. This can mimic peripheral cyanosis. Most commonly caused by fluorescent lighting in neonatal units, but can also be caused by drug exposure.
 7. **Cyanosis caused by methemoglobinemia** causes a diffuse persistent **slate gray bluish appearance** of the infant. Drugs such as lidocaine, benzocaine, and nitrates may result in acquired methemoglobinemia.
 8. **Differential cyanosis.** See Section II.I below.
- B. Does the infant have respiratory distress?** If the infant has increased respiratory effort with increased rate, retractions, and nasal flaring, **respiratory disease** should be high on the list of differential diagnoses. **Cyanotic heart disease** usually presents without respiratory symptoms (“happy blue baby”) but can have effortless tachypnea (rapid respiratory rate without retractions). **Methemoglobinemia syndromes** usually present without respiratory symptoms, but **polycythemia** can present with or without respiratory symptoms. **CNS disease** can present with respiratory symptoms (ie, respiratory muscle weakness, hypoventilation with a decreased respiratory drive).
- C. Does the infant have a murmur?** A murmur usually implies heart disease, but in infants with congenital heart malformations, <50% have a murmur in the newborn period. Transposition of the great vessels can present without a murmur (~60%). **Muffled heart sounds** can indicate pericardial effusions or pneumopericardium.
- D. Was the infant cyanotic at birth?** Infants just born can have central cyanosis for a brief period after birth. Once their oxygen saturation normalizes, they are no longer cyanotic. They can also have differential cyanosis soon after birth while transitioning. If cyanotic at birth and cyanosis persists, consider that transposition of the great vessels (transposition of the great arteries [TGA]) and tricuspid atresia can present immediately at birth. Infants with TGA with ventricular septal defect (VSD), left ventricular outflow obstruction (LVOTO), and restricted pulmonary blood flow (PBF) present with intense cyanosis at birth. In the perinatal period, infants with

truncus arteriosus, total anomalous pulmonary venous return, and tetralogy of Fallot can present with persistent cyanosis. Most infants with airway abnormalities or congenital diaphragmatic hernia will usually present shortly after birth and will have persistent cyanosis. Infants with hereditary methemoglobinemia usually have cyanosis present at birth.

- E. Is the cyanosis continuous, intermittent, cyclical, sudden in onset, or occurring only with feeding or crying?**
- 1. Continuous cyanosis** is more commonly associated with intrinsic lung disease or heart disease.
 - 2. Recurrent episodes of cyanosis.** Consider phrenic nerve paralysis.
 - 3. Intermittent cyanosis** is more common with neurologic disorders; these infants may have apneic spells alternating with periods of normal breathing.
 - 4. Cyclical cyanosis** can occur with nasal obstruction.
 - 5. Sudden onset of cyanosis** may occur with an air leak, such as pneumothorax.
 - 6. Cyanosis with feeding** can occur with esophageal atresia, tracheoesophageal atresia, and severe gastroesophageal reflux. **Feeding hypoxia** occurs more commonly with bottle feeding than breast feeding.
 - 7. Cyanosis in supine position that decreases when the infant is placed in prone position.** Micrognathia, retrognathia, Pierre Robin sequence.
 - 8. Cyanosis only with crying** can occur in infants with tetralogy of Fallot.
 - 9. Cyanosis that disappears with crying** may mean bilateral choanal atresia. These infants are cyanotic when quiet and at rest and pink when crying with their mouth open.
 - 10. Cyanosis that gets worse with crying, feeding, respiratory infections, and supine position.** Severe laryngomalacia and tracheomalacia.
 - 11. Crying may improve cyanosis in respiratory disease** and worsen it in cardiac disease.
 - 12. Cyanosis after crying.** Some term infants have a prolonged apnea after crying that results in a marked decrease in oxygen saturation and **central cyanosis** (central apnea immediately after crying with a decrease in SpO₂ to 60%).
- F. Is the pulse oximeter reading low in an infant who is cyanotic with a normal PaO₂ on arterial blood gases?** Consider methemoglobinemia, hemoglobin variants, or some cases of peripheral cyanosis. The pulse oximeter estimates oxygen saturation by using light absorbance measurements at 2 wavelengths to determine the percentage of hemoglobin that is saturated with oxygen. It is inaccurate when more than 2 types of hemoglobin are present, as in methemoglobinemia. In infants with a high concentration of methemoglobin, the pulse oximeter will show a falsely low reading (regardless of the real hemoglobin oxygen saturation. **It falsely indicates arterial hypoxemia in infants with peripheral cyanosis or with abnormal hemoglobin.** Laboratory blood gas analysis can differentiate deoxyhemoglobin from abnormal hemoglobin; therefore, it only indicates hypoxia in infants with central cyanosis. Some newer pulse oximeters can measure methemoglobin and oxygen saturation (eg, Masimo Rainbow SET Radical-7 pulse oximeter; Masimo, Irvine, CA). **In some infants with peripheral cyanosis** with poor perfusion in the extremities, deeply pigmented skin, or jaundice, the pulse oximeter can be inaccurate and can indicate arterial hypoxemia in patients with normal arterial oxygenation.
- G. What is the hemoglobin concentration?** The degree of visible cyanosis on physical examination depends on both oxygen saturation and hemoglobin concentration. The appearance of cyanosis depends upon the absolute amount of reduced hemoglobin. Normally cyanosis is perceptible at 85% saturation when the hemoglobin concentration is 15 g/dL and the reduced hemoglobin is >3 g/dL. In a polycythemic infant one will detect cyanosis at a higher level of oxygen saturation (Hgb 20 g/dL detects cyanosis at 87% saturation) and in anemic infant cyanosis may not be apparent since one will only detect cyanosis at a lower level of oxygen saturation (Hgb of 6 g/dL detects cyanosis at 62.5% saturation).

- H. Has the baby had the pulse oximetry screening test for critical congenital heart disease (CCHD)?** This increases the detection rate of CCHD by 28% as physical examination can miss up to 50% of cyanotic congenital heart disease. This is a required test now in all newborns (see Chapter 7) as a useful method for screening for cyanotic CCHD. It can identify the following 7 core heart conditions that present with hypoxemia before cyanosis develops: hypoplastic left heart syndrome, pulmonary atresia with an intact septum, tetralogy of Fallot, total anomalous pulmonary venous connection, TGA, tricuspid atresia, and truncus arteriosus.
- I. Is there differential cyanosis?** Differential cyanosis (DC) is when there is cyanosis of the upper or lower part of the body only, and it usually signifies serious heart disease. **The prerequisite for this is the presence of a right-to-left shunt through the patent ductus arteriosus (PDA).** To diagnose this, oxygen saturation should be measured preductal (right hand is preferred since it accurately reflects preductal value) and postductal (foot). There are 2 different types of DC.
- 1. Pink upper half of the body, cyanosis lower part of body (more common).** Oxygen saturation is greater in the right hand than in the foot. It usually occurs with severe coarctation of the aorta with PDA, interrupted aortic arch with a PDA, mitral stenosis with a PDA, persistent pulmonary hypertension with a PDA, and Eisenmenger syndrome (PDA with severe pulmonary hypertension).
 - 2. Cyanosis in the upper half of the body, pink lower part of the body.** This type is very rare (reversed differential cyanosis [RDC]) and occurs when oxygen saturation is lower in the right hand than in the foot. This is usually seen in TGA and a PDA associated with severe coarctation of the aorta, interrupted aortic arch, or pulmonary hypertension. It can also be seen in an infant with supracardiac total anomalous pulmonary venous connection (TAPVC) to the superior vena cava with a shunt through the PDA.
- J. What is the prenatal and delivery history?** Did the mother have a prenatal sonogram? It may show a cardiac anomaly. Certain perinatal conditions increase the incidence of congenital heart disease. The delivery history may provide clues for the diagnosis of cyanosis.
- 1. An infant of a diabetic mother** has an increased risk of hypoglycemia, transient tachypnea of the newborn (TTN), polycythemia, respiratory distress syndrome, and congenital heart disease (TGA, VSD, hypertrophic cardiomyopathy).
 - 2. Mother with connective tissue disorder:** causes heart block (anti-Ro/SSA and anti-La/SSB antibodies).
 - 3. Risk of infection** (eg, premature rupture of membranes, maternal fever, chorioamnionitis) can all increase the risk of infection in the neonate which can be associated with cyanosis. Coxsackie B viral infection in the mom can cause myocarditis in newborn infants. Congenital intrauterine infections (eg, cytomegalovirus, herpesvirus, rubella) can cause cardiac abnormalities and cyanosis.
 - 4. Amniotic fluid abnormalities**, such as oligohydramnios (associated with pulmonary hypoplasia and renal defects) or polyhydramnios (associated with esophageal atresia or neurologic or airway conditions), may suggest a cause for the cyanosis.
 - 5. Cesarean section** is associated with increased respiratory distress, TTN, and persistent pulmonary hypertension of the newborn (PPHN). If sedatives or general anesthesia were used, suspect apnea or respiratory depression.
 - 6. Hypertension early in pregnancy increases the risk of a congenital heart defect.** Pregnancy-induced hypertension can be associated with intrauterine growth restriction, polycythemia, and hypoglycemia.
 - 7. Advanced maternal age** can be associated with birth defects such as Down syndrome and Turner syndrome, which include heart defects.
 - 8. Meconium at delivery** can be associated with meconium aspiration syndrome and PPHN.

9. **Preterm delivery.** Consider respiratory distress syndrome.
 10. **Medications used by the mother can cause an increase in congenital heart disease.** Anticonvulsants, lithium, indomethacin, nonsteroidal anti-inflammatory drugs (NSAIDs), ibuprofen, sulfasalazine, thalidomide, trimethoprim, sulfonamide, high-dose vitamin A, antihypertensive medications, selective serotonin reuptake inhibitors (SSRIs), marijuana, alcohol, cigarette smoking, cocaine, and exposure to organic solvents. Maternal lithium treatment increases the risk of Ebstein anomaly.
 11. **Maternal illnesses that increase the risk of congenital heart disease.** Untreated phenylketonuria, maternal pregestational diabetes, febrile illness during the first trimester, influenza, maternal rubella (increased risk pulmonary artery stenosis and PDA), epilepsy, and maternal lupus/connective tissue disease.
 12. **Maternal congenital heart disease and/or congenital heart disease in a first-degree relative.** Increased incidence of heart disease in the infant.
- III. **Differential diagnosis.** Cyanosis becomes visible when there is >3 g/dL of deoxygenated hemoglobin in arterial blood. Cyanosis is caused by either a disorder involving deoxygenated hemoglobin or disorders involving abnormal hemoglobin. The causes of cyanosis can be classified as arising from respiratory, infectious, cardiac, CNS, hematologic, or other disorders. **Central cyanosis** in the neonate is secondary to hypoxia by one or more of the following reasons: **hypoventilation** (eg, CNS depression, neuromuscular disorders, obstruction of the airway, metabolic causes), **impairment of alveolar arterial diffusion** (eg, congestive heart failure/pulmonary edema), **right to left shunting** (eg, PPHN, cyanotic congenital heart disease), or **ventilation perfusion mismatch** (eg, RDS, pulmonary hemorrhage, pneumonia, pleural effusion, pneumothorax, atelectasis, pulmonary hypoplasia, TTN). **The most common etiology of cyanosis in a newborn infant is respiratory, and this should be excluded first.**
- A. **Respiratory diseases.** These include: primary pulmonary diseases, airway obstruction, extrinsic compression of the lungs, congenital defects, hypoventilation, and pulmonary edema. The majority of airway abnormalities usually present right after birth. Newborns with lung disease will usually present with respiratory distress.
1. **Primary pulmonary diseases.** Respiratory distress syndrome, TTN (rarely associated with visible cyanosis), aspiration (meconium, blood, amniotic fluid) syndromes, pneumonia, bronchopulmonary dysplasia/chronic lung disease, pulmonary hemorrhage, atelectasis, pulmonary edema.
 2. **Airway obstruction.** Choanal atresia/stenosis, micrognathia, retrognathia (Pierre Robin sequence), laryngomalacia and tracheomalacia, bilateral vocal cord paralysis (severe respiratory distress and cyanosis), tracheal stenosis, macroglossia, subglottic stenosis, atelectasis, mucus plug, and others. Vascular rings cause compression of the trachea and cyanosis.
 3. **External compression of the lungs.** Any air leak syndrome (eg, pneumothorax, pulmonary interstitial emphysema), pleural effusion, chylo-/hemothorax, thoracic dystrophy, and others.
 4. **Congenital defects.** Congenital diaphragmatic hernia, pulmonary hypoplasia, cystic pulmonary airway malformation, tracheoesophageal fistula/esophageal atresia, congenital lobar emphysema (rarely presents at birth), subglottic stenosis, pulmonary artery sling, asphyxiating thoracic dystrophy/dysplasia (Jeune syndrome), congenital laryngomalacia, arteriovenous fistulas, Pierre Robin sequence, and others.
 5. **Hypoventilation.** Sedation, sepsis, neuromuscular diseases, CNS depression or lesions.
- B. **Infections. Sepsis is the second most common cause of cyanosis in infants.** Sepsis causes increased oxygen utilization, capillary leak, and pulmonary edema, which results in cyanosis.
- C. **Cardiac diseases.** The majority of congenital heart diseases that present in the first couple of weeks of life are ductal-dependent cardiac lesions.

1. **More common cyanotic heart diseases include the 5 Ts.** Central cyanosis results from right-to-left shunting.
 - a. **Transposition of the great arteries.** This is the most common cause of cardiac cyanosis in newborns.
 - b. **Total anomalous pulmonary venous return/connection.**
 - c. **Tricuspid valve abnormalities (tricuspid atresia).**
 - d. **Tetralogy of Fallot is the most common cyanotic congenital heart disease in older children.**
 - e. **Truncus arteriosus.**
 - f. **Often a 6th and 7th T are added to the mnemonic of the 5 Ts:**
 - i. **Tiny heart (hypoplastic left heart syndrome)**
 - ii. **Seventh T (“tons of others”/“terrible Ts”)** includes all the others: critical pulmonary stenosis, double outlet right ventricle, pulmonary atresia with intact ventricular septum or with VSD, variations on single ventricle, Ebstein anomaly of the tricuspid valve, total anomalous pulmonary venous connection with and without obstruction, single-ventricle complexes, and absent pulmonary valve syndrome.
2. **Severe congestive heart failure.** This can occur from cardiomyopathies (infant of diabetic mother [IDM], inborn errors of metabolism, genetic or neuromuscular disease), myocarditis (bacterial or viral), congenital cardiac disease, sepsis, perinatal asphyxia, and sustained tachyarrhythmias. **Cyanosis and heart failure can be seen in left-sided obstructive lesions** (hypoplastic left heart syndrome [HLHS], severe coarctation of the aorta, interrupted aortic arch, and critical valvar aortic stenosis). These lesions are ductal dependent for systemic flow, and when it closes, these patients become cyanotic and experience shock and hypotension, pulmonary edema, and metabolic acidosis.
3. **Pneumopericardium or pericardial effusion.**
4. **Other congenital anomalies** such as those associated with cardiac malformations: Turner syndrome, Noonan syndrome, and others. **Pulmonary arteriovenous malformation** is a rare cause of cyanosis in the newborn. See Table 94–1 for congenital anomalies associated with heart defects.
5. **Primary intracardiac tumors** with obstructive symptoms (eg, cardiac rhabdomyoma presenting with cyanosis in a 3-day-old infant).
- D. **Persistent pulmonary hypertension of the newborn causes right-to-left shunting with resultant cyanosis.** In PPHN, infants do not transition from fetal to newborn circulation. Pulmonary hypertension causes **right-to-left shunting of blood**, a decrease in PBF, and cyanosis.
- E. **Central nervous system disorders** can cause apnea, seizures, and decreased respiratory drive (hypoventilation and cyanosis).
 1. **Infectious.** Bacterial or viral CNS infection (meningitis, encephalitis).
 2. **Seizures.** Infection, metabolic, CNS injury, genetic syndrome, congenital disorder, primary seizure disorder.
 3. **Neonatal encephalopathy/hypoxic ischemic encephalopathy.**
 4. **Hemorrhage.** Periventricular/intraventricular hemorrhage, subdural hemorrhage, subarachnoid hemorrhage, intracerebellar hemorrhage, infarction.
 5. **Congenital disorders.** Congenital hydrocephalus, spinal muscle atrophy, congenital central hypoventilation syndrome.
 6. **Drug toxicity (eg, opioid toxicity).**
- F. **Neuromuscular disorders cause hypoventilation.** Werdnig-Hoffmann disease, Pompe disease, Barth syndrome, Duchenne or Becker muscular dystrophy, limb girdle muscular dystrophy, congenital myopathy, neonatal myasthenia gravis, phrenic nerve injury, and congenital myotonic dystrophy.
- G. **Hematologic disorders.** A hemoglobin disorder can interfere with the transport of oxygen and cause cyanosis. Suspect methemoglobinemia when administration of

oxygen does not resolve the cyanosis. The typical infant with methemoglobinemia is cyanotic, has no respiratory distress, and has a low oxygen saturation and normal PaO₂.

1. **Methemoglobinemia (normal arterial oxygen)** is characterized when red blood cells contain a high level of methemoglobin. Methemoglobin is caused by iron being oxidized from the normal ferrous state to the abnormal ferric form within the heme moiety of hemoglobin, and it is incapable of transporting oxygen or carbon dioxide. Because the arterial blood is brown in color, it gives off a bluish hue in the skin of white people (“chocolate cyanosis”). It can be congenital (genetic) or acquired.
 - a. **Congenital methemoglobinemia** is typically caused by autosomal recessive inheritance of the deficient *cv5R* gene.
 - b. **Acquired methemoglobinemia** can be caused by exposure to certain medications (eg, eutectic mixture of lidocaine and prilocaine [EMLA], metoclopramide, nitrites, sulfonamides, benzocaine, dapsone, lidocaine, amyl nitrate, nitric oxide, nitroglycerin, nitroprusside, phenazopyridine, prilocaine, quinones, sulfonamides) or toxin oxidizing chemicals (eg, nitrates, nitrous gases, chlorobenzene, isobutyl nitrate, aniline dye derivatives, naphthalene), environmental substances, or dietary etiologies. Transient neonatal methemoglobinemia can be caused by maternal pudendal anesthesia with prilocaine.
 2. **Congenital familial sulfhemoglobinemia** is an extremely rare disease caused by excess sulfhemoglobin in the blood and can cause cyanosis. It is caused by sulfur-containing drugs or intestinal microbiota (eg, *Morganella morganii*).
 3. **Other rare variants of hemoglobin.** Fetal HB and fetal M hemoglobin variants are rare causes of cyanosis. Clinical clues are a positive family history in an infant with a decreased hemoglobin oxygen saturation with a normal PaO₂. Six identified mutations can cause cyanosis at birth, with the cyanosis resolving as the adult β-globin chain replaces the fetal γ-globin chain.
 4. **Polycythemia/hyperviscosity syndrome (normal arterial oxygen)** presents with peripheral cyanosis, tachypnea, congestive heart failure (CHF), and cardiomegaly. Infants can appear cyanotic because of an elevated hemoglobin even though their oxygen saturations are normal. Cyanosis is detectable at a higher value of SaO₂ (eg, in polycythemic infants [polycythemia can cause persistent pulmonary hypertension and cyanosis]). Mild hypoxia can cause cyanosis in polycythemia.
 5. **Severe anemia** from hemorrhage or bleeding disorders. Patients who have anemia do not develop cyanosis until the oxygen saturation falls below normal hemoglobin levels.
- H. Metabolic abnormalities can present with cyanosis secondary to hypoventilation from lethargy, apnea, and seizures.**
1. **Drug withdrawal.**
 2. **Severe hypoglycemia, hypermagnesemia, severe metabolic acidosis.**
 3. **Inborn errors of metabolism.**
 4. **Rarely abnormalities of calcium, potassium, and phosphorus** can cause hypoxia and cyanosis. Calcium and potassium abnormalities can cause cardiac arrhythmias.
- I. Other disorders**
1. **Apnea and bradycardia/apnea of prematurity.**
 2. **Hypothermia.**
 3. **Hypoadrenalism/hypopituitarism.**
 4. **Hypotension and shock.** This can be secondary to sepsis or cardiogenic, neurogenic, or hypovolemic, and all can present with cyanosis. (See Chapter 70.)
 5. **Abdominal distension** with elevation of the diaphragm.
 6. **Respiratory depression** secondary to maternal medications (eg, magnesium sulfate and narcotics) or maternal sedation.
 7. **BRUE (brief resolved unexplained events) replaces ALTE (apparent life threatening event).** A BRUE applies to a well-appearing infant (no underlying

health problems) age <1 year who has a brief, <1 minute (usually <20–30 seconds) sudden event that resolves, is unexplained after a history and physical examination, and includes 1 or more of the following: **cyanosis** or pallor; decreased, absent, or irregular breathing; altered level of responsiveness; or marked change in tone (hypertonia or hypotonia).

J. Pseudo-cyanosis. Caused by fluorescent lighting.

IV. Database. Obtain a prenatal and delivery history (see Section II.J). Measure oxygen saturation by a pulse oximeter to confirm central cyanosis.

A. Physical examination

1. Assess the infant for central, peripheral, acrocyanosis, perioral/circumoral, or differential cyanosis. See Section II.A.

a. Central cyanosis. Skin, lips, and tongue appear blue. It may be difficult to assess cyanosis in infants with darker skin pigmentation. Focus on nailbeds, tongue, and mucous membranes.

b. Peripheral cyanosis. Skin is bluish, but the oral mucous membranes are pink.

c. Acrocyanosis. Hands and feet are blue but nothing else.

d. Perioral/circumoral cyanosis. Blue appearance around the mouth.

e. Poor peripheral perfusion with cyanosis. These infants “don’t look good,” “look mottled,” or “look washed out or have poor perfusion.” (See Chapter 77.)

f. Differential cyanosis. Cyanosis of the upper or lower part of the body only (see Section II.I).

2. Assess the heart. Check for any murmurs and the heart rate and blood pressure. Blood pressure ≥ 10 mm Hg higher in the arms than the legs is suggestive of coarctation of the aorta or other aortic arch obstruction. Increased second heart sound can be seen in pulmonary hypertension. Single second heart sound can be seen with transposition of the great vessels, teratology of Fallot, hypoplastic left heart syndrome, severe pulmonary stenosis, tricuspid atresia, aortic atresia, truncus arteriosus, pulmonary atresia with intact ventricular septum, and conditions with pulmonary hypertension. A split S_2 can be seen with total anomalous pulmonary venous connection and Ebstein anomaly. Remember that not all infants with congenital heart disease have a murmur (eg, transposition of the great vessels can have no detectable murmur). Muffled heart sounds can signify pneumopericardium or pericardial effusion. A displaced cardiac impulse may mean dextrocardia or dextroposition.

3. Assess the respiratory system. Are there retractions, nasal flaring, or grunting? Retractions are usually minimal in heart disease. Check the nasal passage for choanal atresia. Try to pass a suction catheter through each nostril into the oropharynx; if it will not pass, then the infant has choanal atresia. Infants with pulmonary disease will have tachypnea and distressed breathing, whereas infants with cardiac disease do not.

4. Assess the abdomen. Check for an enlarged liver. The liver can be enlarged in CHF and hyperexpansion of the lungs. A scaphoid abdomen may suggest a diaphragmatic hernia. Hepatomegaly can indicate high venous pressure.

5. Check the pulses. In coarctation of the aorta or other aortic arch obstruction, the pulses in the lower extremities are decreased or absent, whereas the pulses are strong in the upper extremities. In PDA, the pulses are bounding.

6. Consider neurologic problems. Check for apnea and periodic breathing, which may be associated with immaturity of the nervous system. Observe the infant for seizures, which can cause cyanosis if the infant is not breathing during seizures.

7. Assess for multiple malformations on the examination. These may suggest underlying heart or pulmonary defects (CHARGE [coloboma, CNS abnormalities, heart defects, atresia of the choanae, restricted growth and/or development, genital abnormalities, and ear anomalies] or VATER/VACTERL [vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal

dysplasia/vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and radial abnormalities, and limb abnormalities] anomalies).

B. Laboratory studies

1. **Arterial blood gas measurements on room air.** If the patient is not hypoxic, it suggests methemoglobinemia, polycythemia, or CNS disease. If the patient is hypoxic, perform the hyperoxia test, described later. Pulse oximetry can be used to check arterial saturation but is not a good indicator of central cyanosis. An **increased PaCO₂** can indicate pulmonary disorders, PPHN, heart failure, or CNS disorders. **Metabolic acidosis** can indicate sepsis, severe hypoxemia, or shock from poor perfusion. A **low or normal carbon dioxide** can indicate cardiac disease. **Methemoglobinemia** will have decreased SaO₂, normal PaO₂, and “chocolate brown” blood.
2. **Complete blood count with differential.** This may reveal an infectious process (with a low white blood cell count more common). A central hematocrit of >65% confirms polycythemia.
3. **Sepsis workup.** Blood culture and C-reactive protein, urine culture, and lumbar puncture if indicated.
4. **Serum glucose level.** To detect hypoglycemia.
5. **Methemoglobin level.** If the infant has methemoglobinemia, the blood will not turn red when exposed to air and have a chocolate hue (“chocolate cyanosis”). Examine a drop of blood on white filter paper, and allow the paper to dry; after exposure to room air, it will remain dark brown. To confirm the diagnosis, the laboratory should perform a hemoglobin electrophoresis.
6. **Next-generation sequencing.** Next-generation sequencing (NGS)-based diagnostic approaches can be used to diagnose rare cases of fetal methemoglobinemia. Genetic testing for mutations is important if other laboratory tests are nonconclusive. DNA analysis of the globin gene should be done to diagnose the mutation if a γ -globin gene mutation is suspected.

C. Imaging and other studies

1. **Transillumination of the chest** should be done on an emergent basis if pneumothorax is suspected (see Chapter 44).
2. **Chest radiograph.** If normal, it suggests a CNS disease or other cause for the cyanosis (see Section III). It can verify lung disease, air leak, or diaphragmatic hernia. (See radiographic pearls on page 184). It can also help diagnose heart disease by evaluating the heart size and pulmonary vascularity. Is there dextrocardia or situs inversus (suggests cardiac disease)? The **heart size** may be normal or enlarged in hypoglycemia, polycythemia, shock, and sepsis. In cardiac lesions with cyanosis and increased PBF, there will be **cardiomegaly**. **Decreased pulmonary vascular markings** represent decreased blood flow through the pulmonary circulation and can be seen in tetralogy of Fallot, pulmonary atresia/stenosis, tricuspid atresia, Ebstein anomaly, and idiopathic pulmonary hypertension of the newborn. **Increased pulmonary arterial markings** can be seen in truncus arteriosus, single ventricle, total anomalous pulmonary venous connection without obstruction, and TGA. **Increased venous markings (venous congestion)** can be seen in hypoplastic left heart syndrome and total anomalous pulmonary venous return. The **shape of the heart** can be informative:
 - a. **Boot-shaped heart.** Tetralogy of Fallot, tricuspid atresia.
 - b. **Egg-shaped heart (“egg on a string”).** TGA.
 - c. **Large globular heart/massive cardiomegaly.** Ebstein anomaly
 - d. **Dextrocardia/mesocardia.** Congenital heart disease
 - e. **“Snowman” or “figure 8.”** Total anomalous pulmonary venous return.
3. **Hyperoxia test** is used to differentiate cyanotic congenital heart disease (with right-to-left shunting) from pulmonary and other causes of cyanosis. Because of intracardiac right-to-left shunting, the infant with cyanotic congenital heart disease, in contrast to the infant with pulmonary disease, is unable to increase the

arterial saturation. Some institutions do not use this test because of the concern of using 100% oxygen in preterm infants and instead rely on echocardiography.

- a. Measure PaO_2 in the right radial artery (preductal) on room air.
 - b. Then place the infant on 100% oxygen for 10 minutes and repeat the arterial oxygen (**note:** best not to use pulse oximetry).
 - c. If the oxygen saturation and PaO_2 do not increase, cardiac causes of cyanosis should be considered. **Note:** A value of >150 mm Hg does not always rule out cyanotic heart disease. Diagnosis of cardiac disease can be delayed due to a misleading hyperoxia test, and this has been reported (severe cases of pulmonary disease with intrapulmonary shunts or PPHN, pulmonary disease with cardiac disease, infracardiac total anomalous pulmonary venous connection with $\text{PaO}_2 >250$ mm Hg). Echocardiogram should be done if unsure.
- d. Hyperoxia test interpretation**
- i. **$\text{PaO}_2 >300$ mm Hg:** Normal result.
 - ii. **$\text{PaO}_2 >150$ but <300 mm Hg:** Pulmonary disorders, CNS disorders, methemoglobinemia. In an infant with severe pulmonary disease, the arterial oxygen saturation may not increase significantly.
 - iii. **$\text{PaO}_2 >100$ but <150 mm Hg:** PPHN, truncus arteriosus, hypoplastic left heart syndrome, total anomalous pulmonary venous return without obstruction.
 - iv. **$\text{PaO}_2 <100$ mm Hg:** Dextro-TGA, tricuspid atresia, pulmonary atresia or stenosis, tetralogy of Fallot.
 - v. **Neurologic disease.** $\text{PaO}_2 >150$ but <300 mm Hg.
 - vi. **Methemoglobinemia.** $\text{PaO}_2 >150$ but <300 mm Hg but pulse oximetry remains low.
4. **Right-to-left shunt test.** Done to rule out PPHN; the best way to do this is with pulse oximetry. Place 2 pulse oximeters on the infant (1 preductal on the right hand and 1 postductal on either foot). If the simultaneous difference is $>5\%$ to 10% between preductal and postductal oxygen saturations, it is indicative of a right-to-left shunt. Alternatively, draw a simultaneous sample of blood from the right radial artery (preductal) and the descending aorta or the left radial artery (postductal). If there is a difference of >10 to 20 mm Hg (preductal more than postductal), the shunt is significant.
 5. **Hyperventilation test.** Hyperventilating the infant for 10 minutes (lowering PaCO_2 and increasing the pH) will result in a marked improvement in oxygenation (>30 mm Hg increase in PaO_2) in PPHN. This may help differentiate the infant with PPHN from the infant with cyanotic congenital heart disease (little or no response in congenital heart disease).
 6. **Electrocardiography.** Usually normal in patients with methemoglobinemia or hypoglycemia. With polycythemia, pulmonary hypertension, or primary lung disease, the electrocardiogram (ECG) is usually normal but may show right ventricular hypertrophy. The ECG is usually nondiagnostic in CCHD because it is normal for a newborn to have right axis deviation (up to 180 degrees) and right ventricular dominance in the right chest leads, which is seen in the majority of CCHD ECGs. Tall P waves have been seen in approximately 40% of infants with hypoplastic left heart syndrome. **The ECG is helpful in identifying patients with 2 congenital heart diseases: tricuspid atresia and atrioventricular septal defect.** Both show a left superior axis deviation because of the inferior and posterior displacement of the atrioventricular node. The only difference is that tricuspid atresia has diminished right ventricular forces and atrioventricular septal defect show right ventricular hypertrophy.
 - a. **Tricuspid atresia:** Left superior axis deviation and diminished right ventricular forces.
 - b. **Atrioventricular septal defect:** Left superior axis deviation and right ventricular hypertrophy.

7. **Echocardiography.** Should be performed immediately if cardiac disease is suspected or if the cause of cyanosis is unclear. It is the **gold standard** and definitive diagnostic test for congenital heart disease. It can confirm pulmonary hypertension. See Table 94–1.
8. **Computed tomography and computed tomography angiography.** May help identify anomalies of the pulmonary venous return and identify choanal atresia.
9. **Ultrasonography of the head** to rule out periventricular/intraventricular hemorrhage, subependymal cyst (increased echogenicity or cyst in ganglionic eminence), or respiratory inhibition after crying in term infants.
10. **Polysomnographic recording** to diagnose apnea and its type.
11. **Electroencephalogram.** If seizure disorder is suspected.
12. **Bronchoscopy.** Direct bronchoscopic visualization confirms the diagnosis of tracheal stenosis.

V. Plan

A. General management.

1. **Act quickly and accomplish many of the diagnostic tasks at once.** Perform resuscitation (airway, breathing, and circulation), if necessary. Perform rapid physical examination. Is the infant breathing normally? Is the infant having episodes of apnea? Is there upper airway obstruction? What are the vital signs?
 - a. **Provide respiratory support,** if needed (establish an airway if necessary, provide oxygenation, and make sure there is adequate ventilation). **Give oxygen first, prior to full evaluation.** Assisted ventilation may be necessary in infants with severe cyanosis. Prone position and oral airway may be required. If pneumothorax suspected, transilluminate the chest. If a tension pneumothorax is present, rapid needle decompression may be needed.
 - b. **Establish vascular access for blood sampling** (intraarterial and intravenous) and administering volume and medications. Give volume resuscitation if necessary, especially in infants with hypotension and poor perfusion. Inotropic support may be required for hypotension and correcting metabolic acidosis are essential.
2. **Order immediate laboratory studies and a radiograph.** For example, stat blood gas level, complete blood count, blood glucose, blood culture, electrolytes, and chest radiograph.
3. **Give antibiotics as indicated** for sepsis or pneumonia (usually started unless obvious reason for cyanosis) after doing a sepsis work up.
4. **Symptomatic hypoglycemia and hypocalcemia** should be corrected.
5. **Prostaglandin E₁ (PGE₁) is indicated in infants** with or who have a clinical suspicion for a ductal-dependent congenital heart defect and should be given until a definitive diagnosis or treatment is established. See below.
6. **Perform the hyperoxia test to differentiate pulmonary from cardiac from respiratory causes, or perform an echocardiogram.** See Section IV.C.3.
7. **Suspect methemoglobinemia** when the cyanosis does not improve with oxygen.
8. **Obtain a pediatric cardiology consult if cardiac disease is suspected.**

B. Specific management.

1. **Lung disease.** (See the appropriate disease chapter.) Respiratory depression caused by narcotics at birth should be treated with respiratory support with positive-pressure ventilation and possible laryngeal mask airway placement or endotracheal tube placement if apnea is prolonged.
2. **Air leak (pneumothorax).** See Chapter 75. Depending on the severity of the pneumothorax, urgent needle aspiration or chest tube placement may be necessary.
3. **Congenital defects (eg, upper respiratory).** Surgery may be indicated.
4. **Cardiac disease.** Correction of metabolic acidosis if present, supplemental oxygen, and maintain adequate respiratory support. Prostaglandin E₁ (PGE₁) is indicated in infants with or who have a clinical suspicion for a ductal-dependent congenital heart defect and should be given until a definitive diagnosis or

treatment is established. PGE₁ is indicated for any clinical condition in which blood flow must be maintained through the ductus arteriosus to sustain pulmonary or systemic circulation until surgery can be performed. Dose is 0.01 mcg/kg/min initial intravenous infusion.

- a. **Give prostaglandin E₁ to increase pulmonary blood flow** for pulmonary atresia/stenosis, TGA, tetralogy of Fallot, and tricuspid atresia (if PBF restricted). Other ways of improving PBF are with supplemental oxygen, maintaining a respiratory alkalosis, sildenafil, and inhaled nitric oxide.
- b. **Give prostaglandin E₁ to increase systemic blood flow** for hypoplastic left heart syndrome, coarctation of the aorta, critical aortic stenosis, and aortic arch interruption.
- c. **Give prostaglandin E₁ to improve mixing in transposition of the great arteries.**
- d. **Prostaglandin E₁ is not recommended** in respiratory distress syndrome, PPHN, total anomalous venous return with obstruction (PGE₁ may minimize obstruction but does not help clinically), and dominant left-to-right shunt (PDA, truncus arteriosus, or VSD).
- e. **If the diagnosis is uncertain**, a trial of PGE₁ can be given over 30 minutes in an effort to improve blood gas values.
- f. **Other management**
 - i. **Dextro-transposition of the great arteries with severe cyanosis and restrictive atrial communication.** Urgent Rashkind atrial septostomy under echocardiogram in the nursery will maintain oxygenation until surgery is performed (arterial switch operation). Total anomalous pulmonary venous return, TGA with VSD, and truncus arteriosus require further cardiac evaluation and possible surgery.
 - ii. **Tetralogy of Fallot.** If there is cyanosis in the first 2 weeks, give PGE₁ until surgery can be done. For **tetralogy spells** (usually not seen in the neonatal intensive care unit but can be if the infant has a prolonged stay), treatment includes blow-by oxygen, comforting and feeding, and holding the infant in knee-chest position (decreases right-to-left shunting and increases systemic vascular resistance). If the infant remains cyanotic, give propranolol (0.05 mg/kg) to decrease the heart rate and myocardial contractility. Other treatments include intravenous phenylephrine, ketamine, intubation, and sedation (last resort). A Blalock-Taussig shunt can be done if surgery cannot be done. Surgery consists of closure of VSD, resecting the hypertrophied muscle bundles, and pulmonary valvuloplasty.
 - iii. **Hypoplastic left heart syndrome.** Give PGE₁ infusion, correct metabolic acidosis, avoid oxygen if possible (worsens pulmonary congestion), and avoid excess fluids or inotropic agents. If atrial communication is severe, an urgent Rashkind atrial septostomy can be done. Surgery involves the Norwood procedure in 3 stages.
 - iv. **Tricuspid atresia.** Treatment depends on PBF. If restricted: PGE₁ infusion, Rashkind atrial septostomy, Blalock-Taussig shunt. If increased: pulmonary arterial banding. If normal: observation for cyanosis. Surgery involves 3 procedures: aortopulmonary shunt or pulmonary artery banding procedure, bidirectional Glenn procedure, and then modified Fontan procedure.
 - v. **Truncus arteriosus.** Manage medically in the neonatal unit with diuretics and angiotensin-converting enzyme (ACE) inhibitors. Surgery is required in the first few months once heart failure symptoms worsen.
 - vi. **Total anomalous pulmonary venous connection.** If veins are obstructed: surgical emergency. If veins are not obstructed: avoid PGE₁. Use diuretics and ACE inhibitors. Surgery is needed in all cases, once the infant is stable.

5. **Persistent pulmonary hypertension of the newborn.** See Chapter 115.
6. **Central nervous system disorders.** Treat the underlying disease.
7. **Methemoglobinemia.** Treat the infant with methylene blue only if the methemoglobin level is markedly increased and the infant is in cardiopulmonary distress (tachypnea and tachycardia). Administer intravenously 1 mg/kg of a 1% solution of **methylene blue** in normal saline. The cyanosis should clear within 1 to 2 hours. Methylene blue is not recommended in infants with glucose-6-phosphate dehydrogenase deficiency. Ascorbic acid can be added if needed. If the combination does not work, consider exchange transfusion or hyperbaric oxygen. Recall that methylene blue can cause a low SpO₂.
8. **Shock.** See Chapter 70.
9. **Polycythemia.** See Chapters 76 and 116.
10. **Choanal atresia requires an evaluation by otorhinolaryngology.** Place an oral airway, which should immediately improve the infant's condition until surgery can be performed (see Chapter 125).
11. **Micrognathia, retrognathia, Pierre Robin sequence.** Treatment includes, placing an infant prone, possibly using an oral airway, possible surgical mandibular surgery, possible tracheostomy until the mandible grows.
12. **Tracheal stenosis** requires extensive surgical repair.
13. **Hypothermia.** Rewarming is necessary, as described in Chapter 8.
14. **Hypoglycemia.** See Chapter 67.

57 Death of an Infant

1. **Problem.** A newborn infant is dying or has just died. Even though the overall infant mortality rate in the United States has improved, >23,000 infants die each year, with >15,000 dying in the neonatal intensive care unit (NICU). The mortality rate in the United States for newborns is 5.82 per 1000 live births. The leading causes of infant death are shown in Table 57-1, with the top 5 being birth defects/congenital malformations, preterm birth and low birthweight, sudden infant death syndrome (SIDS), maternal pregnancy complications, and infant accidents (unintentional injuries).

Some researchers found that parents experience more intense grief reactions for an infant who died in the NICU than earlier pregnancy losses, possibly because of the longer time for a stronger attachment. Studies show that bereaved parents who experience an infant death or stillbirth have an increased mortality for up to 25 years compared to

Table 57-1. TOP 10 LEADING CAUSES OF NEONATAL DEATH IN THE UNITED STATES

1. Birth defects/congenital anomalies/malformations
2. Preterm birth and low birthweight
3. Sudden infant death syndrome (SIDS)
4. Maternal pregnancy complications
5. Infant accidents (unintentional injuries)
6. Umbilical cord and placental complications
7. Bacterial sepsis
8. Respiratory distress syndrome
9. Circulatory system diseases
10. Neonatal hemorrhage

parents who did not experience an infant death or stillbirth. Infants in the NICU are usually very ill, and parents may experience prolonged grief. Many bereaved families lack the necessary support at critical times. Recent studies have focused on the importance of bereavement support and the profound effect healthcare providers can have on parents who have lost an infant. A healthcare provider's insensitivity to a parent can contribute to difficulties in coping and may increase the risk of a complicated grief reaction. Nurses, who are more likely than physicians to have received bereavement training, are more likely to have a positive attitude in these difficult situations. Hospitals should be encouraged to establish formal training and defined protocols for an infant death to improve everyone's experience. Good-quality bereavement care decreases the negative psychological, emotional, and social effects for parents. Every bereaved parent is entitled to the best possible care.

II. Immediate questions

- A. Has the family been prepared for the death, or was it unexpected?** It is important to prepare the family in advance, if possible, for the death of an infant. Be ready and available to answer questions after the event.
- B. Was this an early or late neonatal death?** Early neonatal death describes the death of a live-born infant at <7 days of age. Late neonatal death is the death of a live-born infant at 7 to 27 days of age. A postnatal death is a live birth that results in death at 28 to 364 days. Late neonatal deaths result in more protracted grief reactions than early neonatal deaths.
- C. Which family members are present?** Usually, several immediate family members in addition to the parents are present at the hospital, which is usually beneficial for emotional support. Each of the family members may adopt a special role. The family should be allowed to go through the immediate process of grieving the way they feel most comfortable (eg, on their own, with the chaplain, with their favorite nurse, or with the physician they trust) and in the location they feel most comfortable (eg, the NICU or family conference room). Attention should focus on both parents if appropriate.
- D. If the family members are not present, is a telephone contact available?** It is standard practice to ensure there is a contact telephone number available for any sick infant. If the family members are not present, telephone contact must be made as soon as possible to alert the family that their infant is dying or has already passed away. In either case, urge the family to come in and be with their infant.
- E. Are there any religious needs expressed by the family?** The religious needs must be respected and the necessary support provided (eg, priest, rabbi, appropriate clergy, chaplain, or pastoral care). Every hospital has pastoral services, and it is useful to inform the chaplain in advance because some parents may request that their child be baptized before death. It is essential to be sensitive to the family's culture or religion as this may influence the family's decision on how to handle the death, autopsy, and funeral.

III. Differential diagnosis. Although there is not a differential diagnosis for this situation, when a death occurs, it is important to accurately report and define the perinatal death. The American Academy of Pediatrics Committee on Fetus and Newborn established standard terminology for fetal, infant, and perinatal deaths based on standards set by the World Health Organization and the National Center for Health Statistics of the Centers for Disease Control and Prevention (2016). The following definitions are recommended:

- A. Live birth.** "Extraction or complete expulsion from the mother of a product of human conception, irrespective of the duration of pregnancy, which after such expulsion or extraction, breathes or shows any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, regardless of whether the umbilical cord has been cut or the placenta is attached." It is important to distinguish heartbeats from transient cardiac contractions and respirations from fleeting respiratory efforts or gasps.

- B. Fetal death.** “Death before the complete expulsion/extraction from the mother of a product of human conception, irrespective of the duration of the pregnancy, that is not an induced pregnancy termination. After expulsion, the fetus does not show any evidence of life (breathing, beating of the heart, pulsation of the umbilical cord, or movement of voluntary muscles).
1. **Early fetal death:** 20 to 27 weeks’ gestation.
 2. **Late fetal death:** >28 weeks’ gestation.
- C. Infant death.** A live birth that results in death within the first year (<365 days).
1. **Early neonatal death:** A live birth that results in death at <7 days of age.
 2. **Late neonatal death:** A live birth that results in death at 7 to 27 days of age.
 3. **Postnatal death:** A live birth that results in death at 28 to 364 days of age.
- D. Perinatal death.** This is a combination of fetal deaths and live births with only a brief survival. Perinatal death is not reportable but is used for statistical purposes. Three definitions are used:
1. **Infant deaths** that occur at <7 days of age and fetal deaths with a period of gestation of ≥ 28 weeks.
 2. **Infant deaths** that occur at <28 days of age and fetal deaths with a period of gestation of ≥ 20 weeks.
 3. **Infant deaths** that occur at <7 days of age and fetal deaths with a period of gestation of ≥ 20 weeks.
- IV. Database.** It is essential to recall that the dying infant may continue with a gasp reflex for some time even without spontaneous respiration and movement. The heart beat may be very faint; therefore, auscultation for 2 to 5 minutes is advisable. Legal definitions of “death” vary by state or other jurisdiction. Providers must be familiar with the local legal requirements for declaring death.
- V. Plan**
- A. Preparations.** A review has reported on the provider behaviors viewed most favorably by parents after their infant has died; these are outlined in Table 57–2.
1. **The neonatal intensive care unit environment.** The noise level should be kept to a minimum. The staff should be sensitive to the emotions of the parents and the family. In one study, sensitivity, kindness of staff, and time spent with the baby were ranked as very important. The infant and family members should be provided privacy (but should not be abandoned) in an isolated quiet room or a screened-off area in the NICU. Examination of the infant by the physician to confirm the death may be done in that same private area, with the family.
 2. **The infant.** The equipment (eg, intravenous [IV] lines and endotracheal tubes) may be removed from the infant unless an autopsy is anticipated. In that case, it is best to leave in place central catheters and possibly the endotracheal tube. The parents should be allowed to hold the infant for as long as they desire. This type of visual and physical contact is important to begin the grieving process in a healthy manner and try to relieve any future guilt. Careless treatment of the infant by staff members is not tolerated well by parents. The practice reported in the literature of placing the deceased infant on an uncovered metal table or into a bucket after delivery is unacceptable. Parents are acutely aware of how staff cares for the deceased infant. Bathing and dressing the infant in a caring manner and treating the deceased infant with respect are appreciated by the family. Families may also appreciate if nurses take special photos of the infant and provide the family with special mementos so they can have some memories.
- B. Discussion of death with the family**
1. **Location.** Parents and immediate family members should be in a quiet, private consultation room, and the physician should calmly explain the cause and inevitability of death.
 2. **News of the death.** Studies show that parents value clear communication. The physician needs to offer condolences to the family concerning their loss. News

Table 57–2. BEHAVIORS VIEWED MOST FAVORABLY BY PARENTS AFTER PERINATAL DEATH

Offering emotional support

- Stay with the family and spend extra time with them as much as practical.
- Talk about the baby by name.
- Allow parents to grieve or cry.
- Be sensitive to comments that could be perceived as trite or minimizing of grief.
- Return to see family on multiple occasions, if possible.

Attending to physical needs of parents and baby

- Continue routine postpartum nursing and medical care for mother.
- Treat infant's body respectfully.
- Consider dressing, bathing, or wrapping infant as for a live baby.
- Be flexible about hospital policies that may not be appropriate for bereaved families.
- Help parents create tangible memories of their infants.

Educating parents

- Communicate loss to all staff to help avoid inappropriate comments or actions.
- Help parents anticipate what normal grieving will be like.
- Provide straightforward information about cause of death if known. Use lay language.
- Take time to sit down with parents when discussing information.

Reproduced with permission from Gold KJ: Navigating care after a baby dies: a systematic review of parent experiences with health providers, *J Perinatol*. 2007 Apr;27(4):230-237.

of the infant's death can be very difficult for the physician to convey and the family to accept. The physician must be sensitive to the emotional reactions of the family. **Nurses, in one review, were perceived as the healthcare providers who were most likely to provide key emotional support.** The nurse's ability to partner with the family is very important in helping the family take steps in their ability to grieve. It is important that nurses participate in this process because they can provide more ongoing support through this difficult time. They can also guide new mothers and fathers of caring tasks that they can perform for their baby and create memories that will provide them a sense of comfort later on. **Communicate the news of the death to all staff members who will be taking care of the mother if she is still hospitalized at the time of the infant death. This includes dietary staff and housekeepers so they know the appropriate way to act.**

3. **Areas of dissatisfaction noted by parents.** Reviews have emphasized that parents are upset by lack of communication between staff members. Staff who did not know the infant had died and made comments, staff who avoided or were silent with the family, and staff who showed insensitivity or lack of emotional support all created great stress in the families of the deceased. Treating the mother and deceased infant with respect is important.

C. Effects on the family

1. **Emotional (grieving).** A brief outline of the normal grieving process may be discussed with the family members. The stages **Kübler-Ross identified** are **denial** ("This isn't happening to me!"); **anger** ("Why is this happening to me?"); **bar-gaining** ("I promise I'll be a better person if . . ."); **depression** ("I don't care anymore"); and **acceptance** ("I'm ready for whatever comes"). **Temes has described 3 particular types of behavior** exhibited by those suffering from grief and loss: **numbness** (mechanical functioning and social insulation), **disorganization**

(intensely painful feelings of loss), and **reorganization** (reentry into a more “normal” social life). Physicians who offered specifics to the family regarding what to expect in the grieving process were rated as the most competent physicians. In one study, 3% of mothers experienced prolonged periods of grief and 18% had posttraumatic stress.

2. **Physical.** Loss of appetite and disruption of sleep patterns can occur.
3. **Siblings.** It is important to discuss the impact of the death on a sibling. A study was done to assess the developmental impact of surviving a sibling who died in the NICU; it showed that siblings born both before and after a death of an infant are at emotional risk and are in need of psychological support. Photos and family rituals are important for parents and siblings. Clinicians should allow siblings to be active participants in the infant’s life and death.
4. **Surviving twin or multiple.** Staff must be aware of the added stress on the parents looking in on a surviving twin or multiple birth.

D. Practical aspects

1. **Perinatal bereavement programs.** Because the neonatal staff plays a major role in helping families cope with the loss of their infant, it is important for each unit to set up a comprehensive program to help families deal with their grief. Some units have set up a bereavement support service that includes a bereavement suite, bereavement coordinators, and bereavement support (funerals and blessings, 24-hour communication, financial advice and benefits, provision of mementos and keepsakes, sibling involvement and counseling, and follow-up). It is important to not only focus on the neonate’s physical needs, but also to address the family’s spiritual, religious, and existential needs. Recent studies show that intergenerational services should be offered and provide benefit for the entire family.
2. **Hospice care teams** are becoming more involved in the prenatal arena, such as for mothers with infants with known lethal anomalies, and give support while the infant is in utero and also in the NICU to address the process of dying and stages of grief for parents. See also Chapter 24 on palliative care.
3. **Multiple organizations are offering practice guidelines or direct help.** Some of these include: Pregnancy Loss and Infant Death Alliance, M.E.N.D. (Mommies Enduring Neonatal Death; www.mend.org), HAND (Helping After Neonatal Death), MISS Foundation (www.missfoundation.org), Now I Lay Me Down to Sleep (www.nowilaymedowntosleep.org), and others including at the local medical center level. The ATTEND model (attunement, trust, touch, egalitarianism, nuance, and death education) is an interdisciplinary paradigm for providers that is a mindfulness-based bereavement care model (Figure 57–1).
4. **Parental education.** Recent reviews have reported that parents appreciated education from the healthcare providers. Parents want to have information regarding why the infant died and also specific information on the grieving process. Parents have indicated that staff members who kept them informed and provided honest answers with consistent information were valued the most. *When Hello Means Goodbye* by Paul Kirk and Pat Schwiebert (www.griefwatch.com) is an often-recommended lay book that can help the family cope with the loss of an infant.
5. **Additional support.** Family members should be asked whether they need any support for transport or funeral arrangements and whether they need a note to the employer regarding time off from work and so on. Social workers or case workers are usually available to assist in these practical matters in the hospital setting. Questions regarding maternity leave benefits and returning to work can be answered. Some units offer a 24-hour dedicated telephone line for bereaved families.

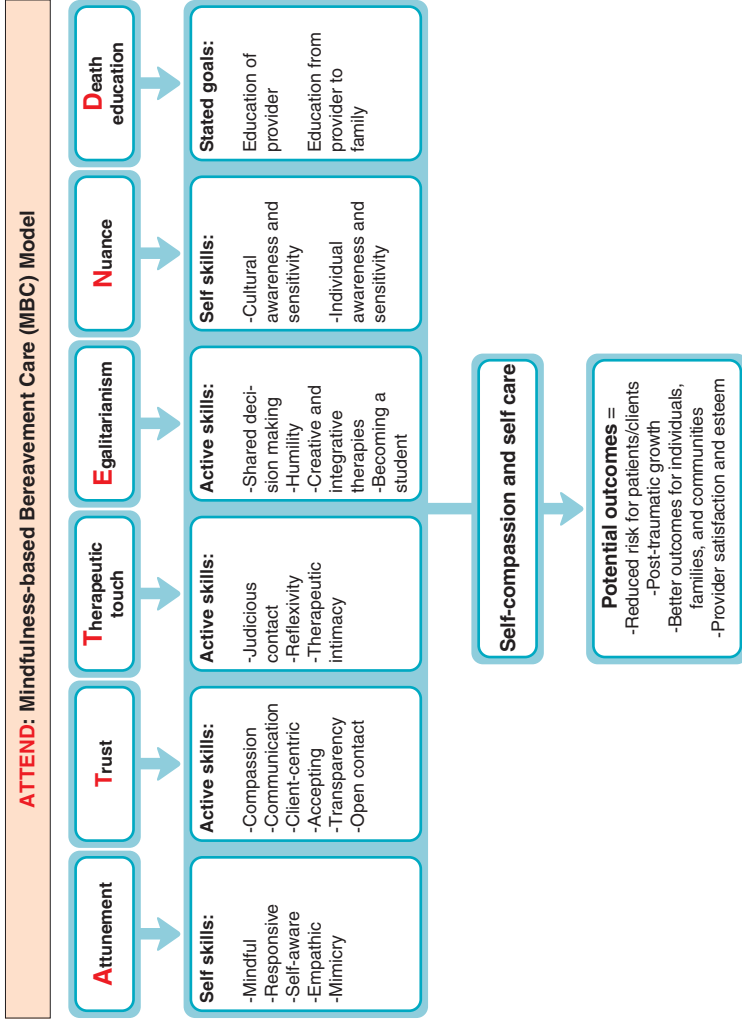

FIGURE 57-1. The ATTEND bereavement care model is useful in the setting of neonatal death. (Data from Cacciatore J, Flint M. ATTEND: toward a mindfulness-based bereavement care model. *Death Stud.* 2012 Jan;36(1):61-82.)

6. **Bereavement photography (also called “memento mori photography”).** Photographs were positively regarded by most parents after perinatal death. This includes pictures of the infant either alone or with family members done by staff, a professional photographer, or other organizations that help to ease the grief of NICU parents by taking professional photographs. These images can serve as a link to memories and feelings and help parents grieve and heal. Parents may wish to dress their baby in clothes or include mementos in the pictures. It is most important to respect the parents’ wishes. It is considered essential to obtain parental consent for any bereavement photograph.
 7. **Rituals.** Rituals provide an ordered way to say goodbye to a loved one. They can be beneficial to individuals and families who have experienced the death of a child. These can include funerals, memory boxes (with name bands, cord clamp, lock of baby’s hair, etc.), naming the baby, religious practices, and specific cultural traditions.
 8. **Written permission.** Should be obtained for the following: bereavement photography, obtaining mementos, autopsy, or biopsy of the deceased for any further inquiry.
 9. **Organ donation.** Occasionally, parents and immediate family members may have discussed organ donation before the death of the infant. If not, it can be brought up gently with the family, who will be given adequate time to reflect on it, taking into consideration the requirements for organ donation. Sometimes the parents may want to donate an organ, but this may not be possible because of the presence of infection or inadequate function of the organ before death. This should be explained carefully to the parents. Follow your institution’s defined procedure for discussing requests for organ procurement with the family.
 10. **Autopsy.** Autopsy can be a vital part of determining the cause of death and may be important in counseling the parents for future pregnancies. It is always a very sensitive issue to discuss with the parents, especially after the loss of their loved one. Parents should always be allowed adequate time to discuss this themselves and with the family if they have not already made up their minds. A recent study on bereaved parents’ perception on autopsy revealed that it is important to openly discuss the benefits of an autopsy; 90% of parents valued autopsy as a way to find out why their child died, and 77% knew it contributed to medical knowledge. Forty-two percent felt that the autopsy examination added to their grief, 30% found it a comfort, and 41% said it helped them with their loss.
 11. **Documentation (Figure 57–2).** Refer to local hospital guidelines for proper reporting of live births, infant deaths, fetal deaths, and induced terminations of pregnancy.
 - a. **Neonatal death summary note.** The physician may include a brief synopsis of the infant’s history or a problem list. The events leading up to the infant’s death that day, whether it was sudden or gradual, and the treatment or interventions performed must be noted. It is also important to note conversations with family members while the infant was dying, if not written earlier in separate notes.
 - b. **Death certificate.** The physician declaring the infant dead initiates the death certificate; it is important to obtain accurate information on state/country law to file the fetal death certificate according to the state/country requirements.
- E. Follow-up arrangements**
1. **Family contact.** A telephone call from a medical team member should be arranged within the first week of death. A letter of sympathy is strongly encouraged based on local policy. Another contact can be made at the end of the first month to comfort the family, share any further information, and answer questions. Some NICU teams may choose to make contact again at the 1-year anniversary.

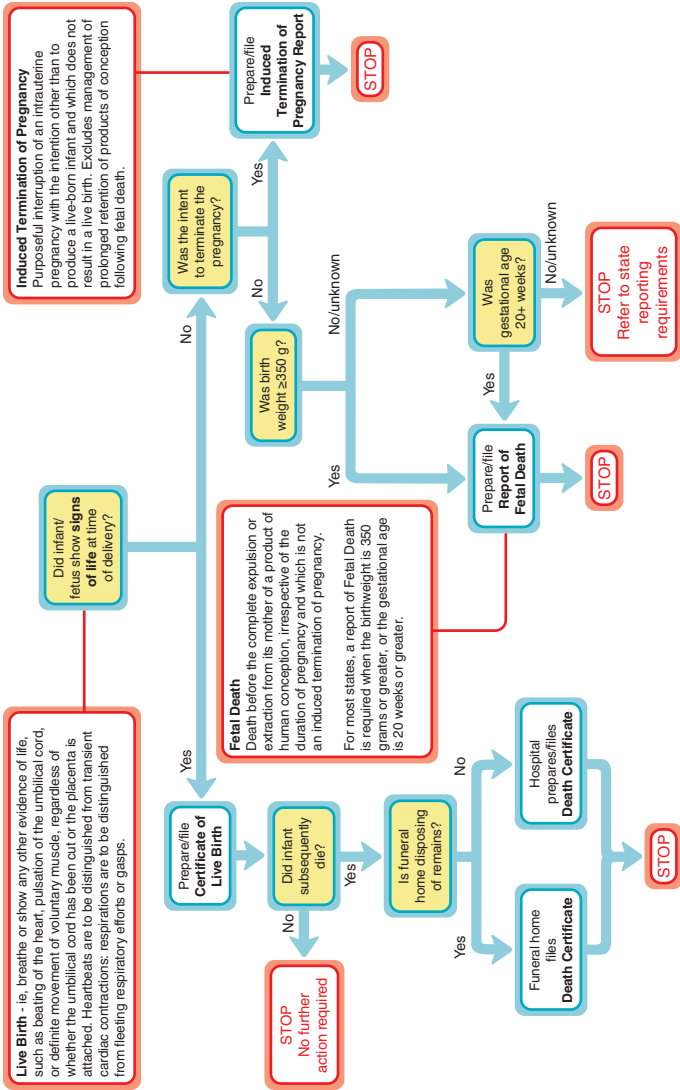

FIGURE 57-2. Hospital guidelines for reporting live births, infant deaths, fetal deaths, and induced terminations of pregnancy. (Reproduced with permission from Barfield WD; Committee on Fetus and Newborn; Standard Terminology for Fetal, Infant, and Perinatal Deaths, Pediatrics. 2016 May;137(5). pii: e20160551.)

2. **Counseling.** It is extremely important to discuss the arrangements for future counseling and refer the parents to high-risk obstetrics if appropriate. Genetic counseling may also be appropriate based on the specific case. Parents should be allowed to grieve for the death of their child and should be given the opportunity to contact the physician at a later date when they are more receptive emotionally. Siblings are at risk and may require psychological support. Recent study shows that having another child after infant loss may promote resilience, so parents should not be discouraged or asked to wait a certain amount of time if they choose to have another child.
3. **Autopsy follow-up.** If consent for autopsy has been obtained, an autopsy follow-up conference after approximately 6 to 8 weeks is essential. The presence of a geneticist at this follow-up may be appropriate. This autopsy conference not only provides the parents with concrete information but also assists in the process of grieving.
4. **The obstetrician, pediatrician, and family physician** involved with the care of the mother or family should be notified of the death.
5. **The needs of the caregivers also should be considered.** Dealing with grief, loss, and bereavement is one of the major stressors to the staff in the NICU setting. Several units have developed specific programs in this area, and resources should be made available to the staff as well. Some units have a palliative care team that receives specific training. They offer debriefing sessions for anyone in the NICU to attend.

58 Eye Discharge and Conjunctivitis

- I. **Problem.** A purulent eye discharge is noted in a 3-day-old infant. Eye discharge in a neonate is usually caused by neonatal conjunctivitis (also known as **ophthalmia neonatorum**) or **congenital nasolacrimal duct obstruction** (CNLDO or congenital dacryostenosis). **Neonatal conjunctivitis** (conjunctivitis occurring within the first 4 weeks of life) is an inflammation of the surface or covering of the eye that presents with eye discharge and hyperemia. It is the most common ocular disease in neonates. Etiology is chemical, bacterial, or viral. Most infections are acquired during vaginal delivery, but ascending infection can occur. In the United States, the incidence of infectious conjunctivitis is 1% to 2%, and in the world, it is 0.9% to 21%. Neonates with conjunctivitis require a thorough clinical and appropriate laboratory evaluation so appropriate treatment can be started as soon as possible if necessary. **CNLDO** is a membranous obstruction at the valve of Hasner, which is at the distal end of the nasolacrimal duct. Incidence is 6% to 20% in infants (studies show higher incidence in preterm infants when compared to full-term infants). The symptoms are persistent tearing and a mucoid discharge in the inner corner of the eye.
- II. **Immediate questions**
 - A. **How old is the infant?** Age may be helpful in determining the cause of eye discharge, noting that bacterial infections can occur anytime.
 1. **First day of life.** Conjunctivitis is most often due to ocular prophylaxis secondary to medications such as silver nitrate drops, tetracycline, erythromycin, gentamicin, povidone iodine solution, and chloramphenicol.
 2. **2 to 5 days old.** Conjunctivitis is most often due to *Neisseria gonorrhoeae* (but can present earlier with premature rupture of membranes).

3. **5 to 12 days old.** Conjunctivitis is most often due to *Chlamydia trachomatis*. It is usually seen during this time and can present as late as the second or third week.
 4. **5 to 14 days old.** Conjunctivitis is often due to other bacterial microbes. This includes pathogens from the skin, respiratory, gastrointestinal, or vaginal tract. See Table 58–3.
 5. **5 to 28 days old.** *Pseudomonas aeruginosa* infections are typical during this time.
 6. **6 to 14 days old.** Conjunctivitis can be due to herpes simplex virus (HSV).
 7. **2 weeks old.** CNLDO usually manifests at 2 weeks of age but can sometimes be seen in the first few days to the first few weeks after birth.
- B. Is the discharge unilateral or bilateral?** Typical symptoms are persistent tearing and a mucoid discharge in the inner corner of the eye.
1. **Unilateral conjunctivitis** is most often seen with *Staphylococcus aureus*, *P aeruginosa*, HSV, and adenovirus.
 2. **Bilateral conjunctivitis** is seen with infection caused by *N gonorrhoeae* or by the use of ocular prophylaxis.
 3. **Unilateral, then bilateral.** Chlamydia usually develops in 1 eye but affects the other after 2 to 7 days. Lacrimal duct obstruction usually causes unilateral discharge, but up to 20% of infants have bilateral obstruction.
- C. What are the characteristics of the discharge (eg, purulent, serous, greenish)?**
1. **Purulent discharge:** More common with bacterial infection. Gonorrhea has a classic profuse purulent discharge.
 2. **Serous discharge:** More common with a viral infection.
 3. **Greenish discharge:** More characteristic of *P aeruginosa*.
 4. **Serosanguinous (light/pale red) discharge:** Watery with a mixture of serum and blood can be seen with herpes conjunctivitis. Nonpurulent discharge can also be seen with herpes.
 5. **Watery early, purulent later** (may be blood stained): Chlamydial infection.
 6. **Watery tears or mucus or yellow discharge in eye: CLNLDO** can cause watery tears in the corner of the eye or tears draining from the eyelid down the cheek. It can also cause mucus or yellowish discharge in the eye.
- D. Did the infant receive eye prophylaxis, and was it properly given?** Ocular prophylaxis against gonococcal ophthalmia neonatorum is used to prevent gonorrheal infection (prevent blindness), and certain prophylactic agents (silver nitrate, povidone-iodine, and erythromycin) prevent **nongonococcal and nonchlamydial conjunctivitis** during the first 2 weeks of life. The majority of medical groups recommend prophylactic ocular topical medication for all newborns for the prevention of gonococcal ophthalmia neonatorum (Table 58–1). Various conjunctivitis prophylactic regimens are presented in Table 58–2. Infants can still get gonococcal conjunctivitis with prophylaxis, but the risk drops from 50% to 2%. **Gonorrheal ophthalmia neonatorum prophylaxis is mandatory in the United States** but may not be in other countries (eg, Denmark, Norway, Sweden, Great Britain, Belgium, Australia, The Netherlands). A reevaluation of the mandatory prophylaxis is being considered by the American Academy of Pediatrics (AAP) because of improved prenatal screening, testing at the time of delivery, and maternal treatment to prevent exposure to the neonate, especially in areas where the maternal infection is low. There is concern that some strains of gonorrhea have shown resistance to erythromycin.
1. **Proper ocular administration technique is as follows:** Give shortly after birth or within 1 hour of birth (to facilitate parent–infant bonding), whether cesarean or vaginal delivery.
 - a. **For the term infant,** wipe each eyelid with sterile cotton or gauze; instill the prophylactic agent (single-dose tubes or ampules preferred, 1-cm ribbon of ointment or 2 drops of solution) in each of the lower conjunctival sacs. Massage the eyelids gently to spread the agent. Wipe away any excess ointment after 1 minute. Do not irrigate or flush the eyes.

Table 58–1. SOCIETY AND ORGANIZATION RECOMMENDATIONS FOR OPHTHALMIC NEONATORUM PROPHYLAXIS

AAP	Universal prophylaxis of all newborns shortly after birth with 0.5% ophthalmic erythromycin ointment. Erythromycin is the only antibiotic ointment recommended. If not available, see AAP alternative recommendations.
USPSTF	All newborns within 24 hours after birth: 0.5% erythromycin ophthalmic ointment, 1% silver nitrate solution, 1% tetracycline ointment. All equally effective but latter 2 not available in the United States.
CDC	All newborns as soon as possible after birth. Erythromycin 0.5% ophthalmic ointment in each eye single application. If not available, in infants at risk for <i>Neisseria gonorrhoeae</i> , give ceftriaxone 25–50 mg/kg intravenously or intramuscularly (125-mg maximum single dose).
CPS	Erythromycin ocular prophylaxis may no longer be useful and should not be routinely recommended. The CPS recommends maternal screening over eye prophylaxis. If prophylaxis must be given (based on territorial regulations), use erythromycin ophthalmic ointment 0.5%.
WHO	For all infants, topical application to both eyes immediately after birth. WHO suggests 1 of the following: erythromycin 0.5% eye ointment, tetracycline hydrochloride 1% eye ointment, silver nitrate 1% solution, povidone-iodine 2.5% solution (water based); do not use alcohol-based povidone-iodine solution or chloramphenicol 1% eye ointment.

AAP, American Academy of Pediatrics (<https://redbook.solutions.aap.org/chapter.aspx?sectionid=88187322&bookid=1484>); CDC, Centers for Disease Control and Prevention (<https://www.cdc.gov/std/tg2015/gonorrhea.htm#op-neo>); CPS, Canadian Pediatric Society (<https://www.cps.ca/en/documents/position/ophthalmia-neonatorum>); USPSTF, US Preventive Services Task Force (<https://www.uspreventiveservicestaskforce.org/Page/Document/UpdateSummaryFinal/ocular-prophylaxis-for-gonococcal-ophthalmia-neonatorum-preventive-medication>); WHO, World Health Organization (<http://apps.who.int/medicinedocs/en/d/Jh2942e/4.1.3.html>).

- b. For the very premature infant** with fused eyes, apply the prophylactic agent without separating the eyelids.
- 2. Agents used for infectious prophylaxis:** 0.5% erythromycin ophthalmic ointment, 2.5% povidone-iodine solution, 1% silver nitrate solution, and 1% tetracycline ophthalmic ointment.
 - a. 0.5% erythromycin ophthalmic ointment.** A 1-cm ribbon is given in each eye. AAP, Centers for Disease Control and Prevention (CDC), and US Preventive Services Task Force (USPSTF) recommend only erythromycin ophthalmic ointment for prophylaxis, and it is the only approved agent in the United States. It causes less chemical conjunctivitis than other agents such as silver nitrate. There is some concern for *N gonorrhoeae* strains being resistant to erythromycin.
 - b. 1% silver nitrate solution.** This is recommended over erythromycin if the patient population has a high number of penicillinase-producing *N gonorrhoeae*. It is highly irritating and frequently causes a chemical conjunctivitis (see later in chapter). It is not available in the United States but is used elsewhere. The World Health Organization (WHO) recommends 2 drops in each eye.
 - c. 1% tetracycline ophthalmic ointment** is as effective as silver nitrate but is not available in the United States.
 - d. 2.5% povidone-iodine ophthalmic solution (water based; do not use alcohol-based solution)** is widely available, low cost, and effective. It is used in

Table 58–2. AGENTS FOR CONJUNCTIVITIS PROPHYLAXIS

Medication	Form	Concentration	Frequency	Class	Indication	Side Effects	Availability	Organizations That Recommend Agent
Erythromycin	Ophthalmic ointment	0.50%	1 time	Macrolide antibiotic	Prophylaxis of gonococcal ophthalmia neonatorum	Contact dermatitis ^a	Global	AAP, CDC, USPSTF, WHO
Silver nitrate	Ophthalmic solution	1%	1 time	Astringent	Prophylaxis of gonococcal ophthalmia neonatorum	Contact dermatitis	Not in United States	USPSTF, WHO
Tetracycline	Ophthalmic ointment	1%	1 time	Tetracycline antibiotic	Prophylaxis of gonococcal ophthalmia neonatorum	Contact dermatitis	Not in United States	USPSTF, WHO
Povidone-iodine	Ophthalmic solution	1.25%, 2.5%	1 time	Antiseptic	Prophylaxis of gonococcal ophthalmia neonatorum	Contact dermatitis	Global	WHO
Chloramphenicol	Ophthalmic solution	0.50%	1 time	Synthetic antibiotic	Prophylaxis of gonococcal ophthalmia neonatorum	Contact dermatitis	Not in United States	WHO

AAP, American Academy of Pediatrics; CDC, Centers for Disease and Prevention; USPSTF, US Preventive Services Task Force; WHO, World Health Organization.

Note. Routine prophylaxis with topical antibiotics carries the risk of resistance, especially in patients with ophthalmia neonatorum due to gonococcal infection. Povidone-iodine as a topical anti-infective appears to be an effective and cheap alternative. Further epidemiologic research and monitoring on the incidence of ophthalmia neonatorum and the prevalence of the various agents in different parts of the world are needed, so that prevention and treatment can be adjusted accordingly and experience with new options can be analyzed for wide use. See <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2566367>.

^aContact dermatitis side effects include blurred vision, eye irritation, eyelid erythema and edema, conjunctival hyperemia, and punctate keratitis.

developing countries and is not available in the United States. Some data suggest that povidone-iodine is more effective against *C trachomatis* than silver nitrate or erythromycin. There are 3 doses available (5%, 2.5%, and 1.25%); 5% is used for preoperative use. The 2.5% solution is most commonly used. **Note:** Use the ophthalmic solution and not the detergent version of povidone-iodine, which can damage the cornea.

- e. **Other topical agents that have been used when erythromycin is not available.** Recommended backup agents per the AAP *Red Book* include the following:
 - i. **Use first:** Azithromycin ophthalmic solution 1%; 1 to 2 drops are placed in each conjunctival sac. Note this is not an ointment but a solution, so care must be used when placing these drops. CDC recommendations for this medication: 2 people are required to administer this medication. One person holds the lids open, while the other instills the drops.
 - ii. **Use second:** Either gentamicin ophthalmic ointment 0.3% or tobramycin ophthalmic ointment 3%.
 - iii. **Use last:** Ciprofloxacin ophthalmic ointment 0.3% is generally not recommended because of high gonococcal resistance.
 - f. **Fatty acid–based formulas** (monocaprin and myristoleic acid), which are bactericidal against virulent bacteria and effective against *S aureus*, are being studied for prevention of ophthalmia neonatorum.
3. **Society and organization recommendations** for ophthalmic neonatorum prophylaxis can be found in Table 58–1.
- E. **Does the mother have a history of sexually transmitted infections?** Infants who pass through the birth canal of an infected mother with gonorrhea or chlamydia have an increased conjunctivitis risk. Neonatal conjunctivitis is frequently diagnosed in infants born to human immunodeficiency virus (HIV)-infected mothers.
- F. **Is the infant at high risk?**
1. **Conjunctivitis.** Neonates are at increased risk for conjunctivitis and more serious cases of conjunctivitis because of decreased tear production, lack of immunoglobulin A (IgA) in tears, decreased immune function, absence of lymphoid tissue of the conjunctiva, and decreased lysozyme activity. Risk factors may include mode of delivery, exposure of the infant to infectious organisms, no or inadequate prophylaxis after birth, ocular trauma/local eye injury during delivery, poor hygienic conditions, premature rupture of membranes, prolonged delivery, prematurity, mechanical ventilation, increased birthweight, history of midwife interference, HIV-infected mother, poor prenatal care, documented or suspected sexually transmitted infection, infection after delivery from direct contact from health care worker, or aerosolization. **Performing red reflex examinations** increases the rate of neonatal conjunctivitis.
 2. **Congenital nasolacrimal duct obstruction.** Neonates are at an **increased risk for CNLDO** if they have Down syndrome, Goldenhar sequence, clefting syndromes, any midline facial anomaly, hemifacial microsomia, or craniosynostosis.
- G. **Is the infant low birthweight and low gestational age?** An infant with conjunctivitis who has a low birthweight and low gestational age has a higher risk of having a conjunctivitis caused by a **gram-negative organism** (*Klebsiella* spp., *Escherichia coli*, *Serratia marcescens*, *P aeruginosa*, and *Enterobacter* spp.). Premature infants have an increased risk of CNLDO.
- III. **Differential diagnosis.** As noted, eye discharge in the neonate most commonly is caused by **conjunctivitis** (chemical/inflammatory, bacterial, or viral) or is due to an **obstruction** (CNLDO). **Other less common diagnoses that may cause an eye discharge in an infant** are foreign body, orbital or preseptal cellulitis, entropion, trichiasis, eye trauma (corneal abrasion following delivery), dacryocystitis, infectious keratitis, subconjunctival hemorrhage (breakage of vessels during delivery), vitreous hemorrhage (associated with

Table 58–3. COMMON CAUSES OF INFECTIOUS AND NONINFECTIOUS CONJUNCTIVITIS IN THE NEONATE

Chemical	Viral	Bacterial Gram Negative	Bacterial Gram Positive
Silver nitrate (most common)	Herpes simplex virus Adenovirus <i>Enterovirus</i>	<i>Chlamydia trachomatis</i> <i>Neisseria gonorrhoeae</i> <i>Pseudomonas aeruginosa</i>	<i>Staphylococcus aureus</i> <i>Staphylococcus epidermidis</i>
Povidone-iodine solution	<i>Parechovirus</i> Zika virus (perinatal transmission)	<i>Klebsiella pneumoniae</i> <i>Escherichia coli</i>	<i>Streptococcus pneumoniae</i>
Tetracycline		<i>Serratia marcescens</i>	<i>Streptococcus viridans</i>
Gentamicin	Chikungunya (perinatal transmission)	<i>Enterobacter</i> spp.	Methicillin-resistant
Erythromycin		<i>Haemophilus influenzae</i>	<i>S aureus</i> (MRSA)
Chloramphenicol		<i>Neisseria mucosa</i> <i>Proteus</i> spp. <i>Neisseria cinerea</i> <i>Eikenella corrodens</i> <i>Acinetobacter baumannii</i> <i>Moraxella catarrhalis</i> <i>Neisseria meningitidis</i> <i>Stenotrophomonas maltophilia</i>	<i>Streptococcus haemolyticus</i> <i>Streptococcus mitis</i> <i>Streptococcus marcescens</i> Group A and B <i>Streptococcus</i> <i>Corynebacterium</i> spp.

thrombocytopenia and polycythemia), congenital anomalies of the nasolacrimal system, corneal epithelial disease, neonatal abstinence syndrome (lacrimation), and congenital glaucoma. Common causes of infectious and noninfectious conjunctivitis can be found in Table 58–3.

A. Chemical/inflammatory conjunctivitis. Usually secondary to silver nitrate ocular drops (causes a transient chemical conjunctivitis in 50%–90% of infants) and is the most common cause of conjunctivitis in underdeveloped countries. **The incidence of chemical/inflammatory conjunctivitis has decreased in the United States since silver nitrate drops are no longer being used.** Chemical conjunctivitis can occur from all the other prophylactic ocular antibiotics but less often. It is a nonpurulent inflammation of the eye with a watery discharge, conjunctival injection, and swelling within several hours of instilling the medication. The conjunctivitis shows a maximum inflammatory response around 48 hours and usually clears by the third or fourth day.

B. Infectious conjunctivitis. (See Table 58–3.) Infectious conjunctivitis in the newborn is caused by either a bacteria or virus. Causes and their incidence include *C trachomatis* (2%–40%), *N gonorrhoeae* (<1%), *P aeruginosa* (<1%), HSV (<1%), and other bacterial microbes (30%–50%). Common gram-negative organisms are *Klebsiella* spp. (23%), *E coli* (17%), *S marcescens* (17%), *P aeruginosa* (3%), *Enterobacter* spp. (2%), and *Haemophilus influenzae*. Gram-negative isolates cause 38% of conjunctivitis in the neonatal intensive care unit (NICU). Look for a gram-negative etiology in a very low birthweight infant with low gestational age in the NICU. The most common viral cause is herpes, with others including adenovirus, *Enterovirus*, and *Parechovirus*.

1. Mechanisms of infection

a. Infections acquired through an infected maternal genital tract during birth are typically *N gonorrhoeae*, *C trachomatis*, group B streptococci, or HSV. They tend to reflect sexually transmitted infections in the community. Any bacteria that are normally present in the vagina (not sexually transmitted) can also cause neonatal conjunctivitis.

neuritis, chorioretinitis, cataracts encephalitis, and permanent vision impairment and is the most frequent viral cause of conjunctivitis. The conjunctivitis can be superficial or may involve the deeper layers of the cornea; vesicles may appear on the nearby skin (80% of infants with SEM have skin vesicles). The infants can have lid edema, conjunctival injection, and a watery nonpurulent discharge. A conjunctival membrane may be present. Most of these infections are secondary to HSV-2 sexually transmitted infection (maternal genital tract ascending infection, through the birth canal, or by transplacental mechanisms); 15% to 20% are caused by HSV-1. Suspect herpes if the conjunctivitis is not responding to antibiotic therapy. Most neonatal HSV-1 infections are related to contact with someone with an active infection (fever blister or cold sore) in the perinatal period.

6. **Viral causes (other than herpes).** Infection usually occurs through direct contact, through contamination of the hands, or via respiratory tract spread. These are usually associated with other symptoms of respiratory tract disease due to adenovirus (most common), *Enterovirus*, or *Parechovirus*. There is usually redness, and it is more commonly unilateral. Infants with adenovirus can have petechial hemorrhages. The discharge is usually mild and watery and is rarely purulent. Lymphadenopathy and preauricular adenopathy can be seen in approximately 50% of cases. Epidemic keratoconjunctivitis from adenovirus can occur by direct contact or from equipment during an eye examination. The CDC site states that Zika virus can cause a conjunctivitis when an infant acquires the infection perinatally (from women who become infected within 2 weeks of delivery). Perinatal transmission of chikungunya virus can also cause conjunctivitis.
 7. **Other bacterial infections (nongonococcal, nonchlamydial).** (See Table 58–3.) Conjunctivitis can be caused by other microbial agents (not listed earlier), and these usually present as a **milder form of conjunctivitis**. There may be conjunctival injection, chemosis, and a discharge. Infections caused by *Haemophilus* spp. and *Streptococcus pneumoniae* are associated with **dacryocystitis** (inflammation of the nasolacrimal sac). Staphylococcal conjunctivitis is usually a nosocomial infection. It is the most frequent isolate but may not be a cause of conjunctivitis in infants who are colonized and can cause mild conjunctival hyperemia. Methicillin-resistant *S aureus* conjunctivitis can also occur and has been associated with nurseries and NICUs.
- C. **Congenital nasolacrimal duct obstruction (dacryostenosis) occurs in approximately 5% to 20% of infants.** The nasolacrimal duct may fail to canalize completely at birth, and the obstruction is usually at the nasal end of the duct (distal nasolacrimal duct). It is usually unilateral. The symptoms are persistent tearing and a mucoid discharge in the inner corner of the eye. One in 5 infants may have transient discharge (watery and sticky, particularly after sleep) due to a delay in the normal development and opening of the tear duct that resolves spontaneously. CNLDO is the most common of the lacrimal duct anomalies in congenital rubella syndrome. **Dacryocystitis** is a secondary infection in the lacrimal sac.

IV. Database

A. Physical examination

1. **Ophthalmic examination.** Examine both eyes/eyelids for swelling and edema, and check the conjunctiva for injection (congestion of blood vessels) and chemosis (conjunctival swelling). A purulent discharge, edema, and erythema of the lids and injection of the conjunctiva are suggestive of bacterial conjunctivitis. Check for ulcerations and the presence of a red reflex.
2. **Perform a complete physical examination** to rule out signs of respiratory or systemic infection. Evaluate for any adenopathy.

B. Laboratory studies

1. **Gram-stained smear of the exudate discharge** to check for white blood cells (WBCs) (a sign of infection) and bacteria (to identify the organism). **A sample**

of the discharge should also be submitted for culture and sensitivity testing (chocolate agar and/or Thayer-Martin agar for *N gonorrhoeae* and blood agar for other bacteria). Typical findings on Gram stain:

- a. ***N gonorrhoeae* conjunctivitis.** Gram-negative intracellular diplococci (kidney bean shaped) and increased WBCs (neutrophils). **Note:** A presumptive diagnosis can be made based on the Gram stain, but remember that other nonpathogenic *Neisseria* species and *Moraxella catarrhalis* can look like *N gonorrhoeae* on Gram stain, so it is best to support the diagnosis with a culture.
 - b. ***S aureus* conjunctivitis.** Gram-positive cocci in clusters and WBCs.
 - c. ***P aeruginosa* conjunctivitis.** Gram-negative bacilli and WBCs.
 - d. **Conjunctivitis caused by *Haemophilus* spp.** Gram-negative coccoid rods.
 - e. **Streptococcal or enterococci.** Streptococci are gram-positive spherical cocci, and enterococci are gram-positive lancet-shaped encapsulated diplococci.
 - f. **Other gram-positive organisms.** *S pneumoniae*, *Streptococcus viridans*, *S epidermidis*, group A and B streptococci, and *Corynebacterium* species.
 - g. **Other gram-negative organisms.** *E coli*, *Klebsiella pneumoniae*, *S marcescens*, *Proteus*, *Enterobacter*, *H influenzae*, *Acinetobacter*, *P aeruginosa*, *Neisseria cinerea*, *M catarrhalis*, *Eikenella corrodens*, and *Stenotrophomonas maltophilia*.
 - h. **Herpes simplex.** See lymphocytes, plasma cells, and multinucleated giant cells.
 - i. ***C trachomatis*.** Difficult to stain but classified as gram negative, typically coccoid or rod shaped bacteria. Neutrophils, lymphocytes, and plasma cells.
 - j. **Chemical conjunctivitis.** Neutrophils and lymphocytes (occasionally).
 - k. **CNLDO.** The Gram stain is negative, or there is normal conjunctival flora unless there is a secondary infection.
2. **If a chlamydial infection is suspected, methods to diagnose chlamydia ophthalmia** include:
 - a. **Culture identification of the organism (gold standard)** by a conjunctival swab specimen with 100% specificity and sensitivity. A result can be obtained after 48 to 72 hours.
 - b. **Nonculture testing**
 - i. **Antigen detection methods** include direct fluorescent antibody (DFA) and enzyme immunoassay (EIA) tests. DFA is the only US Food and Drug Administration (FDA)-approved nonculture test for chlamydia conjunctivitis in the neonate. An example of one such platform is the commercially available Pathfinder Chlamydia DFA (Bio-Rad Laboratories, Hercules, CA).
 - ii. **Nucleic acid amplification tests, which use a method of amplifying *C trachomatis* DNA or RNA sequences.** Nucleic acid amplification tests (NAATs) are not FDA approved for use in conjunctivitis in infants but can be used if available through a Clinical Laboratory Improvement Amendments–certified laboratory. Some believe that NAAT has higher sensitivity and specificity than the DFA assays and may actually outperform culture results.
 - c. **To obtain the swab specimen,** use a Dacron-tipped swab or swab from the manufacturer (do not use calcium alginate or wood shafted swabs) and evert the eyelid; then swab the everted eyelid to obtain conjunctival cells. The exudate is not adequate for the test.
 3. **If herpes is suspected.** Historically a histologic exam of lesions for multinucleated giant cells and eosinophilic intranuclear inclusions was performed (Tzanck smear), but is no longer recommended due to low sensitivity. Recommended test is the cell culture of swab specimens (surface and other), skin vesicles, and cerebrospinal fluid (CSF). HSV polymerase chain reaction (PCR) assay can be done on all the specimens including whole blood sample (a positive result does not mean disseminated disease) but has not been studied in neonates. Rapid

diagnostic techniques such as DFA and EIA are available but less sensitive than cultures. A rapid culture test, ELVIS ID HSV test system (Quidel Corporation, San Diego, CA), is available.

4. **In gonococcal infection, cell culture is the most widely used test for nongenital sites.** NAATs are not FDA approved for *N gonorrhoeae* testing on nongenital sites.
5. ***Pseudomonas* infection.** Suspect based on Gram stain and send culture of the exudate.

C. **Imaging and other studies.** Imaging tests usually do not have a role in the workup of conjunctivitis but neuroimaging may be done in herpes conjunctivitis.

1. **Blot test for nasolacrimal duct obstruction.** Apply gentle digital pressure over the lacrimal sac. If there is moisture, it indicates an obstruction. If there is a mucopurulent reflux (positive blot test) from the punctum, this suggests a complete obstruction.
2. **Fluorescein dye disappearance test.** Best test to rule out CNLDO. Instill 1 drop of 0.5% proparacaine followed by 1 drop of 2% fluorescein/moistened fluorescein strip into the lower conjunctiva of each eye. Wipe away any excess dye. After 5 to 10 minutes, evaluate if any dye is still present. If there is significant dye present in the eye and failure of the dye to appear in the nose after 10 to 15 minutes, then an obstruction may exist. If the dye disappears, then there is no obstruction. Alternatively, dim the room and use a cobalt blue light or Burton lamp to see if the dye is still present.
3. **Slit lamp examination with fluorescein staining by an ophthalmologist.** Can help differentiate viral versus bacterial conjunctivitis. With viral one can see conjunctival follicles, with bacterial one can see papillae. One will see dendritic keratitis with HSV keratitis.
4. **Tests for viral conjunctivitis.** Viral cell culture with immunofluorescence assay and PCR. Rapid antigen testing (Adeno Plus, Rapid Pathogen Screening, Inc.) is available for adenovirus.

V. **Plan.** Complications (perforation of the cornea, blindness, *Chlamydia* pneumonia, sepsis, meningitis) can be severe, so it is important to treat as soon as possible. **Do not wait for the culture results to treat the infant.** Send the culture, and based on the Gram stain, start empirical treatment,

A. **Important facts in the management of conjunctivitis**

1. **Infection can spread easily from one eye to another** or to other people by touching the eye or drainage. Proper and frequent hand washing and wearing gloves are essential. **Isolation is recommended for gonococcal, herpes, and *Pseudomonas* conjunctivitis.** See Appendix F for specific isolation guidelines.
2. **Drainage is contagious for 24 to 48 hours** after beginning treatment.
3. **Irrigate eye with sterile isotonic saline** to remove accumulated purulent drainage.
4. **Systemic treatment is required for gonococcal, *Chlamydia*, *Pseudomonas*, and herpetic conjunctivitis.** Some recommend systemic treatment for *H influenzae* conjunctivitis since it is often associated with otitis media or other severe infections such as sepsis and meningitis. **Topical and systemic treatment** is recommended for *Pseudomonas* and herpes infection.
5. **Avoid eye patching.**
6. **Consultation with a pediatric ophthalmologist or pediatric infectious disease specialist should be considered.**
7. **Evaluate for signs of systemic disease.** Infants with conjunctivitis are at risk for secondary infections such as sepsis, meningitis, and pneumonia.
8. **Follow daily for signs of improvement** or worsening.
9. **Breast milk/colostrum to treat conjunctivitis.** Colostrum and breast milk contain antimicrobial and anti-inflammatory properties and have been used to treat conjunctivitis or mucopurulent discharge from nasolacrimal duct obstruction.

Colostrum is more effective than mature breast milk because it contains leukocytes and has higher concentrations of antibodies, especially IgA. Studies suggest that the use of breast milk or colostrum is safe, has no side effects, and may help as a treatment for blocked tear ducts and that the use of colostrum may be effective against certain type of infections. However, because evidence is limited and studies are conflicting, this treatment is not recommended. Preventive effects of colostrum (2 drops in each eye) against neonatal conjunctivitis have been documented when compared to no prophylaxis.

- B. Chemical conjunctivitis.** Observation only is needed because this usually resolves within 2 to 4 days. Lubrication with artificial tears (4 times a day) may be helpful.
- C. Gonococcal conjunctivitis.** This is considered an emergency, as it can result in perforation of the globe, corneal scarring, and blindness. Because of the high prevalence of penicillin-resistant *N gonorrhoeae*, the treatment is not penicillin but a third-generation cephalosporin (eg, ceftriaxone). **Note:** Gonococcal conjunctivitis can occur even with appropriate eye prophylaxis in infants delivered to mothers with positive maternal gonococcal infection.
- 1. Infants with evidence of gonococcal conjunctivitis, scalp abscess, or disseminated infection** need to be hospitalized.
 - 2. Isolate the infant during the first 24 hours** of parenteral antibiotic therapy. Both **mother and partner need full medical examinations and treatment** for *N gonorrhoeae*. Mother cannot visit the baby, breast feed, or room-in until she receives 24 hours of antibiotics.
 - 3. Evaluate for disseminated disease if the infant has gonococcal ophthalmia** (arthritis, meningitis, sepsis, scalp abscess caused by scalp electrodes from fetal monitoring). Cultures should include blood, eye discharge, CSF, joint aspirate, and any other sites, as noted earlier. Conjunctival exudates need to be cultured for *N gonorrhoeae* and tested for antibiotic susceptibility.
 - 4. Tests for concomitant infection** with *C trachomatis*, congenital syphilis, and HIV. The mother and her sexual partner should also be evaluated and presumptively treated for gonorrhea. Check maternal hepatitis B surface antigen results. Do not treat empirically for chlamydia unless the test comes back positive.
 - 5. Parenteral antibiotics.** Ceftriaxone is the preferred antibiotic treatment because of the high frequency of penicillin-resistant *N gonorrhoeae*. **Ceftriaxone is not recommended** in a neonate with hyperbilirubinemia or in a neonate receiving or planning on receiving calcium-containing intravenous (IV) fluids. Ceftriaxone can displace bilirubin from binding to serum albumin, possibly causing bilirubin encephalopathy. **Cefotaxime is recommended in any infant** with hyperbilirubinemia and in infants on calcium-containing IV fluids.
 - 6. For uncomplicated gonococcal conjunctivitis (without dissemination)**, administer a single dose of ceftriaxone 25 to 50 mg/kg IV or intramuscularly (IM) (up to a maximum of 125 mg). **WHO recommends** 1 of the following: ceftriaxone (50 mg/kg IM single dose [maximum 150 mg]), kanamycin (25 mg/kg IM single dose [maximum 756 mg]), or spectinomycin (25 mg/kg IM single dose [maximum 75 mg]).
 - 7. For gonococcal conjunctivitis with dissemination (arthritis, septicemia) and scalp abscess**, ceftriaxone 25 to 50 mg/kg IV or IM may be given once every day for 7 days. An alternative therapy is cefotaxime (recommended for hyperbilirubinemic infants or infants receiving calcium-containing IV fluids) at 25 mg/kg every 12 hours, given IV or IM for 7 days. If **meningitis is present**, treatment should be given for a total of 10 to 14 days.
 - 8. Healthy infants (no conjunctivitis) born to mothers with untreated or inadequately treated gonococcal infection.** These infants are treated with systemic antibiotics because gonococcal ophthalmia or disseminated infection can occur. A single dose of ceftriaxone (25–50 mg/kg IV or IM; not to exceed 125 mg) is

given. Topical antimicrobial therapy is not necessary if systemic therapy has been given.

9. **Irrigate the eyes with sterile isotonic saline (normal saline) solution** immediately and at frequent intervals (every 1–2 hours) to remove mucopurulent discharge until clear. **Topical antibiotics are not necessary** when systemic antibiotics are used and are only recommended when a corneal ulcer is present. Use topical atropine if there is corneal involvement.
 10. **Pediatric ophthalmologic consultation** is usually requested because gonococcal ophthalmia can lead to corneal perforation and blindness. **Infectious disease consultation** is usually requested also to help manage the infant.
- D. **Chlamydial conjunctivitis.** Evaluate for systemic disease (pneumonia, otitis, pharyngeal and rectal colonization). Pneumonia has been reported in 20% of infants with chlamydial conjunctivitis.
1. **Recommended neonatal prophylaxis** does not prevent neonatal chlamydial conjunctivitis, extraocular infection, or nasopharyngeal colonization.
 2. **Topical treatment with antibiotics** is ineffective and unnecessary when systemic therapy is given, but some institutions use erythromycin drops (4 times a day).
 3. **Oral erythromycin base or ethylsuccinate**, 50 mg/kg/d, in 4 divided doses for 14 days by mouth, is recommended. Azithromycin suspension (20 mg/kg/d for 3 days) is an alternative regimen. A second course of erythromycin is sometimes required because approximately 20% of cases recur after therapy because erythromycin is only about 80% effective. **Infantile hypertrophic pyloric stenosis (IHPS) has been seen in infants <6 weeks old (especially <2 weeks) treated with erythromycin. It has been seen with azithromycin, but the risk is unknown.** These infants should be followed and parents should be counseled about the risk and signs of IHPS. The AAP still recommends erythromycin because other treatments have not been well studied. **WHO recommends azithromycin** (20 mg/kg/d orally; 1 dose daily for 3 days) over erythromycin.
 4. **Infants born to mothers with untreated chlamydia are at high risk for infection.** Prophylactic antibiotic treatment is not indicated. Monitor for infection. If adequate follow-up is not possible, treatment should be considered.
 5. **Treat the mother and sexual partner** if the infant has *C trachomatis* infection.
- E. ***Pseudomonas conjunctivitis***
1. **Isolate the patient and implement standard precautions** unless infection is resistant, in which case contact precautions are indicated.
 2. **Evaluate for systemic disease because superficial infection can progress rapidly to serious systemic infection (sepsis, meningitis).** Infants with low birth-weight and lower gestational age have an increased risk for systemic disease. *Pseudomonas* infection can lead to devastating consequences: corneal ulceration and perforation, endophthalmitis, blindness, serious systemic infection, and subsequent death.
 3. **Parenteral therapy is recommended** because *Pseudomonas* is a virulent organism. Use an aminoglycoside for a minimum of 10 to 14 days. Systemic therapy with an antipseudomonal β -lactam may also be indicated.
 4. **Topical therapy is required because systemic antibiotics have poor penetration in the eye.** Treat with topical therapy for 2 weeks with an aminoglycoside, such as gentamicin ophthalmic ointment or tobramycin ophthalmic ointment/solution. Some will treat with ciprofloxacin ophthalmic ointment/solution because gentamicin and tobramycin can cause a chemical conjunctivitis. See doses in Table 58–4.
 5. **Ophthalmology consultation** is critical because the infection may be devastating. **Infectious disease consult** may also be helpful, especially with *Pseudomonas* meningitis. For *Pseudomonas* meningitis, careful follow-up is recommended (check for hearing loss, developmental delay, and neurologic abnormalities).

Table 58–4. COMMON TOPICAL AGENTS TO TREAT CONJUNCTIVITIS

Medication	Form	Concentration	Frequency	Class	Indication	Side Effects
Acyclovir	Ophthalmic ointment	3%	3–6 times daily	Antiviral	Not currently commercially available	Contact dermatitis ^a
Bacitracin	Ophthalmic ointment	500 U/g	3–6 times daily	Polypeptide antibiotic	Gram-positive organisms such as staphylococci (including some penicillin-resistant staphylococci), streptococci, anaerobic cocci, corynebacteria, and clostridia	Contact dermatitis
Chloramphenicol	Ophthalmic solution	0.50%	3–6 times daily	Synthetic antibiotic	Aerobic gram-positive bacteria and many gram-negative aerobic bacteria	Contact dermatitis
Ciprofloxacin	Ophthalmic ointment or solution	0.30%	3–6 times daily	Fluoroquinolone antibiotic	Most gram-negative aerobic bacteria and many gram-positive aerobic bacteria including <i>Pseudomonas</i> and <i>methicillin-resistant Staphylococcus</i>	Contact dermatitis
Erythromycin	Ophthalmic ointment	0.50%	3–6 times daily	Macrolide antibiotic	Gram-positive cocci (staphylococci and streptococci) and gram-positive bacilli. Erythromycin also effective against some gram-negative cocci (<i>Neisseria</i> spp.) and some gram-negative bacilli including some <i>H. influenzae</i> and <i>Moraxella lacunata</i> . Erythromycin also active against <i>Chlamydia</i> and <i>Treponema</i> .	Contact dermatitis
Ganciclovir	Ophthalmic gel	0.15%	5 times daily	Antiviral	Herpetic keratitis caused by herpes simplex virus (HSV) type 1 or 2 (HSV-1 or HSV-2)	Contact dermatitis
Gentamicin	Ophthalmic ointment	0.30%	3–6 times daily	Aminoglycoside antibiotic	Aerobic gram-negative bacteria and some aerobic gram-positive bacteria	Contact dermatitis

(Continued)

Table 58–4. COMMON TOPICAL AGENTS TO TREAT CONJUNCTIVITIS (CONTINUED)

Medication	Form	Concentration	Frequency	Class	Indication	Side Effects
Iododeoxyuridine	Ophthalmic solution	0.1%	4–6 times daily	Antiviral	Herpetic keratitis caused by herpes simplex virus (HSV) type 1 or 2 (HSV-1 or HSV-2)	Conjunctival scarring
Moxifloxacin	Ophthalmic solution	0.50%	3–6 times daily	Fluoroquinolone antibiotic	Aerobic gram-positive bacteria, some aerobic gram-negative bacteria	Contact dermatitis
Neomycin	Ophthalmic ointment	0.35%	3–6 times daily	Aminoglycoside antibiotic	Aerobic gram-negative bacteria and some aerobic gram-positive bacteria	Contact dermatitis
Polymyxin B	Ophthalmic ointment	10,000 U/g	3–6 times daily	Polymyxin antibiotic	Aerobic and anaerobic gram-negative organisms	Contact dermatitis
Povidone-iodine	Ophthalmic solution	1.25%, 2.5%, 5%	1–6 times daily	Antiseptic	Wide range of bacteria, viruses, fungi, protozoa, and spores	Contact dermatitis
Sulfacetamide	Ophthalmic ointment or solution	10%	3–6 times daily	Sulfonamide antibiotic	Aerobic and anaerobic gram-negative organisms	Contact dermatitis
Tetracycline	Ophthalmic ointment	1%	3–6 times daily	Tetracycline antibiotic	Aerobic and anaerobic gram-negative and gram-positive bacteria	Contact dermatitis
Tobramycin	Ophthalmic ointment or solution	0.3% or 15 mg/mL	3–6 times daily	Aminoglycoside antibiotic	Aerobic gram-negative bacteria and some aerobic gram-positive bacteria	Contact dermatitis
Trifluridine	Ophthalmic ointment	1%	6 times daily	Antiviral	Herpetic keratitis caused by herpes simplex virus (HSV) type 1 or 2 (HSV-1 or HSV-2)	Contact dermatitis
Vancomycin	Ophthalmic solution	25 mg/mL	3–6 times daily	Tricyclic glycopeptide antibiotic	Aerobic and anaerobic gram-positive bacteria	Contact dermatitis
Vidarabine	Ophthalmic ointment	3%	3–6 times daily	Antiviral	Not currently commercially available	Contact dermatitis

^aBlurred vision, eye irritation, eyelid erythema and edema, conjunctival hyperemia, punctate keratitis.

F. Herpes simplex conjunctivitis

1. **Isolate the patient and implement contact precautions.** Infant can room-in if low risk of infection, and mother can visit and breast feed if there are no vesicular herpetic lesions in the breast area and all lesions are covered.
 2. **Obtain a complete set of viral cultures** (PCR assays on skin and mucus have not been studied in neonates; do this in addition to the gold standard cultures). A positive culture obtained from any of the surface sites >12 to 24 hours after birth is considered positive and not intrapartum exposure contamination.
 - a. **Obtain a surface culture from the mouth, nasopharynx, conjunctivae, and anus for HSV surface culture and HSV PCR assay (if desired).** Any positive culture from any surface area >12 to 24 hours after birth indicates viral replication and is suggestive of an infection in the infant and not contamination by intrapartum exposure.
 - b. **Skin vesicle (if present) culture** for HSV and PCR assay.
 - c. **Cerebrospinal fluid and whole blood culture for HSV and PCR assay,** as clinical findings may be absent in CSF disease early on.
 - d. **Whole blood sample for serum alanine aminotransferase.** Can be elevated in HSV hepatitis.
 - e. **Direct fluorescent antibody staining of vesicle scrapings** or EIA detection of HSV antigens. These methods are specific but less sensitive than a culture.
 3. **Administer a topical therapy with ocular herpes simplex virus:** 1% trifluridine solution/drops or 0.15% ganciclovir gel (both are proven to be effective) 5 times per day for 10 days (every 2 hours).
 4. **Parenteral acyclovir for all neonates with herpes simplex virus disease (including conjunctivitis):** 60 mg/kg/d IV divided 3 times a day for a minimum of 14 days for SEM disease. If central nervous system (CNS) disease or disseminated disease is present, treat for a minimum of 21 days. (For dosage, see Chapter 155.)
 5. **Ophthalmologic evaluation and follow up** are required for all infants with neonatal HSV disease because chorioretinitis, cataracts, and retinopathy may develop. **Infectious disease consultation** is also recommended.
 6. **Neuroimaging** should be done for a baseline brain anatomy (magnetic resonance imaging is the most sensitive, but computed tomography or ultrasound is also acceptable). Neurologic follow-up is important.
 7. **With cerebrospinal fluid involvement,** a repeat lumbar puncture (LP) needs to be done near the end of the therapy to document that CSF is negative for HSV DNA on PCR assay; if positive, another week of therapy needs to be given and another repeat LP needs to be done. Parenteral treatment should not be stopped until CSF PCR is negative.
 8. **Suppression therapy with oral acyclovir** (300 mg/m²/dose) 3 times a day for 6 months is recommended following acute neonatal HSV disease. Adjust dose for growth. This prevents skin recurrences and improves neurodevelopmental outcomes in infants with CNS disease. Check absolute neutrophil counts at 2 and 4 weeks after starting therapy and then monthly.
- G. Other bacterial infections once gonococcal, chlamydial, and *Pseudomonas* infections have been ruled out.**
1. **Local saline irrigation.**
 2. **Topical antibiotics** only are usually required. (See Table 58–4.) For gram-positive organisms: bacitracin or erythromycin. For gram-negative organisms: gentamicin, tobramycin, or ciprofloxacin ointment or solution. Ointments are preferred over eye drops for neonates because they have reduced washout effect.
 - a. **Ophthalmic ointment:** 0.5- to 1-cm ribbon in each eye every 6 hours for 7 to 14 days.
 - b. **Ophthalmic solution:** 1 to 2 drops into each eye every 4 hours for 7 to 14 days.

3. ***H influenzae* infection** may require further evaluation of the infant (rule out sepsis, meningitis, and other infections if indicated), and systemic antibiotics may be necessary. Topical conjunctivitis can be treated with any fluoroquinolone topical antibiotic.
 4. **Methicillin-resistant *S aureus* conjunctivitis.** Treatment depends on the clinical situation; some do not need to be treated. Topical chloramphenicol eye drops and fortified vancomycin drops can be compounded under the direction of an ophthalmologist. See Chapter 141.
 5. **For gram-negative conjunctivitis in premature low birthweight infants** and increasing antibiotic resistance (especially noted among the β -lactam antibiotics), third- and fourth-generation antibiotics are recommended.
 6. **Viral infections other than herpes simplex conjunctivitis.** Treatment of viral conjunctivitis is mainly supportive (artificial tears, cool compresses). It usually resolves without specific treatment. One study found that conjunctival irrigation with 2.5% povidone-iodine was effective for the treatment of adenoviral conjunctivitis (“pink eye”) in infants and reduced the spread of infection.
- H. Congenital nasolacrimal duct obstruction** is the most common cause of persistent tearing and discharge in infants. Treatment can involve nonsurgical or surgical methods. Nonsurgical treatment consists of observation or digital massage (**Crigler massage**). Surgical treatment consists of probing the nasolacrimal duct to open the membranous obstruction, nasolacrimal duct stent insertion, balloon catheter dilation, or dacryocystorhinostomy.
1. **Observation.** Most cases clear spontaneously without treatment. Studies show varying results (66% to 88% to 96% resolution in 6 to 10 months to 1 year). Some physicians will treat with topical antibiotic eye drops to treat the discharge or matting around the eye.
 2. **Digital (Crigler) massage.** Massaging the inside corner of the eye over the lacrimal sac, in a downward motion with expression toward the nose, can exert hydrostatic pressure on the lower end of the lacrimal duct and may help to open any obstruction and establish patency. The massage method involves 5 to 10 strokes 4 times a day.
 3. **Nasolacrimal probing.** If the problem does not resolve and symptoms persist (usually after 6 months), the infant should be evaluated by an ophthalmologist. Probing of the duct is usually indicated. It can be done as an office procedure or under general anesthesia. Probing will not work if the duct is swollen due to infection or if the obstruction is caused by a bony protrusion of the inferior turbinate. Probing is not without risk of complications, which can include creation of a false passage, injury to the nasolacrimal duct, bleeding, aspiration, and laryngospasm. There is controversy as to when this should be done (early or later). A Cochrane group performed a review to see if immediate probing versus delayed probing resulted in more treatment success. Results noted that the effects of immediate versus deferred probing are uncertain but found that children who had unilateral CNLDO and immediate office probing had a higher success of treatment compared to deferred probing.
 4. **Nasolacrimal duct stent insertion, balloon catheter tear duct dilation, and dacryocystorhinostomy** are reserved for those cases that have failed other procedures.
- I. Dacryocystitis. This is an infection of the lacrimal (tear) sac.** It is almost always related to nasolacrimal duct obstruction. It can cause redness, swelling, and pain near the nose just below the lower lid.
1. **Congenital dacryocystitis** is a serious disease that can cause orbital cellulitis, brain abscess, meningitis, sepsis, and death if not treated immediately and aggressively with systemic antibiotics. Urgent ophthalmology consult is necessary.
 2. **Acquired dacryocystitis can be acute or chronic.**

- a. **Acute dacryocystitis.** Sudden onset of redness and edema over the lacrimal sac and may have injection of the conjunctiva and preseptal cellulitis. Orbital cellulitis can also occur, and urgent ophthalmology consultation is recommended. Treatment includes heat, systemic antibiotics, and percutaneous drainage of the abscess.
- b. **Chronic dacryocystitis.** Infant presents with tearing and mattering. Inside the lacrimal sac is a chronic low-grade bacterial infection. Treatment includes dacryocystorhinostomy.

59 Gastric Residuals

- I. **Problem.** The nurse alerts you that a bloody gastric residual has been obtained in an infant. Gastric residuals (also known as a gastric aspirates) can be abnormal in appearance or abnormal in volume. **Gastric aspiration** is a procedure by which the stomach is aspirated with an oral or nasogastric tube. The procedure is typically performed before each feeding or at a predetermined interval during continuous feeding to verify correct orogastric/nasogastric tube placement, to assess if feedings are being tolerated and digested (feeding intolerance), and to prevent aspiration of contents of the stomach (prevent ventilator-associated pneumonia). The color is noted. The amount of residual is measured and recorded as the **gastric residual**. Once a standard procedure in the neonatal unit, performing routine gastric residuals is now **controversial** because of the lack of consensus and supporting evidence. Because there is lack of evidence and recommendations, each neonatal intensive care unit (NICU) should develop a standardized protocol to determine the role of gastric residuals in their unit. Recent reviews have found the following:
 - A. **There is no formal consensus on the definition of an abnormal gastric residual.** Definitions include a percentage of previous feedings (range 20%–50%), a preset volume of the previous feeding (range 2–5 mL), or a preset volume based on body weight (>2 mL/kg to >5 mL/kg). **The most common definition used of an abnormal gastric residual is >50% of the previous feeding.**
 - B. **It is not a reliable indicator of the placement of the feeding tube.** Straw-colored gastric aspirates can be seen from a nasogastric tube abnormally placed in the respiratory system.
 - C. **It does not give an accurate estimate of gastric contents.** The volume of the gastric contents is influenced by body position, size of feeding tube, technique, temperature of feed, and viscosity. Abdominal ultrasound has been recommended as an alternative method of measurement of gastric contents.
 - D. **There is lack of evidence that increased residuals indicate feeding intolerance.** Some neonatologists will equate gastric residuals with feeding intolerance. The amount or characteristic of the gastric residual is not predictive of feeding intolerance.
 - E. **The use of gastric residuals prolongs the time to reach full feeds.** The response to a gastric residual can cause interruption of enteral feeding, delay in achieving full enteral feedings, prolonged use of TPN, and decreased growth. A recent review found omitting the evaluation of prefeed gastric residuals in extremely premature infants increased the delivery of enteral nutrition and improved weight gain.
 - F. **It is not an indication of necrotizing enterocolitis.** Studies show there is a possible increased volume of gastric residuals prior to necrotizing enterocolitis (NEC), but there is no definition of the exact volume to guide decisions. Recent survey of 173

physicians from 26 countries showed that neonatologists do rely on increased gastric residuals and abdominal distension to help diagnose NEC.

G. Although refeeding is supported in adults (ie, returning the tube feed residual), there is no evidence in neonates.

H. An isolated gastric residual in very low birthweight infants can reflect delayed gut maturation and decreased intestinal motility and may not signify a gastrointestinal (GI) problem.

I. Bilious and bloody residuals were once considered a red flag, and feedings were stopped and complete workups were initiated. Bilious or bloody residuals in the absence of other clinical signs may not indicate serious disease and are not predictive of NEC or feeding intolerance. Bilious residuals can be secondary to immaturity, and bloody residuals maybe secondary to irritations from trauma. Consider the gestational age of the infant and the infant's clinical status before withholding feeds.

II. Immediate questions

A. Is the gastric residual volume abnormal? The stomach is a secretory organ, and that basal gastric secretions average 2.8 mL over 4 hours in preterm infants; therefore, a gastric residual could contain normal basal gastric secretions plus enteral feeding. There is great variation in definitions of abnormal gastric residuals (see definitions provided earlier). The most common definition of an abnormal gastric residual appears to be >50% of the previous feeding. The volume of the gastric residual can be influenced by:

1. Body position of the infant. Larger residuals if the infant was in the left lateral position or supine compared to prone and right lateral positions.

2. Size of the feeding tube. Bigger feeding tube residual volumes are greater than those of smaller feeding tubes.

3. Feeding viscosity and temperature of the milk. Cool and or room temperature milk produced greater gastric residuals than body temperature milk. Expressed breast milk emptied faster from the stomach than formula. Fortification of breast milk delayed gastric emptying.

4. Position of the feeding tube and the aspiration technique can also affect the amount of gastric contents.

5. Infusion rate of the feeding. Slow rate of infusion caused greater gastric emptying when compared to the fast rate of infusion.

B. Color of the residual used to define a clinically or nonclinically significant gastric residual (eg, bloody, bilious, nonbilious nonyellow, or yellow) and is important in the differential diagnosis (see Section III.A–D). Some NICUs are introducing color charts to help identify bilious residuals because there is lack of consensus when trying to identify a bilious gastric residual.

C. Is the abdomen soft, with good bowel sounds, or distended, with visible bowel loops? Is there abdominal distension? Has the abdominal girth increased? Absence of bowel sounds, distention, tenderness, and erythema are all abnormal signs and may indicate a pathologic process. Absence of bowel sounds suggests an ileus. For abdominal distension, a change of up to 1.5 cm suggests normal variability, but studies showed an increase of 3.5 cm was seen with 1 feeding in normal premature infants.

D. When was the last stool passed? Constipation resulting in abdominal distention may cause feeding intolerance and increased gastric residuals.

E. What medications is the infant receiving? Theophylline delays gastric emptying in very low birthweight infants. Doxapram can cause gastric residuals.

F. Is the infant premature? Delayed gastric emptying and feeding intolerance are common in premature infants. There is an inverse relationship between gestational age and rate of gastric emptying. **Premature infants** have delayed gut maturation, decreased duodenal motor activity, GI dysmotility, and slower intestinal transit time.

G. Is the infant ill appearing? Gastric emptying is delayed in acutely ill infants, especially in those infants with respiratory distress.

III. Differential diagnosis. The characteristics of the residual can provide important clinical clues to the cause of the problem and are outlined next.

A. Bilious residual. A bilious residual is a residual that is light to dark green but can be yellow in the initial phases. It is important to be able to correctly identify a bilious residual because overidentification of bilious residuals can lead to infants being placed nothing by mouth (NPO) and getting unnecessary evaluations. Yellow and light green gastric residuals, especially with a normal exam, were not found to correlate with feeding intolerance or the need to delay feedings. **Dark green (color of collard greens)** may indicate an obstruction or ileus. It is important to remember that a bilious aspirate in a term infant should be approached differently than a bilious aspirate in a preterm infant.

1. Term infant. In the term infant, especially if the residual is persistent and dark green and there are other clinical signs, it can mean an **intestinal obstruction** distal to the ampulla of Vater, usually in the proximal small bowel. GI pathology needs to be investigated, and immediate surgical consultation should be obtained.

2. Preterm infant. In the **premature infant**, bilious residuals, especially isolated green or light green residuals, can occur without serious bowel pathology and may indicate **immaturity of the bowel** (duodenogastric reflux from immaturity of the duodenal motor activity and pyloric sphincter tone).

3. Causes of bilious residual

a. Malpositioned nasogastric tube. Passage of the feeding tube into the duodenum or the jejunum instead of the stomach can cause a bilious residual.

b. Overaggressive/zealous aspiration can cause a bilious residual by sucking back duodenal contents.

c. Bowel obstruction. Bilious gastric aspirates or emesis may indicate bowel obstruction. Studies show that 30% to 38% of infants with bilious vomiting in the first 72 hours of life had obstruction, of whom 20% required surgery. **Bowel perforation with pneumoperitoneum** can present with increased bilious gastric residuals.

i. Malrotation with midgut volvulus. Most common obstruction and was present in 22% of infants with bilious vomiting. Presents at 3 to 7 days of age. Bilious gastric residual may be the only early sign of small bowel volvulus.

ii. Duodenal atresia. If atresia is distal to ampulla of Vater (seen in 80% of cases), one can see bilious emesis without abdominal distension. If atresia is proximal to the ampulla, one can see nonbilious vomiting. Duodenal obstruction is seen with associated anomalies (Down syndrome, VATER/VACTERL [vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial or renal dysplasia/vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and radial abnormalities, and limb abnormalities], and others).

iii. Jejunoileal atresia. Small bowel atresia, including distal duodenum and jejunal and ileal atresia, can cause bilious residuals.

iv. Meconium ileus/plug. Presents soon after birth with abdominal distention and bilious residuals/vomiting.

v. Hirschsprung disease. Usually presents with abdominal distension and no stool but can have bilious or yellow residual or vomiting.

d. Ileus can cause bilious residuals and can be associated with sepsis, prematurity, hypokalemia, effects of maternal drugs (especially magnesium sulfate), pneumonia, hypothyroidism, and other etiologies.

e. Prematurity and bilious residuals. Some premature infants will have bilious residuals from gastric dysmotility and immaturity. These infants do not have a bowel obstruction or pathologic process.

f. Gastroesophageal and duodenogastric reflux can cause bilious residuals/vomiting.

- g. **Necrotizing enterocolitis.** Bilious residuals can be seen with NEC, **but bloody residuals are more common**
 - h. **Idiopathic.** No cause is found.
- B. Nonbilious, nonyellow residual (white, clear, straw colored, cloudy, undigested or digested formula)**
1. **Problems with the feeding regimen.** Undigested or digested formula may be seen in the residual if the feeding regimen is too aggressive and is more likely in small premature infants who are given a small amount of formula initially and then are given larger volumes too rapidly, or after adding fortifier to breast milk.
 - a. **Residual containing undigested formula.** May be seen if the interval between feedings is too short or if too much formula is being given.
 - b. **Residual containing digested formula.** May be a sign of delayed gastric emptying or overfeeding. Also, if the osmolality of the formula is increased by the addition of vitamins, retained digested formula may be seen.
 2. **Other causes**
 - a. **Formula intolerance.** An uncommon cause of residual but should be considered. Some infants do not tolerate the carbohydrate source in some formulas. If the infant is receiving a lactose-containing formula (eg, Similac or Enfamil), perform a stool pH to rule out lactose intolerance. If the stool pH is acidic (>5.0), lactose intolerance may be present. Diarrhea is more common than gastric residuals with lactose intolerance.
 - b. **Constipation.** This is a factor especially if the abdomen is full but soft and no stool has passed in 48 to 72 hours.
 - c. **Pyloric stenosis.** Pyloric stenosis typically presents at 3 to 4 weeks with nonbilious projectile vomiting.
 - d. **Infections can cause gastric residuals.**
 - e. **Hypermagnesemia.** This can present with increased gastric residuals and delayed passage of meconium.
 - f. **Retinopathy of prematurity examination.** Gastric residuals are associated with retinopathy of prematurity (ROP) eye examination. Feeding is recommended 1 hour before ROP examination.
 - g. **Rare causes.** Incarcerated hernia, bowel obstruction, inborn errors of metabolism, and congenital adrenal hyperplasia can present with nonbilious residuals.
- C. Bloody residual.** Includes any color of red or coffee ground color. (See also Chapter 60.) Upper GI bleeding is blood loss proximal to the ligament of Treitz (from the esophagus, stomach, or duodenum).
1. **Swallowed maternal blood.** Must be ruled out to verify true neonatal bleeding.
 2. **Trauma from nasogastric intubation** is a common cause. Upper airway suctioning can also cause blood-tinged residuals.
 3. **Coagulopathies.** Vitamin K deficiency bleeding, disseminated intravascular coagulation due to infection, coagulopathy from liver failure, and any congenital coagulation factor deficiency.
 4. **Stress-related mucosal lesions.** Gastritis; esophagitis; erosions of the esophageal, gastric, or duodenal mucosa; and gastroduodenal ulcers can all have a bloody residual. Absence of bloody residual does not exclude stress-related mucosal lesions.
 5. **Necrotizing enterocolitis.** Hemorrhagic residuals can be seen in NEC, are hypothesized to be a result of disruption in the bowel integrity, and are considered a marker for NEC.
 6. **Allergic colitis.** Causes include milk or soy enterocolitis, milk protein intolerance, and cow milk intolerance. Lower GI bleeding is the more common presentation.
 7. **Severe fetal asphyxia.**
 8. **Medications.** Theophylline, indomethacin, heparin, nonsteroidal anti-inflammatory drugs, and corticosteroids. Maternal use of aspirin, cephalothin, and phenobarbital can cause coagulation abnormalities in infants.

9. **Rare causes.** GI perforations, gastric volvulus or duplication, intestinal duplications, duplication cyst, and vascular anomalies including hemangiomas, telangiectasias, arteriovenous malformations, Hirschsprung enterocolitis, and Meckel diverticulitis.

D. **Yellow residuals. Non–bile-stained yellow residuals** can be associated with intestinal obstruction (early on) and should not be ignored if the infant has other abnormal clinical findings. Clinical evaluation may be warranted in this situation, and further workup may be required depending on the evaluation. Colostrum may also be yellow in color. **Isolated yellow gastric residuals** may be unimportant in very low birth-weight infants or in infants with a normal examination.

IV. Database

A. **Physical examination.** Check for any temperature instability or any new subtle signs that could indicate a pathologic process. How is the infant's perfusion? Is there any apnea? Is there anything else going on besides gastric residuals? Are the stools normal? Pay particular attention to the **abdominal examination**. Check for bowel sounds (absent bowel sounds may indicate ileus), abdominal distention, tenderness to palpation and erythema of the abdomen (may signify peritonitis), or visible bowel loops.

B. **Laboratory studies.** Testing depends on the physical examination of the infant and the infant's clinical status.

1. Initial studies

- a. **Complete blood count with differential and platelets.** To evaluate for sepsis or NEC, if suspected. The hematocrit and platelet count may be checked if bleeding has occurred. Acute NEC is commonly associated with thrombocytopenia.
- b. **Blood culture.** If sepsis or NEC is suspected and before antibiotics are started.
- c. **Serum potassium level if ileus is present.** To rule out hypokalemia.
- d. **Arterial blood gas.** If metabolic acidosis is seen, this is a red flag in this setting, and a further workup should be done.
- e. **Serum electrolytes.** Hyponatremia can be seen with third spacing of fluid.
- f. **C-reactive protein for necrotizing enterocolitis.**

2. Additional studies

- a. **Stool pH.** (See Section III.B.2.a.) If there is a family history of milk intolerance, a stool pH can rule out lactose intolerance (stool pH is usually >5.0).
- b. **Coagulation profile.** (Prothrombin time, partial thromboplastin time, fibrinogen, and platelets.) A bloody residual may signify the presence of a coagulopathy.

C. Imaging and other studies

1. Immediate studies

- a. **Plain radiograph (flat plate) of the abdomen** should be obtained if the residual is persistently bilious or very dark green (especially in a term infant), if there is any abnormality on physical examination, or if residuals continue. The radiograph will show whether the nasogastric tube is in the correct position and will define the bowel gas pattern. Look for an unusual gas pattern, pneumatosis intestinalis, ileus, or evidence of bowel obstruction. Dilated bowel loops and air fluid levels suggest a surgical abdomen. Duodenal atresia has a double bubble sign. (See Chapter 12 for radiographic examples of tube placements and intra-abdominal diseases.)
- b. **A left lateral abdominal decubitus film** is useful because a perforation can be easily missed on the anteroposterior film. A gasless abdomen can be seen with midgut volvulus.

2. Additional studies

- a. **Gastroesophageal reflux scintigraphy (“milk scan”).** See page 450.
- b. **Endoscopy** should be considered for ulcer evaluation.
- c. **Abdominal ultrasound and contrast studies of the gastrointestinal tract** if indicated. Point-of-care ultrasound can be used to diagnose NEC (small intramural gas or changes in bowel wall thickness or peristalsis).

V. **Plan.** The approach to management of the neonate with an abnormal gastric residual is initially based on the nature of the residual and most important if the physical examination is abnormal. **It is so important to not just react to the gastric aspirate. Evaluate the entire clinical picture. Current treatment modalities include:** refeeding or discarding the residual, continuing or stopping feedings, placing the infant NPO, checking an abdominal x-ray, and doing laboratory work to evaluate for sepsis and other conditions.

A. **General recommendations when called to the bedside of an infant with an abnormal gastric aspirate (>50% of the feeding volume)**

1. **Are there any other concerning characteristics of the aspirate?** For example, is it increasing with each feed, bloody, bilious in a term infant, or persistently bilious in a preterm infant? These may signify a more serious condition.

2. **Evaluate the infant.**

a. **If infant has a normal physical examination, normal abdominal examination** (eg, no distension, tenderness, discoloration, palpable loop), **and no other clinical signs that would be concerning** (eg, increasing apnea and bradycardia, temperature instability, frequent emesis, bloody stool, no stool, decreased stooling), keep feeding with close observation. Gastric residuals are usually discarded or refeed. Refeed gastric aspirate if it is undigested formula and discard if it is bilious, contains excess mucus, or is very bloody. If the infant is term, consider a baseline abdominal radiograph.

b. **If infant has an abnormal physical examination and/or worrisome clinical signs**, do an abdominal radiograph.

i. **If abnormal radiograph** (free air, NEC, pneumatosis, gasless, fixed dilated loops, ileus), place NPO, start intravenous (IV) fluids, do laboratory testing, place a nasogastric tube for gastric decompression, and consult pediatric surgery.

ii. **If questionable radiograph**, consider making the infant NPO and reevaluate and repeat radiograph in the next 6 to 8 hours. If improvement is noted and radiograph normal, reinstitute feeding. If no improvement and radiograph still the same or worse, hold feeds and initiate formal workup.

iii. **If normal radiograph but concerning physical examination and/or other clinical signs with no obvious reason for abdominal distension** (eg, CPAP belly). Place NPO and reevaluate over the next 6 to 8 hours.

B. **Treatment of specific types of residuals**

1. **Bilious residual**

a. **Malpositioned nasogastric tube. Rule this out first.** An abdominal radiograph will confirm the position of the nasogastric tube distally in the duodenum. Replace or reposition the tube in the stomach.

b. **Gastrointestinal pathology.** The majority are initially managed by making the infant NPO and placing a nasogastric tube to rest and decompress the gut while doing a workup. Start an IV and give fluids. Obtain laboratory studies, consider antibiotics if indicated, and consult pediatric surgery if indicated.

i. **Necrotizing enterocolitis.** See Chapter 109.

ii. **Ileus.** May be secondary to sepsis, hypokalemia, effects of maternal drugs (especially magnesium sulfate), pneumonia, and hypothyroidism. Place the infant NPO and insert a nasogastric tube for decompression. Diagnose and treat the underlying cause.

iii. **Other surgical problems** (eg, bowel obstruction, malrotation, volvulus, meconium plug). Pediatric surgery consultation should be obtained immediately. Specific radiologic studies may be indicated (other radiologic films, ultrasound, or contrast studies) based on the infant. Surgery may be indicated.

- c. **Prematurity and bilious residuals.** If the infant has a normal examination and it is an isolated bilious residual, it is acceptable to feed with close observation. If the bilious residuals persist or anything changes on the vitals or clinical examination, then the infant needs to be reevaluated, a baseline radiograph should be obtained, and a bowel obstruction needs to be ruled out.
 - d. **Gastroesophageal and duodenogastric reflux.** See Chapter 52.
2. **Nonbilious, noneyellow residual.** Usually means residual involves undigested or digested formula.
- a. **Residual containing undigested formula.** If the volume of undigested formula in the residual does not exceed 50% of the previous feeding and the physical examination and vital signs are normal, the gastric residual can be replaced. There is no evidence that refeeding is supported in neonates, only in adults. Gastric residuals do contain important essential acids and enzymes that aid in digestion, including hydrochloric acid (necessary for limiting intestinal overgrowth of bacteria) and pepsin (enzyme used in digestion in the stomach). Discarding gastric residuals can cause loss of hydrochloric acid (which can increase the bacteria in the intestine and intestinal inflammation and may increase risk of NEC and late-onset sepsis) and loss of pepsin. If gastric residuals continue and the examination of the infant is normal, the following can be tried:
 - i. **The time interval between feedings may not be long enough for digestion to take place.** If the infant is being fed every 2 hours and residuals continue, the feeding interval may be increased to 3 hours.
 - ii. **Decreasing the volume of the feeds.**
 - iii. **Continuous gavage feedings.** The patient may also have to be fed IV to allow the gut to rest.
 - iv. **If elevated residuals still continue or if the residual exceeds >50% of the previous feeding,** the patient must be reevaluated. If the infant has physical findings, work up the infant and withhold feeds. An abdominal radiograph should be obtained.
 - b. **Residual containing digested formula.** The residual is usually discarded, especially if it contains a large amount of mucus. If the physical examination and vital signs are normal, continue feedings. If elevated residuals continue, the patient must be reassessed. If the examination is normal, consider **decreasing the amount of feeds.** The number of calories should be calculated to make certain that overfeeding (usually >130 kcal/kg/d) is not occurring. If the examination is not normal, further workup must be done.
 - c. **Other**
 - i. **Formula intolerance.** A trial of lactose-free formula (eg, ProSobee or Isomil) can be instituted if lactose intolerance is verified. (See formula components in Chapter 11.)
 - ii. **Necrotizing enterocolitis or post-necrotizing enterocolitis stricture.** See Chapter 109.
 - iii. **Pyloric stenosis.**
 - iv. **Constipation.** Anal stimulation can be attempted. If this fails, a glycerin suppository can be given. (See Chapter 72.)
 - v. **Infections.** If sepsis is likely, broad-spectrum antibiotics are started after a laboratory workup is performed. A penicillin (usually ampicillin) and an aminoglycoside (usually gentamicin) are given initially until culture results are available. The patient is usually not fed orally if this diagnosis is entertained; an infant with sepsis usually does not tolerate oral feedings.
 - vi. **Inborn errors of metabolism.** See Chapter 100.
 - vii. **Congenital adrenal hyperplasia.** Hormone/steroid replacement, fluid and electrolyte management, and possible surgery are indicated.
 - viii. **Hypermagnesemia.** See Chapter 105.

3. **Bloody residual.** See also Chapter 60.
 - a. **Swallowed maternal blood.** Observation only.
 - b. **Nasogastric trauma.** Nasogastric trauma may occur if the nasogastric tube is too large or insertion is traumatic. Use the smallest nasogastric tube possible. Observation is indicated. Because the bleeds are usually minimal, active management is not necessary.
 - c. **Coagulopathies.** GI hemorrhage from disseminated intravascular coagulation, vitamin K deficiency bleeding, and others are discussed in detail in Chapter 87.
 - d. **Stress-related mucosal lesions.** See Chapter 60.
 - e. **Necrotizing enterocolitis.** See Chapter 109.
 - f. **Allergic colitis.** Change formula.
4. **Non–bile-stained yellow residual.** If isolated, it is probably unimportant. If it continues or increases in volume, then a full clinical examination and possible abdominal radiograph are warranted. If anything abnormal is found, further studies are needed to rule out any intestinal obstruction. These infants need to be followed closely.
- C. **Medications for feeding intolerance with gastric residuals (*controversial*).** Infants can have GI motility immaturity that causes feeding intolerance. Some institutions have used prokinetic agents such as metoclopramide and erythromycin to improve feeding intolerance (to stimulate and improve gastric emptying [promote motility], improve lower esophageal sphincter tone, decrease gastric residual volume, and decrease time to full enteral feeding). These medications have been shown to improve gastric emptying, decrease regurgitation, and enhance lower esophageal sphincter tone in older infants. They have not been shown to decrease gastroesophageal reflux symptoms in preterm infants. These medications are associated with a lack of data for efficacy and safety and have major side effects (some can cause significant harm) and are not recommended in preterm infants.

60 Gastrointestinal Bleeding from the Upper Tract

- I. **Problem.** Vomiting of bright red blood or active bleeding from the nasogastric (NG) tube is seen in a newborn. **Upper gastrointestinal (GI) bleeding** is bleeding that occurs proximal to the ligament of Treitz (duodenojejunal flexure) which arises from the esophagus, stomach, or duodenum. It usually presents with hematemesis (vomiting of blood) most commonly bright red or less commonly the color of coffee grounds, or it can present with melena (black tarry stools). Rarely, a brisk upper GI (UGI) bleed has such a short intestinal transit time that it presents with hematochezia (fresh blood through the anus). Coffee ground emesis means the blood has been altered by gastric contents, which indicates slow bleeding from the esophagus and duodenum. Diagnosis is made most commonly by blood-stained aspirates in the NG or orogastric (OG) tube, by hematemesis, or by endoscopy (gastric mucosa shows bleeding). UGI bleeding is more common in sick newborns in the NICU, than in term neonates. The majority of UGI bleeds in neonates are benign, self-limiting, and require minimal workup and treatment, but some can be severe, especially those associated with other underlying conditions.
- II. **Immediate questions**
 - A. **What are the vital signs?** If the blood pressure is dropping and there is active bleeding, urgent crystalloid volume replacement is necessary.

- B. Is the infant ill or well appearing?** Is the bleeding mild or severe? **If the infant looks well**, consider swallowed maternal blood first, mild trauma from nasopharyngeal bleeding, esophagitis, or gastritis (most cases are asymptomatic), clinically relevant mucosal lesions of the upper GI tract (seen in healthy term infants), or milk protein intolerance. **If the infant is severely ill** (hypovolemia, shock, near death) with significant upper GI bleeding, most of these cases are related to other problems such as hypoxemia, infection, perinatal stress, respiratory failure, congenital heart disease, increased intracranial pressure. **Milder bleeding:** gastritis, esophagitis, milk protein intolerance. **More severe bleeding:** coagulopathies (VKDB), NEC, Stress ulcer.
- C. What is the hematocrit?** A hematocrit should be done as soon as possible. The result is used as a baseline value and to determine whether blood replacement is needed. **With any acute bleeding, the hematocrit may not reflect the blood loss for several hours.**
- D. Is blood available in the blood bank should transfusion be necessary?** Verify that the infant has been typed and cross-matched so that blood will be quickly available if necessary.
- E. Is there bleeding from other sites?** Bleeding from other sites suggests disseminated intravascular coagulation (DIC), vitamin K deficiency bleeding, or other coagulopathy. If bleeding is only from the NG tube, disorders such as stress-related mucosal lesions, NG trauma, and swallowing of maternal blood are likely causes to consider.
- F. How old is the infant?** During the first day of life, vomiting of bright red blood or the presence of bright red blood in the NG tube is frequently secondary to swallowing of maternal blood during delivery. Infants with this problem are clinically stable with normal vital signs. Vitamin K deficiency bleeding can occur at different times depending on the type (see Chapter 92). Age of the infant can help narrow down the differential diagnosis, but there can be overlap between ages.
- 1. Newborns (<1 month old).** **Common:** stress gastritis, stress-induced ulcer, vitamin K deficiency, sepsis, trauma from NG tube, cow's milk protein allergy medications (nonsteroidal anti-inflammatory drugs [NSAIDs]), idiopathic. **Less common:** vascular anomalies, GI duplications, congenital coagulation factor deficiency, ulcer, esophagitis.
 - 2. Infants (≥1 month old).** Stress esophagitis, peptic ulcer bleeding, vascular anomalies, GI duplications, duodenal or gastric webs, bowel obstruction, varices, medication induced (NSAIDs), Mallory-Weiss syndrome, gastric and duodenal ulcers.
- G. What medications are being given?** Certain medications are associated with an increased incidence of GI bleeding.
- 1. Maternal medications.** Some maternal medications can cross the placenta (aspirin, cephalothin, and phenobarbital) and cause coagulation disorders in the infant. Thiazides in pregnancy can be associated with neonatal thrombocytopenia.
 - 2. Infant medications.** The most common are indomethacin, NSAIDs, theophylline (rare), heparin, and corticosteroids.
- H. Was vitamin K given at birth?** Failure to give vitamin K at birth may result in a vitamin K deficiency bleeding, which can present at different times. See Section III.B.4a.
- I. Is there a history of melena?** Melena signifies significant UGI bleeding or possibly swallowed maternal blood with rapid transit time.
- J. Does the infant have a syndrome or condition that is associated with gastrointestinal bleeding?** These are rare causes of UGI bleeding in a neonate.
- 1. Down syndrome:** Meckel diverticulum, Hirschsprung disease, pyloric stenosis.
 - 2. Turner syndrome:** Venous ectasia, inflammatory bowel disease.
 - 3. Klippel-Trenaunay syndrome and blue rubber bleb nevus syndrome:** Vascular malformations.

4. **Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia):** Epistaxis and vascular malformations, acute and chronic digestive tract bleeding.
5. **Epidermolysis bullosa:** Anal fissures, esophageal lesions, and strictures of the colon.
6. **Ehlers-Danlos syndrome and pseudoxanthoma elasticum:** Fragile blood vessel wall structure.
7. **Hermansky-Pudlak syndrome:** Platelet dysfunction, inflammatory bowel disease.
8. **Glycogen storage disease type 1b:** Inflammatory bowel disease.
9. **Zellweger cerebrohepatorenal syndrome:** GI bleeding.
10. **Curry-Jones syndrome:** UGI bleeding.

III. Differential diagnosis

A. Conditions that are not a true gastrointestinal bleed

1. **Swallowing of maternal blood accounts for approximately 10% of cases.** Typically, blood is swallowed during cesarean delivery, but can be swallowed during a vaginal birth as well. Swallowed blood irritates the stomach and can cause vomiting. Infants with this problem are usually only a few hours old, are not sick, and usually have a positive Apt test result. Infants with swallowed maternal blood can present with hematemesis or melena.
2. **Swallowing of blood from a cracked nipple or fissure** during breast feeding can also cause it.
3. **Swallowing of amniotic fluid** with an antepartum hemorrhage bleeding into the amniotic fluid normally presents with melena stools but can present with UGI bleeding.
4. **Trauma from nasopharyngeal bleeding or endotracheal intubation.**
5. **Medications** that can alter the color of the stool or emesis are rifampin, bismuth, and iron.

B. True gastrointestinal bleed.

UGI bleeding in newborns is usually associated with clinically relevant mucosal lesions of the UGI tract, with gastric ulcers more common than duodenal ulcers. Based on 1 study, 20% of infants admitted to the neonatal intensive care unit and 53% of mechanically ventilated infants have signs of GI bleeding. The most common causes of UGI bleeding are idiopathic, trauma from NG tube, stress-induced gastritis/ulcers, vitamin K deficiency disease, sepsis, and cow's milk protein allergy.

1. **Idiopathic.** A large percentage of cases have no clear diagnosis and usually resolve within several days.
2. **Trauma**
 - a. **Nasogastric trauma.** Forceful insertion or too large a tube can cause trauma. Frequent aspiration to identify gastric residuals can cause trauma. The bleeding from this is usually minimal.
 - b. **Vigorous/continuous suctioning or lavage.**
 - c. **Traumatic esophagitis.** This has been reported in newborns possibly from pharyngeal, esophageal, or gastric suction at birth.
3. **Stress-related mucosal lesions occur in the esophagus, stomach, or duodenum (up to 75% of preterm infants).** These can be caused by an increase in gastric acid secretion and laxity of gastric sphincters in infants. Prematurity, neonatal distress, and mechanical ventilation are associated with stress gastritis. Stress-induced ulceration in the stomach is secondary to birth asphyxia, prolonged labor, RDS, sepsis, caesarean deliveries. Maternal stress in the third trimester with increased maternal gastrin may also play a part. UGI bleeding in healthy full-term infants is often associated with clinically relevant mucosal lesions of the UGI tract. Absence of bloody aspirate does not exclude stress-related mucosal lesions. Many infants with these lesions on endoscopy do not have UGI bleeding.

- a. **Esophagus.** Esophagitis (hemorrhage or ulcerative), Mallory-Weiss tear (associated with vomiting).
 - b. **Gastric.** Stress gastritis from illness, trauma, increased ICP, stress induced ulcer (occur more frequent in stomach than duodenum in neonates), gastritis due to viral infections including cytomegalovirus.
 - c. **Duodenum.** Duodenitis, duodenal mucosal lesions, vascular malformation single stress ulcers.
 - d. **Gastroesophageal lesions.** Infants tend to have gastric and esophageal lesions together.
4. **Coagulopathy.** Vitamin K deficiency bleeding and DIC account for 20% of the cases of UGI bleeding in newborns.
- a. **Vitamin K deficiency disease.** There are 3 forms:
 - i. **Early form** (first day of life) is related to maternal medications affecting production of vitamin K by the neonate (barbiturates, oral anticoagulant, anticonvulsants, phenytoin, rifampin, isoniazid, warfarin).
 - ii. **Classic form** (between days 2 and 7) of life is more commonly seen in infants with inadequate intake of breast milk and when an infant has not received vitamin K at birth (eg, home delivery).
 - iii. **Late form** (between 2 weeks and 6 months of age) is secondary to inadequate vitamin K intake (breast-fed infants) or hepatobiliary disease.
 - b. **Disseminated intravascular coagulation.** This can occur after infection, shock, liver failure, and severe fetal asphyxia.
 - c. **Congenital coagulopathies.** Most commonly factor VIII deficiency (hemophilia A) and factor IX deficiency (hemophilia B).
5. **Allergic colitis** is caused by allergy to cow's milk (milk protein intolerance) or soy protein after it has been introduced. Can present with esophagitis but lower GI bleeding is more common.
6. **Medications (drug-induced bleeding).** Indomethacin, corticosteroids, heparin, NSAIDs, sulindac, theophylline (rare), and other drugs may cause UGI tract bleeding. High-dose dexamethasone is associated with stress and perforated ulcers and hemorrhage in the newborn. **Maternal use** of aspirin, cephalothin, and phenobarbital can cause coagulation disorders in the infant. Thiazides in pregnancy can be associated with neonatal thrombocytopenia.
7. **Congenital gastrointestinal defects** such as intestinal duplications (most common) (eg, esophageal duplication). Less common: gastric volvulus, duodenal web, antral web, heterotopic pancreatic tissue in the stomach, malrotation with volvulus, Hirschsprung disease with enterocolitis, intussusception, duplication cyst, and Meckel diverticulitis. Bowel obstruction can cause UGI bleeding.
8. **Congenital vascular anomalies** such as arteriovenous malformations, hemangiomas (isolated cavernous hemangioma of the stomach), extensive telangiectasias, and GI hemangiomas with or without a related syndrome can present with GI hemorrhage. Arteriovenous malformations associated with Osler-Weber-Rendu syndrome or blue rubber bleb nevus syndrome can cause bleeding.
9. **Liver disease/failure in the newborn.** Usually presents in older infants. Severe bleeding can occur from the following:
- a. **Esophageal varices** from portal hypertension from intrinsic liver disease caused by cirrhosis from biliary atresia, parenteral nutrition-induced liver disease, hemochromatosis, or extrahepatic causes (portal vein thrombosis due to umbilical vein catheterization or sepsis).
 - b. **Metabolic disorders that cause liver failure** have associated coagulopathies that can present with GI bleeds.
 - c. **Ischemic injury to the liver.**
10. **Necrotizing enterocolitis** is a rare cause of UGI tract bleeding.

11. **Pyloric stenosis** presents at the third to fourth weeks of life with nonbilious projectile vomiting (occasionally bloody). Hypertrophic pyloric stenosis has presented with hematemesis in the newborn.
12. **Rare causes:** Gastric teratoma/gastric tumors, Dieulafoy lesion, infection with *Serratia marcescens*, complication from intrapulmonary percussive ventilation therapy, telangiectasia involving the entire GI tract, pyloroduodenal intestinal duplication, heterotopic pancreatic tissue in the stomach, and focal foveolar hyperplasia of the gastric mucosa.

IV. Database

A. Physical examination should focus attention on other potential bleeding sites. Carefully examine the nares and oropharynx to rule out respiratory causes of bleeding. Bruising or petechiae suggest a bleeding disorder. Note bowel sounds, abdominal distension, splenomegaly, and if there is any abdominal wall erythema. Is there evidence of portal hypertension (splenomegaly, prominent abdominal vessels)?

B. Laboratory studies

1. Initial tests

- a. **Testing for blood.** The Hemocult ICT (HemoCue), an immunochemical test that gives fewer false-positive results, can be used to test the emesis or stool. Gastrocult (HemoCue) is used to test gastric fluid for blood.
- b. **Apt-Downey test** is performed to determine if swallowed maternal blood is a possible cause. This test differentiates maternal from fetal blood; fetal/newborn hemoglobin F is not hydrolyzed by a strong base, whereas maternal hemoglobin A hydrolyzes to a yellow brown. A negative test does not completely rule out swallowed maternal blood.
- c. **Hematocrit.** Should be checked as a baseline and serially to gauge the extent of blood loss. It is not a reliable index of the severity of the acute GI bleed.
- d. **Complete blood count with differential.** A change in the white blood cell count may indicate infection. Thrombocytopenia is associated with necrotizing enterocolitis (NEC) and sepsis. A low mean corpuscular volume of red cells suggests a chronic bleed.
- e. **Coagulation studies** (platelet count, prothrombin time [PT], partial thromboplastin time [PTT], fibrinogen, thrombin time, and international normalized ratio). See Table 60–1. All neonates with UGI bleeding should be screened for coagulopathy. An elevated PT and prolonged PTT suggest a coagulopathy.
- f. **Chemistry panel.** An elevated blood urea nitrogen can be seen in a massive UGI bleed.
- g. **Type and cross match** blood in case of transfusion is necessary.

Table 60–1. COAGULATION TESTING IN VARIOUS DISEASE STATES

Test	Vitamin K Deficiency	DIC	Liver Disease	Hemophilia Bleeding
Platelets	Normal	Reduced	Normal	Normal
PT	Prolonged	Prolonged	Prolonged	Normal
PTT	Prolonged	Prolonged	Prolonged	Prolonged
TT	Normal	Prolonged	Prolonged	Normal
Fibrinogen	Normal	Reduced	Reduced	Normal

DIC, disseminated intravascular coagulation; PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time.

2. **Additional tests**
 - a. **Liver function tests.** If cholestasis is a concern, total and direct bilirubin and liver function tests should be done. Elevated liver enzymes may indicate liver disease.
 - b. **Serum pepsinogen level.** Elevated levels can indicate severe atrophic gastritis and gastric atrophy; levels can be elevated in infants with gastric and duodenal lesions.
- C. **Nasogastric lavage.** Used to confirm the diagnosis and determine whether the bleeding is ongoing. Place NG tube for gastric lavage.
 1. **Nasogastric lavage is negative (no blood is seen):** No active UGI bleeding or the bleeding has stopped.
 2. **Nasogastric lavage is positive (fresh blood in stomach):** Diagnostic of UGI bleeding, including duodenal hemorrhages.
 3. **Repeated nasogastric lavage**
 - a. **Clearing of the fluid:** Bleeding has stopped.
 - b. **Persistent red or pink fluid:** Ongoing bleed.
- D. **Imaging and other studies**
 1. **Immediate tests**
 - a. **Abdominal radiograph.** Assess the bowel gas pattern and rule out NEC. The film also shows the position of the NG tube and indicates a possible surgical problem. It can help identify a bowel obstruction, pneumoperitoneum, small bowel dilatation, and pneumatosis intestinalis.
 2. **Additional tests**
 - a. **Upper gastrointestinal series.** A barium contrast study can be done for non-emergent bleeding. It can evaluate for UGI bleed or midgut volvulus. Not recommended when acute bleeding is occurring.
 - b. **Endoscopy.** Fiberoptic/flexible UGI endoscopy (esophagogastroduodenoscopy) is the test of choice to evaluate for hematemesis. It is used for both diagnosis and therapy. It reveals the source of bleeding in 90% of patients with UGI bleeding. It is safe (smaller endoscopes) and should be considered in bleeding that is persistent or recurrent or in cases of severe hemorrhage requiring blood transfusion. Gastric lavage and intravenous (IV) erythromycin (*controversial*) can be used prior to the test to clean the area and improve visualization of the gastric mucosa. In 1 study, the most common lesion identified by endoscopy was gastroesophagitis (unique to neonates). Erythema, erosions, diffuse bleeding, or ulcerations can also be seen.
 - c. **Ultrasound.** Ultrasound can show portal hypertension. If pyloric stenosis is suspected, ultrasound of the abdomen should be done.
 - d. **Hepatobiliary scan.** To rule out biliary atresia and neonatal hepatitis.
- V. **Plan**
 - A. **Prophylactic treatment of high-risk neonates** at risk for stress-induced gastric UGI bleeding. Cochrane review (July, 2019) found that use of an H₂ receptor antagonist decreases the risk of GI bleeding in newborns at high risk of GI bleeding.
 - B. **Consider giving parenteral vitamin K** to infants if vitamin K deficiency bleeding is suspected, even before the coagulation results are done.
 - C. **General measures.** Evaluate the infant, verify if the bleed is a true GI bleed (eg, rule out swallowed maternal blood, trauma from ETT, nasopharyngeal trauma), assess if bleeding is minimal or significant, if the bleeding is ongoing, if there is any hemodynamic compromise (check heart rate, blood pressure, capillary refill).
 - D. **If the infant appears well and bleeding is minimal and there is no evidence of hemodynamic compromise,** rule out more benign causes (mild esophagitis or gastritis, milk protein allergy, and other causes). Do the Apt test if swallowed maternal blood is suspected as the cause. Treatment depends upon the cause: observation, possible antisecretory medications can be used (if indicated), possible formula change.

E. If the infant is actively bleeding, and the bleeding is significant/severe: Do a quick airway, breathing, and circulation assessment. Order stat laboratory tests including a type and cross to ensure blood is available if needed. These infants may show signs of hemodynamic instability with decreased vascular volume, hypotension, and impending shock. The most important goal is to stabilize the infant and stop the active bleeding. Pediatric gastroenterologist/pediatric surgery consultation is recommended for a significant UGI bleeding.

1. **Airway/breathing.** Assess the airway and breathing and make sure the infant does not require intubation and mechanical ventilation. Supplemental oxygen should be started.
2. **Circulation.** Verify vascular access. Assess if volume replacement is necessary. Check blood pressure, heart rate, and capillary refill. If the blood pressure is low or dropping, crystalloid (usually normal saline) can be given immediately. **Blood replacement** may be indicated, depending on the amount of blood loss and the result of hematocrit values obtained from the laboratory. Fresh-frozen plasma and platelet transfusions may be necessary.
3. **Stop the acute episode of gastrointestinal bleeding**
 - a. **Gastric lavage** (with room temperature or tepid water, 1/2 normal saline [NS], or NS 5 mL/kg) by NG tube until the bleeding has subsided. This should not be done beyond 10 minutes if the NG fluid does not clear. (**Note:** There is *controversy* about which fluid to use. Hyponatremia may occur if water is used and hypernatremia if NS is used. Follow your institution's guidelines.) **Never use ice or cold water lavages** as it lowers the infant's core temperature. Gastric lavage is *controversial*, and there is no definitive evidence to support that it controls hemorrhage.
 - b. **Epinephrine lavage (*controversial*)**. Use 0.1 mL (1:10,000 solution) diluted in 10 mL of sterile water. Considered if tepid water lavages do not stop the bleeding.
 - c. **Therapeutic endoscopy.** This has been recommended in patients with active bleeding that cannot be controlled to avoid surgery. Gastric lavage and IV erythromycin (*controversial*) can be used prior to the test to clean the area and improve visualization of the gastric mucosa. **Endoscopic hemostatic techniques may be necessary in massive bleeds** and include cautery (electrocoagulation, laser photocoagulation, heater probe thermocoagulation), injection therapy (sclerosing agents, dilute epinephrine), and mechanical therapy (hemoclips and endoscopic band ligation).
 - d. **Intravenous acid suppression therapy** has been used in adults and has reduced the rate of rebleeding. Cochrane review (July, 2019) found that there is low-quality evidence that the use of an H₂ receptor antagonist or proton pump inhibitor decreases the duration of UGI bleeding. Many physicians will treat infants with GI bleeding with acid suppression medications. **Use of ranitidine (H₂ blocker) has been shown to control mild-to-moderate bleeding in 24 to 48 hours.**
 - e. **Somatostatin and a long-acting synthetic peptide analog octreotide.** These are typically used to decrease bleeding in some cases of variceal bleeding. These medications decrease blood flow to the portal system, thereby decreasing variceal bleeding. These medications have been associated with a decreased risk of continued bleeding in some patients. Their use in acute bleeding ulcer disease is *controversial* because they also decrease splanchnic blood flow and prevent gastric acid secretion.

F. Disease-specific measures

1. **Swallowing of maternal blood.** Observation only.
2. **Trauma** is usually self-limiting, requiring observation only.
3. **Stress-related mucosal lesions.** Commonly diagnosed after an episode of GI bleeding by endoscopy. This disorder is difficult to confirm using radiologic

studies. Remission usually occurs, and recurrence is rare. Acid suppression agents are used even though evidence-based recommendations are not available. The following medications have been used: antacids, acid suppression medications (proton pump inhibitors [PPIs], H_2 receptor antagonists), and mucosal protective agents (sucralfate and bismuth salts).

- a. **Antacids neutralize gastric acid in the lumen of the esophagus or stomach and inhibit pepsin activity** such as aluminum/magnesium hydroxide (eg, Maalox) 0.5 to 1 mL/kg or 0.25 mL/kg, 6 times per day, placed in the NG tube until bleeding has subsided. This is **controversial** because it may cause concretions in the GI tract and may increase the risk of infection and feeding intolerance in infants receiving gavage feedings. Calcium- and aluminum-containing antacids cause diarrhea, and magnesium-containing antacids can cause constipation. Possible side effects include hypermagnesemia, hypophosphatemia, and intestinal obstruction. Chronic use of antacids can be associated with aluminum toxicity and milk-alkali syndrome.
 - b. **Acid suppression medications** are recommended for erosive esophagitis and gastric and duodenal ulcers and are only beneficial if the infants have acid-related problems. The majority of these medications are not approved for infants <1 month of age. A few are approved for infants >1 month of age.
 - i. **Proton pump inhibitors** block gastric acid production and decrease pepsin secretion. They are superior to H_2 blockers in the treatment of peptic ulcers after endoscopy. Studies show they have faster healing times than H_2 blockers. These include esomeprazole (Nexium), omeprazole (Prilosec), lansoprazole (Prevacid), rabeprazole (AcipHex), and pantoprazole (Protonix). Studies with these agents are promising, but they are not all approved in neonates. Esomeprazole is currently recommended only as treatment for erosive esophagitis. Esomeprazole and omeprazole are approved in infants >1 month of age for erosive esophagitis. There is an increased risk of pneumonia and diarrhea. See doses in Chapter 155.
 - ii. **H_2 receptor antagonists** suppress gastric acid production by binding to H_2 receptors, which inhibits the effects of histamine. They have a faster onset of action but shorter duration of action than PPIs. These are less effective than PPIs in decreasing gastric acidity. **Ranitidine and famotidine are preferred** because they have fewer side effects. See Chapter 155 for dosing information. Follow your institution's guidelines. Cimetidine is rarely used because of adverse effects and clinically significant drug interactions. H_2 -blocker therapy is associated with higher rates of NEC in very low birthweight infants and infections.
 - iii. **Mucosal protective agents (sucralfate or bismuth salts)** are medications that provide physical protection of the gastric mucosa and promote mucosal healing. These may play a role in prophylaxis of UGI bleeding in neonates.
4. **Coagulation disorders.** See also Chapter 92.
- a. **Vitamin K deficiency bleeding.** When vitamin K deficiency is suspected, vitamin K should be administered IV or subcutaneously. Intramuscular injection can result in severe hematoma. One milligram of vitamin K IV stops the hemorrhage within 2 hours.
 - b. **Disseminated intravascular coagulation.** Associated with bleeding from other sites. Coagulation studies are abnormal (increased PT and PTT with decreased fibrinogen levels; see Table 60–1). Treat the underlying condition and support blood pressure with multiple transfusions of colloid as needed. Platelets may be required. The cause of DIC (eg, hypoxia, acidosis, bacterial or viral disease, toxoplasmosis, NEC, shock, or erythroblastosis fetalis) must be investigated. Several obstetric disorders, including abruptio placentae, chorioangioma, eclampsia, and fetal death associated with twin gestation, may give rise to DIC.

- c. **Congenital coagulopathies.** The most common that present with bleeding are secondary to factor VIII deficiency (hemophilia A) and factor IX deficiency (hemophilia B). Specific laboratory testing and appropriate consultation with a pediatric hematologist are appropriate.
- 5. **Allergic colitis.** Eliminate the formula and change to a hypoallergenic formula.
- 6. **Drug-induced bleeding.** The drug responsible for the bleeding should be stopped, if possible.
- 7. **Congenital defects** such as gastric volvulus, malrotation with volvulus, Hirschsprung disease with enterocolitis, and gastric duplication require urgent surgical consultation.
- 8. **Gastrointestinal bleeding due to liver disease.** Usually due to variceal bleeding. The following medications decrease blood flow to the portal system, thereby decreasing variceal bleeding.
 - a. **Octreotide (Sandostatin) is an analog of somatostatin.** Dosage recommended (safety and dosing not firmly established) is 1 mcg/kg IV bolus, followed by 1 mcg/kg/h IV infusion. If no bleeding occurs in 12 hours, decrease the dose by 50%. Then stop the medication when the dose is 25% of the initial dose.
 - b. **Vasopressin (Pitressin).** Used in neonates but has many adverse effects, so it not recommended.
 - c. **Terlipressin** is a long-acting analog of vasopressin with a good safety profile, but hyponatremia and seizures have been reported in the pediatric population.
- 9. **Necrotizing enterocolitis.** See Chapter 109.
- 10. **Pyloric stenosis.** Hydration and surgical pyloromyotomy are necessary.

61 Hematuria

- I. **Problem.** A nurse reports that an infant has a red-stained diaper and states the infant may have hematuria. **Hematuria is the presence of gross or microscopic blood in the urine.** It is more common in premature infants in the neonatal intensive care unit than in healthy newborns. Studies on incidence are lacking, but one older retrospective study reporting gross hematuria in 0.21 per 1000 admitted infants <1 month old. The differential diagnosis in neonates is different than in older children. Gross hematuria requires an immediate evaluation, whereas microscopic hematuria is usually transient and benign in the neonate.
- II. **Immediate questions**
 - A. **Does the infant really have hematuria?** A red-stained diaper usually signifies hematuria but may be due to **pseudohematuria** (red-colored urine in the absence of red cells or hemoglobin) or **blood from a nonurinary source** that is mistaken for gross hematuria in the diaper or **myoglobinuria or hemoglobinuria**. First it needs to be decided whether the urine dipstick is positive or negative for blood. If urine is negative for blood then it is pseudohematuria. If it positive for blood microscopic urinalysis needs to be done to confirm RBCs are from the urine.
 - 1. **Negative dipstick for blood**
 - a. **Urate crystals** can present as pinkish to reddish brown discoloration in the diaper. It is more commonly seen in volume depletion, especially in breast-fed neonates. This is a benign condition, and treatment is increased fluid intake.

is common in critically ill infants. The most common cause of gross hematuria is renal vein thrombosis.

A. Verify it is true hematuria. Rule out causes that are not hematuria first. See Section II.A above.

B. Causes of hematuria

1. **Trauma.** Gross hematuria can be seen after a traumatic birth (rare) or after a suprapubic bladder aspiration (more common up to 3.4%), urethral catheterization (especially if urethra narrow or obstructed), cystoscopy, or placement of percutaneous nephrostomy tubes. Trauma to the urethral mucosa usually causes microscopic hematuria. Bladder hematomas or a lacerated vessel on the anterior bladder wall can occur from a suprapubic bladder aspiration and cause hematuria. It is important to note that mild birth trauma can cause bleeding in a kidney with hydronephrosis.
2. **Vascular thrombosis of an artery or vein can cause hematuria.** Neonates are at an increased risk for thrombosis because of their small-caliber vasculature, their kidney has a lower perfusion pressure, imbalance of coagulation factors, and decreased level of clotting inhibitors. Multiple maternal factors (diabetes, chorioamnionitis, thrombotic states) and infant factors (sepsis, hypotension, hypoxia, dehydration, polycythemia, umbilical artery catheterization) also increase their risk.
 - a. **Renal vein thrombosis.** Renal vein thrombosis (RVT) is the most common thrombosis in newborns not associated with an intravascular catheter. It is most common in males and on the left side and is more commonly unilateral. It usually presents within 24 hours or on the second day of life. The classic triad (only present in up to 22% of patients) is gross hematuria, flank mass, and thrombocytopenia. Consider RVT in an infant of a diabetic mother or an infant with cyanotic congenital heart disease, birth asphyxia or in utero fetal distress, dehydration, coagulation abnormalities (activated protein C-resistance, factor V Leiden mutation), polycythemia, infection, prematurity, conjoined twin, or an umbilical venous catheter.
 - b. **Renal artery thrombosis.** Less common than RVT, renal artery thrombosis (RAT) is associated with aortic thrombus (often) and an umbilical artery catheter (almost always). Infants present with gross or microscopic hematuria, thrombocytopenia, and hypertension.
3. **Renal diseases**
 - a. **Renal cortical necrosis** can be secondary to a kidney insult (cortical ischemia secondary to sepsis, blood loss, NEC, dehydration, severe hypoxic ischemic injury, placental abruption, twin–twin transfusion, or nephrotoxic medications). It can cause microscopic or gross hematuria and oliguria, hypertension, abnormal electrolytes, and an increased creatinine.
 - b. **Acute tubular necrosis** rarely causes gross hematuria.
 - c. **Glomerulonephritis** (rare in neonates) causes microscopic or gross hematuria, proteinuria, hypertension, and edema. Neonatal lupus, syphilis, and neonatal hemolytic-uremic syndrome are potential causes.
4. **Structural abnormalities/malformations in the urinary tract.** Any cause of obstruction or anatomic anomaly can cause hematuria.
 - a. **Posterior urethral valves.** Most common cause of lower urinary tract obstruction (males). Most are diagnosed prenatally with hydronephrosis. A small percent of neonates can have gross hematuria within the first month of life.
 - b. **Congenital ureteropelvic junction obstruction (rare).** Presents with hydronephrosis and gross hematuria.
 - c. **Cystic kidney disease.** Autosomal recessive polycystic kidney disease and autosomal dominant polycystic kidney disease can present with gross or microscopic hematuria and proteinuria. Infants with ARPKD can have a flank mass and respiratory symptoms.

- d. **Medullary sponge kidney and ureterocele** (rare causes of hematuria in newborn).
5. **Urolithiasis**
- a. **Nephrocalcinosis (calcium salts within the renal tissue) or nephrolithiasis (formation of stones in the kidney)**. Nephrocalcinosis caused by calcium oxalate (most common) or calcium phosphate is more common in preterm infants (up to 40%) because of renal immaturity and use of medications. Both nephrocalcinosis and nephrolithiasis can cause hematuria, but it is more common in nephrolithiasis. Term infants with distal renal tubular acidosis, Dent disease, or hyperparathyroidism can have nephrocalcinosis associated with hypercalciuria. Certain medications can cause nephrocalcinosis (dexamethasone, glucocorticoids, methylxanthines).
- b. **Urolithiasis** (formation of stones anywhere in the urinary track) can be seen after chronic furosemide administration.
6. **Tumors**. Renal tumors are very rare in neonates, with the majority identified by prenatal ultrasound. Clinically, they present with an abdominal mass (more common) and hematuria. The most common renal tumor in neonates is congenital mesoblastic nephroma, followed by Wilms tumor. Renal tumors are associated with several syndromes (Beckwith-Wiedemann, Denys-Drash, and WAGR [Wilms tumor, aniridia, genitourinary anomalies, and intellectual disability] syndrome). Other tumors include rhabdomyosarcoma, nephroblastoma, angiomas, ossifying renal tumor of infancy, and bladder hemangioma (rare).
7. **Infection**. Infections can cause hematuria specifically: sepsis, UTI, viral infections, infectious endocarditis. Infants with a UTI can have hematuria, but it is not common. Neonates with urosepsis not caused by *Escherichia coli* have an increased risk of structural abnormalities. Viral infections (adenovirus and BK virus) can cause hematuria in immunocompromised children. Infectious endocarditis (rare) is more common in neonates who have congenital heart disease or sepsis and can present with a new or changed heart murmur and hematuria.
8. **Hematologic disorders**
- a. **Vitamin K deficiency bleeding**, previously called hemorrhagic disease of the newborn, can manifest with gross or microscopic hematuria. However, infants more commonly present with bleeding elsewhere (eg, umbilical stump, gastrointestinal tract, skin). It is seen in infants who did not receive vitamin K prophylaxis and exclusively breast-fed infants, and the risk is increased in infants of mothers on certain medications (anticonvulsants, rifampin, isoniazid, and warfarin).
- b. **Thrombocytopenia**. Severe thrombocytopenia (platelets $<60,000 \mu\text{L}$) can cause microscopic hematuria and is more common in premature infants.
- c. **Disseminated intravascular coagulation**. Seen in asphyxia, sepsis, and respiratory distress syndrome.
- d. **Polycythemia** can cause hematuria.
9. **Medications**. Most common are nonsteroidal anti-inflammatory drugs, especially indomethacin, which can cause interstitial nephritis and microscopic hematuria.

IV. Database

A. History

1. **Include timing of onset of hematuria**, persistent or intermittent, correlation with illnesses or trauma, and association with other symptoms (eg, fever). History can guide the full evaluation.
2. **Prenatal history**. Was there a maternal prenatal ultrasound? Was it abnormal? (Any masses or kidney abnormalities? Was amniotic fluid volume within normal limits?)
3. **Maternal history**. Does the mother have kidney disease (genetic, kidney stones, glomerulonephritis, autoimmune disorders)? Any diabetes or bleeding disorders?

What medications was the mother on? Are there any bleeding disorders in the mother? Previous pregnancies?

4. **Family history** should focus on genetic kidney disease, stone disease, or bleeding disorders.
 5. **Birth history** should focus on prematurity or if any resuscitation was required. Was vitamin K given at birth? When did the infant first urinate?
 6. **Postnatal history.** Urine output? Weight gain or loss? Breast fed or bottle? Is the infant on a high calcium formula or on TPN (increased risk of nephrocalcinosis)? Any evidence of syndromes (hemihypertrophy and Beckwith-Wiedemann syndrome associated with medullary sponge kidney)? Beckwith-Wiedemann and Denys-Drash and WAGR are associated with renal tumors.
- B. Physical examination.** Note temperature (infection?), blood pressure (hypertension suggests kidney involvement or ARPKD, hypotension suggests infection or cardiac dysfunction), bruising, petechiae (suggest bleeding disorder), or edema (glomerulonephritis). Abdominal mass (obstruction, neoplasm, ARPKD [flank mass], renal vein thrombosis) may be noted. Is there subcutaneous fat necrosis (hypercalcemia)? Remove the diaper to examine the genitalia and rectum. Note the presence of urinary or umbilical artery catheters.
- C. Laboratory studies**
1. **Urinalysis**
 - a. **Urine dipstick evaluation. A positive urine dipstick confirms the presence of red blood cells or free myoglobin or hemoglobin.** Protein, leukocytes, and nitrates should be evaluated as well. Association with proteinuria is concerning and indicates significant abnormality in the kidney (eg, glomerulonephritis). White blood cells (WBCs) and nitrates suggest infection.
 - b. **Microscopic examination of urine** is done on any positive dipstick of the urine and helps to identify the origin of the hematuria. Normal red blood cells (RBCs) suggest lower tract origin, whereas dysmorphic RBCs suggest upper tract disease. RBC casts are seen in glomerulonephritis, and WBCs with bacteria on a properly collected specimen suggest infection. There are no RBCs in the microscopic examination of urine in hemoglobinuria or myoglobinuria.
 2. **Urine culture.** Collection of urine by catheterization or suprapubic bladder aspiration to rule out UTI.
 3. **Complete blood count and differential and platelet count.** This may help diagnose an infection, thrombocytopenia, or polycythemia.
 4. **Serum blood urea nitrogen and creatinine levels.** Abnormal levels may indicate renal insufficiency; they may also reflect maternal renal function during the first week of life.
 5. **Coagulation studies.** Thrombocytopenia may indicate renal vein thrombosis. Abnormal prothrombin time and partial thromboplastin time may indicate disseminated intravascular coagulation or hemorrhagic diseases of the newborn.
 6. **Electrolytes, calcium, phosphorus, and spot urine calcium/creatinine (if term infant)** and parathyroid hormone level for nephrocalcinosis.
- D. Imaging and other studies**
1. **Renal and bladder ultrasonography is usually the first test** to show upper urinary tract dilation, congenital anomalies of the urinary tract or neoplasms, or renal calcification. In renal cortical necrosis, atrophy of the kidney can be seen with increased echogenicity and loss of cortical medullary differentiation. Ultrasound findings of RVT vary depending on when the scan is done (early: enlarged kidney with increased echogenicity; later: decreased kidney size, calcification of thrombus).
 2. **Renal Doppler ultrasonography** evaluates renal blood flow. In renal cortical necrosis there is decreased perfusion with patent renal vessels. In RVT there is decreased flow in the main renal vein or abnormal flow in the renal vein branches.
 3. **Voiding cystourethrogram** to rule out bladder outlet obstruction.

4. **Computed tomography/magnetic resonance imaging** may be used for evaluation of neoplasms and renal vein thrombosis.
 5. **Radioisotope renography** is rarely required but may be used to assess for functional renal parenchyma. In cortical necrosis, it will show no perfusion of the kidney.
 6. **Cystoscopy is rarely required.** For evaluation of recurrent gross hematuria or for urethral and bladder pathology or if ultrasound shows something suspicious in the bladder.
 7. **Echocardiogram to rule out cardiac vegetations** if infectious endocarditis is suspected.
- V. **Plan.** Most cases of microhematuria are transient and resolve without any specific therapy. Some authors recommend that 2 of 3 urinalyses show microhematuria before an evaluation is undertaken. Persistent hematuria or gross hematuria requires urologic or nephrology consultation. **It is important to note that gross hematuria may cause obstructive ureteropelvic junction clots that may cause hydronephrosis.** Some clinicians recommend serial ultrasounds during the time of the gross hematuria.
- A. **Trauma.** Expectant management for minor birth trauma or instrumentation of the urinary tract. The hematuria is typically self-limited and resolves quickly. Intervention is rarely required.
 - B. **Vascular.** RVT and RAT: supportive care, removal of arterial catheter for RAT, thrombolytic agents, heparin (see Chapter 92).
 - C. **Infections.** Treat with appropriate antibiotics.
 - D. **Obstruction.** Indwelling urethral catheter for bladder outlet obstruction; may require acute or nonurgent operative intervention for congenital anomalies of the urinary tract based on urology consultation.
 - E. **Nephrocalcinosis.** Treated with increased fluids and thiazide diuretic. Long-term follow-up is recommended.
 - F. **Tumors.** Operative intervention may be needed, and consultation with pediatric urologist and oncologist is suggested. For congenital mesoblastic nephroma and Wilms tumor, the treatment is based on stage and may involve radical nephrectomy or a combination of surgery and chemotherapy (see Chapter 127).
 - G. **Hematologic.** Correct coagulopathies if present (see Chapter 92). For vitamin K deficiency bleeding, give vitamin K; for severe bleeding, fresh-frozen plasma may be necessary. For microscopic hematuria and thrombocytopenia no treatment is necessary. For gross hematuria and thrombocytopenia consider platelet transfusion.
 - H. **Renal.** Supportive measures and treatment of the specific cause. Restrict fluid intake and replace insensible losses. May require renal replacement therapy (dialysis or transplantation). (See Chapter 86.) With renal cortical necrosis, acute dialysis may be needed with risk of kidney failure.

62 Hyperbilirubinemia: Conjugated, On Call

- I. **Problem.** An infant's direct (conjugated) serum bilirubin level is elevated at 3 mg/dL. Conjugated bilirubin is the fraction of bilirubin that is conjugated with glucuronic acid in the liver to form bilirubin diglucuronide. It is a biochemical marker of cholestasis. Neonatal cholestasis is **conjugated hyperbilirubinemia** in the newborn period and is an accumulation of bile substances in the liver. It is secondary to decreased bile secretion from the liver to the duodenum and usually signifies an underlying hepatobiliary or metabolic dysfunction. Cholestasis can be **extrahepatic/obstructive** (most commonly biliary atresia, other causes include choledochal/biliary cyst, inspissated bile syndrome,

obstructive tumors, gallstones) or **intrahepatic/nonobstructive** (idiopathic, infectious, metabolic/genetic, autoimmune, or toxic). This chapter incorporates recommendations from the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN), the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN), and the American Academy of Pediatrics (AAP) on the management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. **NASPGHAN defines an abnormal direct bilirubin** as >1 mg/dL. **The AAP defines an abnormal direct bilirubin** as >1 mg/dL if the total serum bilirubin (TSB) level is ≤ 5 mg/dL. If the TSB level is >5 mg/dL, a direct bilirubin $>20\%$ of the TSB is abnormal. The majority of prolonged physiologic jaundice is secondary to breast milk jaundice, but it is important not to misdiagnose cholestasis as physiologic jaundice because this will delay the early diagnosis that is essential for treatment. **Conjugated hyperbilirubinemia is never normal or physiologic and indicates hepatobiliary dysfunction.** It occurs in 1 in every 2500 term infants, and common causes in the newborn infant are biliary atresia (25%–40%), monogenic disorders (25%), and multifactorial or unknown etiologies. The more common causes in premature infants are prolonged parenteral nutrition and sepsis. Timely diagnosis is critical for successful treatment and optimal prognosis, in particular for biliary atresia. Kasai hepatic portoenterostomy should be done as soon as possible to establish bile flow and is best performed within the first 60 days of life (approximately 70% with bile flow vs $<25\%$ with bile flow at >90 days). See also Chapter 98 for additional discussion on conjugated hyperbilirubinemia management.

II. Immediate questions

A. What is the stool and urine color?

1. **Dark urine.** The presence of dark urine is a nonspecific indicator of increased conjugated bilirubin.
 2. **Stool color.** A stool examination is vital to the workup of every infant with cholestasis. A persistent pale or clay-colored stool suggests an extrahepatic obstruction/biliary obstruction. When bile flow decreases, the stool starts to lose its normal pigmentation. One or 2 pale stools usually do not indicate disease, and infants with biliary atresia can have normal stools.
 - a. **Pale/clay/depigmented stool** with increased serum bilirubin can be associated with biliary atresia, choledochal/biliary cyst, biliary sludge (inspissated bile syndrome), Alagille syndrome, neonatal sclerosing cholangitis, cystic fibrosis, and α_1 -antitrypsin deficiency.
 - b. **Normal stool with increased serum bilirubin:** Consider infection, hypothyroidism, panhypopituitarism, cystic fibrosis, α_1 -antitrypsin, progressive familial intrahepatic cholestasis (PFIC), and metabolic and storage disorders.
- B. Does the infant appear sick?** Infants with intrahepatic cholestasis often appear ill, whereas those with extrahepatic cholestasis usually do not. **Infants with cholestasis who are ill appearing warrant an immediate evaluation for bacterial sepsis** because an infection can cause hepatocellular damage and increase bilirubin levels. Other disorders that can present with cholestasis and an ill-appearing infant include urinary tract infection, galactosemia, tyrosinemia, hypopituitarism, fructosemia, gestational alloimmune liver disease (fetal demise with acute liver failure), any metabolic disorder, an acute common duct obstruction, or hemolysis. These disorders also require a rapid diagnosis and treatment.
- C. Is the infant receiving total parenteral nutrition? Parenteral nutrition–associated liver disease (PNALD)** does not occur until the infant has been on total parenteral nutrition (TPN) for >2 weeks. It is more common in premature infants. Resumption of enteral foods improves cholestasis.
- D. Have any risk factors been identified?** The **most important risk factors** are prematurity, prolonged exposure to parenteral nutrition, lack of enteral feeding, and infection. Other risk factors include small for gestational age, congenital infections, hemolytic process (Rh or ABO incompatibility), and trisomy 21.

- E. At what age did the direct hyperbilirubinemia occur?** Age at which the direct hyperbilirubinemia occurs may provide a clue to the diagnosis.
- 1. Early-onset conjugated hyperbilirubinemia** (≤ 14 days). More likely due to nonhepatic causes and more infants were likely to be sick. Causes include: multifactorial liver injury (eg, antibiotics, TPN, sedatives, mechanical ventilation, surgery), sepsis, inborn error of metabolism, idiopathic, biliary atresia, choledochal cyst.
 - 2. Late-onset conjugated hyperbilirubinemia** (15–28 days). Idiopathic, multifactorial liver injury (eg, antibiotics, TPN, sedatives, mechanical ventilation, surgery, inotropic support), biliary atresia, sepsis, cytomegalovirus (CMV) infection/choledochal cyst, inborn errors of metabolism.
 - 3. Presence of direct hyperbilirubinemia immediately after birth** (within hours or few days) may be secondary to congenital infection, hemolysis (with biliary sludging), gestational alloimmune liver disease, genetic disorders, or inborn errors of metabolism.
 - 4. Presence of direct hyperbilirubinemia after feedings** are established suggests that a metabolic disorder such as galactosemia may be present.
 - 5. Onset of jaundice in an asymptomatic infant after the first week of life** may be secondary to an underlying infection such as urinary tract infection.
- F. Is there evidence of liver dysfunction or failure?** If presentation is accompanied by evidence of liver dysfunction or failure, the following should be highly considered in the differential diagnosis: gestational alloimmune liver disease (formerly known as neonatal hemochromatosis), infection (congenital herpes simplex virus [HSV], CMV, viral hepatitis), α_1 -antitrypsin deficiency, inborn error of metabolism (tyrosinemia, galactosemia), congenital leukemia, neuroblastoma, hypoxic-ischemic event, biliary atresia, and hemoglobinopathy.
- III. Differential diagnosis.** There is a significant listing for the differential diagnosis of conjugated hyperbilirubinemia in the neonate. Clues in the history and physical examination may help to narrow the diagnosis. **Remember that any condition that alters the systemic circulation** can cause an acute ischemic injury to the liver that can cause a temporary increase in direct bilirubin 24 to 48 hours after the insult. These conditions include: shock, hypoxia, severe metabolic acidosis, birth asphyxia, and cardiopulmonary arrest. Based on 1 extensive study, causes in order of frequency included: idiopathic neonatal hepatitis, extrahepatic biliary atresia, infection (CMV most common), TPN, metabolic disease (galactosemia most common), α_1 -antitrypsin deficiency, and perinatal hypoxia-ischemia. Another study reported biliary atresia, idiopathic neonatal hepatitis, metabolic and endocrine causes, PFIC, preterm birth, infectious diseases, mitochondrialopathies, and biliary sludge as the most common causes. The **single most common cause in the neonatal intensive care unit is parenteral nutrition related**, especially in premature infants. See Table 98–1 for selected causes of conjugated hyperbilirubinemia.
- A. Common causes**
- 1. Biliary atresia.** This is a progressive obliterative process involving the bile ducts and is fatal if untreated. It may present as part of a syndrome with associated malformations (30% of cases) such as polysplenia, situs inversus, cardiac anomalies, and/or vascular malformations (absent inferior vena cava). It is the most common cause of end-stage liver disease resulting in liver transplantation in children. Clinical findings that should raise index of suspicion include unexplained cholestasis associated with acholic/clay-colored stools and dark urine. These infants typically appear well except for presence of jaundice and associated clinical findings. High γ -glutamyl transferase (GGT) and a small or absent gallbladder on ultrasound are suggestive of biliary atresia. **Mimickers of biliary atresia include α_1 -antitrypsin deficiency, Alagille syndrome, PNALD, and cystic fibrosis.**
 - 2. Idiopathic neonatal hepatitis/neonatal giant cell hepatitis.** Idiopathic neonatal hepatitis is the term given to any hepatitis that is diagnosed from birth up to

the fourth month of life with no known cause, after all other causes have been excluded by clinical and laboratory evaluation. No known infectious or metabolic cause can be found. Most occur sporadically, but some (up to 20%) run in families. Idiopathic neonatal hepatitis can occur in premature infants due to an immature biliary tree and can manifest as feeding difficulties and hypoglycemia.

3. **Genetic intrahepatic cholestasis.** Includes many proposed subtypes of intrahepatic cholestasis. Each of these diseases is rare, but collectively as a group, they may be a common cause of conjugated hyperbilirubinemia. These are chronic diseases, and many progress and require liver transplantation.
 - a. **Progressive familial intrahepatic cholestasis** is a group of autosomal recessive disorders characterized by defective bile export leading to subsequent cholestasis (includes PFIC1 [formerly Byler disease], PFIC2, and PFIC3).
 - b. **Alagille syndrome** is a genetic disorder with multisystem involvement characterized by paucity of the intrahepatic bile ducts (cholestasis), cardiovascular anomalies (peripheral pulmonic stenosis), skeletal abnormalities (butterfly vertebrae), ophthalmologic findings (posterior embryotoxon), and “typical facies” (triangular face, low-set ears, hypertelorism). It is inherited in an autosomal dominant fashion but may occur sporadically due to de novo mutation. Most individuals carry a mutation in *JAG1* gene located in chromosome 30; however, some have mutations in *NOTCH2*.
4. **Hyperalimentation/parenteral nutrition–associated liver disease (PNALD).** **The most common drug-induced liver injury is caused by parenteral nutrition. Incidence is 20% in infants receiving parenteral nutrition for >2 weeks.** The etiology of PNALD is multifactorial. Several theories have been proposed as to the role of soybean-based intralipid in its pathophysiology, including modulation of oxidative stress and inflammation and phytosterols causing inhibition of bile acid–induced bile salt export pump expression. The most important cause of parenteral nutrition–related pathology appears to be the disruption of normal enterohepatic circulation due to lack of feedings, as evidenced by improvement of cholestasis with resumption of enteral feeds. Risk factors identified that contribute to development of PNALD include prematurity, low birthweight, infection, and overall prolonged exposure to TPN. It is rare that cholestasis will develop if exposure is <2 weeks.
5. **Infections.** Bacterial, viral, and protozoal infections have been reported to cause cholestasis. Sepsis and UTI can both cause direct hyperbilirubinemia. Jaundice may be the only presenting sign of urinary tract infection (*Escherichia coli* being the most common organism). Congenital infections such as CMV, toxoplasmosis, rubella, herpes, syphilis, and human immunodeficiency virus may present with early-onset cholestasis (jaundice in the first 24 hours), coagulopathy, and growth restriction. CMV is the most common congenital infectious cause of cholestasis. Adenovirus, enterovirus, echovirus, and parvovirus B19 are less common causes. Viral hepatitis A, B, and C typically do not cause neonatal cholestasis, but case reports exist.
6. **Inspissated bile syndrome.** This condition was first described in infants with blood group incompatibility, in particular Rh disease, complicated by severe hemolysis that can lead to excessive unconjugated hyperbilirubinemia, biliary sludging, and subsequent development of cholestasis. Most cholestasis due to sludge is mild and transient; however, some report a more severe and protracted course of cholestatic liver disease attributed to iron overload in neonates who received multiple intrauterine transfusions. Other reported causes include vitamin K deficiency bleeding, parenteral nutrition, sepsis, ABO incompatibility, medication (ceftriaxone pseudolithiasis, diuretics), and extracorporeal life support.
7. **Choledochal cysts (biliary cysts).** Extrahepatic bile duct cysts have been reclassified to include intrahepatic cysts (now called biliary cysts), and there are 6

different types of cysts. The most common is cystic dilatation of the common bile duct (type 1). They typically present with jaundice at 1 to 3 weeks of life; some may have obvious hepatomegaly, palpable mass in right upper quadrant, and rarely vomiting or fever. It is critical that biliary atresia is ruled out. Diagnosis can be made by performing a fasting abdominal ultrasound.

8. **α_1 -Antitrypsin deficiency. Most common genetic cause of cholestasis, inherited as an autosomal disorder.** These infants can present with intrauterine growth restriction and hepatomegaly, usually with acholic stools.
9. **Galactosemia.** Autosomal recessive disorder and the **most well-known metabolic disorder** that presents with prolonged jaundice. It can be caused by deficiencies in 1 of 3 enzymes involved in the metabolism of galactose: galactose-1-phosphate uridylyltransferase (GALT), galactokinase (GALK), and uridine diphosphate galactose-4-epimerase (GALE). Deficiency of the enzyme GALT is most common and most severe. *E coli* sepsis with liver cell dysfunction is characteristic of galactosemia.
10. **Perinatal hypoxia-ischemia.** This has been identified as an important causal factor in transient neonatal cholestasis. Shock can cause hepatic insult. Acute circulatory failure from congenital heart disease, myocarditis, and severe asphyxia can cause fulminant liver failure and conjugated hyperbilirubinemia.

B. Less common causes of direct hyperbilirubinemia

1. **Cholelithiasis (gallstones), biliary sludge.**
2. **Paucity of intrahepatic bile ducts.**
3. **Cholecystitis (acute and chronic).**
4. **Bile duct stenosis/spontaneous perforation of the bile duct.**
5. **Neonatal sclerosing cholangitis.** Etiology is unknown; presents in early infancy and then resolves.
6. **Select inborn errors of metabolism.** Wolman disease, Niemann-Pick diseases A and C, glycogen storage disease type IV, Gaucher disease, Zellweger syndrome (cerebrohepato-renal syndrome), neonatal hemochromatosis, tyrosinemia, fructosemia, mevalonic aciduria, and citrin deficiency. Cystic fibrosis can rarely present with cholestatic jaundice. Look for early signs of intestinal obstruction and low serum cholesterol. Bile acid synthetic defects, disorders of fatty acid oxidation, and citrin deficiency can all cause cholestasis. Mitochondrial respiratory chain defects can cause liver failure and usually present with a metabolic crisis.
7. **Endocrine disorders.** Congenital hypothyroidism, panhypopituitarism (infant with increased total and direct bilirubin, normal GGT, possible hypoglycemia, and shock).
8. **Congenital disorders.** Rotor syndrome and Dubin-Johnson syndrome are rare disorders of bilirubin metabolism that are noncholestatic; they have high direct and indirect hyperbilirubinemia but normal excretion of bile acid. Caroli disease is a congenital disease that has sacular dilatations of the intrahepatic bile ducts and is associated with polycystic kidney disease. Other rare diseases include: arthrogyrosis-renal dysfunction-cholestasis, Aagaens syndrome, Budd-Chiari syndrome, North American Indian familial cirrhosis, and hair-like bile duct syndrome.
9. **Chromosomal syndromes.** Trisomies 21, 18, and 13; monosomy X; partial trisomy 11; cat eye syndrome.
10. **Immunologic disorder. Neonatal hemochromatosis** is severe liver disease with extrahepatic siderosis in the neonate. It is mainly caused by **gestational alloimmune liver disease (GALD)**, now referred to as **GALD-NH**. Suspect this if there is severe coagulopathy not responsive to parenteral vitamin K and liver failure. Neonatal lupus erythematosus can also cause cholestatic jaundice.
11. **Bile acid synthesis disorders.** Rare disorders of synthesis of bile acids; some present with cholestasis. Patients often have normal or low GGTP and low serum bile acids.

12. **Neoplasms (rare)** include mesenchymal hamartoma, rhabdomyosarcoma of the biliary tree, neuroblastoma, hepatoblastoma, histiocytosis X, and neonatal leukemia.
13. **Medications.** There are case reports of maternal use of carbamazepine and methamphetamine causing neonatal cholestasis. Postnatal infant drugs include prolonged use of chloral hydrate, anticonvulsants, cephalosporins (ceftriaxone), erythromycin, ethanol, isoniazid, sulfa-containing products, rifampin, methotrexate, tetracycline, trimethoprim-sulfamethoxazole, flucanazole, and micafungin.

IV. Database. The physical examination alone cannot distinguish jaundice caused by cholestasis from jaundice caused by physiologic unconjugated hyperbilirubinemia. Physiologic unconjugated hyperbilirubinemia and cholestasis can coexist. That is why it is important to have screening recommendations regarding who to screen for cholestasis. Note that these are only recommendations because any infant in whom you suspect cholestatic disease should be tested. When screening, always measure fractionated bilirubin into unconjugated and conjugated.

A. Who to screen for cholestasis

1. **Testing recommendations from the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition:** any formula-fed infant noted to be jaundiced after 2 weeks of age. For exclusively breast-fed infants, this can be delayed by another week (until the third week of life) as long as they have a normal history and physical examination and no history of acholic stools or dark urine. If the first follow-up is at 4 weeks of age, any jaundiced infant should be tested. Other indications to test is any infant with a red flag (eg, ill infant, poor growth, dysmorphic features, acholic stools, and others).
 2. **Testing recommendations from American Academy of Pediatrics guidelines for jaundiced infants ≥ 35 weeks' gestation:** Any infant receiving phototherapy or if TSB is rising rapidly and unexplained by history and physical examination; also, any sick infant or if jaundice is present at or beyond 3 weeks of age.
- B. History should include family, prenatal, and infant history.** Asking the appropriate questions in order to reveal signs and symptoms that may have been overlooked is critical to getting a good picture of what is going on with the patient.
1. **Family history**
 - a. **Any family members have neonatal cholestasis?** Consider genetic disease: cystic fibrosis, Alagille syndrome, α_1 -antitrypsin deficiency, PFIC.
 - b. **History of consanguinity?** Consider autosomal recessive inheritance.
 - c. **History of fetal loss or early neonatal death?** Rule out gestational alloimmune liver disease.
 - d. **History of hemolytic disease or spherocytosis?** These can worsen conjugated hyperbilirubinemia.
 2. **Prenatal history**
 - a. **Did the mother have a prenatal ultrasound?** Rule out biliary cyst, bowel abnormalities, possible syndromes, and cholelithiasis.
 - b. **Was the mother ill during pregnancy?** Rule out intrauterine infections (toxoplasmosis, rubella, CMV, HSV, other)
 - c. **Did the mother have cholestasis of pregnancy?** Rule out mitochondrial disorder or PFIC gene mutations.
 - d. **Did the mother have acute fatty liver of pregnancy?** Rule out neonatal long-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency.
 3. **Infant history**
 - a. **Is the infant premature?** Increased risk of neonatal hepatitis.
 - b. **Is the infant small for gestation age?** Risk factor for developing neonatal cholestasis and increased risk of congenital infections and neonatal cholestasis.

- c. **Is there a history of acholic or pale stools or dark urine?** Suggestive of biliary atresia. Acholic stools are difficult to assess; they are identified in only 63% of cases by health care providers. Stool color cards are being used in some countries (eg, Taiwan) to help parents identify the correct color of stool and increase awareness of acholic stools.
 - d. **What is the infant being fed? Is it breast milk, formula, or parenteral nutrition?** Consider galactosemia, fructose intolerance, TPN-associated cholestasis.
 - e. **When did the infant present with cholestasis relative to feeding?** A clue to galactosemia.
 - f. **Did the infant have delayed passage of meconium?** Consider cystic fibrosis, panhypopituitarism.
 - g. **Does the infant have vomiting?** Bowel obstruction, pyloric stenosis, metabolic disease.
 - h. **Is the infant lethargic or irritable?** Lethargy suggests hypothyroidism or panhypopituitarism. Irritability can mean sepsis, metabolic disease.
 - i. **Any signs of failure to thrive?** Metabolic or genetic disorder.
 - j. **Any excessive bleeding?** Vitamin K deficiency bleeding or a coagulopathy. Did the infant receive vitamin K?
- C. **Physical examination.** NASPGHAN states: "A thorough physical examination is crucial to the proper evaluation of the jaundiced infant. Attention to hepatomegaly and splenomegaly (which are classic hallmarks of the disease) and ill appearance warrants special consideration. Direct visualization of the stool pigment is a key aspect of the complete evaluation of the jaundiced infant."
- 1. **Ill-appearing infant.** Consider infectious process first and rule that out. Other causes in an ill appearing infant see Section II.B. Infants with biliary atresia usually appear well.
 - 2. **Presence of characteristic physical features or accompanying congenital anomalies?** Consider syndromic etiologies (syndromic biliary atresia). The characteristic facial features of Alagille syndrome rare in the newborn and appear approximately at 6 months.
 - a. **Hearing issues.** Consider congenital infections, PFIC1, mitochondrial disease.
 - b. **Eye examination.** May suggest congenital infection, storage disease, septic optic dysplasia.
 - c. **Cardiac.** Murmur, signs of heart failure: peripheral pulmonic stenosis or teratology of Fallot in Alagille syndrome, septal defects in biliary atresia.
 - d. **Abdominal exam:**
 - i. **Palpable mass in the right side of the abdomen.** Choledochal/biliary cyst.
 - ii. **Prominent left or middle lobe of liver (hepatomegaly).** Biliary atresia.
 - iii. **Splenomegaly.** More common in neonatal hepatitis but can be seen at 2 to 4 weeks in storage or hematologic disorders and as a late sign in biliary atresia.
 - e. **Hypoplastic male genitalia.** Consider panhypopituitarism.
 - f. **Jaundice skin color.** Jaundice has a greenish hue compared with unconjugated jaundice, which is more yellow. "Bronze baby syndrome" (a bronze discoloration of the skin as a result of dermal accumulation of coproporphyrins) occurs in infants with direct hyperbilirubinemia who are exposed to phototherapy.
- D. **Laboratory and imaging studies**
- 1. **Newborn screening.** The routine newborn screen will pick up congenital hypothyroidism, tyrosinemia, classical galactosemia, cystic fibrosis, and other inborn errors of metabolism. Verify these results because these conditions require urgent treatment to prevent serious sequelae. In case of galactosemia,

elimination of galactose in the diet pending confirmatory testing is a must. For congenital hypothyroidism, an immediate confirmatory test with serum thyroid-stimulating hormone (TSH) and thyroid hormone levels should be done.

2. **American Academy of Pediatrics guidelines for infants with hyperbilirubinemia at >35 weeks with elevated direct bilirubin.** Obtain urinalysis and urine culture, and perform a sepsis evaluation if indicated by history and physical examination. Check the results of the newborn thyroid and galactosemia screen, and evaluate the infant for hypothyroidism. Additional evaluation for the causes of cholestasis is recommended. **If the direct bilirubin is $\geq 50\%$ of the total bilirubin**, consultation with an expert in the field is recommended.
3. **Testing guidelines from NASPGHAN and ESPGHAN.** The NASPGHAN and ESPGHAN has recently published guidelines for laboratory evaluation of conjugated hyperbilirubinemia in neonates. They jointly recommend that any infant with an **elevated serum direct bilirubin level of >1 mg** warrants timely evaluation and referral to a gastroenterologist or hepatologist to reduce the time to diagnosis of pediatric liver disease. This includes Tier 1 testing for infants when cholestasis is suspected and Tier 2 testing for confirmed cholestasis to be done in concert with the pediatric gastroenterologist/hepatologist. This enables a focused and targeted workup. (See Figure 98–1.)
 - a. **Tier 1 testing**
 - i. **Serum:** Complete blood count/differential, international normalized ratio (rule out coagulation disorders), aspartate aminotransferase (AST) and alanine aminotransferase (ALT) (liver inflammation), alkaline phosphatase/GGT (marker for biliary obstruction/inflammation), total bilirubin/direct bilirubin/albumin (rule out liver failure), and glucose (rule out hypoglycemia). Check α_1 -antitrypsin phenotype and level. If newborn screening results not available, check thyroxine (T_4) and TSH. Some important facts: GGT is usually elevated in cholestasis, especially disorders such as biliary atresia, α_1 -antitrypsin deficiency, Alagille syndrome, and idiopathic neonatal hepatitis. GGT is normal or low in PFIC1 and PFIC2, some cases of hypopituitarism, and some inborn errors of bile acid metabolism. With increased AST and a normal to mildly increased ALT, total bilirubin, or direct bilirubin, suspect a hematologic or muscle process. With severe coagulopathy, suspect GALT, metabolic disease, and sepsis.
 - ii. **Urine:** Urinalysis and urine culture to rule out urinary tract infection (UTI); check reducing substances (rule out galactosemia).
 - iii. **Consider sepsis workup** if infant is critically ill: blood, urine, cerebrospinal fluid, and other fluid cultures if appropriate.
 - iv. **Obtain a fasting abdominal ultrasound.** Rule out biliary cyst and gallstone disease; look for advanced liver disease and splenic/vascular abnormalities. **Signs of biliary atresia:** a small/undetectable gallbladder, triangular cord sign, abnormal morphology of gallbladder, common bile duct not visualized, diameter of hepatic artery, subcapsular blood flow. Biliary atresia splenic malformation syndrome: polysplenia/asplenia, midline liver, abdominal heterotaxy, preduodenal portal vein, interrupted inferior vena cava.
 - b. **Tier 2 testing.** Confirmed cholestasis with further targeted evaluation with a pediatric gastroenterologist/hepatologist.
 - i. **General:** TSH and T_4 values, serum cortisol, serum bile acids.
 - ii. **Metabolic:** Serum ammonia, lactate, cholesterol, red blood cell GALT. Urine for organic acids, succinylacetone, and bile salt species profiling.
 - iii. **Infectious disease:** Polymerase chain reaction for CMV, HSV, *Listeria*.
 - iv. **Genetics:** Discuss with pediatric gastroenterologist/hepatologist about gene panels or exome sequencing.

- v. **Sweat chloride analysis:** Serum immunoreactive trypsinogen level or *CFTR* genetic testing.
 - vi. **Chest x-ray:** Rule out heart or lung disease.
 - vii. **Spine:** Detect spine abnormalities (butterfly vertebrae).
 - viii. **Echocardiogram:** Evaluate for cardiac anomalies (24% of infants with Alagille syndrome have structural heart disease, as do some infants with biliary atresia).
 - ix. **Intraoperative cholangiogram and histologic exam of the duct remnant:** Gold standard to diagnose biliary atresia.
 - x. **Liver biopsy:** Most supportive test for diagnosis. Approach and timing vary.
 - xi. **Other consultations may be necessary:** Ophthalmology, metabolic/genetic, cardiology/ECHO (if murmur, hypoxic, poor cardiac function), pediatric surgery, nutrition/dietician.
 - xii. **Other diagnostic imaging may be necessary:** Hepatobiliary scintigraphy, endoscopic retrograde cholangiopancreatography, and magnetic resonance cholangiopancreatography have all been used to diagnose biliary atresia but have limited specificity and availability.
- V. **Plan.** The list of causes of cholestasis can be extensive, and diagnosis can be difficult. Early treatment is essential (eg, improved outcome in biliary atresia; prevent bacteremia/sepsis in UTI; prevent severe hypoglycemia in hypopituitarism). It is important to identify the life-threatening and treatable causes of cholestasis. Even with causes that have no specific treatment available, early medical management and dietary modifications are beneficial. It is best to follow a stepwise approach.
- A. **Focus on any ill infants who have conditions that can be treated:**
1. **Bacterial sepsis.** If signs of sepsis are present, appropriate cultures should be performed and empirical antibiotic therapy initiated.
 2. **Viral/intrauterine infections.** Appropriate antiviral agents.
 3. **Urinary tract infection.** Appropriate antibiotic therapy.
 4. **Galactosemia.** Galactose-free diet.
 5. **Tyrosinemia.** Low-tyrosine diet, phenylalanine diet, 2-2-nitro-4 trifluoromethylbenzoyl-1,3-cyclohexanedione (NTBC).
 6. **Hereditary fructosemia.** Fructose/sucrose-free diet.
 7. **Gestational alloimmune liver disease.** Any infant with a suspicion of GALD-NH should be given 1 dose of intravenous immunoglobulin (IVIG) while a workup is being done (eg, biopsy of oral mucosa for iron staining and magnetic resonance imaging, possible liver biopsy). Supportive care and treatment with double volume exchange transfusion and IVIG. Liver transplantation may be necessary.
 8. **Hypothyroidism.** Treatment is L-thyroxine. See Chapter 129.
 9. **Hemolytic disease/hemolysis.** Treatment depends on etiology (eg, vitamin K).
 10. **Panhypopituitarism.** Hormone replacement (thyroid hormone, growth hormone, and cortisol replacement), fluid and electrolyte therapy.
 11. **Acute obstructive gallstones.** Surgery is indicated.
- B. **Focus on infants who will benefit from early surgery to restore bile flow**
1. **Biliary atresia.** Early intervention is critical for successful treatment and optimal prognosis. Kasai hepatportoenterostomy should be done as soon as possible to establish bile flow and is best performed with the first 60 days of life. Liver transplantation if end-stage liver disease.
 2. **Choledochal/biliary cyst.** Resection of the cyst to create bile flow from the liver to the small intestine (eg, type 1 cysts: total cyst excision with Roux-en-Y hepaticojejunostomy).
 3. **Inspissated bile duct syndrome.** Treatment includes removal of the precipitating factor, biliary tract irrigation, or surgery/endoscopic procedures for refractory cases.
 4. **Spontaneous perforation of the common bile duct.** Surgical drainage.

C. Other causes and treatment plans

1. **Parenteral nutrition–associated liver disease.** First confirm the diagnosis and verify the infant does not have biliary atresia or other diagnosis; cases of biliary atresia have been mistaken for PNALD. Treatment involves starting enteral feeding as soon as possible as this stimulates bile flow and prevents biliary stasis. Small oral feedings are recommended. Lipid restriction (1 g/kg/d or less) reduces exposure to parenteral soybean oil, which contributes to hepatotoxicity. Lipid modification replaces parenteral soybean oil with parenteral fish oil.
 2. **α_1 -Antitrypsin deficiency.** Treatment is mostly supportive or liver transplantation if cirrhosis is progressive.
 3. **Cystic fibrosis.** Pancreatic enzymes, ursodeoxycholic acid.
 4. **Bile acid synthetic defects.** Treatment with primary bile acids (cholic acid or chenodeoxycholic acid).
 5. **Alagille syndrome.** Check an α -fetoprotein and ultrasound every 6 months as part of hepatocellular carcinoma screening. No specific treatment and may require liver transplantation.
- D. Supportive measures.** Medical management and optimal nutritional support are beneficial even when there is no curative treatment. These include nutrition, vitamin supplementation, and medications.

1. **Nutrition.** Many of these infants suffer from growth failure because of an increase in metabolic demand, a decreased absorption of fats, and impaired protein and carbohydrate metabolism. Most of these infants require high caloric diets (125% of recommended dietary allowance based on ideal body weight). Protein intake should be 2 to 3 g/kg/d. Special formulas (eg, Pregestimil, Enfaport, Portagen) may be necessary that include medium-chain triglycerides (MCTs) that can be absorbed without the action of bile salts. Oral feeding is preferred for formula, but sometimes nasogastric feedings are required at night to make sure the caloric need is met. Supplemental MCTs can be given to breast-fed infants. Special formulas are recommended for galactosemia, fructosemia, and tyrosinemia. Some infants may require other dietary restrictions.
2. **Vitamins.** Supplemental fat-soluble vitamins (A, D, E, K) are needed in many of these infants since intestinal absorption of these vitamins is impaired. Blood levels should be routinely monitored. See doses of vitamins in Chapter 155.
3. **Medications** are used to promote bile flow and decrease the pruritus (especially in Alagille syndrome and PFIC). Ursodeoxycholic acid, phenobarbital, and cholestyramine are used often and are discussed in detail in Chapters 98 and 155. Rifampin has been used for pruritus but has limited experience in neonates.

63 Hyperbilirubinemia: Unconjugated, On Call

- I. Problem.** An infant's indirect (unconjugated) serum bilirubin level is elevated at 10 mg/dL. Unconjugated (indirect) bilirubin is the fraction of serum bilirubin that has not been conjugated with glucuronic acid in the liver. The exact definition of a physiologic range and management of indirect hyperbilirubinemia are complex and based on many factors, including gestational age (GA), postnatal age, birthweight, disease state, risk factors, ethnicity, and hydration and nutritional status. **Total serum bilirubin (TSB)** is the sum of direct (conjugated) and indirect (unconjugated) bilirubin. The **indirect**

bilirubin is calculated by subtracting the direct bilirubin from the total bilirubin. **Transcutaneous bilirubin (TcB)** is a measurement of TSB from an instrument that uses reflectance measurements on the skin and correlates well with the laboratory TSB value. **Unconjugated hyperbilirubinemia** is usually transient and physiologic in the newborn period, but it is important to note that kernicterus (chronic bilirubin encephalopathy) is still occurring in the developed world.

II. Immediate questions

- A. **How old is the infant? What is the gestational age? High indirect serum bilirubin levels during the first 24 hours of life are never physiologic.** Hemolytic disease (Rh isoimmunization or ABO incompatibility), infection, occult hemorrhage, and polycythemia are common causes of early-onset jaundice. GA and age in hours of the infant determine the bilirubin level at which phototherapy should be initiated. The risk of unconjugated hyperbilirubinemia is inversely proportional with GA. In premature infants, hyperbilirubinemia is usually more severe and lasts longer.
- B. **Is the infant being breast fed? Breast-feeding jaundice (early onset)** occurs within the first week of life and is secondary to decreased intake of breast milk resulting in dehydration and caloric deprivation. **Breast milk jaundice (late onset)** occurs after the first week of life and can last up to the third or fourth week. Current literature supports a genetic predisposition. High levels of the enzyme β -glucuronidase can also be a contributing factor leading to increased enterohepatic circulation.
- C. **What is the family ethnicity?** The incidence of neonatal jaundice is increased in infants of Native American Indian, Inuit, Mediterranean (Greece, Turkey, Sardinia), Sephardic Jewish, Nigerian, and Eastern Asian descent. Native Greeks have a higher incidence than Greeks in the United States. The incidence is lower in African Americans. Glucose-6-phosphate dehydrogenase (G6PD) deficiency, which is a cause of unconjugated hyperbilirubinemia, is more common in many of these groups and may be partially responsible. Immigration and intermarriage have increased the incidence of G6PD in the United States.
- D. **Is the infant dehydrated? If evidence of dehydration exists** (eg, weight loss of $>12\%$ from birthweight, increased sodium, decreased urine out), fluid administration may help to lower serum bilirubin level. Supplemental formula feedings or expressed breast milk should be considered if breast-feeding failure is the reason for hyperbilirubinemia; otherwise, intravenous (IV) fluids should be given. Adequate hydration is essential, but excess hydration by causing dilutional effects of IV fluids and enhancing peristalsis to decrease enterohepatic circulation by oral fluid supplements will not clear bilirubin any faster. **Cochrane review found that there is no evidence that IV fluid supplementation affects major clinical outcomes associated with excessive bilirubin in healthy full term infants.**
- E. **What are the important risk factors for severe hyperbilirubinemia in infants ≥ 35 weeks' gestation?** Lower gestational age, predischarge total serum, or transcutaneous bilirubin measurement in the high-risk or high-intermediate risk zone, exclusive breastfeeding, especially if nursing is not going well and weight loss is exclusive, jaundice observed in the first 24 hours, isoimmune or other hemolytic disease (G6PD deficiency), previous sibling with jaundice, cephalhematoma or significant bruising, east Asian race.
- F. **Are there any factors increasing risk for bilirubin-induced neurologic dysfunction (BIND)?** BIND occurs when bilirubin crosses the blood-brain barrier and targets brain tissue producing clinical signs associated with bilirubin toxicity. Bilirubin-induced neurotoxicity risk factors include isoimmune hemolytic disease, G6PD deficiency, asphyxia, sepsis, acidosis, and albumin <3.0 mg/dL. Infants with lower GA, significant lethargy, and temperature instability are at much higher risk of developing bilirubin toxicity. In this context of increased risk factors, the bilirubin threshold for starting phototherapy and exchange transfusion is at a much lower level.

III. Differential diagnosis. Indirect (unconjugated) bilirubin is derived mainly from hemoglobin metabolism. Hemoglobin by-products must be conjugated by the liver before they can be excreted in the bile, stool, or urine. Unconjugated bilirubin cannot be directly measured in the blood and is never present in urine. Newborn jaundice can be caused by an increase in enterohepatic circulation, decrease in the clearance of bilirubin, decrease in conjugation and hepatic uptake, impaired bile flow, and increase in production. In premature infants, bilirubin can reach a higher level and lasts longer than in term infants, some up to 6 weeks of age. See also Chapter 99 for further discussion on unconjugated hyperbilirubinemia.

A. Common causes of indirect hyperbilirubinemia. The majority of infants have hyperbilirubinemia in the first week of life. It is important to differentiate **physiologic from nonphysiologic hyperbilirubinemia**. The timing of onset and duration aid in diagnosis. The following are more likely associated with **nonphysiologic indirect hyperbilirubinemia**: onset of jaundice before 24 hours of life, jaundice lasting >2 weeks in full-term infants, higher level requiring treatment, or jaundice present in a clinically ill infant.

1. Physiologic hyperbilirubinemia is a transient and common process that almost all newborns will experience. It is secondary to 2 factors: (1) the shorter life span of red blood cells (RBCs), which causes mildly elevated bilirubin levels due to increased turnover of heme, and (2) the relative deficiency of uridine 5'-diphospho-glucuronosyltransferase leading to decreased conjugation, which causes a decrease in bilirubin clearance. It commonly appears after the second day, peaks between the third and fifth days, and resolves within 1 week of life. **Exaggerated or severe physiologic jaundice** can occur when higher bilirubin levels require therapy and hyperbilirubinemia lasts longer than 2 weeks.

2. Nonphysiologic hyperbilirubinemia

a. Breast-feeding failure or breast milk jaundice. Breast-feeding failure jaundice is due to dehydration and decreased caloric intake. **Breast milk jaundice** has a genetic etiology and once was considered an extension of physiologic jaundice, but serious complications can occur, such as kernicterus.

b. Infection. Jaundice as the only sign of sepsis is rare. Jaundice secondary to congenital viral infection may be associated with conjugated hyperbilirubinemia.

c. Hemolysis. Major and minor blood group incompatibilities may cause exaggerated hyperbilirubinemia. Signs of hemolytic disease of the newborn include a positive direct Coombs test, elevated cord bilirubin, and hemolytic anemia.

d. Increased bilirubin load from a breakdown of red blood cells. Subdural hematoma, intraventricular hemorrhage in premature infants, cephalohematoma, excessive bruising, pulmonary hemorrhage, and polycythemia/hyperviscosity can contribute.

e. Infant of a diabetic mother. Polycythemia seems to be the most important factor associated with hyperbilirubinemia. Other factors related to hyperbilirubinemia in an infant of a diabetic mother include prematurity, macrosomia, and poor maternal glycemic control.

B. Other causes of indirect hyperbilirubinemia

1. Glucose-6-phosphate dehydrogenase deficiency.

2. Pyruvate kinase deficiency.

3. Red blood cell membrane defects: Hereditary spherocytosis, hereditary elliptocytosis, pyknotocytosis.

4. Disorders of bilirubin clearance: Lucey-Driscoll syndrome (familial neonatal jaundice), Crigler-Najjar syndrome (CNS) (type I and type II), and Gilbert syndrome.

5. Hypothyroidism/hypopituitarism.

6. Hemoglobinopathies: α - and γ -Thalassemia.

7. **Metabolic disorders:** Early galactosemia or fructose intolerance.
8. **Medications:** Penicillin, oxytocin, sulfonamides, vitamin K, nitrofurantoin, novobiocin (not available in United States). Maternal use of naproxen, atazanavir, or methyldopa can cause a positive direct antiglobulin test and jaundice in the newborn. Maternal oxytocin and valium are risk factors.

IV. Database

- A. **History.** What is the infant's feeding regimen and frequency of voiding (hydration status)? Ask about jaundice in previous siblings and family ethnicity. Is there a familial history of significant hemolytic disease? Is there a history of light-colored stools or dark urine? Any maternal medication use? History of lethargy?
- B. **Physical examination.** The accumulation of bilirubin in body tissues produces jaundice (yellow skin) and scleral icterus. Jaundice is first seen in the face (forehead) and progresses caudally to the trunk and extremities. Pressure on the skin often reveals jaundice. The TSB can be roughly estimated (not 100% reliable, note that visual estimation can lead to errors especially in darkly pigmented infants or difficult to assess in polycythemic infants) by examining the skin of different areas of the body for jaundice (face, ~5 mg/dL; upper chest, ~10 mg/dL; abdomen, ~12 mg/dL; palms and soles, usually >15 mg/dL). Note signs of bruising, cephalohematoma, or intracranial bleeding. Check for hepatosplenomegaly. A complete neurologic examination should be performed because bilirubin encephalopathy can occur. Look for signs such as poor feeding, lethargy, hypotonia, or seizures.
- C. **Laboratory studies.** In normal and healthy term infants whose jaundice appears within physiologic time line, few tests are necessary. It is useful to save cord blood for future testing if necessary.
 1. **Jaundiced infant of ≥ 35 weeks' gestational age.** These recommendations are based on the American Academy of Pediatrics (AAP) Subcommittee on Hyperbilirubinemia. All bilirubin levels should be interpreted based on infant's age in hours. See also the algorithm in Figure 63-1 for when to perform laboratory studies and on the management of jaundice in the newborn nursery.
 - a. **Infant jaundiced in the first 24 hours.** Measure TSB and TcB. TcB is determined by a portable transcutaneous instrument that measures the amount of yellow color in the skin, which correlates with the laboratory measurement of TSB. Repeat TSB or TcB depends on initial result, age of the infant, and evolution of the hyperbilirubinemia.
 - b. **Jaundice seems excessive for the infant's age or there is uncertainty regarding the degree of jaundice.** Obtain TcB and TSB.
 - c. **Infant is receiving phototherapy or total serum bilirubin is rising rapidly and unexplained by history and physical examination.** Obtain:
 - i. **Direct (conjugated) bilirubin.**
 - ii. **Blood type and Coombs test.** If not obtained on the cord blood.
 - iii. **Complete blood count with differential and smear.** Observe RBC morphology.
 - iv. **Reticulocyte count (optional).**
 - v. **Glucose-6-phosphate dehydrogenase level (optional).**
 - vi. **End-tidal carbon monoxide (concentration) if available (optional).** End-tidal carbon monoxide corrected for ambient carbon monoxide (ETCOc) is a measurement of the rate of heme catabolism and rate of bilirubin production. It is used to confirm hemolysis and can help identify infants at risk for developing high bilirubin levels.
 - vii. **Repeat total serum bilirubin in 4 to 24 hours,** depending on infant's age and TSB level.
 - d. **TSB is approaching exchange levels (see Figure 99-3) or is not responding to phototherapy:**
 - i. **Reticulocyte count.**
 - ii. **Glucose-6-phosphate dehydrogenase level.**

- iii. **Albumin.** An albumin of <3.0 g/dL is a risk factor for lowering the threshold for phototherapy. Obtaining a serum albumin will allow you to calculate the bilirubin-to-albumin (B/A) ratio, which can help determine the need for exchange transfusion (see Figure 99–3).
 - iv. **End-tidal carbon monoxide (concentration).** See Section IV.C.1.c.vi.
2. **Jaundiced infant <35 weeks' gestational age (controversial).** There are no formal guidelines for laboratory values for jaundiced infants age <35 weeks. Follow institutional guidelines. (See also tests for infant >35 weeks, discussed earlier.)

V. Plan

A. Phototherapy

1. **Principles of phototherapy.** Bilirubin absorption of visible light in the blue region of the spectrum transforms unconjugated bilirubin (bound to albumin) into bilirubin “photoproducts,” mostly isomers of bilirubin. Practice considerations for devices and the optimal administration of phototherapy in infants >35 weeks' gestation per AAP Committee on Fetus and Newborn are as follows:
 - a. **Ensure maximum exposure of patient's body surface area under phototherapy.**
 - b. **Irradiance level of ≥ 30 $\mu\text{W}/\text{cm}^2/\text{nm}^{-1}$ over waveband of 460 to 490 nm (blue-green region).**
 - c. **Phototherapy should be implemented in a timely/urgent fashion.**
 - d. **Briefly interrupt for feeding and other care.**
 - e. **Measure bilirubin load reduction and discontinue when desired level reached.** Beware of rebound increase in bilirubin.
2. **Phototherapy for the hospitalized infant ≥ 35 weeks' gestation (per AAP guidelines, 2004).** (See Figure 99–2.) Phototherapy is started when the TSB exceeds the line (or an option is to start 2–3 levels below the line) indicated for each category. The risk factors were selected because these conditions have a negative effect on the albumin binding of bilirubin, the blood–brain barrier, and the susceptibility of the brain cells to damage by bilirubin. When using this figure, follow the following guidelines:
 - a. **Use total serum bilirubin.** Do not subtract direct bilirubin from the total.
 - b. **Measure serum albumin.** If <3 g/dL, it is considered a risk factor. Lower the phototherapy threshold.
 - c. **Risk factors.** Isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL.
 - d. **Infants at low risk.** Infants who are ≥ 38 weeks and well.
 - e. **Infants at medium risk.** Infants who are ≥ 38 weeks and have risk factors (see earlier). Other infants at medium risk include those infants who are 35 to 37 6/7 weeks and well. It is optional to intervene at a lower TSB level for those infants who are closer to 35 weeks and at a higher level for those infants who are closer to 37 6/7 weeks.
 - f. **Infants at high risk.** Infants who are 35 to 37 6/7 weeks with risk factors listed earlier.
3. **Preterm infants <35 weeks' gestation.** There are no good evidence-based bilirubin level guidelines for initiation of phototherapy or exchange transfusion in preterm infants. Maisels and colleagues published their recommendations on bilirubin threshold for initiation of treatment in this patient population (Table 63–1).
 - a. **Use the lower range number if the infant is at a greater risk for bilirubin toxicity.** Risk includes lower GA, serum albumin <2.5 g/dL, rapidly rising TSB (suggesting hemolytic disease), and those who are clinically unstable (see later).
 - b. **When a decision is being made about the initiation of phototherapy or exchange transfusion,** infants are considered to be clinically unstable if they have 1 or more of the following conditions:

Table 63–1. SUGGESTED USE OF PHOTOTHERAPY AND EXCHANGE TRANSFUSION IN PRETERM INFANTS <35 WEEKS' GESTATIONAL AGE

Gestational Age (weeks)	Initiate Phototherapy Total Serum Bilirubin (mg/dL)	Exchange Transfusion Total Serum Bilirubin (mg/dL)
<28 0/7	5–6	11–14
28 0/7 to 29 6/7	6–8	12–14
30 0/7 to 31 6/7	8–10	13–16
32 0/7 to 33 6/7	10–12	15–18
34 0/7 to 34 6/7	12–14	17–19

This table reflects the authors' recommendations for operational or therapeutic total serum bilirubin threshold levels at or above which treatment is likely to do more good than harm.

Reproduced with permission from Maisels MJ, Watchko JF, Bhutani VK, et al: An approach to the management of hyperbilirubinemia in the preterm infant less than 35 weeks of gestation, *J Perinatol*. 2012 Sep;32(9):660-664.

- i. **Blood pH <7.15.**
 - ii. **Blood culture–positive sepsis in the prior 24 hours.**
 - iii. **Apnea and bradycardia requiring cardiorespiratory resuscitation (bagging and/or intubation) during the previous 24 hours.**
 - iv. **Hypotension requiring pressor treatment during the previous 24 hours.**
 - v. **Mechanical ventilation at the time of blood sampling.**
- c. **Prophylactic phototherapy.** Some institutions use prophylactic phototherapy (at birth) for ELBW infants. Maisels et al state that it is an option to use PT prophylactically soon after birth in infants <26 weeks of age. Cochrane review found that “prophylactic phototherapy helps to maintain a lower serum bilirubin concentration and may have an effect on the rate of exchange transfusion and the risk of neurodevelopmental impairment, but further studies are needed to determine the efficacy and safety on long term outcomes.” Studies have shown that prophylactic phototherapy does not decrease the total bilirubin or the duration of phototherapy. Aggressive phototherapy (started earlier and continued at lower bilirubin levels) in one trial was found to increase mortality in the smallest and sickest infants while decreasing their impairment and profound impairment.
 - d. **For infants <1000 g, start phototherapy at lower irradiance levels.** If TSB continues to rise, additional phototherapy should be provided by increasing the surface area exposed (consider adding bili-blanket); if TSB continues to rise despite increased surface area exposed, increase irradiance level by switching to higher intensity settings.
 - e. **For infants < 35 weeks. Special blue fluorescent lamps or light-emitting diode (LED) systems** that will deliver irradiance predominately in the 430- to 490-nm band are recommended. Fluorescent and LED light sources can be brought closer to the infant than halogen or tungsten lamps (burn risk).
 - f. **Discontinue phototherapy when total serum bilirubin is 1 to 2 mg/dL** below the initiation level for the infant's postmenstrual age.
 - g. **Attempt regular feedings if possible, and feed frequently.** Feeding inhibits the enterohepatic form of bilirubin and helps lower the serum bilirubin level. Studies indicate that increasing the frequency of breast feeding will not have a significant effect on the serum bilirubin level in the first 3 days of life.
4. **There is no universal standard for discontinuing phototherapy.** Phototherapy may be discontinued once serum bilirubin levels have fallen 1 to 2 mg/dL

below the level at which phototherapy was initiated. Factors to consider when stopping phototherapy are the cause and the age at which it was initiated. A repeat TSB measurement is recommended in all infants within 24 hours of stopping phototherapy.

5. **If total serum bilirubin continues to rise or does not decrease on phototherapy**, hemolysis may be present.
 6. **If infant has an elevated direct bilirubin level and is receiving phototherapy**, the infant may develop **bronze baby syndrome**. This is not a contraindication to phototherapy.
 7. **Contraindications to phototherapy**. Congenital porphyria and use of medications that are photosensitizers.
- B. Exchange transfusion.** (See Chapter 34.) Exchange transfusions should be performed only by trained personnel in a neonatal intensive care unit. There is considerable *controversy* concerning the exact level at which to initiate exchange transfusion.
1. **Exchange transfusion for infants ≥ 35 weeks' gestation.** See Figure 99–3. This figure is based on guidelines from the AAP and displays the suggested levels for exchange transfusion (see lines) in jaundiced infants >35 weeks' GA despite phototherapy. When using this figure, follow these guidelines:
 - a. **Use total serum bilirubin.** Do not subtract direct bilirubin.
 - b. **Risk factors.** G6PD deficiency, asphyxia, sepsis, temperature instability, acidosis, isoimmune hemolytic disease, and lethargy that is significant.
 - c. **The first 24 hours.** (See dashed lines on Figure 99–3.) Represents uncertainty secondary to the wide range of clinical circumstances and a range of responses to phototherapy.
 - d. **Immediate exchange transfusion.** Indicated if the infant shows signs of bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, or high-pitched cry) even if the TSB is falling or if the TSB is 5 mg/dL above these lines in Figure 99–3.
 - e. **Measure serum albumin and calculate bilirubin-to-albumin ratio at which exchange transfusion should be considered.** If an exchange transfusion is being considered, the serum albumin should be measured so the B/A ratio can be calculated and used with the TSB levels to help decide whether an exchange transfusion needs to be done. The ratio of B/A correlates with measured unbound bilirubin in newborns, which if elevated can be associated with kernicterus in sick preterm newborns and transient abnormalities in audiometric brainstem response in infants.
 2. **Exchange transfusion for infants <35 weeks.** See consensus guidelines in Table 63–1. Recommendations for exchange transfusion are only for those infants whose TSB levels are rising who are on intensive phototherapy to the maximal surface area. Exchange transfusion is recommended for any infant who shows signs of **acute bilirubin encephalopathy** (hypertonia, arching, retrocollis, opisthotonos, high-pitched cry), although these signs rarely occur in very low birth-weight infants. Exchange transfusion is recommended at lower levels in infants with hemolytic disease and at high risk, as discussed earlier.
- C. Drug therapy.** Medications can be used to inhibit hemolysis, increase conjugation/elimination, and inhibit formation of bilirubin. These agents include phenobarbital, metalloporphyrins, albumin, and IV immunoglobulin. See Chapter 99 for detailed discussion.
1. **Phenobarbital** increases the concentration of ligandin in liver cells, which induces production of uridine diphosphate glucuronyl transferase (UDPGT) and enhances bilirubin excretion. It is used for treatment of CNS type II and Gilbert syndrome and can also be used as an adjunct therapy for treatment of exaggerated unconjugated hyperbilirubinemia in the newborn period. It is not helpful in acute management since it takes 3 to 7 days to be effective.

2. **Metalloporphyrins** reduce bilirubin production by competitive inhibition of heme oxygenase, the rate-limiting enzyme in the catabolism of heme. A recent (2016) clinical trial showed that prophylactic predischARGE administration of a single intramuscular injection of 4.5 mg/kg of Sn-mesoporphyrin (SnMP) decreased the duration of phototherapy, reversed total bilirubin trajectory, and reduced the severity of subsequent hyperbilirubinemia. Long-term safety of SnMP remains to be studied. It remains an unlicensed drug and is available on an investigational or "compassionate use" basis.
 3. **Albumin** increases bilirubin binding capacity and results in a decreased free bilirubin. Albumin infusion may be considered when albumin level is <3.0 mg/dL, when TSB/albumin ratio is >6 , and prior to double-volume exchange transfusion.
 4. **Intravenous immunoglobulin** works by competing with sensitized neonatal RBCs at the Fc receptors in the reticuloendothelial system, thus preventing further hemolysis. It is recommended in patients with isoimmune hemolysis when TSB is rising despite intensive phototherapy. Dose is 1 g/kg given over 2 to 4 hours; it can be repeated if needed in 12 to 24 hours (2 doses).
- D. Breast-fed infants.** The AAP does not recommend interruption of breast feeding in healthy term newborns with hyperbilirubinemia and encourages continued and frequent breast feeding. Infants who require phototherapy should continue breast feeding. The AAP recommends that mothers nurse their infants at least 8 to 12 times per day the first several days. The AAP does not recommend routine supplementation of non-dehydrated breast-fed infants with water or sugar water. **Supplementing with water or dextrose water does not lower the bilirubin level.** Different options are available, and the decision regarding which treatment option to use depends on the specific infant, whether phototherapy is indicated, the physician's judgment, and the family circumstances.
1. **If phototherapy is not recommended:**
 - a. **Observation and close follow-up of serial total serum bilirubin levels.**
 - b. **Continue breast feeding but supplement with formula**, while following serial TSB levels.
 - c. **Interrupt breast feeding and substitute formula**, while following serial TSB levels.
 2. **If phototherapy is recommended:**
 - a. **Continue breast feeding, and administer phototherapy (American Academy of Pediatrics recommendation).** **Supplementation with expressed breast milk** is indicated if the infant's intake is inadequate, weight loss is excessive, or there is a question of dehydration. Although phototherapy does not reduce the serum bilirubin concentration in breast-fed infants as quickly as it does in formula-fed infants, it is still effective.
 - b. **Continue breast feeding, and administer phototherapy (American Academy of Pediatrics recommendation).** **Supplementation with formula** is indicated if the infant's intake is inadequate, weight loss is excessive, or there is a question of dehydration.
 - c. **Interrupt breast feeding temporarily and substitute formula and administer phototherapy (American Academy of Pediatrics optional recommendation).** This reduces bilirubin levels and improves the efficacy of phototherapy.
- E. Breast-fed infants with persistent jaundice after 2 weeks.** Approximately 30% of healthy term infants have persistent jaundice after 2 weeks of age. Treat as follows:
1. **Observe.** If the physical examination is normal and pale stools and dark yellow urine are not present.
 2. **Screen for congenital hypothyroidism.** A rare cause of direct hyperbilirubinemia.

3. If jaundice is still present at 3 weeks, total and direct serum bilirubin should be obtained to evaluate for cholestasis. If elevated direct bilirubin level, proceed with cholestasis workup (see Chapter 62).
- F. Early follow-up should be provided for all neonates (especially those discharged at <72 hours of age) to monitor for bilirubin-related problems.**
1. **Perform a risk assessment of all infants before discharge.** The AAP recommends 2 clinical options used individually or in combination: the predischarge TSB or TcB and/or a thorough evaluation of clinical risk factors. Recent studies state that combining these 2 options offers the best estimate for predicting the risk of later hyperbilirubinemia. Appropriate follow-up is always recommended, because even with a low predischarge level, the risk of subsequent hyperbilirubinemia is never zero.
 - a. **Predischarge measurement of total serum bilirubin or transcutaneous bilirubin level can then be plotted on the nomogram on Figure 99–1.** This predicts subsequent significant hyperbilirubinemia. This table is for risk in well newborns at 36 weeks' GA with birthweight ≥ 2000 g or 35 weeks' GA with birthweight > 2500 g.
 - i. **Total serum bilirubin at discharge in the low-risk zone.** 0% risk of developing a TSB level > 95 th percentile.
 - ii. **Total serum bilirubin at discharge in the low-intermediate-risk zone.** 12% risk of developing a TSB level > 95 th percentile.
 - iii. **Total serum bilirubin at discharge in the high-intermediate-risk zone.** 46% risk of developing a TSB level > 95 %.
 - iv. **Total serum bilirubin at discharge in the high-risk zone.** 68% risk of developing a TSB level > 95 %.
 - b. **Risk factors based on American Academy of Pediatrics recommendations in order of importance.** The greater the number of risk factors present, the greater is the risk of significant hyperbilirubinemia. Certain risk factors before discharge were noted to be more frequently associated with hyperbilirubinemia: breast feeding, significant jaundice in a previous sibling, GA < 38 weeks, and jaundice noted before discharge. Factors that are most predictive of hyperbilirubinemia when combined with the risk zone are lower GA and exclusive breast feeding.
 - i. **Decreased risk.** TSB or TcB in low-risk zone, GA ≥ 41 weeks, exclusive bottle feeding, black race, discharge after 72 hours.
 - ii. **Minor risk factors.** Predischarge TSB or TcB in the high-intermediate-risk zone, GA 37–38 weeks, jaundice observed before discharge, previous sibling with jaundice, macrosomic infant of a diabetic mother, maternal age ≥ 25 years, and male gender.
 - iii. **Major risk factors.** Predischarge TSB or TcB in the high-risk zone, jaundice observed in the first 24 hours, blood group incompatibility with positive direct antiglobulin test (other known hemolytic disease, elevated ETCCc), GA 35–36 weeks, previous sibling who received phototherapy, cephalohematoma or significant bruising, exclusive breast feeding (especially if nursing is not going well, with excessive weight loss), and East Asian race.
 - c. **Key points**
 - i. **Clinical judgment is necessary in determining follow up.** For some neonates sent home before 48 hours, 2 follow up visits may be necessary (first between 24 and 72 hours, second between 72 and 100 hours).
 - ii. **Infant with risk factors for severe hyperbilirubinemia.** Earlier and more frequent follow-ups are recommended.
 - iii. **If follow up cannot be guaranteed, consider delaying discharge for infants with increased risk for severe hyperbilirubinemia.**

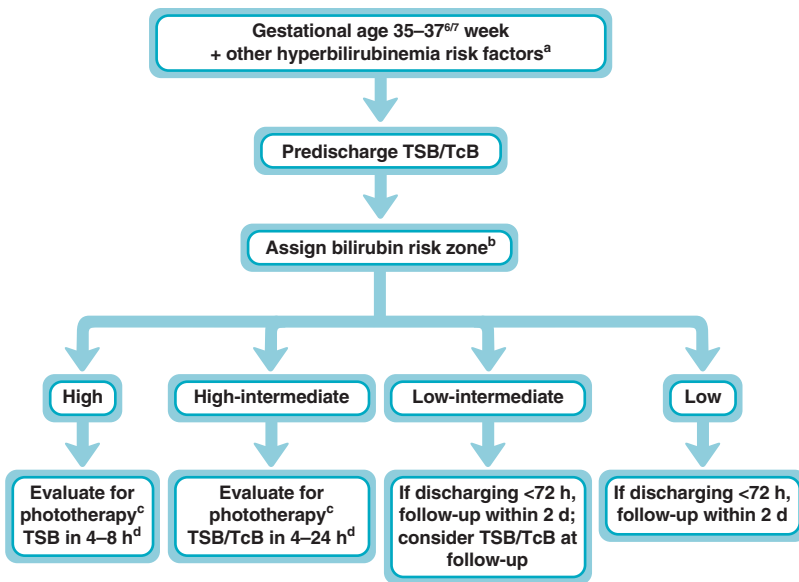

2. Follow-up schedules.

a. AAP recommendations for follow up:

- i. Infant discharged before 24 hours of age: see by 72 hours.
- ii. Infant discharged between 24 and 47.9 hours of age: see by 96 hours.
- iii. Infant discharged between 48 and 72 hours of age: see by 120 hours.

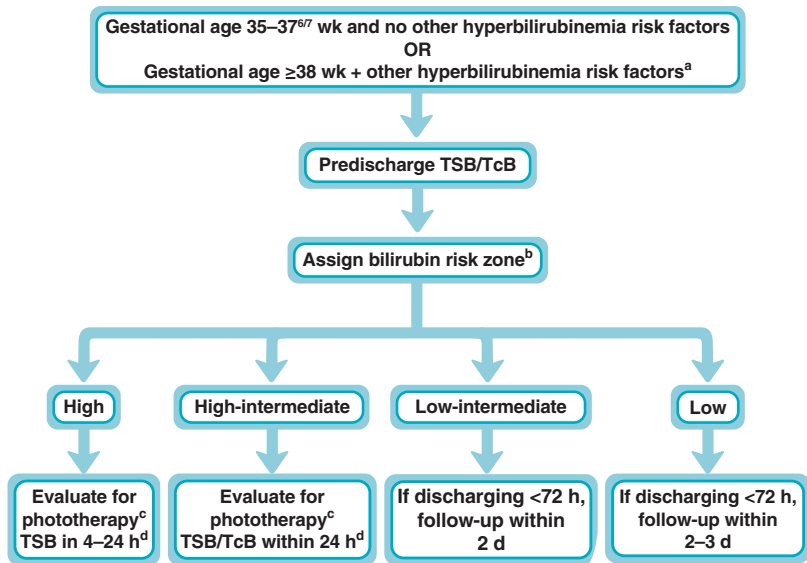

b. **Combining the risk zone (as per bilirubin nomogram) and clinical risk factors** can be used to predict subsequent risk for hyperbilirubinemia and to formulate plans for management and follow-up (Maisels et al). See Figures 63–2A through C for management and follow-up according to predischARGE bilirubin measurements, gestation, and risk factors.

3. **Follow-up assessment.** Should include weight, intake, voiding and stooling pattern, and presence of jaundice. Use clinical judgment in deciding whether a TSB should be obtained.

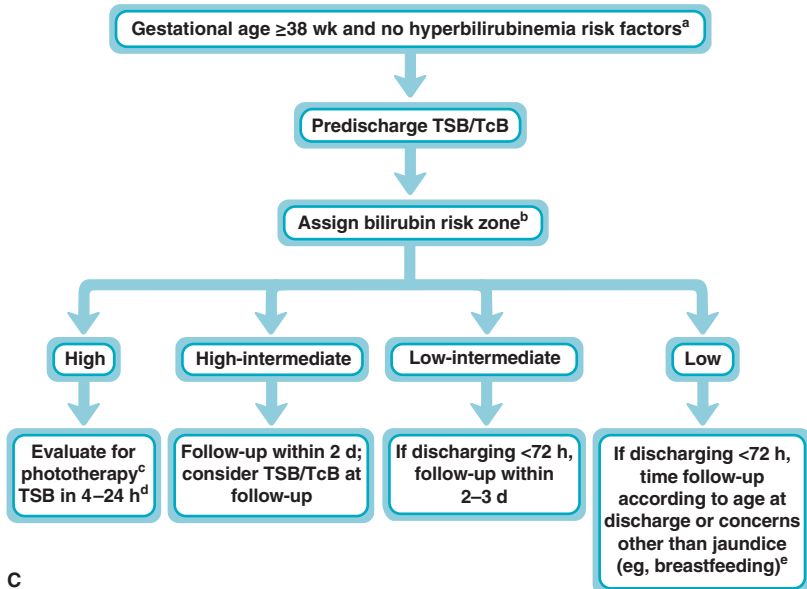

A

FIGURE 63–2. Algorithm providing recommendations for management and follow-up according to predischARGE bilirubin measurements, gestation (≥ 35 weeks), and risk factors for subsequent hyperbilirubinemia. Provide lactation evaluation and support for all breast feeding mothers. Recommendation for timing of repeat TSB or TcB measurement depends on infants' age at measurement and how far the level is above the 95th percentile (see Figure 99–1); higher and earlier initial levels require an earlier repeat measurement. Perform standard clinical evaluation at all follow up visits. For evaluation of jaundice see the 2004 American Academy of Pediatrics guideline. TcB, transcutaneous bilirubin; TSB, total serum bilirubin. FIGURE 63–2. (Continued)

64 Hyperglycemia

- I. **Problem.** The nurse reports an infant has a high blood glucose level of 240 mg/dL. Hyperglycemia is very common in premature low birthweight and extremely low birthweight infants and in extremely sick or stressed newborn infants. There is no universally accepted set definition of hyperglycemia in the newborn. An operational definition, a blood glucose level that triggers an osmotic diuresis, has yet to be defined by sufficient evidence. The treatment of hyperglycemia is also *controversial*. Following are some of the definitions used in the literature:
- A. **Whole blood glucose >120 to 125 mg/dL or a plasma glucose >145 to 150 mg/dL regardless of gestational or postnatal age or weight.**
 - B. **Whole blood glucose >125 mg/dL in term and >150 mg/dL in preterm infant.**
 - C. **Whole blood glucose >215 mg/dL (operational definition), proposed by Dr. Edmund Hey.**

A major concern with hyperglycemia is that it can cause hyperosmolality, osmotic diuresis, and subsequent dehydration. For every 18 mg/dL increase in plasma glucose, the plasma osmolality increases by 1 mOsm/L. In hyperglycemia, the high filtered load of glucose exceeds the amount the kidney tubules can reabsorb, and the excess glucose ends up in the urine. Because glucose is a solute, it draws water into the urine by osmosis (**osmotic diuresis**). Therefore, a high volume of glucose-containing urine is produced, which can lead to dehydration. It is difficult to know the exact level of blood glucose that triggers an osmotic diuresis in neonates. Significant osmolar changes have been reported to occur at a serum glucose >360 mg/dL.

The other concern is that preterm infants with hyperglycemia are at an increased risk of mortality, infection, intracranial hemorrhage, neurodevelopmental impairment (prolonged or symptomatic hyperglycemia), white matter reduction on magnetic resonance imaging, retinopathy of prematurity, and developmental delay. Hyperglycemia is an independent risk factor for the prediction of death (57% likelihood of death when present in critically ill neonates). In the first 12 hours in asphyxiated term infants, it is associated with poor gross motor outcome, and if it occurs on the first day in infants undergoing therapeutic hypothermia for hypoxic ischemic encephalopathy, it is associated with a poor outcome. Hyperglycemia is common in infants with NEC and is associated with a poor outcome (increase in late mortality and longer NICU stay).

II. Immediate questions

- A. **Are there any signs of hyperglycemia?** Hyperglycemia is most common during the first week of birth, and most infants are asymptomatic or can have signs of an underlying disorder (eg, sepsis). Signs that are specific but unreliable in hyperglycemia include weight loss, fever, failure to thrive, glycosuria, metabolic acidosis, and dehydration secondary to an osmotic diuresis. Signs that are common in transient or permanent neonatal diabetes are glycosuria, ketosis, and metabolic acidosis.
- B. **What is the serum glucose value on plasma laboratory testing?** Plasma glucose measurement by a laboratory performed method is the gold standard for measuring blood glucose levels. Point-of-care bedside glucose testing using reagent strips and glucose reflectance meters are widely used for screening but are not always accurate or reliable. Contamination of the blood sample with alcohol has been shown to increase the blood glucose level in reagent strips. The reagent strips measure glucose concentration in whole blood, which is 10% to 15% lower than laboratory plasma glucose levels. Confirm a serum glucose level from the laboratory before initiating treatment.

- C. **Is glucose being spilled in the urine (glucosuria)?** The amount of glucose in the urine, which is an indication of the renal threshold for glucose, has been used to evaluate hyperglycemia and whether too much glucose is being administered. In neonates, glucosuria can be an unreliable marker for both hyperglycemia and the evaluation of the glucose infusion rate. Glycosuria can occur with normal blood levels, and hyperglycemia can be associated with mild or no glucosuria. It is important to remember the renal threshold is lower in premature infants, because nephrogenesis is not complete until 36 weeks' gestation. Normal renal threshold for glucose is 160 to 180 mg/dL; urinary glucose will start to be detected above this level. General findings on reagent strip testing of the urine are as follows:
1. **Trace glucose:** Urine contains 100mg/dL glucose.
 2. **+1 glucose:** Serum glucose >180 mg/dL; urine contains 250 mg/dL of glucose.
 3. **+2 glucose:** Serum glucose >200 mg/dL; urine contains >500 mg/dL of glucose.
 4. **+3 glucose:** Serum glucose >300 mg/dL; urine contains >1000 mg/dL glucose.
 5. **+4 glucose:** Serum glucose >400 mg/dL; urine contains >2000 mg/dL glucose.
- A trace amount of glucose in the urine is accepted as normal. If the **urinary glucose level is +1, +2, or greater, the renal threshold has been reached with an increased chance of osmotic diuresis.** Significant glucosuria is uncommon, and some sources indicate that osmotic diuresis is not a concern until the urine contains greater than +2 to +3 glucose. Some institutions accept a urinary glucose level of +1 without treating the patient (*controversial*), whereas some authors suggest that greater than +1 glucosuria indicates early osmolar changes and should be treated.
- D. **How much glucose is the patient receiving?** High glucose intake is a common cause of hyperglycemia in a preterm infant. Dextrose (D-glucose) infusions >10 to 12 mg/kg/min may result in hyperglycemia, and hyperglycemia may occur at lower levels if the infant is stressed. Normal initial maintenance dextrose therapy in infants not being fed orally is 6 to 7 mg/kg/min on days 1 to 8 to 9 mg/kg/min on days 2 to 7. ELBW infants should be started at 4 to 6 mg/kg/min (see Chapter 13).
- E. **Are there signs of stress?** Stressful situations such as surgery may cause hyperglycemia by inducing a catecholamine-mediated stress response. When an infant who has had normal glucose levels develops hyperglycemia and there is no change in intravenous (IV) fluids, or if an infant who is being fed only enterally suddenly develops hyperglycemia, suspect either sepsis or necrotizing enterocolitis (NEC).
- F. **What is the birthweight of the infant? Is the infant preterm?** Low birthweight and lower gestational age are significant risk factors for hyperglycemia. The incidence is ≤5% in full-term infants, 68% in infants weighing 1000 to 1500 g, 72% in infants weighing <1000 g, and 80% in infants weighing <750 g.
- G. **Does the infant have any of the high-risk factors for hyperglycemia?** Risk factors include gestational age <37 weeks, postnatal age <72 hours, weight <2500 g (lower birthweight), hypoxia, infection, use of inotropes, lipid infusions, high glucose infusion rate, respiratory distress syndrome, and sepsis. These infants should have frequent monitoring of their blood sugars. Low phosphate can be associated with hyperglycemia in ELBW neonates.
- H. **What are the current medications?** Steroids (most common), methylxanthines, and vasoactive drugs can cause hyperglycemia. Caffeine rarely has an effect on blood glucose levels, but an overdose can cause hyperglycemia.
- III. **Differential diagnosis.** Hyperglycemia in preterm or low birthweight infants used to be attributed only to excess IV glucose infusion, but other mechanisms may be responsible. These infants have limited reserve since glycogen storage does not occur until the third trimester. There is also immaturity or defective glucoregulatory hormone control, poor insulin response to elevated blood glucose levels, insulin resistance in peripheral tissues, a lack of negative feedback on hepatic glucose production during dextrose infusion, inability to suppress glucose production, and glucose intolerance. **Neonatal**

hyperglycemia is usually related to a clinical condition and not a specific abnormality in glucose metabolism.

A. Factitious hyperglycemia

1. **Blood drawn from an intravenous line** containing glucose or shortly after a bolus of glucose was given.
2. **False bedside hyperglycemia from a glucose meter.** Some glucose meters will overestimate the serum glucose in an infant with **galactosemia** because of the lack of specificity of the enzyme used by the assay. Always confirm with a serum sample if glucose meter is high.

B. True hyperglycemia

1. **Glucose infusion** can play a major role in hyperglycemia. Giving infants more glucose than they can handle needs to be evaluated first. Incorrect calculation of glucose levels or errors in the formulation of IV fluids may cause hyperglycemia. Infants often need their glucose infusion rates frequently adjusted because their needs have changed or other factors are causing hyperglycemia (sepsis, prematurity, stress).
 - a. **Extremely low birthweight infants (<1000 g).** These infants have greater fluid requirements because of their immature renal function and increased insensible water loss. This often leads to a high volume of fluid and administering too much glucose. They also may have insulin resistance or an immature insulin response and thus may be unable to stop gluconeogenesis when IV glucose is given.
 - b. **Preterm infants/small for gestational age infants.** Preterm infants receiving a glucose challenge show variable increases in insulin levels consistent with **insulin resistance**. This resistance may be related to immaturity or down-regulation of peripheral receptors or inadequate development of the insulin dependent GLUT-4-mediated glucose transport system. Transient hyperglycemia can also be seen in small for gestational age (SGA) infants from impaired glucose homeostasis.
2. **Sepsis.** Suspect sepsis-related hyperglycemia in a neonate who had normal glucose levels with no change in the rate or amount of IV glucose. The etiologies can include the stress response, a reduction in the peripheral utilization of glucose, or a decrease in release of insulin. Hyperglycemia is more frequent in **fungal** than bacterial sepsis in the neonate. Hyperglycemia may be the first sign in neonatal sepsis; in *Candida* sepsis, it can appear 2 to 3 days before other signs.
3. **Hypoxia** can cause increased glucose production and hyperglycemia.
4. **Hyperosmolar formula.** Ask how the formula was made. An inappropriate dilution can lead to a hyperosmolar formula, which in turn can cause transient hyperglycemia. Signs can look the same as those of transient neonatal diabetes (hyperglycemia, glycosuria, dehydration).
5. **Lipid infusion.** Lipids and lipid components (especially free fatty acids) can cause hyperglycemia. Infants who receive lipid infusion even with low rates of glucose administration may develop hyperglycemia. Lipids are emulsified in a dextran solution, a glucose polymer which can increase blood glucose levels. The lipid component may also cause a glycemic response and a decrease in peripheral glucose utilization and may inhibit insulin's effect. One study found that giving lipid infusion increased plasma glucose concentrations by 24% over baseline values. If the lipid infusion is given rapidly at a rate >0.25 g/kg/h, it can cause hyperglycemia.
6. **Stress/surgical procedures/therapeutic hypothermia.** Pain, painful procedures (venipuncture, vascular cutdowns, and others), surgical procedures (during surgery and postoperative), mechanical ventilation, NEC, acute intracerebral bleeding, hypoxia, catecholamine infusions, and respiratory distress can all cause hyperglycemia secondary to increased stress hormones. During surgical procedures and postoperatively, infants are often given too much glucose-containing

IV fluids, which can lead to hyperglycemia. Increased cortisol secretion during surgery and increased catecholamine release after induction of anesthesia also play a role. Infants undergoing therapeutic hyperthermia can become hyperglycemic and often require insulin therapy. Hypothermia can decrease insulin sensitivity and the amount of insulin secretion by the pancreas, which leads to hyperglycemia.

7. Medications

a. Maternal use of diazoxide can cause hyperglycemia in the infant.
b. Medications used in infants that have been associated with hyperglycemia include steroids (most common, especially in ELBW infants), theophylline, caffeine, inotropic agents, diazoxide, and phenytoin. Inhaled fluticasone propionate can cause hyperglycemia.

8. Chromosome 13 deletion (46,xxDq-) has been associated with hyperglycemia in an SGA neonate.

9. Neonatal diabetes mellitus is a rare form (1 in 500,000 live births) of diabetes and usually has a monogenic etiology. It is defined as persistent hyperglycemia that lasts >2 weeks and requires insulin therapy. Neonatal diabetes mellitus (NDM) occurs in infants <6 months old; it is not an autoimmune disease and is most commonly caused by genetic defects. Molecular analysis of chromosome 6 anomalies and the *KCNJ11* and *ABCC8* genes can provide a way of differentiating transient from permanent neonatal diabetes. Infants with NDM can have hyperglycemia, metabolic acidosis, ketosis, weight loss, polyuria, volume depletion, and glycosuria. **There are 2 types of NDM, and it is clinically difficult to differentiate whether an infant has transient NDM (TNDM) or permanent NDM (PNDM):**

a. Transient neonatal diabetes mellitus (40%–60% of cases) is a developmental disorder of the production of insulin that usually resolves. It is primarily a genetic disorder, and the gene responsible can be ascertained in 90% of the cases (mutation of imprinting gene *ZAC/PLAGL1* on chromosome 6q24 a major cause; mutation of the *ABCC8* gene, which encodes SUR1, can cause transient and permanent diabetes mellitus). Most infants are SGA or have intrauterine growth restriction (IUGR); they present from 2 days to 6 weeks of age with hyperglycemia and require insulin therapy. TNDM persists for >2 weeks and usually resolves by 18 months. It lasts a median of 12 weeks. Common findings are hyperglycemia, dehydration, glycosuria, polyuria, progressive wasting, hypoinsulinism, ketosis, metabolic acidosis, absent ketonuria, and normal or transiently low C-peptide levels in urine and serum. There is a positive family history in approximately 33% of cases. About half of these patients relapse later in life (in adolescence or adulthood) and require medication.

b. Permanent neonatal diabetes mellitus. PNDM is less common than TNDM. It develops in the neonatal period, does not go into remission, and requires lifelong medical treatment. It is genetically heterogeneous with mutations in >20 different genes (most common are the *KCNJ11* gene encoding Kir6.2; mutation of the *ABCC8* gene, which encodes SUR1; and mutations in *INS* gene). These infants are usually SGA, and some may have DEND syndrome (developmental delay, epilepsy, neonatal diabetes). **Preterm infants can have neonatal diabetes mellitus secondary to a monogenic etiology (*GATA6* mutations and chromosome 6q24 imprinting abnormalities are more common).**

10. Idiopathic hyperglycemia. No identifiable cause is found; a diagnosis of exclusion.

11. Rare causes. Pancreatic lesions (pancreatic aplasia, pancreatic hypoplasia, congenital absence of insulin-secreting B cells) are extremely rare in neonates and they rarely survive. The prevalence of cystic fibrosis-related diabetes mellitus

(CFRD) in infants <10 years is 2%. The majority of infants with inborn errors of metabolism have hypoglycemia, but organic acidemias (isovaleric, methanolic, and propionic acidemias) can present with hyperglycemia.

IV. Database

A. Physical examination and history. Is the infant premature or SGA, or does the infant have IUGR? Determine whether there is a family history of diabetes and ask about maternal and infant medications. Infants with hyperglycemia usually have no obvious signs. Look for dehydration, weight loss, and fever. Evaluate for subtle signs of sepsis (eg, temperature instability, changes in peripheral perfusion) or changes in gastric aspirates if the infant is feeding. Look for signs of NEC.

B. Laboratory studies

1. Initial studies

- a. **Serum glucose level.** Confirm any rapid bedside paper-strip test result with a serum glucose level. It is advisable to repeat serum blood glucose before treating.
- b. **Urine dipstick testing for glucose.** Because of the immaturity of the proximal tubule in premature infants, glucosuria is not the most accurate marker of hyperglycemia. Glucosuria can occur at normal blood glucose levels. High levels may indicate osmotic diuresis.
- c. **Complete blood count with differential** as a screening test for sepsis.
- d. **Blood, urine, and spinal cultures.** For sepsis workup if indicated.
- e. **Serum electrolytes.** Hyperglycemia may cause osmotic diuresis, which may lead to electrolyte losses and dehydration. Monitor serum electrolyte levels in significantly hyperglycemic patients.
- f. **Arterial blood gas.** If concerned about hypoxia; metabolic acidosis can be seen in sepsis and neonatal diabetes.
- g. **Phosphate levels.** Hypophosphatemia can be associated with hyperglycemia in ELBW neonates.
- h. **Liver transaminases** can be elevated secondary to steatosis and impairment in secretion of hepatic triglycerides.

2. Further studies

- a. **Serum ketones** can be positive in NDM. **Ketonuria** can be absent or mild.
- b. **Serum insulin level** is low to normal in TNDM and normal to high in sepsis.
- c. **Serum or urine C-peptide levels** are low in TNDM.
- d. **Genetic evaluation and testing (molecular diagnosis) for neonatal diabetes are recommended** for all patients diagnosed with diabetes in the first 6 months of life. It is important because the results may change the treatment plan, predict prognosis, and improve glycemic control. Testing identifies which types of PNDM will respond to oral sulfonylurea therapy and which will require insulin. Molecular analysis of chromosome 6q24 anomalies and the *KCNJ11* and *ABCC8* genes will help to differentiate TNDM from PNDM.

C. Imaging and other studies. None are usually required; however, a **chest radiograph** may be useful in the evaluation of respiratory distress and sepsis, and an **abdominal film** may be useful for NEC. **Head ultrasound** is recommended in premature infants to rule out a bleed.

V. Plan. The standard treatments of hyperglycemia are observation, glucose restriction, insulin therapy, or a combination of glucose restriction and insulin therapy. A Cochrane review of trials of interventions (decreasing amount of glucose or giving insulin) for treatment of neonatal hyperglycemia in very low birthweight (VLBW) infants found “evidence from randomized trials was insufficient to determine the effects of treatment on death or major morbidities and it remains uncertain whether the hyperglycemia per se is a cause of adverse clinical outcomes or how the hyperglycemia is treated.” Recommended treatment is conservative since most cases of hyperglycemia are transient. Treatment values and method of treatment vary; follow institution’s guidelines.

- A. Early insulin therapy and low versus high glucose infusion rates to prevent hyperglycemia.** Routine early continuous insulin infusion is not recommended in VLBW infants. A multicenter trial of early insulin therapy in VLBW infants addressed whether early insulin therapy reduced hyperglycemia. It showed that the infants who received early insulin therapy had lower glucose levels, were less likely to be hyperglycemic, had less weight loss, and received more calories because of the increased amount of glucose infusion. It did not improve growth and increased the episodes of hypoglycemia and death before 28 days. A Cochrane review states there is insufficient evidence comparing lower or higher glucose rates **to prevent hyperglycemia in VLBW infants**. They also found that the evidence does not support the routine use of insulin infusions to prevent hyperglycemia in VLBW neonates.
- B. Permissive hyperglycemia in extremely low birthweight infants.** Permissive hyperglycemia (allowing a higher than normal serum glucose to give additional calories to promote growth) is practiced in some neonatal intensive care units. A study was done in ELBW infants that showed that permissive hyperglycemia up to <300 mg/dL without insulin in the first 14 days of life was associated with faster weight gain and was not associated with osmotic diuresis or increased mortality or morbidity. **Permissive hyperglycemia allows increased caloric intake** to support nutrition and prevents the frequent episodes of hypoglycemia and increase in mortality associated with early insulin treatment.
- C. Initial management**
- 1. Rule out factitious hyperglycemia.** Check to see how the blood glucose was drawn, make sure to get a serum blood glucose, and recheck another one before treatment to confirm.
 - 2. Recalculate how much glucose the infant is receiving** and make sure the infant is not getting too much glucose (see Chapter 13). ELBW infants, especially <1000 g, cannot tolerate high glucose loads, and giving >4 mg/kg/min may cause hyperglycemia. Some infants may need less glucose because of stress or sepsis or some other clinical situation.
 - 3. Treat any underlying causes of hyperglycemia**, such as sepsis, hypoxia, pain, respiratory distress, or postsurgery; stop medications that may cause hyperglycemia; check formula dilution; and institute other measures to address underlying cause. **Monitor blood glucose levels and glycosuria frequently**, especially in preterm, low birthweight, ELBW, stressed, or septic infants and infants with symptoms suggestive of hyperglycemia or whose glucose levels have not been stable. Monitor all infants on parenteral glucose therapy and insulin therapy. It is important to monitor blood glucose levels during observation and treatment since hypoglycemia can occur.
 - 4. Enteral feeding.** Feed as early as possible since early feeding promotes pancreatic function and secretion of insulin and can be beneficial for maintaining euglycemia. Even minimal enteral feeds induce insulin secretion. If the clinical situation is severe, feeding may not be possible.
 - 5. Parenteral nutrition and lipids.** Early introduction of parenteral infusion is associated with a decreased incidence of hyperglycemia. It provides a substrate for gluconeogenesis and helps stimulate insulin release in infants receiving glucose. If the infant is on lipids, some institutions decrease the lipid infusion rate to help decrease the hyperglycemia. Infants with persistent hyperglycemia on parenteral nutrition may warrant treatment with insulin. **Clinical guidelines from the American Society for Parenteral and Enteral Nutrition for infants on parenteral nutrition and hyperglycemia include the following:**
 - a. Check blood glucose by laboratory serum glucose** or glucose electrode measurements. Keep serum glucose concentration <150 mg/dL.
 - b. Avoid excess dextrose and add fat emulsion.** Lower the dose of fat emulsion if hyperglycemia occurs.
 - c. Do not use early insulin therapy.**

d. Persistent hyperglycemia in the neonate receiving parenteral nutrition may require treatment with insulin. First try other methods to decrease glucose: decrease amount of glucose infusion rate, remove medications that cause hyperglycemia, and correct any underlying causes of hyperglycemia.

D. Treatment of hyperglycemia

1. **Observation only.** If the glucose is not too high (usually <180 mg/dL) and the urinary glucose is negative or trace, observation with close monitoring of blood glucose levels is usually all that is needed. Some providers accept $+1$ glucose in the urine and will not treat. Monitor with bedside glucose testing every 4 to 6 hours, and check for glucose in the urine with each void.
2. **Decrease the amount of glucose administered.** This can be done by decreasing the concentration of glucose or the rate of infusion until a normal serum glucose level is present. If the glucose is >180 to 200 mg/dL or if the infant is spilling greater than $+2$ glucose in the urine, treatment is usually necessary. The presence of glucose in the urine may indicate osmolar changes, which could indicate hyperosmolarity, osmotic diuresis, and dehydration. Monitor with bedside glucose testing every 4 to 6 hours, and check for glucose in the urine with each void.
 - a. **Decrease the concentration of glucose.** Typically, the concentration can be reduced from 10% to 5%. Do not use a solution that has a dextrose concentration of $<5\%$. Such a solution is hypo-osmolar and could cause hemolysis, with resulting hyperkalemia.
 - b. **Decrease the rate of glucose infusion.** The rate can be safely decreased by 1 to 2 mg/kg/min every 2 to 4 hours. Typically, the rate can be decreased to 4 to 6 mg/kg/min, with some sources reporting 3 to 4 mg/kg/min.
3. **Insulin therapy. Although routine early insulin is not recommended, persistent hyperglycemia may warrant treatment with insulin.** Indications for insulin therapy are controversial. Most physicians treat infants with persistent hyperglycemia that occurs after the amount of glucose is decreased, infants with osmotic diuresis, or infants on a decreased glucose infusion rate who need more calories because they are not gaining weight (failure to thrive). Levels vary widely on recommendations, but many will treat the infant with insulin for persistent blood glucose levels >200 to 250 mg/dL (some sources use 300 mg/dL). Guidelines are institutional dependent and *controversial*. Use **regular insulin (100 U/mL)** diluted in normal saline to a concentration of 0.5 U/mL or 0.1 U/mL. Several regimens are available for insulin dosing.
 - a. **Bolus infusion**
 - i. **Insulin 0.05 to 0.1 U/kg/dose** over 15 minutes every 4 to 6 hours as needed.
 - ii. **Monitor glucose every 30 to 60 minutes after dose.**
 - iii. **Consider continuous infusion** if the bolus does not work after 2 to 3 doses (blood glucose >200 mg/dL).
 - b. **Continuous insulin infusion** (most common and preferred method)
 - i. **Insulin infusion rate:** 0.01 to 0.2 U/kg/h.
 - ii. **Usual starting dose** is between 0.01 and 0.05 U/kg/h.
 - iii. **Adjust in small increments** (0.01 U/kg/h) as needed.
 - iv. **Flush the tubing with >25 mL of the insulin-containing solution** for at least 20 minutes so that all sites in the tubing will be saturated satisfactorily before beginning the infusion. This is done because insulin binds to the tubing, preventing the entire dose of insulin getting to the infant. Adding albumin to the bag to prevent insulin from adhering to the plastic tubing is now considered unnecessary.
 - v. **Potassium** should be added to the solution to limit hypokalemia; monitor potassium levels.
 - vi. **Bedside glucose testing** must be performed within 30 minutes of starting the infusion and after every change made. Check every hour until the blood glucose is stable.

65 Hyperkalemia

I. Problem. The serum potassium level is 7.0 mEq/L in an extremely low birthweight (ELBW) infant. Normal potassium levels are generally between 3.5 and 5.5 mEq/L, with a potassium >5.5 mEq/L indicating hyperkalemia. The exact definition varies and can be based on maturity or severity. Some reported definitions of hyperkalemia include the following:

- A. **Serum potassium >6 mEq/L** in full-term neonates.
- B. **Serum potassium >6.5 mEq/L** in premature infants.
- C. **Moderate hyperkalemia: Serum potassium 6 to 7 mEq/L**
- D. **Severe hyperkalemia: Serum potassium >7 mEq/L**

Hyperkalemia is common in preterm and ELBW infants because of an immature tubular function and a decreased potassium excretion caused by a lower glomerular filtration rate. Plasma potassium concentration also increases in ELBW infants in the first few days after birth from the shift of potassium from the intracellular to the extracellular compartment. **This is the most serious of electrolyte abnormalities because it can cause fatal arrhythmias.** If electrocardiogram (ECG) changes relating to hyperkalemia are present, this is an emergency situation. Plasma potassium should be monitored in all premature infants <30 weeks postmenstrual age during the first 3 days of life because they can develop nonoliguric hyperkalemia (NOHK) and have serious complications (cardiac arrhythmias, periventricular leukomalacia, brain hemorrhage, and sudden death).

II. Immediate questions

- A. **How was the specimen collected? What is the central serum potassium level? Is it a true level or factitious level?** Blood obtained from a heel stick or drawn through a small-bore intravenous (IV) line or tiny needle may yield falsely elevated potassium levels secondary to hemolysis. Clot formation can also cause a falsely elevated potassium. The blood should not be obtained from a heparin-coated umbilical catheter (release of benzalkonium from a heparin-coated umbilical catheter can elevate the potassium reading). **Note:** Serum potassium level is 0.4 mEq/L higher than the plasma level. Always do a serum potassium level from a venous sample (free flowing) before treatment.
- B. **Does the electrocardiogram show cardiac changes characteristic of hyperkalemia?** This may be the first indication of hyperkalemia. In neonates, serum potassium >6.7 mEq/L is associated with ECG changes. Early cardiac changes include tall, peaked, “tenting” T waves, followed by loss of or flattened P wave, widening QRS, ST-segment depression, bradycardia, sine wave QRS-T, first-degree atrioventricular block, ventricular tachyarrhythmias, and finally cardiac arrest if the potassium levels continue to increase. Classic ECG changes include the following:
 - 1. **Serum potassium of 5.5 to 6.5 mEq/L.** Tall peaked T waves with a narrow base, shortening of PR interval, normal or decreased QT.
 - 2. **Serum potassium of 6.5 to 8 mEq/L.** Tall peaked T waves, prolonged PR interval, loss or decreased P wave, amplified R wave, widening of QRS.
 - 3. **Serum potassium >8 mEq/L.** Absent P wave, wide bizarre diphasic QRS, progressive QRS widening merging with the T wave, bundle branch blocks, ventricular fibrillation or asystole.
- C. **How much potassium is the infant receiving?** Normal amounts of potassium given for maintenance are 1 to 3 mEq/kg/d.
- D. **What are the blood urea nitrogen and creatinine levels? What are the urine output and body weight?** Elevated blood urea nitrogen (BUN) and creatinine levels suggest renal insufficiency. Another indication of renal failure is decreasing or inadequate urine output with weight gain.

- E. Is there associated hyponatremia, hypoglycemia, and hypotension?** With low sodium and glucose, high potassium, and hypotension, consider adrenal insufficiency.
- F. Does the infant have any of the common characteristics of premature newborns prone to hyperkalemia?** These include small for gestational age, female sex, severe respiratory distress syndrome, very low birthweight, requirement of exogenous surfactant, need for inotropic medications, and delayed feeding. Mildly elevated potassium (>5.6 mEq/L) and phosphate levels (>2 mEq/L) within 6 hours of birth may predict the development of hyperkalemia. NOHK risk factors in ELBW infants are younger gestational age and infants whose mothers did not use antenatal steroids. Electrolyte imbalance (hyponatremia, hypocalcemia, and hyperphosphatemia) occurs more often in infants with NOHK.
- III. Differential diagnosis.** True hyperkalemia can be caused by an increase in potassium intake (usually not a problem if kidneys able to excrete potassium), an increase in potassium release, a decrease in potassium excretion or inability to excrete potassium by the kidneys, medications, a shift of potassium into the extracellular space, or impaired aldosterone activity causing decreased renal excretion.
- A. Pseudohyperkalemia is a falsely elevated potassium level (plasma potassium is normal).** It can be due to hemolysis (trauma causes destruction of red blood cells [RBCs] with leakage of potassium into serum samples) during **phlebotomy or heel stick** or by drawing the sample proximal to an IV site infusing potassium. If an unspun sample is allowed to sit or if there is a delay in processing (after 2 hours), potassium release from the cells and causes pseudohyperkalemia. Laboratory error (multiple processing variables) can also be a reason. **Thrombocytosis (increase in platelets) and leukocytosis (increase in WBCs)** can lead to a false elevation of **serum potassium levels** because potassium leaks out of an increased number of white blood cells and platelets during clotting. The serum potassium increases by 0.15 mEq/L for every 100,000/mL elevation of the platelet count. Two rare genetic syndromes that can cause pseudohyperkalemia are **familial pseudohyperkalemia** and **hereditary spherocytosis**.
- B. True hyperkalemia**
- 1. Common causes of hyperkalemia**
- a. Increased potassium administration or intake.** Excessive amount in IV fluids, excessive oral supplementation (excess potassium chloride supplementation in an infant with bronchopulmonary dysplasia/chronic lung disease), or potassium-containing medications. Potassium supplements usually are not necessary on the first day of life and often are not necessary until day 3, with the typical requirement of 1 to 3 mEq/kg/d. This is a rare cause because the kidneys usually excrete any excess potassium.
- b. Pathologic hemolysis of red blood cells.** May be secondary to intraventricular hemorrhage, use of a hypotonic glucose solution (<4.7% dextrose), sepsis (most commonly *Pseudomonas*), intravascular hemolysis, cephalohematoma, bleeding, asphyxia, or Rh incompatibility.
- c. Tissue necrosis and breakdown.** In certain disease states, such as necrotizing enterocolitis (NEC) or bowel infarction, tissue necrosis can occur and hyperkalemia may result. Trauma and severe hypothermia can cause rhabdomyolysis.
- d. Renal failure/insufficiency.** Impaired kidney function can lead to hyperkalemia. Oliguria can cause decreased potassium clearance and hyperkalemia. **Acute kidney injury or chronic kidney disease** can impair potassium excretion in the urine.
- e. Nonoliguric hyperkalemia (NOKH). NOKH is hyperkalemia in the absence of oliguria and potassium intake.** There are multiple definitions of NOHK, one that is frequently used is serum potassium ≥ 7 mmol/L in the presence of urine output of ≥ 1 mL/kg/h during the first 72 hours of life. Incidence varies between 11% and 52%. It occurs more commonly in ELBW infants than term infants, with 80% of NOHK cases in ELBW infants <28 weeks' gestation. These

infants usually did not have exposure to antenatal steroids, which seems to protect some infants. Pathophysiology is unknown but current evidence states that NOHK results from a shift of potassium from the intracellular to extracellular space due to the immature function of Na/K-ATPase activity in premature neonates. It can cause life-threatening cardiac arrhythmias.

- f. **Metabolic acidosis.** Causes potassium to move out of cells, resulting in hyperkalemia. For every 0.1-unit decrease in pH, the serum potassium increases approximately 0.3 to 1.3 mEq/L. Respiratory acidosis rarely causes significant hyperkalemia.
 - g. **Dehydration.** Volume depletion and congestive heart failure can cause renal hypoperfusion and therefore hyperkalemia.
 - h. **Medications. Medication error is one of the most common causes of hyperkalemia in the neonatal intensive care unit. Penicillin G potassium** contains potassium salts and can cause hyperkalemia. **Digoxin therapy** can lead to hyperkalemia secondary to redistribution of potassium. **Potassium-sparing diuretics** cause decreased potassium losses. Both **propranolol** and **phenylephrine** are associated with hyperkalemia. **High glucose load** can lead to hyperkalemia secondary to increases in plasma osmolality. **Heparin** can cause hyperkalemia by blocking aldosterone biosynthesis in the adrenal gland. **Other medications**, including tromethamine, enalapril, indomethacin, angiotensin-converting enzyme inhibitors, α -blockers, trimethoprim, captopril, amiloride, and nonsteroidal anti-inflammatory drugs, have been associated with hyperkalemia. **Medications that cause decreased potassium output include** potassium-sparing diuretics (spironolactone, triamterene, amiloride), cyclosporine, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, heparin, tacrolimus, pentamidine, and trimethoprim.
 - i. **Adrenal insufficiency seen in congenital adrenal hyperplasia and bilateral adrenal hemorrhage.** In salt-losing congenital adrenal hyperplasia, infants have low serum sodium, chloride, and glucose and elevated levels of potassium and hypotension. In bilateral adrenal hemorrhage, anemia, thrombocytopenia, and jaundice are seen, and bilateral adrenal masses are often palpable. Renal tubular hyperkalemia/hyperkalemic distal renal tubular acidosis type IV occurs secondary to hypoaldosteronism. Infants present with metabolic acidosis and hyperkalemia. Hyperkalemia is seen in adrenal disorders (hypoaldosteronism, congenital adrenal hyperplasia), obstructive uropathy, reduced renal mass, renal reflux, urinary tract infection, and pseudohypoaldosteronism.
 - j. **Decreased insulin levels** can cause hyperkalemia as insulin drives potassium into cells.
 - k. **Transfusion-induced hyperkalemia.** Transfusions that require a large amount of blood transfused (eg, exchange transfusion and major surgery) can contribute to hyperkalemia. Smaller volume transfusions do not cause hyperkalemia. Irradiation of RBCs accelerates the leakage of potassium out of stored RBCs, which can increase the risk of transfusion-induced arrhythmias from hyperkalemia. Washing of irradiated RBCs reduces potassium and lactate loads. It is best to use fresh blood when possible.
 - l. **Hyperosmolality.** Caused by inappropriately diluted formula, hyperosmolar amino acid solution, or glucose infusions.
2. **Less common causes**
- a. **Neonatal Bartter syndrome (a variant of this with ROMK mutation presents with early hyperkalemia).** This is a group of renal tubular disorders usually characterized by hypokalemic metabolic alkalosis.
 - b. **Hereditary hyperkalemic disorders.** Hereditary pseudohyperkalemia, hereditary hyperkalemic periodic paralysis, various types of hypoaldosteronism, and hereditary tubular defects that cause hyperkalemia.

- c. **Disorders that cause decreased renal excretion of potassium.** Renal failure, Addison disease, mineralocorticoid deficiency, primary hypoaldosteronism, aldosterone synthase deficiency, and pseudohypoaldosteronism.

IV. Database

- A. **Physical examination.** Typical clinical manifestations of symptomatic hyperkalemia include muscular or respiratory paralysis, bradycardia, ventricular arrhythmias (ventricular fibrillation/tachycardia), shock, and cardiac arrest. It is difficult to state an exact potassium level when clinical signs will appear, but most agree that when the serum potassium increases to >7 mEq/L, signs can be identified. Signs include polyuria and abdominal distension; lethargy with muscle weakness occurs if potassium level is >8 mEq/L but is hard to evaluate in a newborn. Tendon reflexes can be decreased. Pay special attention to the abdomen for signs of NEC (abdominal distention, decreased bowel sounds, and visible bowel loops). Evaluate for signs of other underlying diseases.

B. Laboratory studies

1. Immediate tests

- a. **Serum potassium level measured by a properly collected venous sample.** A repeat serum potassium level is usually recommended before treatment.
- b. **Serum and urine electrolytes.**
- c. **Complete blood count and differential.** To rule out sepsis and hemolysis.
- d. **Serum ionized and total calcium levels.** Hypocalcemia may potentiate the effects of hyperkalemia. Maintain normal serum calcium concentrations.
- e. **Serum pH and bicarbonate.** To rule out acidosis, which may potentiate hyperkalemia.
- f. **Blood urea nitrogen and serum creatinine levels.** May reveal renal insufficiency.
- g. **Urine dipstick and specific gravity.** To assess renal status and blood and hemoglobin for tissue breakdown secondary to hemolysis. Examine for casts or sediment.

2. Further testing

- a. **17-hydroxyprogesterone (17-OHP)** by tandem mass spectrometry for classic congenital adrenal hyperplasia. Other tests include serum cortisol, 11-deoxycortisol, 17-hydroxypregnenolone, androstenedione, and dehydroepiandrosterone.
- b. **Serum renin, angiotensin, and aldosterone** for hypoaldosteronism and pseudohypoaldosteronism.

C. Imaging and other studies

1. **Abdominal radiograph** if NEC is suspected.
2. **Electrocardiogram** may reveal the cardiac changes characteristic of hyperkalemia and provides a baseline study (see Section II.B).

- V. **Plan.** First, rule out pseudohyperkalemia and confirm true hyperkalemia with a repeat stat serum potassium level (make sure it is free flowing venous sample). Obtain an ECG and place the infant on a cardiac monitor. **Document any ECG changes, and if present, this is a medical emergency and needs to be treated immediately.** Treatment is also recommended when the serum potassium reaches a certain level (>6.0 – 6.5 mEq/L) but level recommendations vary depending upon the source.

A. General management for hyperkalemia (see Table 65–1)

1. **Stop all exogenous potassium intake.** Check the calculation of potassium in the IV fluids/TPN to verify that excess potassium was not given. Consider stopping any potassium containing medications, oral potassium supplements or medications known to induce hyperkalemia.
2. **If hypocalcemia is also present,** treat it by infusing 100 to 200 mg/kg of calcium gluconate (diluted in appropriate fluid given over 10–30 minutes). This will lower the cell membrane threshold and be cardioprotective. Use caution

Table 65–1. HYPERKALEMIA MANAGEMENT IN NEONATES

Drug	Dosing Regimen	Onset	Comments and Side Effects
MOA: Cardiac membranes stabilization			
Calcium gluconate 10%	60 mg/kg IV over 5–10 minutes	Immediate	Vesicant—undiluted drug must be given via CENTRAL line only Dilute with equal volume of D5W or NS to yield final concentration of 50 mg/mL to be given via peripheral IV Do not administer in the same line with sodium bicarbonate due to possible precipitation
Calcium chloride 10%	20 mg/kg IV over 3–5 minutes	Immediate	Vesicant—must be given via CENTRAL line only
MOA: Intracellular shifting of potassium			
Insulin regular and dextrose (bolus)	0.1 unit/kg mix in 5 mL/kg D10W OR 2 mL/kg D25W IV over 15–30 minutes	10–20 minutes	Insulin: Regular only for intravenous administration. Prime and flush IV tubing with insulin continuous infusion solution prior to administration to minimize insulin adsorption to plastic
(Continuous infusion)	0.05–0.1 units/kg/h co-infuse with D10W at 2–4 mL/kg/h		
Albuterol inhalation	1.25–2.5mg/dose every 2–6 hours	20–30 minutes	Do not use as sole agent for treating severe hyperkalemia
Premature neonates use only:	0.4 mg in 2 mL NS, may repeat after 2 hours if needed		
Sodium bicarbonate 4.2%	1 mEq/kg IV over 10–15 minutes; may repeat after 10–15 minutes if needed	15 minutes	Do not use as sole agent for treating severe hyperkalemia Do not administer in the same line with calcium product due to possible precipitation
MOA: Potassium removal			
Sodium polystyrene sulfonate (without sorbitol)	1 g/kg PO or PR; may repeat after 4–6 hours if needed	1–2 hours	1 g resin binds 1 mEq of potassium Use is contraindicated in preterm neonates or term neonates with bowel obstruction or ileus, intestinal hypomotility, or at risk for necrotizing enterocolitis Avoid sorbitol containing product due to concern for intestinal necrosis Consider lactulose use to prevent colonic impaction

(Continued)

Table 65–1. HYPERKALEMIA MANAGEMENT IN NEONATES (CONTINUED)

Drug	Dosing Regimen	Onset	Comments and Side Effects
Furosemide	1 mg/kg IV; repeat after 6 hours	1–2 hours	Monitor fluid losses and replace as needed
Renal replacement therapy: hemodialysis/ peritoneal dialysis			Hemodialysis is more effective in removing potassium, but peritoneal dialysis is generally used since it is easier to perform

MOA, mechanism of action.

Data from Lexi-Comp Online™, Pediatric & Neonatal Lexi-Drugs Online™, Hudson, Ohio: Lexi-Comp, Inc.; 2018; April 19, 2018; Michael J. Somers MD. Management of hyperkalemia in children. Post TW, ed. UpToDate. Waltham, MA: UpToDate Inc. <http://www.uptodate.com> (accessed April 19, 2018).

in giving calcium to infants on digitalis because it may increase the risk of arrhythmias.

3. **Rule out and treat any specific cause/disease** that may be contributing to the hyperkalemia.
 - a. **Renal failure** can be treated with fluid restriction.
 - b. **Congenital adrenal hyperplasia.** Cortisol therapy.
 - c. **Hypovolemia.** Give isotonic fluids to promote tubular secretion of potassium.
 - d. **Metabolic acidosis.** Correct metabolic acidosis with sodium bicarbonate. The most rapid method is hyperventilation but it is not recommended as decreases reported in serum potassium has only been 0.1 to 0.3 mE/L for every 0.1 increase in serum pH and there is a risk of decreased cerebral perfusion.
 4. **Monitor electrocardiogram changes, serial potassium and calcium levels** during therapy.
 5. **Remember the role of each medication and its use.**
 - a. **Calcium** prevents cardiac arrhythmias by stabilizing the cell membrane of the myocardium; it does nothing to the serum potassium.
 - b. **Insulin and glucose, albuterol, and sodium bicarbonate** decrease the serum potassium level by moving potassium into cells, which reduces the risk of immediate complications but does not remove potassium from the body.
 - c. **Furosemide, sodium polystyrene (Kayexalate), and dialysis (exchange transfusion, peritoneal dialysis)** remove potassium from the body by renal excretion, gastrointestinal loss, or removal by dialysis.
 6. **If the renal status is abnormal.** Consider the following to treat hyperkalemia: albuterol, furosemide (if oliguric), sodium polystyrene (Kayexalate), and dialysis (exchange transfusion, peritoneal dialysis).
 7. **Preterm infants.** The combination of insulin and glucose as a treatment has more immediate results and is preferred over the treatment with Kayexalate (sodium polystyrene).
- B. Hyperkalemia with ECG changes.** Arrhythmias from hyperkalemia are difficult to treat. The usual steps of defibrillation, epinephrine, and antiarrhythmic drugs will not work without lowering the potassium level.
1. **First, give calcium to protect the heart from the toxic effects of potassium with calcium.** It stabilizes the myocardium and lowers the threshold potential to protect against arrhythmias. **For ECG changes or arrhythmia:** dose is calcium gluconate 10% solution (60–100 mg/kg/dose) IV diluted in appropriate fluid (NS or D5W to yield a concentration of 50 mg/mL or less) and given over 5 to 10 minutes. It can be repeated every 10 minutes as needed. Administer slow IV

infusion over 10 minutes, optimally through a central line, not a scalp IV. Observe the ECG while infusing the medication; improvement in the ECG should occur within 1 to 5 minutes. Once the arrhythmia or ECG changes disappear, the bolus can be stopped. It is necessary to give a medication immediately that will begin to decrease potassium. If the infant is on digoxin therapy, remember that calcium therapy can worsen digoxin toxicity and a slower infusion may be necessary. **For cardiac arrest, calcium chloride can be used** since it results in a more rapid increase in serum calcium. Dose is 20 mg/kg IV given over 10 minutes. Repeat dose may be needed if ECG changes persist. If effective, consider IV infusion 20 to 50 mg/kg/h.

2. **Second, start a medication (glucose and insulin or β -adrenergic agonists or sodium bicarbonate)** that causes cellular intake of potassium which will reduce serum potassium levels but does not reduce total body stores. Sodium bicarbonate has a more immediate onset; glucose, insulin, and albuterol take a minimum of 15 minutes to work. If there is no IV access, one can start a β -adrenergic agonist while starting an IV. Deciding which one to use depends on your unit's preference.
 - a. **Insulin and glucose.** Insulin drives potassium into the cells. The usual dose is 0.1 to 0.2 U/kg/h insulin in combination with a continuous infusion of 0.5 g/kg/h of dextrose. If the infant is hyperglycemic, only insulin is recommended. Adjust infusion rates based on serum glucose and potassium concentrations. Time to onset is 10 to 20 minutes. Monitor the glucose levels.
 - b. **Sodium bicarbonate** is considered most effective if the infant is acidotic but can be used even when blood pH is normal (*controversial*). Sodium bicarbonate use is no longer recommended in the management of the majority of cases of metabolic acidosis in a neonate (see Chapter 51); in addition, it is not recommended as monotherapy and is to be used with caution in premature infants. Some suggest using it only in life-threatening hyperkalemia or not at all. For every 0.1 increase in serum pH, serum potassium will decrease by approximately 0.6 mEq/L. Dose, **give sodium bicarbonate 1 to 2 mEq/kg over 10 to 15 minutes IV (some recommend over 30–60 minutes; works in 5–15 minutes)**. Inducing alkalosis drives potassium ions into the cells. In very tiny infants, sodium bicarbonate may have associated risks. Avoid rapid infusion of sodium bicarbonate to decrease the risk of intraventricular hemorrhage. Use with caution in infants with renal failure or heart failure because the extra sodium could cause fluid retention. Use is not recommended in infants with respiratory failure.
 - c. **β -Adrenergic agonists (albuterol and others).** Most studies have been in infants with hyperkalemia with chronic renal failure. Some infants do not respond to the effect of albuterol, so this should not be used as first line treatment for urgent hyperkalemia. Onset of action is approximately 20 to 30 minutes. (Case studies report a decrease of potassium 1–1.5 mEq/L within an hour of giving the medication.) The most commonly used medication is albuterol, nebulized 1.25 to 2.5 mg/dose every 2 to 6 hours as needed. Dosage for premature infants: 0.4 mg in 2 mL of saline. If no IV access is available this can be used while obtaining access.
3. **Third, give medications to cause potassium excretion** and lower total body stores, such as furosemide, sodium polystyrene (Kayexalate).
 - a. **Diuretics (furosemide [Lasix]).** Enhances potassium excretion in the urine and can be given if **renal function is adequate**; the usual dose is 1 mg/kg IV every 6 hours (*controversial*). It takes 5 to 10 minutes to work. Value is limited in renal failure, with higher doses required. Remember that the amount of potassium excretion is variable and does not always correlate with the furosemide dose. Useful in hyperkalemia associated with congestive heart failure and hypoaldosteronism.
 - b. **Sodium polystyrene sulfonate (Kayexalate), a potassium-exchange resin, can be given.** It removes potassium from the gut (1 g of resin removes ~1 mEq

of potassium) in exchange for sodium. (Sorbitol free is recommended in neonates as sorbitol can cause bowel necrosis and sodium retention.) The usual dose is 1 g/kg/dose orally every 6 hours or rectally every 2 to 6 hours. **Rectal route is preferred** as it has faster onset of 1 to 2 hours. Administered orally, it lowers the potassium level slowly and therefore is of limited value acutely. Cochrane review states that oral and rectal ion exchange resins should be avoided. **This therapy should not be used in ELBW infants because of risk of irritation, concretions, hemorrhagic colitis, gastrointestinal hemorrhage, colonic necrosis, sodium overload, and NEC.** This treatment can cause an increase in sodium and calcium. Repetitive rectal use can cause local bleeding. Do not use with obstructive bowel disease and infants with decreased gut motility (risk of intestinal necrosis). Complications include hyponatremia and NEC. **Use in refractory cases only.**

- C. Hyperkalemia without electrocardiogram changes.** Treatment is recommended when serum potassium is >6 to 6.5 mEq/L (*controversial*). Deciding which medication to use to decrease potassium and to cause excretion of potassium depends on your institution.
- 1. Follow recommendations in general management above.**
 - 2. Start a medication (glucose and insulin or β -adrenergic agonists or sodium bicarbonate)** that causes cellular intake of potassium which will reduce serum potassium levels. See doses above.
 - 3. Third, give medications to cause potassium excretion** and lower total body stores, such as furosemide, sodium polystyrene (Kayexalate). See doses above.
- D. Persistent hyperkalemia.** Continuous infusion of insulin with glucose is recommended. Infants with chronic kidney disease and renal insufficiency may require dialysis.
- E. Refractory hyperkalemia.** If all of these measures fail to lower the potassium level, other measures, such as renal replacement therapy must be considered. The methods used include hemodialysis, peritoneal dialysis, and continuous renal replacement therapy. Deciding on which one depends upon the clinical status of the infant and the availability of the different therapies. Hemodialysis is more effective than peritoneal dialysis and is preferred when hyperkalemia is secondary to cell breakdown. See Chapter 73.
- F. Nonoliguric hyperkalemia**
- 1. Prophylactic treatments**
 - a. Antenatal steroid use in the mother** results in maturation of the kidneys (Na/K-ATP enzyme maturation) and decreases the risk and possibly prevents NOHK in ELBW infants.
 - b. Early aggressive nutrition and high-dose calcium supplementation** significantly reduced the incidence of NOHK after 24 hours of life in one study.
 - 2. Treatment guidelines vary and most are adapted from hyperkalemia from renal failure.** Follow guidelines for treatment as stated above or based on your recommendations from your institution. Cochrane review has no firm recommendations for treatment of hyperkalemia in NOHK in the preterm infant, except that the combination of insulin and glucose is preferred over treatment with a rectal cation resin. IV calcium use is recommended with ECG changes. Some recommend using insulin and glucose when the serum potassium is >6.5 mmol/L.
 - a. Potassium should not be administered in the first days of life** until good urinary output is established and serum potassium is normal and not rising. Potassium levels should be monitored every 6 hours in the first few days of life. Remember potassium can rise rapidly and lead to cardiac disturbances in these infants.
 - b. Because of increased electrolyte imbalances** (eg, hypocalcemia, hyponatremia, hyperphosphatemia, increased BUN), monitor these labs.
 - c. Early administration of amino acids (first day of life)** may stimulate endogenous insulin secretions and prevent the need for insulin infusion.

66 Hypertension

- I. Problem.** A premature infant has a systolic blood pressure (BP) of >95 mm Hg. **Normal BP values depend on the infant's gestational age, postnatal age, and birthweight.** There is no set definition of hypertension in newborns. American Academy of Pediatrics (AAP) clinical practice guidelines for children and adolescents state that normal BP is <90th percentile, but no guidelines have been established for infants. Hypertension has been defined as follows:
- A. Blood pressure >2 standard deviations above the mean.**
 - B. Blood pressure >95th percentile for postmenstrual age.**
 - C. The Task Force on Blood Pressure Control in Children defines hypertension as a blood pressure reading \geq 95th percentile on 3 separate occasions.**

Hypertension occurs in 1% to 2% of all neonates in the neonatal intensive care unit (NICU); it is less common in term infants (0.2%), and more common in premature infants (75% of hypertensive infants in NICU). It typically occurs either early on (within the first couple of weeks of life) or later on (infant who is a couple of months old with a chronic condition). Persistent hypertension should be treated because it can cause hypertensive cardiomyopathy, nephropathy, encephalopathy, and retinopathy. For a rapid reference of BP ranges for premature and term infants, see Table 70–1. For estimated BP levels at the 95th and 99th percentiles in infants after 2 weeks of age, see Table 66–1. For other detailed BP values, see Appendix C.

II. Immediate questions

A. How was the blood pressure measured? BP can be measured either by invasive or noninvasive methods. Invasive methods include an indwelling intra-arterial catheter. Noninvasive methods include palpation, auscultation, Doppler ultrasound, and use of an oscillometric device. The most common methods used in the NICU are the indwelling intra-arterial catheter and the oscillometric device.

- 1. Invasive method. BP reading from an indwelling intra-arterial catheter** is the most accurate (**gold standard**) of all methods and is the preferred method. It is most commonly placed in the umbilical artery (aorta) or the radial artery, but can also be in the posterior tibial artery. This system uses a pressure transducer where the pressure waveform of the arterial pulse is transmitted by a column of

Table 66–1. ESTIMATED BLOOD PRESSURE LEVELS AT THE 95TH AND 99TH PERCENTILES IN INFANTS AFTER 2 WEEKS OF AGE

	Postconceptional Age in Weeks									
	26	28	30	32	34	36	38	40	42	44
95th percentile (systolic/diastolic)	72/50	75/50	80/55	83/55	85/55	87/65	92/65	95/65	98/65	105/68
99th percentile (systolic/diastolic)	77/56	80/54	85/60	88/60	90/60	92/70	97/70	100/70	102/70	110/73

Data from Dionne JM, Abitbol CL, Flynn JT: Hypertension in infancy: diagnosis, management and outcome, *Pediatr Nephrol*. 2012 Jan;27(1):17-32. Based on studies using Doppler and oscillometric blood pressure measurements.

fluid to an electrical signal. If measurements are taken by means of an umbilical artery catheter (UAC), be certain that the catheter is free of bubbles or clots and the transducer is calibrated; otherwise, erroneous results will occur. It provides continuous readings.

2. Noninvasive methods

- a. **Blood pressure measurement by palpation.** This is not used because it only measures the systolic BP.
- b. **Blood pressure measurement by auscultation.** The systolic pressure determination is the appearance of Korotkoff sounds, and the diastolic pressure is the disappearance or muffling of the Korotkoff sounds. This is not recommended because the arterial sounds are either unobtainable or are not reliable in newborns.
- c. **Doppler ultrasound method** is time consuming and labor intensive and underestimates the systolic BP.
- d. **Automated oscillometric devices** (electronic pressure sensor) are the **most common noninvasive method** used in the NICU. This device uses a BP cuff to detect oscillations in the artery to measure the mean arterial pressure. An algorithm is then used to give the systolic and diastolic BP. Oscillometric devices compare to intra-arterial measurements in well infants. Intra-arterial measurements may be preferred in ill infants. There are conflicting studies because one study showed that the oscillometric method overestimated the systolic and diastolic BP in ill preterm and term neonates, and another study showed that oscillometric measurements underestimated systolic and diastolic BP in small for gestational age infants. Dionne and colleagues state that oscillometric measurements are generally 3 to 8 mm Hg higher than intra-arterial measures for mean arterial pressure.
 - i. **Choosing the appropriate site.** The site most often used is the upper extremity, most often the right upper extremity. Do not place the cuff on the extremity where an intravenous (IV) or intra-arterial line is placed or where there is injured skin.
 - ii. **Blood pressure cuff size is important in noninvasive methods.** Often providers will choose a cuff that is too small, which can lead to high BP readings. The BP cuff should encircle two-thirds of the length of the upper extremity. Some cuffs have index lines to ensure the correct size of cuff is used. If the cuff is too narrow, the BP will be falsely elevated. **The AAP recommendations for BP cuff bladder width are as follows:** newborn—4 cm; infant—6 cm. **For length:** newborn—8 cm; infant—12 cm. **Maximum arm circumference:** newborn—10 cm; infant—15 cm. The **American Heart Association** recommends a 4 × 8 cm cuff size for newborns and infants.
 - iii. **Choose the correct placement of the cuff.** The majority of cuffs have an artery mark indicator, so one can palpate the brachial artery and align it with the artery mark on the cuff.
 - iv. **Make sure all the air is out of the cuff** and that it is snug around the arm; it should not impede venous return by being too tight.
 - v. **Blood pressure protocols have been established to standardize blood pressure measurement in infants.** This was done to minimize incorrect readings since multiple factors can influence BP. Because the first reading is usually the highest, it is best to take at least 3 confirmatory measurements. BP rises when the infant is feeding (by 20 mm Hg), is crying, has pain, is agitated, is sucking on a pacifier, or has the head in an upright position. BP is 5 mm Hg lower in sleeping infants than in infants who are awake. Most BP data are from measurements taken from the right arm. One standardized method using an oscillometric device suggested by Nwankwo and colleagues is as follows:

- (a) **Measure blood pressure 1.5 hours after feeding** or a medical intervention.
- (b) **Make sure the infant is asleep or in a quiet state**, lying prone or supine.
- (c) **Place an appropriate-sized cuff** on the right upper arm, and let the infant rest undisturbed after cuff placement for 15 minutes.
- (d) **Measure by oscillometric device**, and do 3 successive BP readings at 2-minute intervals.

vi. **The American Academy of Pediatrics** does not recommend universal screening in term healthy newborns but states it is important to screen BP in infants in whom coarctation of the aorta or renal disease is suspected.

- B. Is an umbilical artery catheter in place, or has one been in place in the past?** Incidence of hypertension is approximately 9% with a UAC. UACs are associated with an increased incidence of renovascular hypertension. The hypertension is probably related to endothelial disruption and thrombus formation at the time of line placement. The longer the UAC is in, the higher is the risk of thrombus formation. Thrombi have been demonstrated to be present on 25% to 81% of catheters studied. The following conditions are risk factors for thrombus formation in the aorta: bronchopulmonary dysplasia/chronic lung disease (BPD/CLD), patent ductus arteriosus (PDA), hypervolemia, and certain central nervous system (CNS) disorders. Improved catheter design and the use of heparin have helped decrease the incidence of thrombus formation. A Cochrane review found that hypertension appears with equal frequency in infants with high versus low catheters.
- C. Are signs of hypertension present?** The presentation of hypertension varies and can range from no signs to massive heart failure and cardiogenic shock. Infants with high blood pressure usually show no signs, and the hypertension is noted incidentally on routine continuous monitoring. Alternatively, it can manifest the following signs: irritability, tachypnea, cyanosis, seizures, lethargy, increased tone, apnea, abdominal distention, failure to thrive, irritability, feeding difficulty, respiratory distress, fever, and mottling. Infants with severe hypertension can have congestive heart failure (CHF), cardiogenic shock/hypotension masking hypertension, seizures, renal dysfunction, and/or hypertensive retinopathy. Specific causes can cause specific presentations: hypertension causing CHF with respiratory distress, tachypnea, and hypoxia; kidney-related hypertension with oliguria/polyuria; or neurologic symptoms mimicking intraventricular hemorrhage (IVH) with apnea, seizures, lethargy, and tremors.
- D. What is the blood pressure in the extremities?** The BP in a healthy infant should be higher in the legs than in the arms. If the pressure is lower in the legs, **coarctation of the aorta** may be the cause of the hypertension. **Coarctation of the aorta** is the most common heart malformation that causes hypertension in a neonate.
- E. What is the birthweight, gestational age, postmenstrual age, and postnatal age of the infant?** Gestational age, birthweight, and postmenstrual age have the strongest influence on determining BP. **Normal BP values increase with increasing birthweight (data on birthweight are conflicting in term infants), gestational age, and postconceptual age.** Values rise approximately 1 to 2 mm Hg per day during the first week of life and then approximately 1 to 2 mm Hg per week over the next 6 weeks. Postmenstrual age is a primary determinant of BP in preterm infants after day 1, and there is a progressive increase in BP over 2 weeks in infants <31 weeks. Normal term infants experience a significant rise only from day 1 to day 2. In infants <27 weeks' gestation, the BP decreases over the first 3 hours of life, with the lowest point at 4 to 5 hours of life, and then it increases.
- F. Is the infant in pain or agitated?** Pain from an invasive procedure, crying, agitation, or suctioning can cause a transient rise in BP. The systolic pressure can be 5 mm Hg lower in sleeping infants.

- G. Does the infant have bronchopulmonary dysplasia/chronic lung disease or an intraventricular hemorrhage?** Infants with BPD/CLD have a significant problem with hypertension (6% up to 40%). It often occurs after discharge from the nursery. Infants with an IVH (3% incidence) also have an increased risk of hypertension.
- H. Does the infant have any risk factors that would be associated with the development of hypertension?** Risk factors from 2 different studies include the following: lower birthweight, renal failure, acute kidney injury (AKI), renal disease/chronic renal failure, necrotizing enterocolitis, seizure, asphyxia, UAC catheterization, neonatal abstinence syndrome, extracorporeal membrane oxygenation/extracorporeal life support treatment, IVH, maternal hypertension, antenatal steroids, BPD/CLD, PDA, and indomethacin treatment. Other reported risk factors include congenital anomalies of the kidney and urinary tract (CAKUT), prematurity, low birthweight, coarctation of the aorta, perinatal hypoxia, increasing severity of illness, hemolytic uremic syndrome, and cytochrome P450 (CYP2D6) CC genotype in preterm infants.
- I. Were recent boluses of fluids or blood products given?** Fluid overload is a common iatrogenic cause of hypertension, especially in infants with decreased urine output.
- J. Was there maternal drug use (cocaine or heroin)?** Maternal drug use of cocaine and heroin has been associated with hypertension in newborn infants because of drug withdrawal or the direct effects on the developing kidney.
- K. Are there any maternal factors that would contribute to the hypertension?** Maternal factors include maternal body mass index >30, maternal diabetes, hypertension, certain maternal medications, maternal anesthesia, mode of delivery, preeclampsia, and abnormal uteroplacental perfusion. Antenatal steroid treatment resulted in an increased BP in the neonate in the first 24 to 48 hours of life with a decreased need for BP support. There is scant and conflicting evidence about whether maternal age, maternal anesthesia, mode of delivery, and maternal medications (eg, magnesium sulfate, β -blockers, α_1 -adrenergic agonists, calcium antagonists, and direct vasodilators) affect neonatal BP. Maternal hypertension and diabetes may increase the risk of neonatal hypertension in the first month of life.
- L. Did the mother have a prenatal ultrasound?** Congenital abnormalities of the genitourinary tract are the most common malformations identified on ultrasound (15%–20% of all prenatal diagnosed congenital anomalies). Polyhydramnios and oligohydramnios are strong risk factors for CAKUT.
- III. Differential diagnosis.** Hypertension is rare in the healthy term newborn infant. The incidence ranges from 0.2% (healthy newborn) up to 43% (in infants with BPD/CLD). Hypertension in the neonate is most commonly secondary hypertension, which means that it is caused by an underlying identifiable condition or cause. Hypertension in newborns is most commonly renal in origin (renal vascular and renal parenchymal diseases). BPD/CLD is the most common nonrenal cause. One study reported the 3 most common causes are UAC-associated thrombosis, BPD/CLD, and coarctation of the aorta. Common causes are listed here. See Table 66–2 for a comprehensive list.
- A. Renal and vascular causes**
- 1. Umbilical artery catheter-associated thrombosis.** Thromboembolic occlusion of the renal artery occurring after umbilical artery catheterization is the most common cause of hypertension in neonates. The thrombi embolize to the renal vessels, causing occlusion and infarction and increased release of renin and hypertension.
 - 2. Renal artery stenosis.** The infant is hypertensive from birth and has symptoms of CHF, cardiomegaly on chest x-ray, and left ventricular hypertrophy on electrocardiogram. This accounts for 20% of cases of hypertension in infants. It can be secondary to fibromuscular dysplasia. Congenital rubella infection can cause arterial calcification and renal artery stenosis.
 - 3. Renal vein thrombosis.** Seen in hypovolemic or asphyxiated infants, infants of diabetic mothers, and infants with coagulopathies. Only 13% of neonates present with the classical triad of hypertension, gross hematuria, and an abdominal mass.

Table 66–2. CAUSES OF HYPERTENSION IN NEWBORNS

Cardiac	Coarctation of the aorta, aortic arch interruption, hypoplastic aorta, patent ductus arteriosus
Drugs: infant	Glucocorticoids (dexamethasone), theophylline, caffeine, vitamin D intoxication, pancuronium (prolonged use), high dose of adrenergic agents, phenylephrine eye drops, doxapram, opiate withdrawal
Drugs: maternal	Cocaine (may harm neonatal kidney and cause withdrawal) and heroin (causes withdrawal), antenatal steroid administration (<i>controversial</i>)
Endocrine	Adrenal hemorrhage/hematoma/tumors, adrenogenital syndrome, congenital adrenal hyperplasia (secondary to 11 β - and 17 α -hydroxylase deficiencies), Cushing syndrome, primary hyperaldosteronism, hyperthyroidism, pseudohyperaldosteronism type II, familial hyperaldosteronism type II, Gordon syndrome, pheochromocytoma
Metabolic	Hypercalcemia
Neurologic	Elevated intracranial pressure secondary to intracranial hemorrhage, hydrocephalus, meningitis or subdural hemorrhage/hematoma, seizures, subdural hematoma, familial dysautonomia, drug withdrawal (opiate), neural crest tumor, cerebral angioma
Pain/agitation	Usually causes episodic hypertension
Pulmonary	Bronchopulmonary dysplasia/chronic lung disease, pneumothorax (rare)
Renal parenchymal diseases (acquired)	Acute tubular necrosis, cortical and medullary necrosis, interstitial nephritis, hemolytic uremic syndrome, nephrolithiasis/nephrocalcinosis, obstructive uropathy (eg, tumor or stones), pyelonephritis, glomerulonephritis, perirenal hematoma or urinoma, renal failure/renal insufficiency, renal infection
Renal parenchymal diseases (congenital)	Polycystic kidney disease (autosomal recessive or autosomal dominant), multicystic dysplastic kidney disease, hypoplastic/dysplastic kidney, congenital nephrotic syndrome, unilateral renal hypoplasia, tuberous sclerosis, renal tubular dysgenesis, obstructive uropathy (posterior urethral valves, ureteropelvic junction obstruction), congenital mesoblastic nephroma
Renovascular/vascular	Renal artery thrombosis, renal artery stenosis, renal vein thrombosis, midaortic syndrome (abdominal coarctation), congenital rubella syndrome (causes arterial calcification), idiopathic arterial calcification, renal artery compression, hypoplastic aorta, abdominal aorta aneurysm, aortic thrombosis, thrombosis of the ductus arteriosus, intimal hyperplasia, mechanical compression of 1 or both arteries (abdominal mass or tumor)
Syndromes/malformation syndromes	Noonan, Williams, Turner, Liddle (glucocorticoid remediable aldosteronism), and Cockayne syndromes; neurofibromatosis; tuberous sclerosis complex
Tumors (compression of renal vessels or production of vasoactive substances)	Wilms tumor, mesoblastic nephroma, neuroblastoma, nephroblastoma, pheochromocytoma

(Continued)

Table 66–2. CAUSES OF HYPERTENSION IN NEWBORNS (CONTINUED)

Miscellaneous	Birth asphyxia, closure of abdominal wall defects (eg, omphalocele or gastroschisis), abdominal surgery, ECLS, essential hypertension, iatrogenic (volume overload secondary to excess administration of sodium or intravenous fluids), idiopathic, long-term total parenteral nutrition related, infantile polyarteritis nodosa, maternal hypertension, environmental cold or noise stress, cytochrome P450 (CYP2D6) genotype in preterm infants (elevated systolic blood pressure after discharge from neonatal intensive care unit), idiopathic (5%–57%)
---------------	--

4. **Acute kidney injury.** Postnatal AKI is associated with hypertension. Acute tubular necrosis (ATN) is the most common cause of AKI. ATN can be secondary to perinatal asphyxia or sepsis.
 5. **Persistent nephrocalcinosis in infants** can cause hypertension.
 6. **Congenital anomalies of the kidney and urinary tract** cause hypertension more often than acquired kidney abnormalities. Autosomal dominant or autosomal recessive polycystic kidney disease can present in the neonate with hypertension and enlarged kidneys. Multicystic dysplastic kidney rarely causes hypertension. Ureteropelvic junction obstruction can activate the renin-angiotensin system and cause hypertension.
- B. **Bronchopulmonary dysplasia/chronic lung disease is the most common cause of nonrenal hypertension in the neonate.** The origin is unclear but is probably multifactorial (increased renin activity and catecholamine secretion and chronic hypoxemia may be associated with CLD). The majority of these infants develop hypertension after being discharged from the hospital at 4 to 5 months of age and present with irritability and failure to thrive.
 - C. **Coarctation of the aorta.** A common cause of hypertension in newborns. Occurs with an increased incidence in Turner syndrome.
 - D. **Neurologic.** Increased intracranial pressure and seizures can cause episodic hypertension. IVH can cause increased intracranial pressure.
 - E. **Medications.** Such as corticosteroids (antenatal and postnatal), theophylline, caffeine, adrenergic agents, pancuronium, and topical mydriatic agents (phenylephrine eye drops). Maternal use of cocaine can cause damage to the kidneys of the fetus and resultant hypertension. Drug withdrawal from heroin can cause hypertension.
 - F. **Fluid/electrolyte overload.** Chronic total parenteral nutrition can cause chronic solute and water overload.
 - G. **Pain or agitation.** This usually causes episodic hypertension.
 - H. **Other.** ECLS (up to 50% of infants), abdominal surgery (closure of an abdominal wall defect), pneumothorax, PDA, and indomethacin treatment.
 - I. **Endocrine disorders.** Hyperthyroidism, congenital adrenal hyperplasia, hyperaldosteronism, and pheochromocytoma.
 - J. **Idiopathic/essential hypertension.** In 5% to 57% of neonates (depending on the study), there is no identifiable cause.
- IV. **Database.** In a hypertensive crisis, data gathering is not the first priority. In some cases, treatment will need to be the priority before investigation of the cause.
 - A. **History.** Evaluate maternal factors: Was cocaine or heroin used during pregnancy, or were antenatal steroids used? Did the mom have diabetes or preeclampsia? Was a prenatal ultrasound done? Was there prenatal oligohydramnios/polyhydramnios (these are strong risk factors for CAKUT, and oligohydramnios is a good indicator of renal dysfunction)? Does the infant have a predisposing illness that would account for the

hypertension (eg, BPD/CLD, CNS disorder, PDA)? Evaluate the current medication list. Does or did the infant have a UAC?

- B. Physical examination.** In most infants, hypertension is discovered on vital signs with no other overt signs. Focus on the cardiovascular and abdominal (to include genitourinary) examination. What is the volume status of the infant (is there weight gain)? **Life-threatening presentations** can include CHF with cardiogenic shock or seizures. Some infants present with apnea, feeding difficulties, failure to thrive, irritability, lethargy, unexplained tachypnea, and mottling of the skin. Check for tachycardia and flushing for hyperthyroidism.
- 1. Perform a complete cardiac examination to rule out CHF.** Is there a heart murmur (coarctation of the aorta)? Is there cyanosis? Is there tachycardia? Are there mottling and signs of vasomotor instability? Are there absent or decreased femoral pulses? Check the femoral pulses in both legs, which are absent or decreased in coarctation of the aorta. Is there a difference in the BP in the upper and lower extremities? Check BP in all 4 extremities (BP discrepancies between the upper and lower extremities, arterial hypertension in the upper extremities with normal to low BP in the lower extremities, which is a hallmark of coarctation of the aorta).
 - 2. Are there any dysmorphic features** that would indicate a genetic abnormality or a syndrome that would explain the hypertension? Are there widely spaced nipples and webbed neck to suggest Turner syndrome? Is there elfin facies? Consider Williams syndrome.
 - 3. Respiratory.** Is there tachypnea or cyanosis?
 - 4. Examine the abdomen** for masses and to determine the size of the kidneys. Is there abdominal distension? An enlarged kidney or flank mass may indicate tumor, polycystic kidneys, obstruction, or renal vein thrombosis. An epigastric/flank bruit can indicate renal artery stenosis. Palpable kidneys can indicate hydronephrosis, polycystic kidney disease, or multicystic dysplastic kidney.
 - 5. Examine the genitalia (is it ambiguous/is there virilization?)** to look for signs of congenital adrenal hyperplasia.
 - 6. Neurologic signs** may include apnea, lethargy, tremors, seizures, asymmetric reflexes, and hypertonicity.
- C. Laboratory studies.** Few tests are usually needed and should be dictated by history and physical examination. **Common tests should include:** complete blood count and platelet count, serum electrolytes (sodium, potassium, chloride, bicarbonate), blood urea nitrogen and creatinine, urinalysis, renal ultrasound with Doppler, and echocardiography. **More detailed tests include:** serum calcium, serum cortisol, thyroid studies, plasma renin activity, aldosterone, head ultrasound, angiography, and renal scintigraphy. Assessment of renal function is important and is as follows:
- 1. Assess renal function** with the following:
 - a. Serum creatinine and blood urea nitrogen.** Elevation suggests renal insufficiency, which may be associated with hypertension.
 - b. Urinalysis.** May show gross or microscopic hematuria or proteinuria. Red blood cells in the urine suggest obstruction, infection, or renal vein thrombosis.
 - c. Urine culture.** To evaluate for urinary tract infection.
 - d. Serum electrolytes and carbon dioxide.** A low serum potassium level and a high carbon dioxide level suggest primary hyperaldosteronism. Hypokalemia suggests congenital adrenal hypoplasia.
 - e. Urine protein/creatinine ratio, urine albumin/creatinine ratio.** To evaluate significant proteinuria and renal parenchymal disease.
 - 2. Other useful tests in selected infants**
 - a. Plasma renin levels (plasma renin activity)** may be elevated in patients with renovascular disease. Levels will be low in primary hyperaldosteronism. Rarely elevated in normal infants, plasma renin activity can be falsely elevated because of medications such as aminophylline. Direct renin assay has been used, but normal neonatal values are not readily available.

- b. **Thyroid studies (thyroid-stimulating hormone, free thyroxine)** to rule out hyperthyroidism.
- c. **Serum cortisol.**
- d. **Serum aldosterone.**
- e. **Urine vanillylmandelic acid/homovanillic acid.** Twenty-four-hour urinary catecholamines to evaluate for pheochromocytoma or neuroblastoma.
- f. **Urinary 17-hydroxysteroid and 17-ketosteroid levels** to evaluate for Cushing syndrome and congenital adrenal hyperplasia.
- g. **Urine toxicology screen.**
- h. **Coagulation panel.**

D. Imaging and other studies

1. **Ultrasound.** Renal ultrasound with Doppler evaluation is the preferred screening test in neonates and should be done in all hypertensive infants. It will identify congenital anomalies of the urinary tract, renal masses, tumors, and renal cystic disease; assess adrenals; and check for renal vein thrombosis as well as kidney obstruction. Color Doppler flow ultrasonography can be used to screen for arterial or venous problems (thrombosis), renal and aortic thrombi, renal venous thrombosis, and renal artery stenosis. Infants who had a UAC should have their aorta and renal arteries studied for thrombi.
2. **Chest radiograph.** Evaluate heart size. May help in infants with CHF and infants with a murmur. Cardiomegaly can be seen.
3. **Echocardiography.** To assess structural lesions (if coarctation of the aorta is suspected) or to evaluate end-organ damage and dysfunction caused by hypertension (eg, left ventricular hypertrophy/dysfunction or decreased contractility). Severe hypertension can cause hypertensive cardiomyopathy.
4. **Cranial imaging with ultrasound.** To rule out IVH.
5. **Further studies.** The following procedures and studies are sometimes necessary to further evaluate the infant with hypertension:
 - a. **Angiography** to evaluate renovascular disease or venacavography to evaluate renal vein thrombosis. This is most commonly done through the UAC. Renal angiography or scan helps quantitate the function of each kidney. Magnetic resonance angiography is the gold standard for renal vascular hypertension and is recommended in infants >3 kg.
 - b. **Abdominal computed tomography scan** if needed to obtain more specific anatomic information on an abdominal mass (pheochromocytoma). A computed tomography angiogram can evaluate the aorta and renal arteries.
 - c. **Voiding cystourethrography** if urinary tract pathology is possible.
 - d. **Nuclear medicine studies.** Radionuclide imaging (nuclear scan) of the kidneys (renal scintigraphy/renal scans) can show renal perfusion abnormalities and increased isotope concentration in an obstructed kidney. A **dimercaptosuccinic acid (DMSA) renal scan** can rule out arterial infarctions. **Percutaneous femoral renal arteriography** with bilateral renal vein renin measurement is usually needed to rule out renovascular hypertension. **Captopril-enhanced renal scintigraphy** can detect significant renovascular disease.

V. Plan

- A. **General.** First confirm the BP measurement. Treat any obvious or correctable causes of hypertension. Some infants may require antihypertensive medications while corrective therapy is being done. Consultations with pediatric cardiology and nephrology to help manage hypertension are recommended. Other consults may be required such as endocrinology, urology, or surgery depending on the underlying cause of hypertension. **The following are treatable causes of hypertension:**
 1. **Fluid overload.** Restrict sodium and fluids. Consider diuretics.
 2. **Pain.** Administer pain medications. See Chapter 15.
 3. **Stop any medications,** if possible, that can cause hypertension (adjust inotropic medications, steroids, caffeine).

4. **Hyperthyroidism.** Medications include methimazole, iodine preparations, and propranolol for tachycardia. See Chapter 129.
 5. **Congenital adrenal hyperplasia.** Steroid therapy. See Chapter 95.
 6. **Hypercalcemia.** See Chapter 91.
 7. **Aortic or renal thromboembolic events** should be treated with close monitoring and supportive care unless severe enough that they need anticoagulation or fibrinolytic therapy. Remove UAC if possible. See Chapter 92.
 8. **Surgical intervention. This is an option in <10% of infants.** Used for relief of obstructive uropathy, repair of coarctation of the aorta, nephrectomy for unilateral renovascular disease, and angioplasty for renal artery stenosis. Others that may require surgery include Wilms tumor and neuroblastoma, arterial or venous renal thrombosis (usually medically treated first), rare cases of autosomal recessive polycystic kidney disease, and multicystic dysplastic kidney.
- B. Drug therapy.** (See Chapter 155.) To guide drug therapy, determine whether the hypertension is **mild, moderate, or malignant/life threatening. Note that treatment thresholds are unclear, and many of the recommendations are controversial.** One important consideration is end-organ damage (damage to organs affected by hypertension). The most prominent evidence of end-organ damage is thickening of the left ventricle (left ventricular hypertrophy), which is a sign of hypertensive cardiomyopathy. Other examples are hypertensive retinopathy, hypertensive encephalopathy, and hypertensive nephropathy. Some experts believe that **any asymptomatic infant with hypertension with no end-organ involvement should only be observed.** Most believe that hypertension should be treated if there is evidence of target organ dysfunction, if BP is >95th percentile with end-organ involvement, if BP is consistently >99th percentile, if there is underlying renal disease, or if the infant is symptomatic. **Which medication and route should be used?** This depends on the severity of the hypertension, whether the infant can tolerate an oral medication, the gestational age of the infant, if the infant's kidneys can handle the medication, and if the infant has CLD.
1. **Important points when using antihypertensive medications in the neonate:**
 - a. **Avoid the use of β -blockers** (propranolol, esmolol) or **α - β -blockers** (labetalol, carvedilol) **in infants with BPD/CLD** because of a potential risk of bronchoconstriction. **β -Blockers** should not be used in emergency hypertension or as long-term therapy.
 - b. **Do not use angiotensin-converting enzyme inhibitors (captopril, enalapril, or lisinopril) until the end of 44 weeks of postmenstrual age** or in infants with bilateral renovascular disease or disease in a solitary kidney, infants with acute renal failure, or infants with hyperkalemia. These drugs cause a profound decrease in BP. These medications, if given before 36 weeks of age, have the following effects on postnatal kidney development: atrophy of the renal papilla, tubular alterations (fibrosis and atrophy), urinary concentration impairment, and reduction in the nephron number. These medications are contraindicated in bilateral renovascular disease or renovascular disease in a solitary kidney because they can cause acute renal failure. Captopril in premature infants has been associated with severe drops in BP that do not respond to fluids or inotropes. Up to 20% of infants on enalapril have experienced hyperkalemia, hypotension, or death.
 - c. **Do not use furosemide for chronic treatment in neonates** because it may result in hypokalemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis. Furosemide may also have an effect on renal development as it has been shown to reduce nephron formation in organ culture. Furosemide should be used in neonates with oliguric renal insufficiency and edema.
 - d. **Spironolactone, a potassium-sparing diuretic,** is recommended for hypertension with hypokalemic metabolic acidosis (hyperaldosteronism).
 - e. **Esmolol** is a good choice in infants who cannot tolerate β -blockers.

- f. **Isradipine and amlodipine are good choices** for long-term antihypertensive therapy.
 - g. **Vasodilators are the most common class of antihypertensive medications** used in NICUs, with hydralazine being the most common.
 - h. **Many infants will require >1 medication (up to 51%).** Start with 1 medication and increase the dose if necessary. If at the maximum dose and there is still hypertension, a second drug can be added. Term infants usually require more medications than preterm infants.
 - i. **Continuous intravenous medications to consider for severe hypertensive crisis:** Nicardipine, labetalol, esmolol, sodium nitroprusside, and fenoldopam mesylate.
 - j. **Intermittent intravenous medication to consider for mild to moderate hypertension or if oral therapy is not tolerated:** Furosemide, hydralazine, propranolol, labetalol, and enalapril.
 - k. **Oral medications for hypertension (mild to moderate hypertension, infants being converted to oral long-term therapy):** Furosemide, captopril, clonidine, enalapril, hydralazine, isradipine, amlodipine, minoxidil, propranolol, labetalol, spironolactone, furosemide, hydrochlorothiazide, and chlorothiazide.
2. **Recommendations for treatment depending on the type of hypertension.** See Table 66–3 for agents and doses.
- a. **Life-threatening hypertension or hypertensive crisis.** If BP is well above the 99th percentile or >30% above mean value for age with signs of end-organ dysfunction (left ventricular hypertrophy, CHF, neonatal encephalopathy, cardiogenic shock, seizures) or without signs of end-organ dysfunction but with the potential to cause end-organ damage, parenteral treatment for hypertension is recommended. **Avoid too rapid of a decrease in the BP**, as this may cause cerebral ischemia and hemorrhage, especially in the premature infant. Monitor the BP every 5 to 15 minutes. One recommendation is to decrease the BP by 33% in the first 6 hours, by another 33% over the next 24 to 36 hours, and by the last 33% over the next 48 to 72 hours. AAP target BP goal has not been established for infants, but for children, it is <90th percentile. The medications chosen depend on your institutional guidelines. **With life-threatening hypertension, short-acting continuous IV infusions should be used** and are preferred because these can be titrated, and the BP should begin to fall within 15 minutes to an hour. It is best to monitor BP continuously through an intra-arterial catheter in these infants. The following medications can be used for hypertensive crisis:
 - i. **Nicardipine.** A calcium channel blocker, nicardipine is considered the **drug of choice** because of its advantages and few side effects (reflex tachycardia and edema). **If the infant does not respond or the BP remains elevated**, one can add or substitute 1 of the following medications based on institutional guidelines: labetalol, esmolol, sodium nitroprusside, or fenoldopam mesylate. **See Table 66–3** for doses, concerns, and side effects.
 - ii. **If intravenous infusion medication is not available**, short-acting IV or oral antihypertensives can be used. Examples include short-acting IV medications (hydralazine or labetalol) or short-acting oral antihypertensives (isradipine [used successfully in neonates with severe acute hypertension] or clonidine).
 - b. **Moderate hypertension.** There are no data on choice of medication and no clinical trials comparing the specific medications. Which medication to use depends on your institution. Medications that can be used include diuretics, calcium channel blockers, β -blockers (avoid in CLD), and angiotensinogen-converting enzyme (ACE) inhibitors (if infant is >44 weeks of postconceptional age). Oral medications can be used depending on the infant's condition and the ability to tolerate oral medications. Follow your institution's guidelines.

Table 66–3 MEDICATIONS FOR NEONATAL HYPERTENSION: EMERGENCY AND ROUTINE

Drug Dosing Regimen	Drug Class	Comments and Side Effects
Hypertensive Crisis Medications		
Nicardipine: 0.5–4 mcg/kg/min as continuous infusion	Calcium channel blocker ^a	Infusion via central line is advised Caution use in perinatal asphyxia May cause reflex tachycardia
Labetalol: 0.25–3 mg/kg/h as continuous infusion OR Labetalol: 0.2–1 mg/kg/dose as IV bolus undiluted over 2 minutes; do not exceed 10 mg/min OR Labetalol: 1 mg/kg/dose PO every 8–12 hours scheduled; do not exceed 12 mg/kg/d	α - and β -Blocker ^b	Caution use in chronic lung disease, heart block, unstable heart failure, and neurological injury
Esmolol: 50–500 mcg/kg/min as continuous infusion; may titrate to a maximum of 1000 mcg/kg/min	β -Blocker ^b	Caution in chronic lung disease, heart block, and unstable heart failure
Fenoldopam: 0.2 mcg/kg/min as continuous infusion; may titrate every 20–30 minutes up to a maximum of 0.8 mcg/kg/min	Dopamine agonist ^c	Dose-related tachycardia can occur; tachycardia has been shown to persist for at least 4 hours with infusion rate >0.8 mcg/kg/min in pediatric patients. Monitor blood pressure closely; hypotension can occur.
Nitroprusside: 0.25–8 mcg/kg/min as continuous infusion; may titrate up to a maximum of 10 mcg/kg/min	Vasodilator ^d	Caution in elevated intracranial pressure, renal and hepatic failure Monitor for thiocyanate and cyanide toxicity, especially when used in high infusion rates (≥ 2 mcg/kg/min) or for prolonged period (>72 hours). May consider co-administering nitroprusside with sodium thiosulfate at a 1:10 ratio when infusion rate is ≥ 4 mcg/kg/min.
Other Antihypertensive Medications		
Amlodipine: 0.1–0.3 mg/kg/dose PO every 12 hours; do not exceed 0.6 mg/kg/d or 20 mg/d	Calcium channel blocker ^a	Caution in hepatic failure requiring lower starting dose
Captopril: • Premature and term neonates, PNA ≤ 7 days: 0.01 mg/kg/dose PO every 8 to 12 hours • Term neonates, PNA >7 days: 0.05–0.5 mg/kg/dose PO every 6 to 24 hours	ACE inhibitor ^e	Caution in renal failure, hyponatremia, hypovolemia, severe CHF, and concurrent diuretics use May cause hyperkalemia, cholestatic jaundice, cough, and angioedema

(Continued)

Table 66–3 MEDICATIONS FOR NEONATAL HYPERTENSION: EMERGENCY AND ROUTINE (*CONTINUED*)

Drug Dosing Regimen	Drug Class	Comments and Side Effects
Chlorothiazide: 2.5–10 mg/kg/dose IV every 12 hours OR Chlorothiazide: 5–20 mg/kg/dose PO every 12 hours	Diuretic	May cause hypokalemia, hyponatremia, hypochloremic alkalosis, and hypercalcemia; IV not generally recommended in infants
Clonidine: 2–5 mcg/kg/dose PO every 6–8 hours PRN	Central α -agonist ^f	May cause somnolence, xerostomia, and rebound hypertension with abrupt discontinuation
Enalapril: 0.04–0.3 mg/kg/dose PO every 12 to 24 hours scheduled	ACE inhibitor ^g	Caution in renal failure, hyponatremia, hypovolemia, severe CHF, and concurrent diuretic use May cause hyperkalemia, cholestatic jaundice, cough, and angioedema
Furosemide: 1–2 mg/kg/dose IV every 6 to 24 hours OR Furosemide: 1–6 mg/kg/dose PO every 6–24 hours	Diuretic, loop	May cause hypokalemia, hyponatremia, ototoxicity, and nephrocalcinosis
Hydralazine: 0.1–0.6 mg/kg/dose every 4–6 hours PRN as IV bolus undiluted over 1–2 minutes; do not exceed 5 mg/min OR Hydralazine: 0.25–1 mg/kg/dose PO every 6–8 hours; do not exceed 7.5 mg/kg/d	Vasodilator ^d	Caution in renal failure requiring lower starting dose May cause blood dyscrasias, tachycardia
Hydrochlorothiazide: 1–3 mg/kg/d PO every 24 hours or divided every 12 hours	Diuretic	May cause hypokalemia, hyponatremia, hypochloremic alkalosis, and hypercalcemia
Isradipine: 0.05–0.15 mg/kg/dose PO every 6–8 hours PRN; do not exceed 0.8 mg/kg/d or 20 mg/d	Calcium channel blocker ^a	Caution in hepatic failure and QTc prolongation
Minoxidil: 0.1–0.2 mg/kg/dose PO every 8–12 hours	Vasodilator ^d	Most potent oral vasodilator and not a first-choice agent Caution in renal failure, ischemic heart disease, pericardial effusion May cause fluid retention and tachycardia. Concurrent use with a diuretic and a β -blocker is recommended.
Propranolol: 0.25–0.5 mg/kg/dose PO every 8 hours; do not exceed 5 mg/kg/d	β -Blocker	May cause bradycardia and not a first-choice agent Caution in chronic lung disease and unstable heart failure

(Continued)

Table 66–3 MEDICATIONS FOR NEONATAL HYPERTENSION: EMERGENCY AND ROUTINE (CONTINUED)

Drug Dosing Regimen	Drug Class	Comments and Side Effects
Spirolonactone: 1–3 mg/kg/d PO every 24 hours or divided every 12 hours	Diuretic, potassium sparing	May cause hyperkalemia Caution in renal failure

ACE, angiotensin-converting enzyme; CHF, congestive heart failure; IV, intravenous; PNA, postnatal age; PO, oral; PRN, as needed.

Neonate indicates birth to 28 days PNA.

Mechanisms of action are as follows:

^aCalcium channel blockers: prevent calcium from entering vascular smooth muscle and myocardium cells, which leads to relaxation of the vascular smooth muscle, resulting in coronary vasodilation and reduction in blood pressure.

^b α - and β -blockers: block norepinephrine and epinephrine, which causes the blood vessel to dilate, thereby lowering the blood pressure.

^cDopamine agonists: bind to dopamine receptors on vascular smooth muscle cells and within the sympathetic nervous system, which causes a decrease in peripheral vascular resistance and inhibition of sympathetic nervous system activity, which results in lower blood pressure.

^dVasodilators: cause relaxation of smooth muscle cells within the vessel walls, which causes the vessels to dilate, thereby lowering blood pressure.

^eACE inhibitors: decrease angiotensin II, which allows blood vessels to relax and widen, and decrease amount of water the body retains, which lowers the blood pressure.

^fCentral α -agonists: stimulate α_2 -adrenoceptors in the brainstem, thus activating an inhibitory neuron and leading to a reduction in sympathetic outflow, which ultimately decreases peripheral resistance and blood pressure.

Data from Nickavar A, Assadi F. Managing hypertension in the newborn infants. *Int J Prev Med*. 2014;5(Suppl 1):S39-S43; Flynn JT, Kaelber DC, Baker-Smith CM, et al. Clinical practice guideline for screening and management of high blood pressure in children and adolescents. *Pediatrics*. 2017; 140(3):e20171904; Lexi-Comp Online. *Pediatric & Neonatal Lexi-Drugs Online*. Hudson, OH: Lexi-Comp, Inc.; 2017; November 5, 2017.

Begin diuretics first, such as furosemide, hydrochlorothiazide, or chlorothiazide. Thiazide diuretics (chlorothiazide and hydrochlorothiazide) are preferred to loop diuretics (furosemide) due to less side effects. Add a second-line drug if necessary.

- c. **Mild hypertension.** Usually managed by observation (recommended) or oral medications (usually diuretics).
 - i. **Simple observation** is best for asymptomatic patients with no readily identifiable cause and no evidence of end-organ involvement and is supported in recent reviews. Observe closely with BP measurements every 6 to 8 hours.
 - ii. **Consider treatment (medication)** if there is proven underlying renal disease, if the BP elevation continues or increases, or if there is evidence of end-organ involvement (eg, left ventricular hypertrophy or decreased contractility on echocardiography). If medication is needed, **thiazide diuretics** are considered **first-line treatment** and are preferred over furosemide because of fewer electrolyte disturbances. They work well in cases of volume overload but may cause hypotension when used with other agents.
- d. **Infants with mild to moderate hypertension who cannot tolerate oral therapy because of gastrointestinal problems.** These infants are good candidates for IV bolus or intermittently administered IV agents:

- i. **Diuretics.** Furosemide can be used short term. Monitor electrolytes.
- ii. **Hydralazine.** Side effects include tachycardia.
- iii. **Labetalol.** Side effects include heart failure. Avoid in BPD/CLD patients.
- e. **Long-term oral antihypertensive medications.** These are typically used in infants with moderate to severe hypertension who are ready to go on long-term oral therapy. Medication choice depends on your institution's preference. The most common classes recommended are ACE inhibitors, α - and β -blockers, calcium channel blockers, vasodilators, and diuretics. See doses in Table 66–3.
 - i. **Angiotensin-converting enzyme inhibitors.** Do not use if renal vascular disease is suspected.
 - (a) **Captopril.** A commonly used oral drug, but because of the concern of renal development problems, especially in premature infants, it is preferred in infants at least 38 to 40 weeks (some state 44 weeks). Contraindicated in hyperkalemia and unilateral renal disease. Avoid use in preterm infants. Do not use in neonates with glomerular filtration rate <30 mL/min/1.73 m².
 - (b) **Enalapril.** Close monitoring is recommended. Monitor serum sodium, potassium, and creatinine. Up to 21% of infants exposed to enalapril for hypertension and CHF in the first 120 days of life suffered an adverse event, most commonly hyperkalemia (13%).
 - (c) **Lisinopril.** Not approved in infancy.
 - ii. **β -Blockers, α -/ β -blockers.** Do not use in infants with BPD/CLD.
 - (a) **Propranolol (β -blocker).** This is the most commonly used β -blocker.
 - (b) **Labetalol (α -/ β -blocker).**
 - (c) **Carvedilol (α -/ β -blocker).** May be good to use in heart failure.
 - iii. **Vasodilators**
 - (a) **Hydralazine.** May cause increase in heart rate, flushing, and edema.
 - (b) **Minoxidil.** Most useful for refractory hypertension.
 - iv. **Calcium channel blockers**
 - (a) **Amlodipine.** Due to its slow onset, it is useful in chronic hypertension.
 - (b) **Isradipine.** Optimal dosing is difficult for smaller preemies due to small volumes needed for doses from the drug's stable suspension.
 - v. **Central α -agonists** Clonidine can be used.
 - vi. **Diuretics.** Diuretics are good for hypertension with BPD/CLD. Monitor electrolytes. Hydrochlorothiazide and chlorothiazide are preferred over furosemide. Spironolactone can be used for hypertension with hyperaldosteronism.

67 Hypoglycemia

- I. **Problem.** An infant has a low blood glucose level on bedside glucose testing. **Hypoglycemia is the most common metabolic problem in neonates in the newborn nursery and neonatal intensive care unit (NICU).** Neonatal hypoglycemia occurs most often (47%–52%) in at-risk infants who are small for gestational age (SGA) or large for gestational age (LGA), late preterm infants, or infants of diabetic mothers (IDM). It can occur in up to 10% of healthy term newborns. There is controversy surrounding neonatal hypoglycemia, including **no absolute definition of hypoglycemia.** Low glucose values may or may not result in clinical signs; the low value and duration of hypoglycemia that result in neurologic injury are unknown, and there are

differing viewpoints from the **American Academy of Pediatrics (AAP) and Pediatric Endocrine Society (PES)** on hypoglycemia screening and guidelines. There is agreement that there are 2 forms of hypoglycemia in neonates: **transitional hypoglycemia**, which usually resolves within 48 hours after birth, and **persistent hypoglycemia**, which continues and can be pathologic. The AAP Committee on Fetus and Newborn states that the “absolute definition of hypoglycemia as a specific value or range cannot be given, as no evidence-based studies can define what clinically relevant neonatal hypoglycemia is.” **Hypoglycemia definitions are based on treatment recommendation target threshold values:**

A. American Academy of Pediatrics: In late preterm (34–36 6/7 weeks), term SGA infants, IDM, and LGA infants, hypoglycemia is defined as:

1. Symptomatic infants at any age and asymptomatic infants from birth to 4 hours of age: <40 mg/dL.

2. Asymptomatic infants (4–24 hours): <45 mg/dL.

B. Pediatric Endocrine Society. Defines hypoglycemia as “a plasma glucose concentration low enough to cause symptoms and signs of impaired brain function.”

1. Infants: <60 mg/dL (normal threshold for neurogenic responses)

2. Neonates with persistent hypoglycemia disorder:

a. High-risk infants without a suspected congenital hypoglycemia disorder: <48 hours, <50 mg/dL; >48 hours, <60 mg/dL.

b. Neonates with a suspected congenital hypoglycemia disorder: <70 mg/dL.

This underscores the challenge in addressing the treatment for hypoglycemia. Because hypoglycemia can present as a neonatal emergency (seizures, loss of consciousness) and it is known to cause neurologic impairment (dose-dependent increased risk of poor executive function and visual motor function) per the Children with Hypoglycemia and Their Later Development (CHYLD) study, it is critical to recognize hypoglycemia and initiate treatment to avoid long-term neurologic impairment.

II. Immediate questions

A. Was a serum sample sent to the laboratory stat? The blood glucose level should be repeated at the bedside, and a serum glucose should be sent to the laboratory stat. There are multiple ways to test for glucose (point-of-care blood glucose reagent test strips/point-of-care glucose meters, subcutaneous continuous glucose monitoring system [CGMS], and formal laboratory test). At present, there is no point-of-care method that is reliable and accurate enough to be used as the sole method for hypoglycemia screening.

1. Point-of-care bedside reagent test strips/point-of-care glucose meter. Blood is obtained (heel stick or other method), and a drop of blood is placed on the strip. It is read by visual color change or by a glucose meter at the bedside. It is quick, inexpensive, and practical but not highly accurate, especially at the low levels of glucose (<40–50 mg/dL). The reading is based on whole blood, which can be 15 mg lower than the plasma blood level. The readings are affected by high hematocrit value, presence of bilirubin, and high viscosity, which can all falsely lower the level of glucose. Commercially available glucose meters will overestimate serum glucose level in the setting of galactosemia. Capillary blood is considered more accurate than venous. US Food and Drug Administration (FDA) guidelines state that 95% of glucose results have to fall within 15 mg/dL at glucose concentrations <75mg/dL. (Therefore, an infant with a glucose of 40 mg/dL can range from 25 to 55 mg/dL.) If the bedside value is very low or the infant is showing signs of hypoglycemia, draw a stat serum blood glucose for the lab, and empirically treat the infant.

2. Subcutaneous continuous glucose monitoring system is a method that aims to improve glucose control and decrease the frequency of blood samples needed. A small flexible glucose oxidase sensor is inserted under the skin usually in the abdomen or arm. A water-resistant transmitter sits on the skin and sends glucose readings wirelessly to a receiver. The CGMS sensors measure glucose values every

5 minutes and require calibration twice a day. CGMS was studied in variety of infants at risk for hypoglycemia and was found to be accurate with a reduced exposure to procedural pain. It can also detect trends in glucose levels. Three CGMSs have been approved as of this writing by the FDA for use in newborns: DexCom Seven (DexCom Inc.), Guardian RT (Medtronic Diabetes, Inc.), and Navigator 40 (Abbott Diabetes). CGMSs are not yet used routinely in clinical practice.

3. **Laboratory diagnosis of blood glucose.** This is the **gold standard** and uses an enzymatic-based laboratory analyzer. PES guidelines indicate to only use plasma glucose concentrations determined by a clinical laboratory method. It measures plasma/serum glucose using 1 of 3 reactions (glucose oxidase, dehydrogenase, or hexokinase). It is not affected by the hematocrit. The only disadvantages include the time it takes, need for blood draw, and risk of pain and infection. It should always be ordered stat. Considerations specific to this method include the following:
 - a. **Plasma glucose** can be lower by 6 mg/dL per hour if it is not processed soon in the laboratory (erythrocytes in the sample metabolize the glucose).
 - b. **Whole blood glucose** values are approximately 15% lower than plasma blood glucose values.
 - c. **An arterial sample has a higher glucose concentration** compared to a venous or capillary sample.
- B. **How old is the infant?** If the infant was just born or is <48 hours of age, consider transitional hypoglycemia. If the infant is >48 hours, suspect persistent hypoglycemia.
- C. **Has the infant been normoglycemic and then suddenly become hypoglycemic, consider the following:**
 1. **Intravenous line issues** such as abrupt cessation of high-glucose infusion in a neonate or infiltration of intravenous (IV) line containing a high-glucose infusion.
 2. **Insulin dosing issues** if the infant is on insulin.
 3. **Malpositioned umbilical artery catheter** near vessels supplying the pancreas (celiac and superior mesenteric arteries) at T11–12: stimulates insulin release.
 4. **Postexchange blood transfusion** with fluids containing high glucose concentration.
 5. **Other underlying disorders** such as infection should also be considered.
- D. **Was there a delayed onset of feeding after birth?** Infants need to be fed soon after birth (breast/bottle feed usually right after birth or within the first hour of life) or they can become hypoglycemic. AAP recommends that healthy full-term infants “be placed and remain in direct skin-to-skin contact with their mothers immediately after delivery until the first feeding is accomplished.”
- E. **What is the caloric intake?** Inadequate caloric intake can lead to decreased glycogen stores and cause hypoglycemia.
- F. **Does the infant have any physical signs of low blood sugar?** Infants can have documented hypoglycemia and show no outward signs. There is no pathognomonic sign of hypoglycemia; most signs are nonspecific and are commonly seen in sick neonates with other disorders. If these signs disappear with treatment for hypoglycemia and there is normalization of the glucose level, then they can most likely be attributed to hypoglycemia and not another disorder.
 1. **Absence of physical signs that are seen with a low blood glucose.** The majority of infants are diagnosed with hypoglycemia during a routine screening.
 2. **Clinical signs/symptoms from American Academy of Pediatrics:** Jitteriness, irritability, cyanosis, seizures, apnea, tachypnea, weak or high-pitched cry, floppiness, lethargy, exaggerated Moro reflex, poor feeding, and eye rolling. Coma and seizures can occur with severe and prolonged hypoglycemia and repetitive hypoglycemia.
 3. **Clinical signs/symptoms from Pediatric Endocrine Society:** Symptoms/signs can be neurogenic or neuroglycopenic.

a. **Neurogenic (autonomic activation of the sympathetic nervous system) signs appear earlier:** Pallor, jitteriness, tremors, tachypnea, sweating, irritability, tremulousness, vomiting, temperature instability, tachycardia.

b. **Neuroglycopenic (central nervous system deprivation of glucose supply):** Weak or high-pitched cry, apnea, hypotonia, seizures, lethargy, coma.

G. Is the infant receiving glucose, and if so, how much? Glucose requirement depends on the gestational age, weight, and how many days old the infant is. The normal initial glucose requirement in term infants during the first 24 hours of life is 5 to 8 mg/kg/min. If the glucose order was not calculated based on body weight, the infant may not be getting the right amount of glucose. (For glucose calculations, see Chapter 10.)

H. Does the mother have any risk factors that would increase her infant's risk of hypoglycemia, such as pregestational/gestational or insulin-dependent diabetes? Is she on any medications that would cause the infant to be hypoglycemic?

Approximately 40% of IDMs have hypoglycemia. Throughout pregnancy, diabetic mothers can have episodes of hyperglycemia, resulting in fetal hyperglycemia. This fetal hyperglycemia induces pancreatic β -cell hyperplasia, which results in hyperinsulinism. After delivery, hyperinsulinism persists, and hypoglycemia results. An infant of a mother with high body mass index (BMI) but without glucose intolerance can also increase the risk of hypoglycemia in the infant. Infants born to mothers who had preeclampsia, have hypertension, or received IV glucose infusion during delivery can have an infant with hypoglycemia. **Maternal medication history** is very important because certain medications can cause hypoglycemia in the infant. These medications include insulin, oral antidiabetic medications (sulfonylureas, others), β -blockers (propranolol, labetalol), β -sympathomimetic drugs (terbutaline, ritodrine, fenoterol, salbutamol, isoxsuprine), chlorothiazide, and chlorpropamide.

I. Is the infant at risk for hypoglycemia, and does the infant require glucose screening?

1. American Academy of Pediatrics screening recommendations: Late preterm infants (34–36 6/7 weeks), term SGA infants, IDM infants, and LGA infants.

2. Pediatric Endocrine Society screening recommendations: Symptoms of hypoglycemia, LGA (even without maternal diabetes), perinatal stress (birth asphyxia/ischemia, cesarean delivery for fetal distress, maternal preeclampsia/eclampsia or hypertension), intrauterine growth restriction (IUGR; SGA), meconium aspiration syndrome, erythroblastosis fetalis, polycythemia, hypothermia, premature or postmature infants, IDM, family history of a genetic form of hypoglycemia, congenital syndromes (Beckwith-Wiedemann), or any abnormal physical features (microphallus, midline facial malformations).

III. Differential diagnosis. Hypoglycemia is classified as **transitional hypoglycemia** or **persistent** mainly based on the duration of the hypoglycemia. It is often difficult to distinguish between the 2 types, especially in the first 48 hours of life. The majority of hypoglycemia in the newborn period is transient/nonpathologic and lasts only a few days.

A. Rule out other disorders that may mimic hypoglycemia and cause the same symptoms of hypoglycemia. There are no pathognomonic signs of hypoglycemia, and many of these signs can be seen in other disorders such as sepsis, central nervous system disease, toxic exposure, encephalopathy secondary to perinatal asphyxia, congenital heart disease/heart failure, severe respiratory distress syndrome, renal and liver failure, adrenal insufficiency, opioid withdrawal, inborn errors of metabolism, and metabolic abnormalities (hypocalcemia, hypo-/hypernatremia, hypomagnesemia/pyridoxine deficiency). **If the signs of hypoglycemia disappear with treatment for hypoglycemia and there is normalization of the glucose level, then they are most likely attributed to hypoglycemia.** If the signs do not disappear with treatment for hypoglycemia and there is normalization of the glucose level, then one needs to rule out those disorders that can present with the same signs as hypoglycemia.

B. Transitional hypoglycemia only lasts a few days after birth (usually 24 hours but can last up to 72 hours) and is nonpathologic (usually self-limiting and not caused by a disease). It is often related to events occurring during birth and can occur in healthy or sick infants. In utero, the fetus has a constant supply of glucose from his or her mother. At delivery, with the cutting of the umbilical cord, this stops, and the neonate must be able to regulate insulin and maintain his or her glucose level. Blood glucose normally drops after birth and can be as low as 30 mg/dL. Some infants are able to regulate their blood glucose, and thus the level goes up in 2 to 3 hours, but some are not able to (usually at-risk infants, but some infants have no risk factors). Many of these infants are asymptomatic. Infants normally compensate for this drop, and blood glucose levels rise within 48 to 72 hours to values similar to adults. Transitional hypoglycemia probably represents an adaptation to early life because it is seen in other mammals. One concept is that infants with **transitional hypoglycemia** have lower levels of free fatty acids (FFAs; alternate fuel source), have inadequate muscle stores as a source of amino acids, are not efficient at producing ketones, are hyperinsulinemic due to immaturity in B-cell gene expression and regulation, and have inadequate/deficient hepatic glycogen stores. Recent studies suggest that transitional hypoglycemia is a regulated process in normal newborns; it is a hypoketotic form of hypoglycemia felt to be secondary to a lower glucose threshold for suppression of insulin secretion that is normal for infants. **Some cases of transitional hypoglycemia may last longer** than several days (a few weeks up to 6 months). Kallem et al (2017) define transitional hypoglycemia as lasting <7 days and has further divided transient hypoglycemia into **early transitional adaptive hypoglycemia** (due to adaptation: IDM, infants with hypothermia, asphyxiated infants), **secondary associated hypoglycemia** (due to illnesses: sepsis, perinatal asphyxia, intracranial hemorrhage), and **classic transient neonatal hypoglycemia (SGA)**. **Common causes of transitional hypoglycemia include the following:**

- 1. Maternal:** Maternal diabetes mellitus/gestational diabetes, IV dextrose during delivery, hypoglycemic agents during pregnancy (eg, chlorpropamide), maternal use of ritodrine, tocolytic therapy with β -sympathomimetic agents (terbutaline, isoxsuprine, salbutamol), high BMI, preeclampsia/eclampsia/hypertension, other maternal conditions.
 - 2. Infant:** Delayed adaptation, prematurity, postmaturity SGA, LGA (even without diabetes), IDM, late preterm, hypothermia, asphyxia, IUGR, sepsis, erythroblastosis fetalis, polycythemia, transient hyperinsulinemia, stress-induced hyperinsulinemia, *HNF4A/HNF1A* mutation
 - 3. Syndromes that can cause transient (and persistent) hypoglycemia:** Beckwith-Wiedemann, Sotos, Kabuki, and Costello syndromes; mosaic Turner syndrome; and congenital disorders of glycosylation (CDG).
- C. Persistent hypoglycemia.** Usually defined as hypoglycemia that persists longer than 48 to 72 hours after birth and has been referred to as pathologic hypoglycemia. Infants who require higher amounts of glucose (>10–12 mg/kg/min) to maintain a normal glucose, especially over 72 hours, may have persistent hypoglycemia (lasting >7 days). Because some types of transitional hypoglycemia can persist past 6 months, persistent hypoglycemia is typically used to describe the more severe and prolonged hypoglycemia that is caused by rarer disorders such as congenital hyperinsulinemia (CHI), endocrine disorders, or inborn errors of metabolism. Persistent hypoglycemia is also more likely associated with possible neurologic sequelae. Causes of persistent hypoglycemia include the following:
- 1. Congenital hyperinsulinism.** (Older terms include nesidioblastosis, idiopathic hypoglycemia of infancy, persistent hyperinsulinemic hypoglycemia of infancy, and hyperinsulinemic hypoglycemia of infancy.) CHI is an inappropriate or excessive amount of insulin secreted by the pancreatic islet β -cells caused by a group of genetic disorders. It is the **most common cause of persistent hypoglycemia**. Mutations in 9 different key genes have been identified in CHI.

Mutations in the *ABCC8/KCNJ11* genes, which cause diffuse forms of CHI and account for 60% to 75% of the cases, are the most common cause. Focal CHI is due to paternally inherited *ABCC8/KCNJ11* mutation. Incidence is from 1 per 2500 to 1 per 50,000.

2. **Insulin-producing tumors.** Includes nesidioblastosis, B-cell adenoma or islet adenomatosis, islet cell dysmaturity, B-cell hyperplasia/dysplasia including adenoma spectrum, sulfonylurea receptor defect. Insulinoma is rare in children.
3. **Syndromes associated with hyperinsulinemia (syndromic hyperinsulinemia).** Most common is Beckwith-Wiedemann syndrome (hypoglycemia, macroglossia, visceromegaly, omphalocele, ear creases/pits, renal abnormalities, macrosomia). Others include hyperinsulinism/hyperammonemia syndrome and Perlman, Kabuki, Ondine, Usher type IC, Simpson-Golabi-Behmel, and Sotos syndromes. Hypoglycemia associated with growth hormone (GH) and cortisol deficiency is Costello syndrome, and hypoglycemia associated with GH deficiency is Turner mosaicism.
4. **Congenital defects of glycosylation (CDG).** Inherited defects of protein glycosylation. Certain types of CDG can cause hypoglycemia.
5. **Insulin resistance syndromes.** These can cause hyperinsulinemic fasting hypoglycemia and can be genetic or autoimmune.
6. **Endocrine disorders.** Hormone deficiency disorders (rare) caused by deficiencies in cortisol, epinephrine, glucagon, and GH. Some of these disorders may have coexisting hyperinsulinemia.
 - a. **Growth hormone deficiency (isolated).**
 - b. **Adrenal insufficiency (cortisol deficiency).** Congenital adrenal hyperplasia, X-linked adrenal hypoplasia, adrenal hemorrhage, adrenogenital syndrome.
 - c. **Congenital hypopituitarism.** Due to hypoplasia or aplasia of the anterior pituitary gland. Causes GH and cortisol deficiency.
 - d. **Congenital adrenocorticotropic hormone deficiency or familial glucocorticoid deficiency.**
 - e. **Other rare disorders.** Midline central nervous malformations such as congenital optic nerve hypoplasia, congenital hypothyroidism, glucagon deficiency, and epinephrine deficiency.
7. **Inborn errors of metabolism.** Hypoglycemia is more commonly seen in disorders of carbohydrate metabolism or fatty acid oxidation but may be seen in disorders of amino acid metabolism, organic acidurias, and respiratory chain defects.
 - a. **Disorders of carbohydrate metabolism.** These include galactosemia, hereditary fructose intolerance, and glycogen storage diseases.
 - b. **Fatty acid oxidation defects.** Present with isolated nonketotic hypoglycemia or may also have hyperammonemia, metabolic acidosis, and elevated transaminases. The most common is medium-chain acyl-CoA dehydrogenase deficiency. Others include short-chain acyl-CoA dehydrogenase deficiency, long-chain 3-hydroxyacyl-CoA and very-long-chain acyl-CoA dehydrogenase deficiency, and carnitine deficiency disorders (carnitine palmitoyl transferase deficiency types I and II).
 - c. **Disorders of amino acid metabolism.** Maple syrup urine disease and hereditary tyrosinemia are disorders of amino acid metabolism that can present with hypoglycemia.
 - d. **Disorders of organic acidurias that may present with hypoglycemia.** Methylmalonic acidemia, propionic acidemia glutaric acidemia type II, 3-hydroxy-3-methylglutaric aciduria.
 - e. **Respiratory chain defects (oxidative phosphorylation deficiency).** May present only with hypoglycemia.

- f. **Glucose transporter deficiency syndrome. Neurohypoglycemia** is a rare condition in which the infant lacks the transport protein glucose transporter 1 (GLUT-1) that causes glucose to be transported across the blood–brain barrier.
- g. **Drugs/toxins.** The following drugs are associated with hypoglycemia: insulin, alcohol, sulfonyleureas, β -blockers, and salicylates.
- h. **Rare.** Primary lactic acidosis, phosphoenolpyruvate carboxykinase deficiency.

IV. Database

A. History

1. **Family history.** Is there a history of diabetes in the family? If there are siblings, did they have a problem with hypoglycemia? Did they have any infantile seizures? Parental consanguinity suggests autosomal recessive disorders.
2. **Pregnancy history.** Perform a detailed history of the pregnancy (Was there gestational diabetes during the pregnancy, any hypertension, or insulin use? What medications did the mother receive? Was the mother on IV glucose during delivery?).
3. **Delivery history.** Cesarean section, vaginal delivery, Apgar (appearance, pulse, grimace, activity, respirations) score, any asphyxia, any resuscitation, any meconium, or hypothermia.
4. **Gestational age (term, preterm) and weight of the infant.** Note low/high birth-weight, SGA, LGA.
5. **Infant history.** When did the episode of hypoglycemia occur? What was the timing of the episode to feeding history? What was the method of determining the blood sugar?

B. Physical examination.

Evaluate the infant for signs of hypoglycemia (see Section II.E). **Many of the findings below are suggestive of disorders causing persistent hypoglycemia and are more pertinent to that workup.**

1. **Suggestive findings.** Are there signs of sepsis or shock? Is there dysmorphism that may suggest a syndrome? Is the infant plethoric (polycythemia)? Does the infant have atypical genitalia (congenital adrenal hyperplasia)? Is there a midline defect and a micropenis (panhypopituitarism)? Are cataracts present (galactosemia and intrauterine infections)? Does the urine smell like maple syrup (inborn error of metabolism)? Is the growth abnormal (IUGR/SGA and LGA)? Is there a large liver and/or tongue (Beckwith-Wiedemann syndrome, galactosemia, fructosemia)? Is the infant macrosomic (maternal diabetes, Beckwith-Wiedemann syndrome)? Does the infant have hairy pinna (suggests IDM)? Infantile spasms (rare) can be seen in hyperinsulinemic hypoglycemia. Infants with congenital forms of hyperinsulinism may have facial dysmorphism (high forehead, small nasal tip and short columella, and square face).
 2. **Specific exam findings for syndromic hyperinsulinemia.** **Beckwith-Wiedemann syndrome:** LGA, large protruding tongue (macroglossia), large prominent eyes, creases in earlobes, low-set ears, abdominal wall defect/omphalocele, undescended testicles, diastasis recti. **Perlman syndrome:** fetal gigantism, heart defect/malformation, risk of Wilms tumor, deep-set eyes, depressed nasal bridge, agenesis of the corpus callosum. **Costello syndrome:** heart defect/malformation, cutis laxa (loose folds of skin), large mouth. **Usher syndrome type IC:** intestinal malformation, deafness, retinitis pigmentosa. **Sotos syndrome:** LGA, macrocephaly, skeletal malformation, heart defect/malformation. **Timothy syndrome:** syndactyly, heart defect/malformation, long QT syndrome. **Kabuki syndrome:** skeletal malformation, urinary tract anomalies, heart defect/malformation, intestinal malformation. **Simpson-Golabi-Behmel syndrome:** widely spaced eyes, macrostomia, LGA, skeletal malformation, heart defect/malformation, intestinal malformation, tumor risk, corpus callosum agenesis, cerebellar atrophy/hypoplasia, deafness.
- ##### C. Laboratory studies. (Who to screen?)
- Screening depends on risk factors and/or signs of hypoglycemia. AAP and PES guidelines differ on not only who to screen but

also the target glucose to maintain. It is best to follow your institutional guidelines. **Some providers recommend AAP guidelines for infants <48 hours old and then use PES guidelines for those infants >48 hours old.**

1. American Academy of Pediatrics guidelines for hypoglycemia screening.

Neonatal hypoglycemia occurs most commonly in infants who are SGA, IDM/LGA, and late preterm infants. Screen and monitor glucose only in infants who are late preterm and term SGA or IDM/LGA infants unless an infant is symptomatic. AAP does not recommend routine screening in a healthy term newborn after a normal pregnancy and delivery. **AAP recommendations on who to screen:**

- a. Any infant who manifests clinical signs that suggest hypoglycemia** needs a **stat blood glucose** immediately (within minutes) should be screened and monitored.
- b. Any asymptomatic late preterm (34–36 6/7 weeks) and term SGA infants or IDM/LGA infants.** At-risk infants should be screened based on risk factors. IDM can be hypoglycemic as early as 1 hour after birth, SGA or LGA infants can be hypoglycemic by 3 hours of age but can be hypoglycemic for 10 days after birth.
- c. Screening the asymptomatic at-risk infant.** Should include blood glucose within the first few hours of birth and continued through multiple feeding cycles. Gavage feeding can be considered if infant is not feeding well. The target glucose before each feed is 45 mg/dL.
 - i. Birth to 4 hours of age.** Infants should be fed by 1 hour of age and screened 30 minutes after the first feeding.
 - ii. 4 to 24 hours of age.** Screen glucose before each feed. Continue feeds every 2 to 3 hours. Continue this screening for 12 hours for IDM and LGA infants. Continue this screening for 24 hours for late preterm and term SGA infants.
 - iii. After 24 hours of age.** If glucose is still <45 mg/dL, continue screening before each feeding.

2. Pediatric Endocrine Society guidelines for hypoglycemia screening. PES states there is not a definite glucose level to define hypoglycemia, and their definition of clinical hypoglycemia is a plasma glucose concentration low enough to cause symptoms and/or signs of impaired brain function. The guideline recommends to stabilize glucose levels in the first 24 to 48 hours, and after 48 hours, it is important to focus on the etiology of the hypoglycemia. It is important to identify infants with persistent hypoglycemia syndromes (after 48 hours) so serious neurologic sequelae can be prevented. The Pediatric Endocrine Society discusses screening **in terms of evaluating, recognizing, and managing infants.**

- a. Neonates at risk for of hypoglycemia and in whom screening is recommended:** Neonates who have symptoms of hypoglycemia, LGA (even without maternal diabetes), perinatal stress (birth asphyxia/ischemia, cesarean section for fetal distress, maternal preeclampsia/eclampsia or hypertension, IUGR, SGA, meconium aspiration syndrome, erythroblastosis fetalis, polycythemia, hypothermia), premature or postmature infants, IDM, family history of a genetic form of hypoglycemia, congenital syndromes (Beckwith-Wiedemann), or any abnormal physical features (microphallus, midline facial malformations).
- b. Neonates who need to have persistent hypoglycemia ruled out before discharge:** Family history of genetic form of hypoglycemia, severe hypoglycemia (symptomatic hypoglycemia or need IV glucose), inability to maintain a preprandial glucose concentration >50 mg/dL up to 48 hours and >60 mg/dL after 48 hours, congenital syndrome (Beckwith-Wiedemann), or any abnormal physical features (microphallus, midline facial malformations).

- c. **High-risk neonates (without a suspected congenital hypoglycemia disorder) on normal feedings:**
 - i. **<48 hours of age:** Evaluate infants whose blood glucose is <50 mg/dL. Any infant who is unable to maintain a glucose level >50 mg/dL in the first 48 hours is at risk for persistent hypoglycemia. If IV glucose is required, then these infants probably have more severe and prolonged hypoglycemia and should maintain a target blood glucose of >60 mg/dL. Once the blood glucose level is stabilized, normal feedings can be resumed.
 - ii. **>48 hours of age:** Evaluate infants whose blood glucose is <60 mg/dL.
 - d. **Neonates with a suspected congenital hypoglycemia disorder** (infants with increased risk for a persistent hypoglycemia disorder in whom it needs to be excluded before discharge).
 - i. **Maintain a blood glucose >70 mg/dL.**
 - ii. **Evaluate when the infant is >48 hours of age**, so that the transitional period has passed.
 - iii. **Thorough history and physical examination.**
 - e. **High-risk neonates in whom persistent hypoglycemia needs to be ruled out (before discharge):** Any infant with severe hypoglycemia (defined as episode of symptomatic hypoglycemia or need for IV dextrose), any infant not able to maintain a preprandial plasma glucose >50 mg/dL up to 48 hours of age or >60 mg/dL after 48 hours of age, any infant with a family history of a genetic form of hypoglycemia, or any infant with a congenital syndrome or any abnormal physical features.
3. **PES guidelines for laboratory screening of persistent hypoglycemia.** If possible, draw a critical sample at the time of hypoglycemia and before treatment. It is best to draw plasma glucose, bicarbonate, β -hydroxybutyrate (BOHB), and lactate. At the same time, draw an extra tube of blood to hold for other testing (plasma insulin, FFA, C-peptide for hyperinsulinemia; plasma total and free carnitine and acylcarnitine profile for fatty acid oxidation).
- a. **Metabolic clues based on bicarbonate, β -hydroxybutyrate, lactate, and free fatty acid lab testing:**
 - i. **If acidemia is present based on bicarbonate result:**
 - (a) **If β -hydroxybutyrate level is increased:** Suspect ketotic hypoglycemia, glycogenosis, GH deficiency, cortisol deficiency.
 - (b) **If lactate is increased:** Suspect gluconeogenesis defects.
 - ii. **If no acidemia is present based on bicarbonate result:**
 - (a) **β -Hydroxybutyrate decreased, free fatty acids increased:** Suspect fatty acid oxidation defects.
 - (b) **β -Hydroxybutyrate decreased, free fatty acids decreased:** Suspect genetic hyperinsulinism, hypopituitarism, transitional neonatal hypoglycemia, perinatal stress hyperinsulinism.
 - b. **If critical sample at the time of hypoglycemia is not possible, “a provocative fasting test” can be done.** A plasma glucose of 50 mg/dL is low enough to perform the tests. Monitor vital signs, plasma glucose, and BOHB concentrations during the test. Draw necessary labs and stop the fast. Stop the fast if there are symptoms of distress or plasma BOHB is >2.5 mmol/L. Once the fast has been stopped, do the glucagon test. (See below.)
 - i. **Suspected hyperinsulinism:** Give the glucagon test (1 mg IV, intramuscularly [IM], or subcutaneously) when the plasma glucose is <50 mg/dL to measure the glycemic response (>30 mg/dL nearly pathognomonic of hyperinsulinemia). Plasma BOHB and FFA are both low in hyperinsulinemia.
 - ii. **Additional tests to consider:** GH, cortisol, total and free carnitine, acylcarnitine profile, C-peptide, proinsulin, and drug screening. Consider genetic mutation analysis.

- iii. **Suspected adrenal insufficiency:** Obtain plasma adrenocorticotropic hormone and cortisol.
 - iv. **Suspected drug/toxin:** Obtain drug/toxicology screen. For exogenous insulin administration: see high plasma insulin level with low C-peptide level during hypoglycemia.
4. **Other screening recommendations (not American Academy of Pediatrics/ Pediatric Endocrine Society)**
- a. **Laboratory recommendations for infants <34 weeks.** There are no formal guidelines for these infants. Many of these infants will be admitted to a transitional care or special care nursery based on their weight and gestational age, so they will already be getting frequent glucose monitoring.
 - b. **Studies for persistent hypoglycemia in all infants.** Draw any necessary labs at the time of hypoglycemia (plasma glucose <50 mg/dL). There are multiple tests that can be performed, but the primary goal is to determine whether the infant has hyperinsulinemia.
 - i. **Initial studies.**
 - (a) **Serum glucose and insulin (insulin-to-glucose level).** Serum insulin will be high at the time of hypoglycemia with hyperinsulinemia. Some clinicians obtain serum glucose and insulin to determine the ratio of insulin to glucose (I/G). Normal I/G is <0.30. A level >0.30 suggests hyperinsulinemia.
 - (b) **Serum ketones.** Low to absent in the presence of hyperinsulinemia and high in GH and cortisol deficiency.
 - (c) **Hydroxybutyrate and free fatty acids.** Decreased levels can indicate excessive insulin.
 - (d) **Serum lactate.** This can be elevated in metabolic defects.
 - (e) **Serum ammonia.** To rule out hyperinsulinism/hyperammonemia syndrome.
 - (f) **C-peptide levels.** Elevated in hyperinsulinemia and insulinoma.
 - (g) **Insulin-like growth factor binding protein 1.** Decreased in hyperinsulinemia.
 - (h) **Increased serum insulin, C-peptide, and proinsulin level** and decreased glucose, FFAs, ketones, and insulin-like growth factor binding protein 1, and an exaggerated glycemic response after glucagon challenge can diagnose CHI.
 - ii. **Critical labs to diagnose hyperinsulinism**
 - (a) **Plasma insulin** >2 U/mL.
 - (b) **Plasma free fatty acids** <1.0 to 1.5 mmol/L (<28–42 mg/dL).
 - (c) **Plasma** <1.5 mmol/L (<15 mg/dL).
 - (d) **Glucagon challenge 1 mg IV, IM, or subcutaneously** results in >30 mg/dL rise in blood sugar.
 - c. **Other tests.** Serum pH (metabolic disorders), cortisol and adrenocorticotropic hormone stimulation test (adrenal insufficiency), GH levels (GH deficiency), blood ammonia (galactosemia, hyperinsulinism/hyperammonemia), thyroxine (T₄) and thyroid-stimulating hormone (TSH) (hypothyroidism), blood lactate levels (glycogen storage disorders), urine ketones and reducing substances or amino acids and organic acids (inborn error of metabolism), FFA levels (fatty acid oxidation defect), plasma acylcarnitines (3-hydroxyacyl-CoA dehydrogenase [HADH] deficiency).
 - i. **Genetic testing.** To diagnose inherited syndromes or certain disorders of inborn errors of metabolism.
 - ii. **To differentiate a metabolic defect from hypopituitarism and hyperinsulinism.** Obtain a set of laboratory tests before and 15 minutes after the administration of glucagon (1 mg/dose IV, IM, or subcutaneously). These tests include serum glucose, ketones, FFAs, lactate, alanine, uric

Table 67–1. DIAGNOSIS OF PERSISTENT HYPOGLYCEMIA BEFORE AND AFTER PARENTERAL GLUCAGON ADMINISTRATION

Variable	Hyperinsulinism		Hypopituitarism		Metabolic Defect	
	Before	After	Before	After	Before	After
Glucose	↓	↑↑↑	↓	↑/N	↓	↓/N
Ketones	↓	↓	N/↓	N	↑	↑
Free fatty acids	↓	↑	N/↓	N	↑	↑
Lactate	N	N	N	N	↑	↑↑
Alanine	N	?	N	N	↑	↑↑
Uric acid	N	N	N	N	↑	↑↑
Insulin	↑↑	↑↑↑	N/↑	↑	N	↑
Growth hormone	↑	↓	↓	↓	↑	↑
Cortisol	↑	↓	↓ ^a	↓ ^a	↑	↑
TSH and T ₄	N	N	↓ ^a	↓ ^a	N	N

N, normal or no change; ↑, elevated; ↓, lowered; ?, unknown; T₄, thyroxine; TSH, thyroid-stimulating hormone.

^aResponse may vary depending on the degree of hypopituitarism.

acid, insulin, GH, cortisol, glucagon, T₄, and TSH. The results are interpreted as shown in Table 67–1, courtesy of the late Dr. Marvin Cornblath.

D. Imaging and other studies

1. **Ultrasound/computed tomography of the pancreas** to look for adenoma.
2. **Echocardiogram** may show hypertrophic cardiomyopathy in IDM with transient hyperinsulinism.
3. **Electrospray ionization tandem mass spectrometry** can identify inborn errors of metabolism more rapidly (see Chapter 100).
4. **¹⁸F-dihydroxyphenylalanine positron emission tomography/computed tomography** allows preoperative differentiation of focal from diffuse CHI.
5. **Contrast-enhanced computed tomography** technique permits precise preoperative localization of the lesion.
6. **Head magnetic resonance imaging** to rule out pituitary or hypothalamic neoplasms or congenital abnormalities.

V. Plan

- A. **Transitional hypoglycemia.** There are many different recommendations on treatments for **transitional hypoglycemia**. The majority of cases of transitional hypoglycemia respond well to treatment and are associated with an excellent prognosis. **Treatments include early feeding (bottle/breast/gavage), dextrose gel or IV fluids (mini-bolus and/or IV), or a combination of any of these.** There are many guidelines, and they differ in their recommendations (AAP, PES, Sugar Babies dextrose gel trial). It is best to follow the guidelines of your institution. **Some advocate that it is best to follow the AAP guidelines for the first 48 hours.** The overall goal is to maintain normoglycemia. Infants at risk for hypoglycemia and those with established hypoglycemia should have glucose screening every 1 to 2 hours until glucose levels are stable and then every 3 hours. Once the glucose level is stable, the next step is

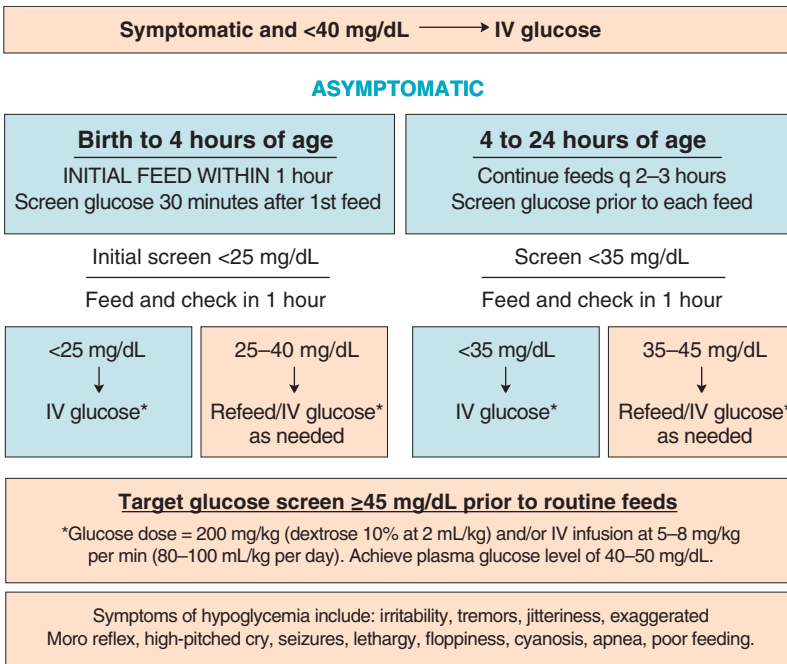

FIGURE 67–1. Screening for and management of postnatal glucose homeostasis in late-preterm (LPT 34–36 6/7 weeks), term small for gestational age (SGA) infants, and infants who were born to mothers with diabetes (IDM)/large for gestational age (LGA) infants. For LPT and SGA, screen at 0 to 24 hours; for IDM and LGA ≥ 34 weeks, screen at 0 to 12 hours. IV, intravenous. (Modified with permission from Committee on Fetus and Newborn, *Adamkin DH: Postnatal glucose homeostasis in late-preterm and term infants, Pediatrics. 2011 Mar;127(3):575-579.*)

to determine why the patient is hypoglycemic. Sometimes the cause is obvious, as in the case of an IDM or an infant with IUGR. If the cause is not obvious, further workup is necessary.

1. The following American Academy of Pediatrics recommendations focus mainly on transitional hypoglycemia:

a. At-risk late preterm (34–36 6/7 weeks) and term small for gestational age infants and infants of diabetic mothers/large for gestational age infants (American Academy of Pediatrics). (See Figure 67–1.)

i. The following are key management concepts:

(a) **Signs of hypoglycemia** can be irritability, jitteriness, tremors, exaggerated Moro reflex, high-pitched cry, seizures, lethargy, floppiness, cyanosis, apnea, and poor feeding.

(b) **Target blood glucose screen** ≥ 45 mg/dL prior to feeds.

(c) **Gavage feedings can be considered** if the infant is not feeding well.

ii. Symptomatic infants: If blood glucose is < 40 mg/dL, treat with IV glucose. Give a 2 mL/kg dextrose 10% in water (D10W) mini-bolus at a rate of 1 mL/min and/or a continuous infusion of D10W at a rate of 5 to 8 mg/kg/min glucose intake (80–100 mL/kg/d D10W infusion) to achieve a plasma glucose of 40 to 50 mg/dL.

iii. **Asymptomatic infants from birth to 4 hours of age:**

- (a) Feed within 1 hour of birth.
- (b) Obtain serum glucose 30 minutes after first feed.
 - (i) **Serum glucose <25 mg/dL:** Refeed and check in 1 hour.
 - (ii) **If serum glucose <25 mg/dL:** Use IV glucose. Give a 2 mL/kg D10W mini-bolus at a rate of 1 mL/min and/or continuous infusion of D10W at a rate of 5 to 8 mg/kg/min glucose intake (80–100 mL/kg/d D10W infusion). Achieve blood glucose level of 40 to 50 mg/dL.
 - (iii) **If serum glucose is 25 to 40 mg/dL:** Refeed/IV glucose as needed.

iv. **Asymptomatic infants 4 to 24 hours of age**

- (a) **Continue feeds** every 2 to 3 hours.
- (b) **Obtain serum glucose** prior to each feed.
- (c) **Serum glucose <35 mg/dL:** Refeed and check in 1 hour.
- (d) **If serum glucose <35 mg/dL:** IV glucose (see earlier).
- (e) **If serum glucose is 35 to 45 mg/dL:** Refeed/IV glucose as needed.

Note for American Academy of Pediatrics recommendations: Correction of hypoglycemia is recommended by infusion of glucose by mini-bolus and/or continuous infusion. Some authors have found that rapid correction of hypoglycemia in asymptomatic newborns >35 weeks of gestational age and at risk for hypoglycemia (maternal diabetes, LGA, fetal growth restriction, and prematurity [gestational age <37 weeks]) had a worse neurodevelopmental outcome at 2 years of age. Because of this finding, **some physicians are advocating bypassing the mini-bolus and just starting a continuous glucose infusion of 4 to 6 mg/kg/min.**

2. **Pediatric Endocrine Society recommendations for high-risk neonate without a suspected congenital hypoglycemia disorder**

- a. **High-risk neonates without a suspected congenital hypoglycemia disorder <48 hours of age:** Maintain a blood glucose >50 mg/dL. Evaluate infants whose blood glucose is <50 mg/dL. Any infant who is unable to maintain a glucose level >50 mg/dL in the first 48 hours is at risk for persistent hypoglycemia. **If IV glucose is required,** then these infants probably have more severe and prolonged hypoglycemia, and a target blood glucose of >60 mg/dL should be maintained. Once the blood glucose level is stabilized, normal feedings can be resumed.
- b. **High-risk neonates without a suspected congenital hypoglycemia disorder >48 hours of age:** Maintain a glucose level >60 mg/dL.

3. **Dextrose oral gel (40%)**

- a. **Dextrose gel as prophylaxis.** A Cochrane review (2017) found insufficient evidence, so this practice cannot be recommended.
- b. **Treatment of neonatal hypoglycemia.** The Sugar Babies Study in 2013 reported that buccal treatment with 40% dextrose gel (200 mg/kg; Table 67–2) was more effective than feeding alone for reversing neonatal hypoglycemia in at-risk term and late preterm infants (35–42 weeks' gestation) in the first 48 hours after birth. This method decreased the number of episodes and recurrence rate of hypoglycemia, decreased the need for admission to the NICU, increased exclusive breast-feeding rates at discharge, did not exhibit rebound hypoglycemia, and supported family bonding. Authors recommend it for first-line management of the late preterm and term hypoglycemic neonate up to 48 hours after birth. Developmental follow-up study at 2 years showed that treatment with dextrose gel did not decrease or increase the rate of neurosensory impairment or processing difficulties compared with placebo. **Cochrane review** (2016) concluded that treatment with 40% dextrose gel decreases the incidence of mother–infant separation for treatment and increases the likelihood of full breast feeding after discharge. There are no adverse effects at 2 years of corrected age. They state it should be considered a **first-line**

Table 67–2 DOSING OF ORAL GLUCOSE (40%) GEL

Neonate Birthweight, kg	Dose of 40% Glucose Gel, g	Amount, mL
2.0	0.4	1.00
2.5	0.5	1.25
3.0	0.6	1.50
3.5	0.7	1.75
4.0	0.8	2.00
4.5	0.9	2.25
5.0	1.0	2.50

Data from Harris DL, Weston PJ, Signal M, et al: Dextrose gel for neonatal hypoglycaemia (the Sugar Babies Study): a randomised, double-blind, placebo-controlled trial, *Lancet*. 2013 Dec 21;382(9910):2077–2083.

treatment for infants with hypoglycemia. Some institutions recommend buccal dextrose gel only for managing asymptomatic infants with hypoglycemia, not for managing symptomatic infants. Many different protocols exist, and it is best to follow your own institutional guidelines.

- c. One example of a protocol implementing glucose gel for treating neonatal hypoglycemia** is based on a study by Bennett and colleagues (*Nursing for Women's Health*, Volume 20, Issue 1, February–March 2016). This protocol resulted in a 73% decrease in NICU admissions for neonatal hypoglycemia diagnosis. Use Table 67–2 for dosing of oral glucose gel.
- i. Any infant with symptomatic hypoglycemia. Check bedside glucose; if <40 mg/dL,** apply dose of dextrose gel by syringe to the neonate's buccal cavity, place skin-to-skin to breast feed, and obtain a serum glucose. Observe neonate closely. Recheck bedside glucose in 30 minutes after the glucose gel is given and check serum glucose.
 - ii. Any infant at risk for hypoglycemia** (SGA, LGA, late preterm, IDM, Apgar score <7 at 5 minutes of age)
 - (a) Breast feed infant within first hour of birth.**
 - (b) Check blood glucose level** 30 minutes after feeding is complete.
 - (c) If blood glucose <35 mg/dL,** give a weight-based dose of 40% glucose gel by syringe to the infant's buccal cavity. Place infant back with mother to feed.
 - (d) Repeat blood glucose level in 1 hour** after gel is given.
 - (e) If the blood glucose is >35 mg/dL:** Check levels before feedings until 2 consecutive readings are >45 mg/dL.
 - (f) If the blood glucose is <35 mg/dL,** give a second dose of glucose gel. Place infant back with mother to feed. Obtain a blood glucose 1 hour after the dextrose was given. If low, contact physician.
- B. Persistent hypoglycemia.** The management of these infants can be complicated, because they can have fluid overload and cardiac failure. Many require a central line to deliver high levels of glucose. Some will require a gastrostomy for frequent feedings. **Endocrinology and possible surgical consultation** should be obtained. Long-term therapy depends on the specific disorder with consultation with specialists in the area.

1. **Pediatric Endocrine Society recommendations for neonates with a suspected congenital hypoglycemia disorder**
 - a. **Maintain a blood glucose >70 mg/dL.**
 - b. **Any episode of severe symptomatic hypoglycemia should be rapidly corrected with intravenous dextrose infusion.** The initial dose is 200 mg/kg, followed by continuous infusion of 10% dextrose at maintenance rate.
 - c. **Glucagon can support to normalize hypoglycemia** caused by hyperinsulinism. Glucagon dose is 0.5 to 1.0 mg IV, IM, or subcutaneously.
 - d. **Long-term therapy** should be based on the etiology of the disorder. Medications, surgery, and nutritional therapy are some of the treatments used.
 - e. **Testing should be done on neonates with ketotic hypoglycemia** who have recurrent episodes for glycogen synthase deficiency (GSD types 0, VI, IX) and *MCT1* gene deficiency.
 - f. **Hyperinsulinemia:** Aim is to prevent recurrent hypoglycemia.
 - g. **Defects in glycogen metabolism and gluconeogenesis:** Aim is to maintain plasma glucose level to prevent metabolic acidosis and growth failure.
2. **General recommendations. Continue IV glucose and increase the rate of IV glucose to 16 to 20 mg/kg/min.** Rates >20 mg/kg/min are usually not helpful. If it is evident at this point that the infant still has problems with hypoglycemia, medications to treat the hypoglycemia should be started.
 - a. **Glucocorticoids (dexamethasone and hydrocortisone).** Formerly used in the nonspecific treatment of persistent hypoglycemia. Some units may still be using corticosteroids as first-line therapy. It is **no longer recommended** because of side effects and is now only used if there is evidence of adrenal insufficiency. (See dosage in Chapter 155.)
 - b. **The following medications can be tried.** It is not necessary to stop the previous agent when trying a new medication. Choice of treatment can be variable and depends on the institution. **Knowledge of the genetic subtype can guide treatment.** Infants with *GLUD1*, *HNF4A*, *HADH*, *GCK*, and *UCP2* mutations respond better to diazoxide than those with *ABCC8* and *KCNJ11* mutations. The type caused by paternal *ABCC8* or *KCNJ11* mutations may be focal and may respond to surgery (lesionectomy). The homozygous/compound heterozygous *ABCC8/KCNJ11* mutations may need near-total pancreatectomy if medical treatment does not work. **Note: Infants with transitional hyperinsulinemia from perinatal stress and syndromic hyperinsulinemia also respond to diazoxide.** See Chapter 155 for dosages.
 - i. **Diazoxide. First treatment of choice for persistent/pathologic hypoglycemia.** Initial dose is 10 mg/kg/d orally in divided doses every 8 hours. Range is 5 to 15 mg/kg/d divided every 8 hours. **Chlorothiazide** is often used with diazoxide for its synergistic effect and to decrease retention of fluid. Diazoxide is started for a trial of 5 days. Responsiveness is based on absence of hypoglycemia on normal feedings and during a 4-hour fast. If nonresponsive, octreotide is tried next.
 - ii. **Octreotide.** A long-acting analog of somatostatin; preferred over somatostatin because the latter has a very short half-life. It can be used if the infant with persistent/pathologic hypoglycemia is nonresponsive to diazoxide. The starting dose is 2 to 10 mcg/kg/d subcutaneously divided every 6–12 hours or by continuous IV infusion. Doses up to 40 mcg/kg/d divided every 6 to 8 hours can be used. It has been used long term in combination with feeding.
 - iii. **Glucagon.** Used if the infant has good glycogen stores. It converts stores of glycogen to glucose. Usually it is only given in temporary situations (eg, waiting for IV/central line access, waiting for surgery, used with octreotide in short-term stabilization of infants with hyperinsulinemia). Lower dose of 0.02 to 0.30 mg/kg/dose IV may work. PES recommends using a 0.5- to 1.0-mg dose (independent of weight) IV, IM, or subcutaneously.

- iv. **Nifedipine reduces glucose tolerance and insulin secretion.** It has been used in some infants, but because of severe hypotension and lack of long-term experience, it is not used often.
 - v. **Sirolimus** has been used in a few infants unresponsive to high doses of diazoxide and octreotide with promising results.
 - vi. **Medications for endocrine deficiency disorders.** GH should be used if there is a GH deficiency. Epinephrine can be used in epinephrine deficiency. Zinc protamine glucagon is indicated for infants with glucagon deficiency.
- 3. Other management strategies for persistent hypoglycemia**
- a. **Pancreatic surgery.** Considered if medical treatment does not work for neonatal hyperinsulinism. It is also recommended for infants with focal lesions (partial pancreatectomy) and some infants with diffuse lesions such as I-cell hyperplasia (subtotal pancreatectomy). Pancreatectomy (removes at least 95% of the organ) is often necessary. Partial pancreatectomy can be done when hypersecretion is shown to be confined to a small area of the pancreas. Studies have shown that some cases of CHI have been managed effectively with diazoxide and octreotide for decades.
 - b. **Congenital hypopituitarism.** Usually responds to administration of cortisone and IV glucose. Administration of human GH may be necessary. (For dosages, see Chapter 155.)
 - c. **Metabolic defects**
 - i. **Type I glycogen storage disease.** Frequent small feedings and avoiding fructose or galactose may be beneficial.
 - ii. **Hereditary fructose intolerance.** Begin a fructose-free diet.
 - iii. **Galactosemia.** Begin a galactose-free diet immediately on suspicion of the diagnosis.
 - iv. **Glucose transporter deficiency syndrome** is treated with a ketogenic diet.
- C. Discharge recommendations by AAP and PES**
- 1. **American Academy of Pediatrics: If inadequate postnatal glucose homeostasis is documented:** Make sure the infant can maintain normal plasma glucose concentrations on a routine diet for at least 3 feed fast periods before discharge.
 - 2. **Pediatric Endocrine Society**
 - a. **Any high-risk neonates without a suspected congenital hypoglycemia disorder on normal feedings:** Consider a safety fast of 6 to 8 hours before discharge to see if the glucose level is maintained >60 mg/dL. If not, additional investigation may be necessary.
 - b. **Any infant with a known genetic or persistent form of hypoglycemia:** Obtain a consultation with a specialist before discharge. Before discharge, do a safety fasting test to make sure the infant can maintain a plasma glucose >70 mg/dL after a feeding is missed (minimum 6–8 hours).

68 Hypokalemia

- I. Problem.** The nurse reports a serum potassium of 2.8 mEq/L in a normal newborn. Normal serum potassium values vary with technique used by the laboratory but are usually between 3.5 and 5.5 mEq/L. **Hypokalemia is defined as a serum potassium <3.5 mEq/L.** Most sources use the following designations:
- A. **Mild hypokalemia** is 3.0 to <3.5 mEq/L,
 - B. **Moderate hypokalemia** is 2.5 to 3.0 mEq/L,
 - C. **Severe hypokalemia** is <2.5 mEq/L.

Hypokalemia causes membrane hyperpolarization and impairs muscle contraction; therefore, the clinical manifestations involve changes to muscle and cardiovascular function. Severe hypokalemia can cause cardiac arrhythmias (can be fatal), respiratory depression, skeletal muscle impairment and weakness, ileus, lethargy, and in extreme cases, rhabdomyolysis. Since 98% of potassium is intracellular and 2% is extracellular, serum potassium levels do not correlate with intracellular potassium levels; therefore, hypokalemia does not reflect total body potassium stores. The body must maintain a normal extracellular potassium in order to avoid any cardiac or neurologic signs or symptoms.

II. Immediate questions

- A. **What is the central serum potassium?** If a low value is obtained by heel stick, central values should be obtained because they may actually be lower than values obtained by heel stick (potassium release from hemolysis of red blood cells). Was the sample sent immediately to the lab? If a sample sat for hours in a warm area, “pseudohypokalemia” can occur.
- B. **Is the infant on diuretics? Are potassium-wasting medications or digitalis being given?** Hypokalemia in a neonate usually occurs from chronic diuretic use. Hypokalemia may cause significant arrhythmias if digitalis is being administered.
- C. **How much potassium is the infant receiving?** Normal maintenance doses are 1 to 2 mEq/kg/d.
- D. **Are there any gastrointestinal losses from diarrhea, a nasogastric/orogastric tube, or ileostomy?** Loss of large amounts of gastrointestinal (GI) fluids can cause hypokalemia. Severe vomiting can also cause hypokalemia such as in infantile hypertrophic pyloric stenosis.
- E. **What is the infant’s magnesium level?** Hypomagnesemia can cause hypokalemia. Consider this diagnosis if the hypokalemia does not correct despite potassium supplementation.
- F. **Does the infant have hypertension?** Consider mineralocorticoid excess: primary aldosteronism, congenital adrenal hyperplasia, or Cushing syndrome.

III. Differential diagnosis. Hypokalemia can be caused by a prolonged inadequate intake of potassium, increased GI losses, increased renal losses, transcellular shifts of potassium from extracellular to intracellular spaces, and medications. **Medications (diuretics, specifically loop or thiazide diuretics) are the most common cause in the neonatal intensive care unit, followed by increased GI losses from the nasogastric (NG) tube.**

- A. **Pseudohypokalemia** can occur if the blood sample has a very high WBC count kept at room temperature for a long time, whereby uptake of extracellular potassium by the WBC occurs. If the blood sample sits at an increased temperature too long (“summertime pseudohypokalemia”), this increases Na^+/K^+ -ATPase activity, which shifts potassium into cells. A blood specimen collected after insulin administration that sits too long can cause pseudohypokalemia. Avoid this by either storing the blood at 4°C or rapidly separating the plasma or serum from the cells.
- B. **True hypokalemia (total body deficit)**
 1. **Inadequate intake (rare)** of maintenance infusion, inadequate oral intake of potassium, or insufficient support in total parenteral nutrition. Extremely preterm small for gestational age infants on recommended early parenteral nutrition are at high risk of hypokalemia. For further discussion, see Chapter 10.
 2. **Gastrointestinal losses**
 - a. **Loss of fluid via nasogastric tube, ostomies, or gastrointestinal fistulas.** Unreplaced electrolyte loss from NG tube (most common) or intestinal drainage (ostomies, GI fistulas). Infants with necrotizing enterocolitis or intestinal anomalies requiring surgery are at risk.
 - b. **Diarrhea.** Congenital chloride diarrhea, any GI fistula, short bowel syndrome.
 - c. **Vomiting.** May cause hypokalemia such as infantile hypertrophic pyloric stenosis with vomiting. In hypertrophic pyloric stenosis in infants, an enlarged pylorus, or “**pyloric olive**,” may be felt in 23% of cases (best felt during or at the end of a feeding).

- d. **Medications.** Kayexalate causes fecal potassium loss.
3. **Renal losses**
- a. **Medications**
- i. **Diuretic use**, especially long-term therapy with any **thiazide or loop diuretic**, is the most common medication-related cause.
 - ii. **Steroids and steroid-like medications.**
 - iii. **Antibiotics.** High-dose penicillin, ampicillin, carbenicillin, vancomycin, aminoglycosides. Combined treatment of aminoglycosides and vancomycin can cause tubular disturbances in extremely low birthweight infants with renal tubular wasting of potassium. Intravenous colistin use was significantly associated with hypokalemia.
 - iv. **Magnesium-depleting medications**, such as amphotericin B, cisplatin, or carboplatin, cause renal magnesium wasting. Amphotericin B can cause direct renal tubular damage with potassium loss.
- b. **Any cause of polyuria**
- c. **Renal tubular losses**
- i. **Renal tubular acidosis types 1 and 2 can both cause hypokalemia.**
 - ii. **Hypomagnesemia.** Exacerbates potassium loss by increasing distal potassium secretion.
 - iii. **Bartter syndrome (antenatal or neonatal).** **Antenatal Bartter syndrome** is a rare autosomal recessive renal tubular disorder caused by mutations in the transporters in the thick ascending limb of the loop of Henle (defective gene *NKCC2*, type I Bartter syndrome; defective gene *ROMK*, type II Bartter syndrome). The infant presents at birth with hypokalemia, hypochloremia, and metabolic alkalosis and also has failure to thrive and recurrent episodes of dehydration. The hypokalemia is a form of potassium wasting, secondary to chloride channel abnormality. **Neonatal Bartter syndrome with sensorineural deafness (type IV)** can be caused by mutations in the *BSND* gene or *CLCNKB* and *CLCNKA* genes (type IVb). **Pseudo-Bartter syndrome** presents with the same clinical and biologic characteristics as Bartter syndrome but without the primary renal tubule abnormalities. It occurs most commonly from administration of diuretic agents or prostaglandin E, from prolonged vomiting and diarrhea, or from a maternal eating disorder. **Congenital hypokalemia with hypercalciuria** resembles Bartter syndrome.
 - iv. **Other syndromes.** Liddle, Gitelman, and Fanconi syndromes.
4. **Transcellular shifts of potassium from serum to cells**
- a. **Alkalosis** (metabolic or respiratory) drives potassium into cells, causing hypokalemia. An increase in blood pH by 0.1 unit causes a decrease in the serum potassium by 0.6 mEq/L. The decrease is less in respiratory than in metabolic alkalosis.
 - b. **Insulin therapy** causes intracellular uptake of potassium.
 - c. **Medications** that cause an increase in intracellular uptake of potassium include **β -adrenergic agonists** (eg, epinephrine, decongestants, bronchodilators, tocolytic drugs) and **xanthine derivatives** (eg, theophylline, caffeine). Overdose related: insulin, verapamil, and epinephrine.
 - d. **Hypothermia** can drive potassium into cells and lower the plasma potassium concentration.
 - e. **Endocrinopathies causing potassium loss (less common)**
 - i. **Congenital adrenal hyperplasia.** 11β -Hydroxylase deficiency accounts for approximately 5% to 10% of cases and causes hypertension, hypokalemic alkalosis, and salt retention.
 - ii. **Primary hyperaldosteronism/Conn syndrome.** Hypertension, hypokalemia, and suppressed renin activity are the 3 laboratory hallmarks of

this disease. **Secondary hyperaldosteronism** can occur from renal artery stenosis, renin-secreting tumors, and coarctation of the aorta.

iii. Cushing syndrome. The most common cause of Cushing syndrome in infants is an adrenal tumor (bilateral hyperplasia, adenoma, or carcinoma).

iv. Syndrome of apparent mineralocorticoid excess. This can be congenital and causes hypokalemia.

v. Hyperthyroidism (thyrotoxicosis).

IV. Database

A. Physical examination. Signs of hypokalemia (muscle weakness, lethargy, myalgia, paresthesia, muscle cramps) are very difficult to assess in the neonate.

1. Mild hypokalemia may not cause any signs or symptoms. There may be slight muscle weakness.

2. Moderate hypokalemia can cause musculoskeletal symptoms (weakness, decreased tendon reflexes, myalgia, muscle cramps, paresthesias, paralysis), GI symptoms (nausea, vomiting, diarrhea, constipation, ileus), and central nervous system signs (lethargy). These are very difficult to evaluate in an infant.

3. Severe hypokalemia can cause lethargy, severe muscle weakness, paralysis, ileus (abdominal distension and hypoactive bowel sounds), cardiac arrhythmias (rare unless <2.5 mEq/L), respiratory depression (flaccid or diaphragmatic paralysis), respiratory arrest, or bradycardia with cardiovascular collapse. Rhabdomyolysis (skeletal muscle destruction) and myoglobinuria (leakage of muscle protein myoglobin in the urine) can occur. Muscle fasciculation and tetany can occur.

B. Laboratory studies

1. Repeat the serum potassium level to confirm the potassium level.

2. Spot check urinary electrolytes. Perform periodic spot checks of urinary potassium levels to determine whether urinary losses are high. This is not accurate with recent diuretic use.

a. Urine potassium is <20 mmol/L: Suspect nonrenal losses.

b. Urine potassium is >20 mmol/L: Suspect renal losses and Bartter syndrome.

c. Urinary chloride level is low (<10 mEq/L): Consider GI losses (vomiting, drainage, fistulas, ileostomy, diarrhea).

d. Urine chloride is normal in Bartter syndrome and diuretic therapy.

e. A low urine sodium level with a high urine potassium level is associated with secondary hyperaldosteronism.

f. If urine magnesium is high, consider renal magnesium loss.

3. Urinary dipstick for blood. Severe hypokalemia can induce rhabdomyolysis. A red or dark brown urine may indicate myoglobin (breakdown of muscle cells). If the urine is dark brown and positive for blood, then send the serum and urine for myoglobin.

4. Serum electrolytes and creatinine. To evaluate renal status and other electrolyte abnormalities.

a. A low serum sodium suggests GI loss or thiazide diuretic use.

b. Urinary potassium-to-creatinine ratio. If the ratio is <1.5 , consider low potassium intake, GI losses, or thyrotoxicosis. If the ratio is ≥ 1.5 , consider aldosteronism, Cushing syndrome, congenital adrenal hyperplasia, renal tubular acidosis (RTA), diuretic use, Bartter/Gitelman syndrome, or vomiting.

5. Blood gas levels. An alkalosis may cause or aggravate hypokalemia (ie, as hydrogen ions leave the cells, potassium ions enter the cells, causing decreased serum potassium levels). **Treatment of acidosis may worsen hypokalemia.** Acidosis is seen with RTA. Alkalosis is seen with Bartter syndrome, diuretic use, emesis, and NG losses. A high serum bicarbonate can be seen with hyperaldosteronism or Bartter syndrome. A low serum bicarbonate can be seen with RTA, diarrhea, or carbonic anhydrase inhibitors.

6. **Serum magnesium.** To rule out hypomagnesemia.
7. **Drug screen.** If the infant is on any medication that can cause hypokalemia, check the levels if available (methylxanthines such as theophylline, aminophylline, caffeine). Check digoxin level if the patient is on a digitalis preparation because hypokalemia can potentiate digitalis-induced arrhythmias.
8. **Serum adrenocorticotropic hormone, cortisol, renin activity, and aldosterone levels.** To evaluate for Cushing and Conn syndromes or adrenal hyperplasia. Low renin and low aldosterone suggest adrenal hyperplasia; low renin and high aldosterone suggest hyperaldosteronism.
9. **Serum insulin and C-peptide tests.** To evaluate for hyperinsulinism.
10. **Rhabdomyolysis.** Send aspartate aminotransferase, alanine aminotransferase, creatinine kinase, and creatinine kinase isoenzyme MB.
11. **Genetic testing in Bartter syndrome** can be performed.

C. Imaging and other studies

1. **Abdominal radiograph.** If ileus is suspected.
2. **Abdominal ultrasound.** In infants in whom pyloric stenosis is suspected, ultrasound is the diagnostic procedure of choice. Can also check for adrenal tumor or hyperplasia.
3. **Electrocardiography.** The electrocardiogram (ECG) may appear normal in hypokalemia or may show conduction defects. The ECG changes do not always correlate with a specific potassium level as they do in hyperkalemia. ECG changes that are seen with hypokalemia include ST-segment depression, presence of or prominent U wave, flattening or inversion of or biphasic T wave, increase in P wave amplitude, prolonged PR interval, and decreased T-wave amplitude. Ventricular and atrial arrhythmias may also develop. The U-wave appearance may mimic atrial flutter. Note that these ECG findings are also seen in hypomagnesemia. There is a risk of significant cardiac arrhythmias if the infant has hypokalemia and is receiving digoxin. Digoxin toxicity is worsened in hypokalemia because digoxin binds to the ATPase pump on the same site as potassium. If potassium levels are low, it enables digoxin to bind more to the ATPase pump and increases digoxin toxicity.
4. **Magnetic resonance image of the head** to rule out pituitary tumor if indicated.

V. Plan

A. General measures. The following are generally accepted approaches to hypokalemia. Follow local institutional protocols if available. Treatment depends on whether the infant has ECG changes, whether the infant has any signs of hypokalemia, the severity of the signs, and the degree of hypokalemia present. Hypokalemia is increasing in neonatal intensive care units because of the widespread use of diuretics.

1. **Prevent life-threatening cardiac and muscular complications first,** and then replenish total potassium stores so that normal blood levels are maintained.
2. **Rapid correction of hypokalemia is not recommended** because of hyperkalemia risk with potential cardiac complications (arrhythmias and cardiac arrest).
3. **Bolus intravenous potassium administration is not recommended** as it may cause damage to the veins and occasionally hyperkalemia, because potassium does not rapidly equilibrate.
4. **Oral replacement is always preferred.**
5. **If an infant is unable to tolerate oral replacement** (ileus, emesis) IV potassium is recommended.
6. **Formula for slow correction (over 24 hours) of potassium replacement is:**

$$\text{Potassium deficit (mEq/L)} = (\text{Normal potassium} - \text{Observed potassium}) \\ \times \text{Body weight in kg} \times 0.3$$

7. **The maximum recommended intravenous concentration is 40 mEq/100 mL (400 mEq/L) of potassium chloride** in patients with a central line. Peripheral intravenous (IV) line should be limited to 20 mEq/L.
 8. **Serum potassium levels should be monitored every 4 to 6 hours** until correction is achieved. Once levels reach high normal, decrease the amount of potassium given.
 9. **If alkalosis is present**, treatment is potassium chloride to replenish chloride.
 10. **If the infant is acidotic**, preferred treatment is potassium acetate (IV) or potassium bicarbonate (oral). **Rapid correction of acidosis may worsen hypokalemia.**
 11. **Correct low magnesium before treating with potassium** (see Chapter 105). It is ineffective to treat hypokalemia without treating the hypomagnesemia. If the low serum magnesium is not treated, the hypokalemia may get worse and become refractory to treatment. Dosage of magnesium sulfate is 25 to 50 mg/kg/dose IV every 8 to 12 hours for 2 to 3 doses.
 12. **Do not dilute potassium salts in a dextrose-containing solution** because it causes secretion of insulin and cellular potassium uptake, which can further lower the potassium. It should be diluted in normal saline.
 13. **Remember that excessive correction of hypokalemia** may result in hyperkalemia.
 14. **Oral potassium supplements** are available as chloride, bicarbonate, citrate, gluconate, and phosphate salts. Recommendations for treatment with oral potassium supplements are as follows:
 - a. **Potassium bicarbonate:** Used in infants with hypokalemia with metabolic acidosis (eg, RTA or diarrhea).
 - b. **Potassium phosphate:** Used only in infants with hypokalemia and hypophosphatemia (eg, proximal RTA with Fanconi syndrome or phosphate wasting).
 - c. **Potassium chloride:** Used in infants with hypokalemia, hypochloremia, and metabolic alkalosis (eg, diuretic therapy–induced hypokalemia, vomiting). Used in infants with hypovolemia.
- B. Emergency treatment.** Limited to infants with life-threatening symptoms of hypokalemia (cardiac arrhythmias, severe respiratory depression/distress, extreme muscle weakness/paralysis) or for a serum potassium level <2.0 to 2.5 mEq/L (**controversial** as to what critical level to treat regardless of clinical signs; varies from 1.5 to 2.5 mEq/L). Aggressive treatment with IV potassium requires ECG monitoring. Never give a bolus of potassium; give potassium chloride 0.5 to 1 mEq/kg/dose over 1 hour (some sources suggest 2 hours) with continuous ECG monitoring (maximum infusion rate: 1 mEq/kg/h).
- C. Moderate symptomatic hypokalemia.** Use IV potassium with ECG monitoring.
1. **Abnormal electrocardiogram: ST-segment depression, T-wave depression, U-wave elevation:** Treat with potassium chloride 0.5 to 1 mEq/kg IV over 3 to 4 hours with ECG monitoring.
 2. **Normal electrocardiogram:** Add 20 mEq of potassium chloride per liter to peripheral vein IV fluids. If higher concentrations are needed a central line is necessary. Otherwise increase the amount in the IV fluids (preferred) or a slow correction over 24 hours (see formula Section V.A.6).
- D. Mild asymptomatic hypokalemia.** May resolve without treatment. The majority of cases can be corrected by increasing the daily potassium intake by 1 to 2 mEq/kg. If the infant is not on potassium supplements and is on oral feeding, oral supplementation with potassium chloride may be given, usually 2 to 3 mEq/kg/d in 3 to 4 divided doses (diluted with feedings), adjusted depending on serum potassium levels.
- E. Hypokalemia with hypovolemia/polyuria.** IV fluid with potassium chloride is indicated.
- F. Specific measures.** Any specific defects (eg, renal defects, adrenal disorders, and certain metabolic problems) require specific evaluation and therapy.

1. **Inadequate maintenance infusion of potassium.** Calculate the normal maintenance infusion of potassium that should be given and increase the amount accordingly (normal maintenance infusion is 1–2 mEq/kg/d, usually only necessary after the first day of life). Make sure potassium intake in early parenteral nutrition is adequate.
 2. **Abnormal potassium losses**
 - a. **Medications.** If the infant is receiving potassium-wasting medications, increase the maintenance dose of potassium (eg, patients with bronchopulmonary dysplasia on long-term furosemide therapy). Oral supplementation with potassium chloride may be given, 1 to 2 mEq/kg/d in 3 to 4 divided doses (with feedings), adjusted depending on serum potassium levels. It was once thought that a potassium-sparing diuretic decreased the amount of potassium supplementation; however, a randomized study showed that the serum electrolytes sodium and potassium were not affected by the addition of spironolactone.
 - b. **Gastrointestinal losses**
 - i. **Severe diarrhea correction.** Withhold oral feedings to allow the gut to rest and give IV fluids to correct dehydration. Add potassium to the IV fluids (initial dose of potassium chloride: 1–2 mEq/kg/d). Serum potassium levels are monitored, and the IV dose is adjusted.
 - ii. **Nasogastric drainage/severe vomiting.** This amount should be measured each shift and replaced milliliter per milliliter with 1/2 normal saline with 10 to 20 mEq of potassium chloride per liter.
 - iii. **Pyloric stenosis.** Correct dehydration or electrolyte issues if present. Surgery (pyloromyotomy) is indicated.
- G. Renal loss of potassium.** Other than induced by medications.
1. **Bartter syndrome.** Correction of fluid and electrolyte imbalance. Potassium supplementation is given orally with a starting dosage of 2 to 3 mEq/kg/d, which is increased as necessary to maintain a normal serum potassium level. Treatment consists of using indomethacin, a prostaglandin synthetase inhibitor that corrects the biochemical abnormalities and decreases the urine volume.
 2. **Hyperaldosteronism.** Surgery and dexamethasone therapy may be indicated.
 3. **Cushing syndrome.** Surgical resection and postoperative glucocorticoid replacement are necessary.
 4. **Renal tubular acidosis types 1 and 2.** Alkaline therapy and potassium supplementation if needed.
- H. Redistribution of potassium**
1. **Alkalosis.** Determine the cause of metabolic or respiratory alkalosis and treat the underlying disorder. Treat the alkalosis before increasing potassium intake.
 2. **Medications.** Should be discontinued if possible, or alternatives should be used that do not affect potassium (see Section III.B.3.a).

69 Hyponatremia

- I. Problem.** An infant has a serum sodium of 127 mEq/L, below the normal accepted value of 135 mEq/L. Hyponatremia, defined as a low sodium, is the most common electrolyte disorder in neonates. It occurs in approximately 33% of very low birthweight infants and is seen in up to 65% of very sick neonates. It is controversial as to what level of sodium constitutes hyponatremia in neonates. In adults, a level <135 mEq/L

is considered hyponatremia; in neonates, various levels have been quoted (from <130 mEq/L to <136 mEq/L). **Most sources agree that hyponatremia in neonates is defined as a serum sodium <135 mEq/L.**

Hyponatremia is not benign and is frequently associated with significant morbidity (poor neurologic outcome [at 2 and 10–13 years of age], intracranial hemorrhage, sensorineural hearing loss, cerebral palsy, and poor growth [at 10–13 years of age]). Infants with late-onset hyponatremia have an increased risk of bronchopulmonary dysplasia (BPD) and retinopathy of prematurity (ROP) requiring surgery and longer hospital stays. If the infant has hyponatremia for >7 days, the infant has an increased risk of moderate to severe BPD, periventricular leukomalacia, and extrauterine growth retardation.

II. Immediate questions

- A. **Is there any seizure activity?** Seizure activity can be seen in patients with extremely low serum sodium levels (usually <120 mEq/L). Most often, seizures are generalized tonic clonic but they can also be focal. **This is a medical emergency**, and urgent correction of intravenous (IV) sodium is needed.
- B. **How much sodium and free water is the patient receiving? Is weight gain or loss occurring?** Be certain that an adequate amount of sodium is being given and that free water intake is not excessive. The normal amount of sodium intake is 2 to 4 mEq/kg/d. Weight gain with low serum sodium levels is most likely a result of volume overload, especially in the first day or 2 of life, when weight loss is expected.
- C. **What is the urine output?** With syndrome of inappropriate secretion of antidiuretic hormone (SIADH), urine output is decreased. If the urine output is increased (>4 mL/kg/h), perform a spot check of urine sodium to determine whether urinary sodium losses are high.
- D. **What medications is the infant receiving? Are renal salt-wasting medications being given?** Diuretics such as furosemide may cause hypovolemic hyponatremia. Other medications that cause hyponatremia include indomethacin, amphotericin B, theophylline, carbamazepine, chlorpromazine, indapamide, amiodarone, and selective serotonin reuptake inhibitors. Most of these cause SIADH (euvolemic hyponatremia). Morphine and barbiturates can also cause hyponatremia. Aminoglycosides and diuretics have natriuretic effects (cause excessive sodium loss in the urine). Caffeine and corticosteroids may also play a role because they increase sodium excretion in adults.
- E. **Did the mother receive hypotonic intravenous fluids or an excessive amount of oxytocin? Was the mother hyponatremic in the intrapartum period?** If so, the infant can have hyponatremia at birth. Infants of mothers with hyponatremia (eg, diet deficient of sodium) can have low levels of sodium after delivery and are at a risk for early-onset hyponatremia. Increased maternal intake of water (psychogenic drinking during labor) can cause maternal hyponatremia, resulting in hyponatremia after birth. Fetal sodium levels mimic maternal levels. Fetal hyponatremia can cause tachypnea, jaundice, and seizures in the fetus and occurs when the fetal sodium equilibrates with the maternal sodium during pregnancy.
- F. **What medications was the mother getting during pregnancy?** Maternal medication use during pregnancy (eg, diuretics, infusion of oxytocin and glucose, nebulolol) can cause hyponatremia in the infant. Tocolytic therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) can cause hyponatremia after birth.
- G. **Is the infant premature and <1 week old (early-onset hyponatremia), or is the infant 2 weeks of age or older after achieving full feeding (late-onset hyponatremia)?**
 1. **Early-onset hyponatremia** is usually due to free total water excess with a normal total body sodium from either increased maternal free water in labor or perinatal nonosmotic release of vasopressin (antidiuretic hormone [ADH]) (occurs in perinatal asphyxia, respiratory distress syndrome, bilateral pneumothoraces, intraventricular hemorrhage [IVH], and with certain medications). It can also occur from too much free water being given or not enough sodium intake in fluids.

2. **Late-onset hyponatremia** is usually from a negative sodium balance. It is usually caused by inadequate or low sodium intake or excessive salt losses (most common in preterm infant due to immature renal or intestinal function). Common causes are low sodium intake, diuretic therapy, and mineralocorticoid deficiency (congenital adrenal hyperplasia most commonly caused by 21-hydroxylase deficiency). Late-onset hyponatremia can also be from excessive ADH release, renal failure in infants, or edema causing retention of free water, but these causes are less common. Preterm infants >28 weeks have a high fractional excretion of sodium. Risk factors for late-onset hyponatremia include lower gestational age, respiratory distress syndrome, shorter duration of parenteral nutrition, use of furosemide, and breast feeding. Infants with late-onset hyponatremia have an increased risk of BPD and ROP requiring surgery and longer hospital stays. If an infant has late-onset hyponatremia for >7 days, the infant is at increased risk of moderate to severe BPD, periventricular leukomalacia, and extrauterine growth retardation.

III. **Differential diagnosis.** Hyponatremia can be categorized based on the osmolality of the serum (hypotonic hyponatremia <280 mOsm/L, hypertonic hyponatremia >295 mOsm/L, or isotonic hyponatremia 285–295 mOsm/L). When considering the differential, first rule out pseudohyponatremia (isotonic hyponatremia) and use of osmotic agents or high glucose (hypertonic hyponatremia). Once those are ruled out, **true hyponatremia is likely present, which is hypotonic.** True hyponatremia can be further divided into 3 categories based on the volume status (hypovolemia, euvolemia, and hypervolemia). **The most common cause of hyponatremia in the neonate is hypervolemia hyponatremia (dilutional) caused by excessive fluid administration or retention of free water.** Causes of hyponatremia in a newborn include the following:

- A. **Pseudohyponatremia** (other names: isotonic hyponatremia, factitious hyponatremia). This occurs in infants with a normal osmolality. Both hyperlipidemia and hyperproteinemia can cause pseudohyponatremia. **Hyperlipidemia** (an increase in lipid levels in the plasma level) or **hyperproteinemia** (an increase in proteins in the plasma level) can cause a decreased sodium because there is less plasma water due to the increase in lipids or proteins. This used to occur with **older lab testing techniques** (flame emission spectrophotometry and indirect potentiometry). Today, because most labs use direct ion-specific electrode potentiometry, this is uncommon (verify local lab technique if isotonic hyponatremia is detected in a patient).
- B. **Hypertonic hyponatremia** (other names: translocation or redistributive hyponatremia). This occurs in infants with a high serum osmolality. Mannitol, hyperglycemia, glycerol, sucrose, maltose, dextran, and IV radiocontrast substances can all cause a hypertonic hyponatremia, whereby an increase in serum osmolality causes water and potassium to be pushed out of cells with an increase in extracellular fluid (ECF) volume, resulting in hyponatremia. In the neonate, it is occasionally seen with **hyperglycemia**; an accumulation of extracellular glucose causes a shift of free water from the intracellular space to the extracellular space. **For every 100 mg/dL increase in glucose, the sodium falls by about 1.6 mEq/L.** Once the hyperglycemia is corrected, the sodium will correct.
- C. **Spurious result.** Can occur from a diluted sample drawn from an indwelling catheter with a low-sodium fluid.
- D. **True hyponatremia is hypo-osmolar** because of its low serum osmolality. It has also been called hypotonic hyponatremia. **There are 3 categories of hyponatremia based on the ECF volume: hyponatremia with hypervolemia, hyponatremia with normo-/euvolemia, and hyponatremia with hypovolemia.** Etiologies are based on whether urine sodium and fractional excretion of sodium are high or low.
 1. **Hyponatremia with hypervolemia.** This occurs with excess of ECF. There is a positive water balance. The total body sodium and total body water are increased. ECF is very increased, resulting in edema and weight gain. One can also see increasing blood urea nitrogen (BUN) and increasing urine specific gravity. Causes include the following:

- a. **Urine sodium <20 mEq/L and low fractional excretion of sodium:** Edematous states, congestive heart failure, liver failure/cirrhosis, nephrotic syndrome, neuromuscular blockage/paralysis, indomethacin therapy (causes water retention), sepsis with decreasing cardiac output, hypoalbuminemia.
 - b. **Urine sodium >20 mEq/L and high fractional excretion of sodium:** Acute kidney injury (AKI) and chronic kidney failure. Hyponatremia was the most common electrolyte disturbance in AKI.
2. **Hyponatremia with hypovolemia.** This occurs with a deficit of ECF and can be caused by either renal or extrarenal losses. The total body sodium and total body water and ECF are all decreased. Signs include weight loss, poor skin turgor, increasing BUN, metabolic acidosis, and tachycardia.
- a. **Urine sodium >20 mEq/L and high fractional excretion of sodium (renal solute loss)**
 - i. **Diuretics** (most common cause of urinary sodium loss in the neonate).
 - ii. **Renal immaturity.** Neonates can have immature kidneys. Preterm infants are prone to hyponatremia because of a lower glomerular filtration rate, lower proximal tubular reabsorption of sodium, and an increase arginine vasopressin level when sick. Often very low birth-weight infants show increased renal tubular sodium and water loss causing hyponatremia.
 - iii. **Salt-losing nephropathies.**
 - iv. **Metabolic alkalosis.**
 - v. **Osmotic diuresis.**
 - vi. **Renal tubular acidosis.**
 - vii. **Obstructive uropathy correction** can cause high urinary losses of sodium.
 - viii. **Bartter and Fanconi syndromes.** Bartter syndrome is associated with polyhydramnios and hypokalemic alkalosis.
 - ix. **Hypertension-hyponatremia syndrome in neonates caused by renovascular pathology.** Renal ischemia from renal microthrombi can be the cause. Suspect if umbilical artery catheter has been placed and unilateral renal arterial stenosis is present.
 - x. **Mineralocorticoid deficiency (adrenal salt-wasting disorders):** Addison disease, hypoadosteronism, congenital adrenal hyperplasia, hypopituitarism, pseudohypoadosteronism types 1 and 2, bilateral adrenal hemorrhage.
 - xi. **Cerebral salt-wasting syndrome.** Occurs when there is loss of sodium in the urine and is secondary to acute or chronic damage to the central nervous system (hemorrhage, increased intracranial pressure). Extracellular volume is decreased, and BUN, albumin, and hematocrit are increased.
 - b. **Urinary sodium <20 mEq/L and low fractional excretion of sodium (extrarenal losses).** Gastrointestinal losses such as vomiting, diarrhea, nasogastric tubes, ostomies, and fistulas. Infants with intestinal surgical diversions (stomas) are at risk for sodium deficiency; **third spacing of fluids** such as ascites, pleural effusion, ileus, sepsis, early necrotizing enterocolitis, or sloughing of skin; chest tube fluid loss; cerebrospinal fluid drainage; radiant warmer skin loss.
3. **Hyponatremia with euvolemia/normovolemia (normal extracellular fluid).** Total body water is increased, total sodium is normal or slightly decreased, and ECF is minimally increased but there is no edema.
- a. **Urine sodium >20 mEq/L and high fractional excretion of sodium**
 - i. **Syndrome of inappropriate secretion of antidiuretic hormone.** ADH is normally secreted when blood volume is decreased. SIADH occurs when there is an inappropriate secretion of ADH despite normovolemia.

It occurs when there is normal renal, hepatic, cardiac, adrenal, and thyroid function. It causes plasma hyponatremia and hypo-osmolality and hyperosmolality of the urine usually with a high urine sodium concentration (>20 mEq/L) unless sodium intake is low. On physical examination, there are no signs of volume depletion or edema. It occurs commonly in central nervous system disorders (eg, IVH, encephalitis, perinatal asphyxia, meningitis) and also with lung disease (eg, respiratory distress, pneumonia, pneumothorax). SIADH is often seen in critically ill premature and term neonates and is seen in association with pain, stress, and general anesthesia. Medications associated with SIADH include opiates, carbamazepine, barbiturates, indomethacin, theophylline, NSAIDs, thiazides, and maternal oxytocin. **Reset osmostat**, a subtype of SIADH, has a subnormal threshold for ADH secretion and is a rare cause of hyponatremia.

ii. **Nephrogenic syndrome of inappropriate antidiuresis** is very rare, is hereditary, and is caused by a gain-of-function mutation in *AVPR2*, which causes prolonged euvolemic hyponatremia. **Nephrogenic syndrome of inappropriate antidiuresis has a low vasopressin level, whereas SIADH has a high vasopressin level.**

iii. **Endocrine related.** Severe hypothyroidism or glucocorticoid deficiency. With unexplained hyponatremia, consider hypothyroidism.

b. Urine sodium <20 mEq/L and low fractional excretion of sodium

i. **Excessive intravenous fluids, free water, or using diluted (hypotonic) formulas.** Maternal fluid overload (with glucose-only sodium-free solutions) or maternal water intoxication can cause dilutional hyponatremia. This is associated with a low urine specific gravity, low urine sodium, low fractional excretion of sodium (FE_{Na}), and high urine output.

ii. **Inadequate sodium intake, sodium restriction.** Preterm infants have increased sodium intake requirements, and it should be provided to maintain serum sodium values and to promote adequate growth. Maintenance sodium is usually 2 to 4 mEq/kg/d. For recommended sodium intake for gestational age and postnatal age, see Table 69–1.

E. Drug-induced hyponatremia. Diuretics (used frequently with BPD/chronic lung disease [CLD]) can lead to sodium losses. Indomethacin causes water retention (dilutional hyponatremia). SIADH can be due to medications, as noted previously. Infusion of mannitol or hypertonic glucose can cause hyperosmolality with salt wasting. Amphotericin B can lead to sodium and potassium imbalances. Maternal medication use during pregnancy (diuretics, infusion of oxytocin and glucose, nebulolol) can cause hyponatremia in the infant.

Table 69–1. RECOMMENDED SODIUM INTAKE (mEq/KG/D) ACCORDING TO GESTATIONAL AND POSTNATAL AGES

Gestational Age	Postnatal Age in Days				
	1–2	3	7	14	30
<28 weeks	3	6–12	4–8	3–6	2–4
29–31 weeks	2	4–7	2–4	2–4	1–2
32–36 weeks	1	3–5	2–3	1–2	1–2

IV. Database

A. Review the bedside data.

- 1. Check for weight loss or gain.** Weight gain is more likely to be associated with dilutional hyponatremia. Weight loss is seen with hyponatremia with decreased ECF.
- 2. Check fluid intake and output over a 24-hour period.** Normally, infants retain two-thirds of the fluid administered, and the rest is lost in the urine or by insensible loss. If the input is much greater than the output, the patient may be retaining fluid, and dilutional hyponatremia should be considered.
- 3. Assess the urine output and specific gravity.** A low urine output with a high specific gravity is more commonly seen with SIADH. In excessive fluid, one sees a low urine specific gravity and a high urine output.

- B. History and physical examination.** Are there maternal factors present (hypotonic IV fluids or an excessive amount of oxytocin), or was there maternal hyponatremia in the intrapartum period? The neurologic status is very important because it might guide treatment. Note any signs of seizure activity (abnormal eye movements, jerking of the extremities, and tongue thrusting). Is there a bulging fontanel or any lethargy? Check for edema, a sign of volume overload (renal failure, congestive heart failure). Decreased skin turgor and dry mucous membranes are seen in dehydration. Is the infant in shock? Does the infant have genital hyperpigmentation (congenital adrenal hyperplasia)? Is there virilization or ambiguous genitalia in a female infant or hypospadias in a male (3- β -hydroxysteroid dehydrogenase deficiency)? Specific signs and symptoms of hypovolemic hyponatremia include decreased blood pressure, depressed fontanelle, reduced capillary refill time, decreased urine output, and decreased skin turgor. Specific signs and symptoms of hypervolemic hyponatremia include edema, ascites, and pulmonary edema.

- C. Laboratory studies.** See Table 69–2 for laboratory findings in specific diagnoses.

1. Specific tests

Table 69–2. HYPONATREMIA AND LABORATORY FINDINGS IN SPECIFIC DIAGNOSES

	Urine Output	Urine Sodium/ FE_{Na}	Urine Osmolality	Urine Specific Gravity
Excess fluid intake	Increased	Decreased	Decreased	Decreased
SIADH	Decreased	Increased	Increased	Increased
GI/skin/third spacing	Decreased	Decreased	Increased	Increased
Renal losses	Increased	Increased	Increased	Increased
Insufficient Na supply	Normal	Decreased	Normal	Normal
AKI prerenal	Decreased	Decreased	Increased	Increased
AKI intrinsic	Increased	Increased	Isoosmolar	Isosthenuric
Dehydration	Decreased	Decreased	Increased	Increased
CHF, hepatic failure	Decreased unless on diuretics	Decreased unless on diuretics	Increased	Increased
Hypoalbuminemia	Decreased	Decreased	Decreased	Decreased

AKI, acute kidney injury; CHF, congestive heart failure; FE_{Na} , fractional excretion of sodium; GI, gastrointestinal; IV, intravenous; NA, sodium; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

- a. **Serum sodium and osmolality** to verify true hyponatremia and rule out pseudohyponatremia and hypertonic hyponatremia.
- b. **Urine sodium, osmolality, and specific gravity.** A urinary sodium content is accepted by many as reflecting total body sodium deficiency, but it can be misleading since the concentration of sodium in the urine is dependent on the free water amount in the urine. There is also no consensus on normal and abnormal urinary sodium values in newborns. Urinary sodium concentrations vary from <10 to 30 mEq/L or >20 to 40 mEq/L.
 - i. **Low urine sodium:** Extrarenal losses (eg, vomiting, diarrhea, ostomies, nasogastric suction, drainage tubes, ileus, necrotizing enterocolitis, pleural effusions, ascites) and edematous states (congestive heart failure, nephrotic syndrome, liver failure/cirrhosis, indomethacin therapy, water intoxication, vomiting, diarrhea, ostomies, nasogastric suction, polydipsia).
 - ii. **High urine sodium:** Diuretic use, renal tubular disorders, SIADH, mineralocorticoid or glucocorticoid deficiency, AKI, chronic renal failure, hypothyroidism, Fanconi/Bartter syndrome, obstructive uropathy and metabolic alkalosis, osmotic diuresis.
 - iii. **Urine osmolality,** a measure of urine concentration, and urine specific gravity, a measure of solutes in the urine, can both help in the differential of hyponatremia.
- c. **Urine creatinine and plasma creatinine to calculate fractional excretion of sodium.** FE_{Na} is the percentage of sodium filtered by the kidney that is excreted in the urine and is calculated by obtaining the urine and plasma sodium and the urine and plasma creatinine. It is considered more accurate than the urinary sodium since urinary sodium concentrations can vary with water reabsorption. FE_{Na} varies inversely with gestational age and postnatal age. Higher values are used in preterm infants. Normal values vary with reference. Some commonly used values are: $FE_{Na} >5\%$ is increased or high and $FE_{Na} <3\%$ is decreased or low.

$$FE_{Na} = \frac{\text{Urinary sodium} \times \text{Plasma creatinine}}{\text{Plasma sodium} \times \text{Urinary creatinine}} \times 100$$

- d. **Serum electrolytes, blood urea nitrogen, creatinine, and total protein** to assess renal function. Serum glucose to rule out hypertonic hyponatremia.
 - e. **Syndrome of inappropriate secretion of antidiuretic hormone.** The diagnosis is made by documenting the following on simultaneous laboratory studies: low urine output, urine osmolality greater than serum osmolality, low serum sodium level and low serum osmolality, and high urinary sodium level and high specific gravity. A plasma ADH concentration and a plasma concentration of atrial natriuretic peptide can be obtained. If they show a high ADH concentration in the presence of low serum osmolality and elevated urinary osmolality, the diagnosis is confirmed.
- D. Imaging and other studies**
1. **Ultrasound of the head or brain magnetic resonance imaging** may reveal IVH as a cause of hyponatremia secondary to SIADH.
 2. **Electroencephalogram** if seizure activity is present and cannot differentiate various electrolyte disturbances. The most prominent feature is slowing of the normal background activity with hyponatremia.
 3. **Electrocardiogram** if there is suspected cardiac arrhythmia. Hyponatremia causes elevated T wave with wide QRS complex.
 4. **Abdominal ultrasound** if obstructive uropathy is suspected; voiding cystourethrogram may also be helpful.

V. **Plan.** Treatment is essential, and an effort should be made to keep sodium in the normal range, especially in the preterm infant, because hyponatremia can cause future problems.

A. **Preventive therapy**

1. **Use of isotonic fluid is recommended in children** but is controversial in newborns. This is due to the risk of hyponatremia since the immature kidneys may not handle the sodium load.

2. **Monitor serum electrolytes in any infant** after initiation of IV fluids.

3. **Monitor high-risk infants at risk for hyponatremia**, including the risk of SIADH, especially in very premature infants.

4. **Make sure sodium supplementation is adequate for gestational and postnatal age.** Sodium supplementation of enteral feedings in very premature infants prevents hyponatremia and enhances weight gain. Serum sodium values should be maintained between 135 and 145 mEq/L to promote adequate growth. See Table 69–1 for recommended sodium intake according to gestational age and postnatal age (in infants who are stable, euvoletic, and not receiving sodium-altering medications).

B. **Treatment of hyponatremia.** If infant is symptomatic and hyponatremia is severe, immediate treatment is indicated. If not symptomatic, hyponatremia should be corrected slowly over 24 to 48 hours.

1. **Emergency treatment.** For symptomatic infants with seizures or infants with repeated apnea requiring intubation, severe neurologic symptoms (**early symptoms:** weakness, irritability, vomiting; **later symptoms:** apnea, coma, arrhythmias, hypothermia) or refractory status epilepticus as a result of low sodium (usually <120 mEq/dL), immediate hypertonic saline solution (3% sodium chloride) should be given. **Rapid corrections** (especially in chronic hyponatremia or a >8–10 mEq/L increase in serum sodium over 24 hours) can cause brain damage (**central pontine myelinolysis**). Suspect this in a neonate who, in the course of the correction, develops cranial nerve dysfunction and quadriparesis. Magnetic resonance imaging shows a round lesion in the central pontine area. **Once symptoms resolve** and the serum sodium is >120 mEq/dL, a slow correction can be given over 24 to 48 hours. There is **controversy** regarding the rate and how it should be given. Follow institutional guidelines.

a. **Intravenous bolus over 10 to 15 minutes (1–2 mL/kg of 3% sodium chloride [513 mEq sodium/L]).** This method should be reserved for only those patients with severe hyponatremia with severe symptoms such as seizures, repeated apnea episodes requiring intubation, signs of brainstem herniation, or refractory status epilepticus (**controversial**). This method (2 mL/kg bolus of 3% sodium chloride over 10 minutes) is recommended for hyponatremic encephalopathy in children. Many NICUS will calculate the deficit to a level of 125 mEq/dL and use hypertonic saline for a correction over 4 to 8 hours.

b. **Twenty-four-hour correction.** The total body deficit can be calculated (see Section V.D.2.c), and half of that is given over 12 to 24 hours. Recommendations include not to give >8 to 10 mEq/L over the first 24 hours for acute hyponatremia and not to give >6 to 8 mEq/L over 24 hours for chronic hyponatremia.
