Only a few drugs such as large peptides (e.g. insulin), papain, streptokinase and foreign antisera can directly induce an immune response. The majority of drugs are simple chemicals of low molecular weight that are not immunogenic unless combined with serum or tissue proteins to form an immunogenic complex. Thus most drugs that cause hypersensitivity reactions must first be made immunogenic by being haptenated onto proteins, a process that occurs as the drug is metabolized. The cytochrome P450-dependent oxidation pathway in the liver is an important enzyme involved in the production of these reactive drug intermediates that covalently bind to serum and membrane proteins. Penicillin is an exception, as it may haptenate proteins directly without previous metabolism. Acylation of serum proteins results from an amine bond formed from the hydrolyzed beta-lactam ring of the antibiotic.

### Diagnosis and management

Diagnosis of drug allergy is largely based on history (Table 33.7) and examination. Although diagnostic testing methods exist, overall they are still of limited practical value for the clinician who is evaluating a patient with suspected drug allergy. One major problem that affects the use of diagnostic tests for drug allergies is that, except for penicillin,

**Table 33.7** Important questions to ask in the history of a patient with suspected drug allergy

1. What drugs were administered, by what route and at what dose?
2. For what reason was the drug administered?
3. How long after starting the drug did the reaction commence?
4. What was the nature of the reaction?
5. What treatment if any was required for the reaction?
6. What happened when the drug was discontinued?
7. Has the patient taken the drug (or similar drugs) before and after the reaction? If so, what was the result?
8. How old was the patient at the time of the reaction?

the immunochemistry of most drugs is still not known. In most instances the definitive test for drug allergy is rechallenge; this must be approached with caution as it may precipitate anaphylactic reactions.

In children where the use of a particular drug is essential and there are no alternatives, hyposensitization can be used to induce tolerance in a highly sensitized patient.<sup>69</sup> The procedure is performed by the cautious administration of incremental doses of the drug to the patient over a period of hours to days. The drug can be administered either by oral or i.v. route. The starting dose for the procedure can be determined by performing intradermal skin tests with the native drug at a dose that does not cause a nonspecific reaction. Typically, doses are doubled every 15–30 min and vital signs, physical examination, and peak flow values are regularly monitored. It is critical that the individuals involved with the hyposensitization procedure understand that it can have serious consequences. While anaphylactic reactions rarely occur if conservative protocols are used, health care personnel must be prepared to treat anaphylaxis if it does happen.

### Penicillin and cephalosporin allergy

Anaphylactic reactions occur in approximately 1 per 10 000 penicillin or cephalosporin courses and are mostly seen in adults between the ages of 20 and 49 years. Only 2–6% of patients with a history of acute penicillin allergy are also allergic to cephalosporins. A history of atopy does not generally place an individual at increased risk for an IgE-mediated penicillin reaction.

Degradation products of penicillin may bind with tissue or serum proteins to form an immunogenic complex that can elicit an immune response. Penicillin allergy is attributed either to the benzylpenicilloyl hapten (the so-called 'major' determinant because 95% of tissue-bound penicillin is in this form), or to a group of compounds collectively called the 'minor' determinants, which are paradoxically responsible for many of the most severe allergic reactions. Adverse reactions to penicillin can be most simply classified by the timing of their occurrence. Immediate reactions occur within 1 h of administration and are usually directed against the minor determinant antigens. Life-threatening reactions occurring beyond 1 h of penicillin administration are rare.

The clinical features include urticaria, laryngeal edema, bronchospasm and anaphylactic shock. Accelerated reactions occur 1–72 h after penicillin administration, have the same clinical features as immediate reactions, and are usually directed against the major determinant. Late reactions, the mechanisms of which are generally less well understood, occur more than 72 h after drug administration. They comprise such disorders as a maculopapular (measles-like) rash, urticaria, serum sickness, erythema multiforme, hemolytic anemia, thrombocytopenia and neutropenia. Rarely, late reactions are due to the new development of an immediate or accelerated reaction. Only 3.5% of patients with a maculopapular rash associated with penicillin administration had adverse reactions to oral challenge with penicillin.<sup>70</sup> Maculopapular eruptions caused by penicillin may subside spontaneously despite continuing use of the drug and may not recur on re-exposure, presumably as many of these exanthema are due to the infectious disease rather than the antibiotic.

Ampicillin can provoke the same allergic reactions as other penicillins, but in addition is associated with a particularly high incidence of a non-allergic maculopapular rash, beginning a week or more after starting therapy.

An inquiry about possible penicillin allergy is mandatory prior to an injection of penicillin. However, not all patients with penicillin allergy give a history of previous penicillin administration. In these patients either the history is incorrect and the patient has received penicillin therapy, or sensitization has occurred through inadvertent exposure to penicillin in other sources such as food, milk or even soft drinks. Almost all deaths from anaphylaxis have resulted from injection of the drug, and the oral route has only been associated with a handful of fatal cases.

The penicillin skin test has no place in the management of patients without a clinical history of an IgE-mediated penicillin allergy, and is unnecessary in the face of a bona fide history of a life-threatening acute reaction, in which case the drug should be avoided. In cases where the history is suggestive of a milder acute hypersensitivity reaction, a negative result to skin testing is associated with tolerance to penicillin in 98% of cases. In contrast, a positive skin test result should lead to avoidance of this antibiotic, or use only after hyposensitization. There are no clinically useful skin tests or IgE tests for use in patients with suspected cephalosporin allergy. On the rare occasions in childhood (e.g. endocarditis) when treatment with penicillin is essential, then it is possible to hyposensitize the patient by oral and then continuous i.v. administration, but this procedure carries a risk of fatal anaphylaxis. The protection from hyposensitization is short lived, although it is possible to maintain a state of hyposensitization by long-term administration of a low dose.

### Aspirin – nonsteroidal anti-inflammatory drug intolerance

The prevalence of aspirin intolerance is around 5–6%. Up to 20% of the asthmatic population is sensitive to aspirin and other NSAIDs and present with a triad of perennial rhinitis, sinusitis and asthma when exposed to the offending drug. Chronic persistent inflammation is the hallmark of patients with aspirin-induced allergy.<sup>21</sup> Of the patients with aspirin-induced intolerance 50% have chronic, severe, corticosteroid-dependent asthma, 30% have moderate asthma that can be controlled with inhaled steroids, and the remaining 20% of patients have mild and intermittent asthma. Up to 25% of hospital admissions for acute asthma requiring mechanical ventilation may be due to NSAID ingestion.

Aspirin intolerance is now thought to be at least partly due to a deviation of the arachidonic acid metabolic pathway towards the production of excessive inflammatory leukotrienes (especially LTC<sub>4</sub> and away from the production of anti-inflammatory prostaglandins (PGE<sub>2</sub>). Leukotriene-modifying drugs (montelukast, zileuton) have been found to attenuate but not abolish aspirin-induced bronchial reactions in aspirin-induced intolerant patients. Salmeterol, a long-acting alpha<sub>2</sub>-agonist has also been found useful in the management of aspirin-induced intolerance.

### Local anesthetic agents

Older amino-ester LA (e.g. cocaine) are documented to cause allergic reactions, including contact dermatitis and redness or edema of the skin or mucous membranes. These compounds are no longer used as injectable local anesthetics and modern amide anesthetics (lidocaine [Xylocaine]), mepicaine [Carbocaine], bupivacaine [Marcain], prilocaine [Citanest] and articaine [Septanest] rarely if ever cause such reactions). Symptoms suggestive of an allergic reaction may be due to vasovagal reactions, adrenaline responses, 'panic attacks' and systemic toxic reactions. These effects are compounded by the fact that patients presenting for minor surgical and dental procedures under local anesthetics are usually anxious to start with, and up to 6% of patients have a problematic fear of needles. Infrequently, reactions may be to confounding factors such as latex or the preservative in preloaded syringes. In the latter case this is due to an irritant rather than allergic reaction to benzalkonium chloride, a quaternary ammonia cationic surfactant

that is also present in some skin disinfectants. If suspected, further reactions can be prevented by using preservative-free vials of the drug.

Local anesthetic agents are too small to be antigenic by themselves but are sufficiently alien to bind as haptens to tissues with antigenic properties. Large series including hundreds or thousands of patients have consistently shown that both skin prick tests and intradermal tests are negative in almost all patients referred with an adverse reaction.<sup>71</sup> Furthermore specific IgE in the few cases where there are reactions have been negative.

## ANAPHYLAXIS

In this chapter, and in the clinical situation, the term 'anaphylaxis' or 'anaphylactic shock' is taken to mean a severe life-threatening reaction of rapid onset, with circulatory collapse or respiratory compromise. In the past the term 'anaphylaxis' was used to describe any immediate allergic reaction caused by IgE antibodies, however mild, but such usage fails to distinguish between, for example, trivial urticaria and a life-threatening event. The mechanisms are believed to be IgE mediated (e.g. penicillin or insulin allergy), the generation of immune complexes (e.g. reactions to blood products), a direct (not involving antigens or antibodies) effect on mast cells or basophils causing inflammatory mediator release (e.g. reactions to radiocontrast media) and presumed abnormalities of arachidonic acid metabolism (e.g. anaphylactoid reactions to aspirin). It is possible to theoretically differentiate between anaphylaxis (immunologically mediated reactions) and anaphylactoid (non-immunologically mediated) reactions.<sup>72</sup> Previous sensitization is required for the former but not the latter.

The major causes of anaphylactic shock are drugs (e.g. penicillin, muscle relaxants), heterologous antisera (used for the prophylaxis and treatment of tetanus, diphtheria, rabies, snake bites and botulism), radiographic contrast media, the administration of blood products, hyposensitization injections, venoms from stinging insects (honeybee, wasp, hornet, yellow jacket) and foods (especially nuts, cows' milk, fish, shellfish and egg).<sup>73</sup> Death from anaphylaxis to medicines given intravenously usually occurs within a few minutes, while in the case of stinging insect stings it is usually delayed by 15 min and with foods by 30 min, although rarely it may be delayed for up to 6 h.<sup>73</sup> In general, the sooner the symptoms occur the more severe is the reaction. The first symptoms are feeling unwell, feeling warm, generalized pruritus, fear, faintness and sneezing. In severe cases these early symptoms are quickly (in seconds or minutes) followed by loss of consciousness, and death from severe bronchospasm, suffocation (edema of the larynx, epiglottitis and pharynx) or shock and cardiac arrhythmia.<sup>74</sup>

## DIAGNOSIS OF ALLERGY – TAKING A HISTORY

The lack of really useful laboratory tests for allergy (see later) means that there is no substitute for a careful history.

### IMPORTANT QUESTIONS WHEN TAKING A HISTORY FOR ALLERGY

The history should include questions about:

1. when symptoms occur (e.g. day or night, time of year – tree pollen allergy occurs in early spring; grass pollen allergy in summer);
2. where symptoms occur (e.g. particular place);
3. when or where the patient is free of symptoms;
4. the presence of other allergic symptoms;
5. family history of allergy or atopic disease;
6. nature and quantity of substance thought to be causing reaction;
7. timing of reaction (e.g. immediate versus delayed);
8. severity of reaction (e.g. skin, respiratory, gut, circulatory, anaphylaxis);
9. time to resolution (e.g. hours, days, weeks);
10. response to treatment (e.g. no treatment required, antihistamines, intramuscular adrenaline);

11. previous contact with trigger and reactions (e.g. has a food previously been tolerated or previously caused a similar reaction?);
12. effect of changes in environment (e.g. if it is worse in a playground this might suggest a grass pollen allergy; if it resolves on holidays this might suggest house dust mite or pet allergy).

## OTHER CLUES FROM THE HISTORY

1. **The symptoms are worse at night.** Both asthma and eczema are often worse at night, but it is wrong to equate all nocturnal symptoms with house dust mite allergy, as there are other possible explanations. Circadian rhythms affecting airway caliber, bronchial reactivity<sup>75</sup> and cortisol secretion may account for some of the increase in symptoms at night in asthma. In eczema, heat, tiredness and low cortisol secretion may contribute to nocturnal symptoms. In theory a high concentration of house dust mite antigen found in some bedrooms could contribute to nocturnal symptoms in asthma, rhinitis or atopic eczema, but in one large study there was no association between worsening at night or on waking and the presence of house dust mite allergy.<sup>76</sup> Only improvement in the symptoms following the complete avoidance of house dust mites in the bedroom (very difficult to achieve – see later), and recurrence of symptoms on re-exposure, will prove the point. A study of the symptoms associated with house dust mite allergy showed that a history of symptoms being provoked during domestic activity that stirs up house dust (bed making, dusting, vacuuming, emptying a vacuum cleaner bag, sweeping, shaking out bedding) when house dust mite antigen becomes airborne, is probably the only reliable pointer to house dust mite allergy.<sup>76</sup>
2. **The symptoms are worse at certain times of the year.** The usual inference is that the symptoms are attributable to a seasonal allergen. Sometimes the history is convincing. For example, where sneezing and conjunctivitis occur each year in June and July on sunny days when the grass pollen count is high, it is highly probable that the symptoms are attributable to allergy to grass pollen. Often, the history is not so easy to interpret. For example, a worsening of asthma in August, September or October is often difficult to explain. Possibilities include allergy to inhaled molds, an increase in the number of house dust mites in the autumn, changes in the weather, or catching viral respiratory infections when returning to school after the summer holidays.<sup>77,78</sup>
3. **The symptoms are worse in certain weather conditions.** The reasons for attacks of asthma after a thunderstorm or heavy rainfall are not fully understood. Allergy to inhaled fungal spores, a fall in the barometric pressure, a sudden fall in air temperature, and release of allergenic starch granules from ruptured pollen grains are all possible explanations.
4. **The symptoms improve when the patient is away from home (e.g. on holiday).** Improvement in atopic eczema when the patient goes on holiday is frequently noted, but the reason is usually obscure. In one study<sup>79</sup> there was a significant correlation between improvement in eczema and a more southerly holiday location; improvement was common in holidays taken in the Mediterranean or further south (63/92 – 69%), while holidays in northern Britain were more likely to be associated with deterioration (27/100 – 27%) than improvement (13/100 – 13%). The absence of pets or house dust mites may be the explanation in some cases, although the improvement that occurs on holidays (the disease often virtually disappears) is far greater than the modest improvement that can be seen after admission to hospital in the same patients. Exposure to sea water, sunlight or lack of stress are believed by some parents to be the explanation for such improvement, but there is no evidence to support these ideas. The improvement or complete disappearance of asthma at high-altitude resorts, seen in some patients, is generally attributed to the absence of house dust mite and pet animal antigens.

5. **The presence or absence of a family history of atopic disease.** Patients with atopic disease often have a positive family history of atopic disease, though atopy is so common in the normal population (wheezing in 21%, eczema in 12% and hay fever in 4% of all children in the UK by the age of 5 years)<sup>80</sup> that a positive family history is a rather nonspecific finding. In an apparently atopic child, the absence of a positive family history is more important, and should make the physician reconsider a diagnosis of atopic disease.
6. **Multiplicity of symptoms.** Allergic symptoms are usually multiple. It is important to inquire if the patient has other symptoms or signs that may be allergic in origin, in addition to the presenting complaint, and these features are: wheezing, sneezing, pruritus, urticaria, perioral erythema, eczema and conjunctivitis. Several symptoms may coexist. Unilateral symptoms, whether nasal, ocular or respiratory suggest the presence of a non-allergic condition.
7. **Symptoms occurring after exposure to pets.** Several situations cause confusion:
  - a. The patient who is noted to have an immediate allergic reaction when stroking or being licked by, for example, a dog, but who is otherwise apparently able to live in the same house as the animal without obvious immediate allergic reactions; delayed reactions or enhanced bronchial reactivity may be overlooked.
  - b. The patient who apparently experiences an immediate allergic reaction to, for example, certain cats but not others; again, delayed reactions or enhanced bronchial reactivity may be overlooked.
  - c. The patient whose atopic disease predates the acquisition of a pet animal; the animal could still be an important trigger continuing to provoke the disease.
  - d. The patient who had a pet animal some years before the onset of symptoms; the animal could still be an important trigger.
  - e. The patient's symptoms did not improve when the pet was sent to live elsewhere for a few weeks; sufficient pet antigen to provoke disease may still be present in the household.

A major source of confusion is that parents equate allergy with immediate reactions and are unaware that constant exposure to pet antigen in the home tends to cause chronic rather than acute symptoms. Many patients who are allergic to pets react to minute traces of the animal, for example a few hairs on someone's clothing, and this explains why the disease in question fails to improve after the pet is removed from the household. For therapeutic trials to be meaningful, extensive cleaning of carpets, upholstered furniture, clothing and bedding is necessary to remove the allergen.

8. **Food intolerance.** Food intolerance is generally associated with multiple symptoms, and it is rare for a single symptom (e.g. asthma, rhinitis, abdominal pain) to be caused by food intolerance. Parents commonly overvalue food intolerance as a cause of symptoms. In one study, double-blind food challenges provoked symptoms in only 27 of 81 (33%) of children whose parents had reported food intolerance.<sup>81</sup>

## UNQUALIFIED REPORTS OF ALLERGY

It is unhelpful to write 'allergy' in a patient's notes without any description of the evidence for the diagnosis. Many untoward events are wrongly labeled as allergies. For example, there are several reasons why penicillin administration may be followed by an adverse event, but few justify a diagnosis of penicillin allergy. A rash during antibiotic therapy may be caused by an underlying infection, or by a coloring agent or preservative included in a liquid preparation of the antibiotic. Loose stools are likely to be due to an underlying viral infection or a disturbance of the gut flora, but it is common to find this described by parents as an allergy to the antibiotic. The incorrect and careless labeling of a child as having penicillin allergy may rob the patient of penicillin treatment for life. Common and similar examples are the patient said to be allergic to cows' milk, in whom inquiry reveals that this is based not on observation of the patient but on the fact that someone has placed the child on a

cows' milk-free diet, or the patient said to be allergic to something solely on the basis of skin or blood tests.

## SIMPLE CAUSE AND EFFECT

The interpretation of the observation that exposure to a single item (e.g. a cat) is followed within minutes by an obvious adverse event (e.g. sneezing and orbital edema) should be quite simple, but there are pitfalls. The history is more reliable if it is based on the parents' unprompted original observations. The parents' observations may be especially unreliable because:

1. There is a strong emotional underlay, e.g. strong attachment to a family pet, leading to underdiagnosis of allergy because the family members do not want to part with the animal.
2. In the case of food intolerance, double-blind studies have repeatedly shown parental histories to be particularly unreliable (see later).
3. In the case of behavioral symptoms, there is a widespread but mistaken belief in the importance of adverse reactions to foods or food additives.<sup>61</sup>
4. A parent's report of alleged allergic reactions may have been fabricated (factitious illness).

In general, the quicker the onset of the allergic reaction, the more reliable is the history. A history of the same allergic symptoms after repeated exposure to an allergen is more reliable than a report of a single episode.

## DIAGNOSTIC TESTING FOR ALLERGY

There is no ideal test that will predict with certainty whether avoidance of a specific allergen will improve or abolish symptoms in an individual. Some of the problems are due to difficulties intrinsic to the test, but some are inherent in the complex nature of atopic disease. Take, for example, a child with asthma who develops sneezing, conjunctivitis and angioedema of the orbit immediately after playing with a cat, and who has a positive skin prick test and positive RAST test to cat dander. Clearly it is logical that the child should avoid cats, but there is no guarantee that cat avoidance will help the patient's asthma. The reasons for the failure of allergen avoidance are discussed later, but can be summarized as:

1. The allergen was incompletely avoided.
2. The allergen was only one of several factors provoking the patient's disease.
3. The allergen was irrelevant to the patient's symptoms.

It is unrealistic to expect any clinical or laboratory test to cope with the first two of these problems. The best that can be hoped for is that a test will help establish the potential clinical relevance of a particular allergy. Regrettably, the currently available tests, described later, all suffer from serious limitations.

## SCRATCH, PRICK AND INTRADERMAL SKIN TESTS

The principle of these skin tests is that the skin wheal and flare reaction to an allergen demonstrates the presence of mast-cell-fixed antibody. This is mainly IgE antibody, although in theory it could also be IgG4 antibody. IgE is produced by plasma cells primarily in lymphoid tissue in the respiratory and gastrointestinal tract, and is distributed via the circulation to all parts of the body, so that the sensitization is generalized and therefore can be demonstrated by skin testing. Age influences the reaction, and a child under 2 years of age produces much less reaction than an older child.

Short-acting antihistamines (H<sub>1</sub> receptor antagonists) must be discontinued at least 5d prior to skin testing. Because of the variability of cutaneous reactivity, it is necessary to include positive and negative controls whenever skin prick tests are performed. The negative control solution should consist of the diluent used to preserve the allergen extracts. The positive control solution usually consists of histamine, and is mainly used to detect suppression of reactivity, for example caused by H<sub>1</sub> antihistamine medication.

### Scratch testing

A drop of allergen solution is placed on the skin, which is then scratched so as to superficially penetrate the skin. The scratch test introduces an inconstant amount of allergen through the skin and is therefore poorly standardized and produces results that are too variable for routine clinical use.<sup>82,83</sup>

### Prick testing

A drop of allergen solution is placed on the skin, which is then pricked with a plastic lance, and the result read after 15 min. The negative control should be negative, unless the patient has dermatographism. The histamine control should be positive, unless the patient has recently received H<sub>1</sub> antihistamines, which would invalidate negative skin test results. The flare is ignored, and the diameter of the wheal is measured. Later reactions may occur, but their significance is unclear. Prick tests can also produce variable results, but the introduction of standardized precision lances for prick testing has made the method potentially more reproducible.

The interpretation of skin prick tests is difficult. There is a lack of agreed definition about what constitutes a positive reaction.<sup>84</sup> Most definitions of a positive reaction are based on the absolute diameter of the wheal, with arbitrary cutoff points for positivity at 1 mm, 2 mm or 3 mm. The problems with the interpretation of prick test results in an individual patient are:

1. Skin prick test reactivity may be present in subjects with no clinical evidence of allergy.<sup>85,86</sup>
  2. Skin prick test reactivity may persist after clinical evidence of allergy has subsided.<sup>87</sup>
  3. Skin prick tests may be negative in some patients with allergies. For example, skin prick tests are negative in 13–17% of those with rhinitis provoked by pollen.<sup>88</sup>
  4. False-negative results may occur in infants and toddlers. The whealing capacity of the skin is diminished in early infancy, and when wheals are produced they are smaller than in later life, so that the criteria for a positive wheal must be adjusted.<sup>86</sup> There are no age-related guidelines for what constitutes a positive reaction.
  5. There is a poor correlation between the results of provocation tests and prick tests.
  6. Skin prick tests for foods are especially unreliable.<sup>60</sup> A positive result using a raw food antigen does not necessarily mean that the cooked food will cause a reaction.
  7. False-negative skin prick tests can occur after anaphylaxis.<sup>89</sup>
- The results of skin tests cannot be taken alone, but need to account for the history and physical findings.<sup>86,90</sup> From a carefully taken history one might suspect a particular allergen, and the finding of a positive prick test would increase the likelihood that the allergen was causing symptoms. Few people, however, would be prepared to ignore a strong history of allergy in the face of a negative prick test, yet it is illogical to regard the prick test as significant when it confirms the history and to disregard it when it fails to do so. The contentious issues in clinical practice are whether a child with atopic disease will benefit from attempts to avoid household pets, house dust mites or certain foods, but skin prick tests are unreliable predictors of response to such measures.

### Intradermal testing

Intradermal testing is painful, can cause fatal anaphylaxis, and is only performed for limited reasons and then only if a preliminary skin prick test is negative.<sup>91</sup> Intradermal tests are more sensitive than skin prick testing, and also produce more false-positive reactions. As with skin prick testing, there is a lack of agreement as to what constitutes a positive reaction. The number of false-positive reactions makes the interpretation of the results of intradermal testing even more difficult than skin prick testing.

### Skin patch testing

Patch testing is used to identify causative allergens in suspected allergic contact dermatitis, and is discussed elsewhere.<sup>92</sup>

### Measurement of circulating IgE antibody

In vitro tests for circulating allergen-specific IgE antibody (e.g. RAST tests) avoid possible confounding variables in skin testing, namely IgE affinity for mast cells, their tendency for degranulation, and skin reactivity to released mediators. Thus, in theory, the in vitro test should be more reliable than skin testing. However, the clinical interpretation of in vitro IgE antibody tests is subject to most of the same pitfalls as the interpretation of skin prick testing. Additional problems with IgE antibody tests are:

1. Cost.
2. The IgE antibody concentration in the plasma varies with allergen exposure. A few patients with allergic rhinitis are RAST negative before the pollen season, but become positive after the pollen season.
3. A very high level of total circulating IgE (e.g. in children with severe atopic eczema) may cause a false-positive result.
4. A very low level of circulating IgE may be associated with false-negative results.
5. A very high level of IgG antibody with the same allergen specificity as IgE antibody can cause a false-negative result.
6. For each allergen, the test differs in the degree to which it is influenced by elevated total serum IgE.
7. In vitro IgE assays are slightly less sensitive than skin testing.

In vitro tests for IgE antibody are only preferable to skin testing where the patient has had a very severe reaction to the allergen in question (because of the small risk of anaphylaxis with skin testing), where the patient has widespread skin disease (e.g. atopic eczema), where the skin shows dermatographism, or when H<sub>1</sub> antihistamines cannot be discontinued.

### Provocation challenge tests

With the exception of food challenges in patients with suspected food intolerance, provocation tests (bronchial, nasal, conjunctival) have little place in routine clinical practice but have been helpful in the study of the pathophysiology and pharmacology of atopic disease. The results suffer from the same major limitation as the results of skin or IgE antibody testing, which is that a positive result from an allergen challenge by no means proves that the allergen is contributing to the patient's disease.

### Blinded oral food challenge

The test comprises the oral administration of a challenge substance, which is either the item under investigation or an indistinguishable inactive (placebo) substance. Neither the child, the parents nor the observers know the identity of the administered material at the time of the challenge. Food challenges are subject to a number of pitfalls:

1. There is a danger of producing anaphylactic shock, even if anaphylactic shock had not occurred on previous exposure to the food.
2. Difficulties arise if a cooked food is used for testing and the patient is only sensitive to a raw food, or vice versa. Cooking reduces the sensitizing capacity of cows' milk, and intolerance to raw but not cooked egg, potato and fish are well described.
3. It is unclear what dosage of different foods is required to exclude food intolerance. The dosage used in studies employing encapsulated foods is inevitably limited. Larger quantities of food may cause an adverse reaction when smaller quantities do not. For example, Hill et al<sup>91</sup> found that whereas 8–10 g of milk powder (corresponding to 60–70 ml of milk) was adequate to provoke a response in some patients with cows' milk protein intolerance, other patients (with late-onset symptoms) required up to 10 times this volume of milk daily for more than 48 h before symptoms developed.
4. Failure to randomize the order of placebo with active substance or to employ a double-blind placebo-controlled methodology are errors common to many studies, especially those of food additives in chronic urticaria.

5. A food challenge performed during a quiescent phase of the disease may fail to provoke an adverse reaction. For example, in chronic urticaria intolerance to salicylates is confined to patients with active disease.
6. The regular administration of salicylates to patients with salicylate intolerance quickly leads to a state of tolerance to salicylate. It is possible, although unproven, that a similar phenomenon occurs with certain food additives. Thus a double-blind challenge performed while a patient is regularly consuming a foodstuff may fail to provoke an adverse reaction.
7. Where food intolerance exists in children with atopic dermatitis, it is common for the patient to be intolerant to several foods. The removal of only one offending item may fail to help the patient and reintroduction may not provoke deterioration.
8. In some situations, factors other than a food are necessary for positive challenges to occur. For example, in a subgroup of patients with exercise-induced anaphylaxis, symptoms only occur if exercise follows the ingestion of a particular food.<sup>94</sup> Exercise or the food alone fail to provoke symptoms.

## DRUG TREATMENT OF ANAPHYLAXIS AND ACUTE ALLERGIES

### Anaphylaxis not associated with circulatory failure/arrest

Adrenaline 10 µg/kg (0.01 ml/kg of a 1:1000 solution), given intramuscularly is the drug and route of choice for most patients with anaphylaxis associated with life-threatening respiratory compromise (Project Team of the Resuscitation Council [UK] 1999). Subcutaneous administration results in slower rates of systemic absorption than via the intramuscular route and is therefore not recommended.

Preloaded adrenaline syringes are available for use in the community. Min-I-jet 1 ml 1:1000 epinephrine with a 6 mm needle is for s.c. injection, requires assembly before use and the dose will need to be adjusted before administration. Thus it is less suitable than the EpiPen or the Anapen, which are spring-loaded devices with a concealed needle giving a single dose of 0.3 ml of 1:1000 or 1:2000 adrenaline (0.15 or 0.30 mg) as a deep i.m. injection. The simplicity of use and concealed needle makes this the most popular option with many patients.

The junior EpiPen or Anapen (0.15 mg) are suitable for children weighing 15–30 kg; above this weight the adult EpiPen or Anapen (0.3 mg) should be used. It will rarely be appropriate to issue epinephrine for children weighing less than 15 kg.

Adrenaline has a short half-life, and if necessary the i.m. injection is repeated at 5-minute intervals. Repeated (i.e. more than one) adrenaline injections are required in approximately 10–40% of patients with anaphylaxis, and therefore it is advisable to prescribe two preloaded adrenaline syringes per patient. I.v. administration of adrenaline has been associated with acute strokes and is therefore to be avoided in most situations.

Only 20% of fatal/near-fatal anaphylactic reactions to foods occur at home. The remainder occurs at the home of friends, at school and at restaurants<sup>95</sup> and thus it is essential that if a pre-loaded adrenaline syringe is prescribed, it is available where the patient is and that there is someone around who is trained in its use. Thus for schoolchildren it is important that two preloaded adrenaline syringes are available at the school and that teachers have appropriate training in the recognition of anaphylaxis and the use of the adrenaline syringe.

### Indications for use of preloaded adrenaline syringes

A major factor predisposing to fatalities in cases of food anaphylaxis was the delay in recognition and instigation of medical treatment. In general it is recommended that a preloaded adrenaline syringe should be given at the first signs of upper airway obstruction, wheeziness not relieved by a bronchodilator inhaler or if there is any faintness. Allergic reactions are frightening and are often associated with panic attacks, which may mimic or

exacerbate the symptoms and signs of anaphylaxis. This often makes it difficult to differentiate between clinical features of allergy and acute anxiety.

### Indications for preloaded adrenaline syringe prescribing

The indications for prescribing preloaded adrenaline syringes vary from center to center.<sup>96</sup> Some authorities recommend, for example, that all children with peanut intolerance should be issued with adrenaline syringes, however mild the previous reactions, on the basis that the next reaction could be life threatening. Others are concerned that adrenaline syringes are vastly overprescribed, and should only be used in very selected cases.<sup>97</sup> Unfortunately it is not possible to predict which individuals are likely to get severe reactions, except to say that those who have had previous severe reactions are those at greatest risk. The possible role of asthma as a risk factor has already been discussed earlier in relation to peanut allergy. Fatal or near-fatal anaphylactic reactions are rare (approximately 1 per million per year), often occur in places where the prescribed preloaded adrenaline syringe is not available, where there is no one trained in its use, or in some cases the reaction occurs so rapidly as to lead to circulatory arrest that is unlikely to respond to i.m. adrenaline (see section on Anaphylaxis associated with circulatory failure/arrest later).<sup>98</sup> Most nonvenom- and non-medication-induced allergic reactions respond to antihistamines. There is no guarantee that treatment with adrenaline will be life saving, and there are well-documented cases in which death has occurred despite the correct use of adrenaline syringes.

#### Preloaded adrenaline syringes

##### Advantages

*Efficacy:* most effective acute treatment for anaphylaxis not associated with circulatory failure/arrest;  
Provides reassurance for the patient and relatives.

##### Disadvantages

*Rarity:* risk of death from anaphylaxis is approximately 1/million/y.

*May not work:* Anaphylaxis associated with circulatory failure is not likely to respond, and some cases of anaphylaxis will prove fatal, even if adrenaline is given early.

*Can cause anxiety:* having to carry an adrenaline syringe everywhere causes considerable anxiety to some patients, relatives, carers and teachers. Exclusion from school trips and social outings have in some cases been associated directly with prescription of a preloaded adrenaline syringe to children.

*Lack of warning signs:* fatal reactions are sometimes not associated with warning signs.

*Side-effects:* preloaded adrenaline syringe use for anaphylaxis has caused death from arrhythmias and strokes.

*Availability:* preloaded adrenaline syringes are often not available at the emergency (i.e. reactions away from home, patient not carrying adrenaline).

*Need for training:* inadequate training may prevent adequate recognition of anaphylaxis or use of preloaded adrenaline syringe.

Based on the current difficulties associated with the use of a preloaded adrenaline syringe, if it is prescribed, it is recommended that the following conditions are met:

- Appropriate training should be given to the patient, their relatives, teachers and work colleagues (see later).
- Preloaded adrenaline syringes should be available at all times, not just at home but also at school, when visiting friends and during all leisure activities.
- All trainees should undergo periodic retraining and reassessment.

### Information that should be given to users of preloaded adrenaline syringes

As mentioned earlier, training of patients and their relatives in the correct use and safe handling of the preloaded adrenaline syringe as well as regular annual review of technique is essential. Table 33.8 lists the information that should be covered at training sessions.

**Table 33.8** Information that should be covered at preloaded adrenaline syringe training sessions

- 
- A. Instructions should be given to the parents and if old enough the patient on the following:
- How to recognize an anaphylactic reaction
  - When to use the preloaded adrenaline syringe(s)
  - Where and how to inject the adrenaline
  - How to dispose of the used preloaded adrenaline syringe
  - What to do if the adrenaline is injected incorrectly
  - When to use other medicines
  - Always to seek medical help if having a reaction
  - When to replace the preloaded adrenaline syringe
- B. The preloaded adrenaline syringe should be checked and the parents/patient told:
- To keep the preloaded adrenaline syringe in the original pack
  - Label with the patient's name
  - Store safely
  - Store at room temperature
  - Always keep accessible for an emergency
- 

The date on which training was given, the people trained, the adrenaline dose and a list of the information given to the patient and the relatives should be documented in the clinical notes. Allergy clinics might use a standardized preloaded adrenaline syringe checklist form, signed and dated by the prescribing doctor, with copies added to the clinical notes, sent to the GP and given to the patient.

### Nebulized adrenaline and other treatment modalities

Nebulized adrenaline is no longer recommended as treatment of anaphylaxis in the UK because the metered-dose aerosol (Medihaler-epi) has been withdrawn from the market. Bronchoconstriction is best treated with a nebulized  $\alpha_2$ -agonist (e.g. salbutamol or terbutaline). I.v. fluid boluses are often required in addition to adrenaline for treatment of hypotension. A number of 20 ml/kg boluses may be required. After injection of adrenaline, an  $H_1$  antihistamine, for example chlorphenamine should be administered, and may be continued for 48 h to prevent recurrences of the reaction. Steroids take some hours to be effective and are unhelpful in the immediate treatment of anaphylaxis, but are of possible benefit in preventing a secondary relapse. Further management consists of avoidance of the cause, and in the case of insect venom stings consideration of hyposensitization.

### Anaphylaxis associated with circulatory failure/arrest

If the patient has life-threatening circulatory compromise with no palpable peripheral pulse, then i.m. adrenaline is unlikely to be effective, as it will not be adequately absorbed. In patients with circulatory failure, basic life support must be commenced, followed by the injection of i.v. adrenaline (at an initial dose of 0.1 ml/kg of a 1:10 000 solution) as per the asystole protocol for advanced pediatric life support (APLS). Great vigilance is needed to ensure that the correct strength of adrenaline is used; anaphylactic shock kits need to make a very clear distinction between the 1 in 10 000 strength normally used for i.v. use and 1 in 1000 strength used for i.m. use. I.v. administration of adrenaline for treatment of patients with anaphylaxis has been associated with death from acute strokes and ventricular fibrillation, and is therefore to be avoided in anaphylaxis not associated with circulatory failure.

### Medication for nonlife-threatening allergic reactions

$H_1$  antihistamines are very useful in controlling symptoms of nonlife-threatening allergic reactions such as acute and chronic urticaria and allergic rhinitis and conjunctivitis. Antihistamines can be divided into two groups (Table 33.9). The older sedating antihistamines are very

**Table 33.9**  $H_1$  Antihistamines used in the treatment of allergic reactions

Antihistamine	Route of administration
<b>Sedating</b>	
Chlorpheniramine (Piriton)	Oral/parenteral
Promethazine (Phenergan)	Oral/parenteral
Trimeprazine (Vallergran)	Oral
<b>Non-sedating</b>	
Loratadine (Clarityn)	Oral
Desloratadine (Neoclarityn)	Oral
Fexofenadine (Telfast)	Oral
Cetirizine (Zirtek)	Oral
Mizolastine (Mistamine)	Oral
Antazoline (Otrivine-Antistin)	Eye drops
Azelastine (Optilast)	Eye drops
Levocabastine (Livostin)	Eye drops
Azelastine (Rhinolast)	Nasal spray
Levocabastine (Livostin)	Nasal spray
Antazoline (Wasp-Eze)	Topical skin ointment
Mepyramine (Anthisan)	Topical skin ointment

effective, but because they cross the blood-brain barrier they are sedative and therefore may adversely affect children's learning ability. In an effort to reduce the sedative side-effects of these drugs, a new generation of nonsedating antihistamines has been developed. Some of these nonsedating antihistamines (in particular astemizole, terfenadine) are associated with life-threatening arrhythmias (torsades de pointes) by inhibiting potassium ion channels in cardiac tissue. Astemizole and terfenadine are therefore no longer available. Mizolastine, which is still available, has been associated with an increased risk of ventricular fibrillation when given together with other drugs (analgesics, antiarrhythmics, sotalol).

Doxepin is classed as a tricyclic antidepressant, but also has anti- $H_1$  and  $H_2$  antihistamine activity (75× more potent than diphenhydramine and 6× more potent than cimetidine). It may be a useful therapeutic adjunct in older children with urticaria not controlled with traditional antihistamines.

### HYPOSENSITIZATION

Hyposensitization comprises the regular administration of allergen with the objective of reducing or abolishing the patient's reaction to the allergen. The basis of allergy or 'immune hypersensitivity' is increasingly recognized as an imbalance between the proinflammatory and regulatory immune responses. Although desensitization or more precisely hyposensitization, as the allergy is rarely completely abrogated, has been used for many decades, it is only now appreciated that it works by resetting the immune balance by increasing the regulatory immune response.<sup>99</sup> All antigens can stimulate both effector and regulatory arms of the immune system. Hyposensitization is the method of presenting the allergen in a way that the regulatory response predominates. The induction of regulatory cell memory is less robust than for proinflammatory responses and therefore regular prolonged exposure to the allergen is usually required to maintain immune tolerance. Prematurely discontinuing immunotherapy prematurely risks development of allergic reactions to the allergen, which may be severe.

Allergy immunotherapy involves exposing the patient to increasing amounts of allergen starting at a low enough dose that does not provoke a proinflammatory response (induction phase), before maintaining tolerance with continuing exposure to the allergen (maintenance phase). Allergen may be given subcutaneously (SCIT), orally, or most recently the possibility of giving it sublingually (SLIT) has been explored. There is no doubt that SCIT and oral hyposensitization can be very effective in patients where the symptoms are being provoked by specific allergens. SCIT is limited by the availability of licensed allergens, and in the UK

is largely used for patients with grass and tree pollen allergen, as well as bee and wasp allergen. As SCIT requires regular injections, initially weekly and then monthly for up to 3–5 years, hyposensitization is not commonly used in children. Oral hyposensitization is almost exclusively used for drug hyposensitization.

### SUBCUTANEOUS IMMUNOTHERAPY (SCIT)

Since Noon's report in 1911, controlled studies have shown that allergen immunotherapy is effective in patients with allergic rhinoconjunctivitis and allergic reactions to *Hymenoptera* venoms. Patients may be considered for immunotherapy if they have well-defined, clinically relevant allergic triggers that markedly affect their quality of life or daily function and if they do not attain adequate symptom relief with avoidance measures and pharmacotherapy. Because of the risk of death from anaphylaxis (26 deaths in the UK between 1967 and 1986), the Committee for Safety of Medicines (CSM) in the UK has concluded that SCIT should only be used for: (1) life-threatening allergy to bee or wasp venom (rare in childhood); and (2) seasonal allergic hay fever (which has not responded to anti-allergy drugs), caused by grass or tree pollen, using licensed products only. In patients with hay fever, those who also have asthma should not be treated with hyposensitizing vaccines as they are more likely to develop severe adverse reactions. Hyposensitization must only be performed in hospitals or clinics with full facilities for cardiopulmonary resuscitation, and patients need to be monitored for 30–60 min after injections. Induction of tolerance requires weekly injections of increasing doses of allergen to reach a maintenance dose of 5–20 mcg over 6 or more weeks. This is often followed by monthly injections of this maintenance dose for 3–5 years.

### ORAL HYPOSENSITIZATION

Oral hyposensitization is used to induce tolerance to essential medication required and can be used for most drugs including antibiotics, anti-epilepsy medication, chemotherapeutic agents and protein, e.g. insulin. Children can be hyposensitized to most drugs using this method. This form of hyposensitization is thought to work through controlled degranulation of mast cells.<sup>100</sup> Clinical reactivity returns within a few days of discontinuing drug administration, implying that continuous presence of the antigen is required for continuing mast cell degranulation and thus maintaining tolerance. Oral hyposensitization has also been achieved in asthmatic patients with aspirin-exacerbated respiratory disease,<sup>101</sup> and in a small number of children with food intolerance, e.g. to milk, but at present must be regarded as experimental.<sup>102,103</sup>

The procedure is performed by the cautious administration of incremental doses of the drug to the patient over a period of hours to days. The drug can be administered either by oral or i.v. route. The starting dose for the procedure can be determined by performing intradermal skin tests with the native drug at a dose that does not cause a nonspecific reaction and may be one hundredth to one thousandth of the usual therapeutic dose. Typically, the dose is doubled every 15–30 min and vital signs, physical examination, and peak flow values are regularly monitored. It is critical that the individuals involved with the desensitization procedure understand that it can have serious consequences. While anaphylactic reactions rarely occur if conservative protocols are used, health care personnel must be prepared to treat anaphylaxis if it does occur.

### SUBLINGUAL IMMUNOTHERAPY

Sublingual immunotherapy (SLIT) has been used with increasing frequency in Europe as a possible means of hyposensitization in hay fever and asthma.<sup>104</sup> The allergen solution or tablet is kept under the tongue for 1–2 min before either spitting it out or swallowing it. This method appears safe in that there are to date no reported severe allergic reactions, although 75% of patients may experience local symptoms in the oral cavity. At present there is no standardization of dose, timing and duration of treatment, which has varied considerably between studies.

In terms of efficacy, a 2006 Cochrane review of SLIT for hay fever concluded that in 22 double-blinded, placebo-controlled trials involving 979 patients (6 house dust mite, 5 grass pollen, 5 *Parietaria*, 2 olive, 5 other) there was a 15–69% reduction of symptoms ( $P = 0.002$ ) and a 23–63% reduction in medication required ( $P = 0.00003$ ).<sup>105</sup> However a larger independent American review of the European studies found that in 47 randomized, controlled studies, although there was a significant improvement in symptom and medication scores in 14 (35%) of 39 studies where data was available, there was no significant improvement in either parameter in 15 (38%) trials. Of the 43 trials that provided symptom scores, 20 (46%) demonstrated no significant improvement, and a total of 20 (51%) of 39 studies that provided medication scores demonstrated no significant improvement.<sup>52</sup> The Cochrane review of the five studies conducted in only children found no benefit. Based on these data, routine use of SLIT cannot be recommended in children at the present time.

### NOVEL TREATMENT APPROACHES

There are a number of novel approaches currently under investigation for the management of allergic diseases. These include reduction of IgE by the infusion of anti-IgE antibodies, attempts to induce tolerance by stimulating regulatory pathways with plasmid DNA, immunostimulatory sequences, cytokines and bacterial agents, as well as complementary medicines such as Chinese herbs.

#### ANTI-IGE THERAPY

Anti-IgE (omalizumab and TNX-901) are humanized monoclonal anti-IgE antibodies that bind to the Fc region of IgE at the same epitope that binds FcεR1. They are given subcutaneously at a dose of 0.016 mg/kg body weight 3–4 weekly. They have been well tolerated in the trials that have so far been conducted in patients over the age of 12 years and there is so far little evidence for the development of antibodies and thus resistance with repeated use. As complete neutralizing of circulating IgE is required for clinical efficacy, their use has so far been restricted to patients with total serum IgE concentrations of < 700–1000 IU/ml. Trials have shown efficacy in seasonal allergic rhinitis and moderate (but not severe) allergic asthma, significantly reducing symptoms and medication use.<sup>83,106</sup> In peanut-allergic patients and at a dose of 450 mg, tolerance to peanuts increases from an average of 1 peanut to 6–8 peanuts.<sup>56</sup> With the restrictions in use to patients with only moderately raised serum IgE levels, and an estimated average annual cost of 4–5 times that of standard asthma therapy, and the need to long-term injections, its place in the management of allergic diseases in adults and particularly children is unclear at the present time.

#### CHINESE HERBAL REMEDIES

Chinese herbal medicines may have a role in the treatment of allergies and atopic diseases. However the complexity of traditional Chinese herbal formulae containing many constituents makes standardization and therefore licensing of herbal products problematic. A 2005 Cochrane review of the four published randomized controlled trials of Chinese herbal remedies for eczema involving 159 participants aged 1–60 years, suggested some clinical benefit, but the conclusion was that further well-designed large-scale trials are required.<sup>107</sup> Attempts are ongoing to reduce the number of components within these remedies to those that are most active and least toxic but these studies are currently in the preclinical or early clinical trial stage. For example, in a murine model of peanut allergy, pretreatment of mice with a modified Chinese herbal formulae was associated with complete abrogation of clinical anaphylaxis.<sup>108</sup> At the present time however, patients should be warned that currently available Chinese herbal remedies are non-standardized and unlicensed and although may be efficacious have also been associated with liver and renal toxicity and therefore must be used with caution.

## PREVENTION OF ATOPIC DISEASE

Since 1930, when Grulee and Sanford reported a significantly lower incidence of eczema in infants who were breast-fed babies,<sup>109</sup> further research has been unable to provide the definitive answer whether the development of allergic disease can be prevented by breast-feeding.<sup>110</sup> One explanation may be that food antigens can pass to the infant via both human milk and also via the placenta prior to birth, but breast-feeding does not necessarily lead to complete avoidance of potentially sensitizing allergens. An alternative explanation is that more children at increased risk of allergic disease may be breast-fed by their mothers.<sup>111</sup> Studies using hydrolyzed formulae would avoid some of these factors and may provide more conclusive data. However a Cochrane review of studies provide no support to the idea that hydrolyzed formula prevents the development of allergy any more than breast-feeding.<sup>112</sup>

With the recognition that early exposure to potential allergens in the gut normally induces and maintains tolerance in young children, and complete avoidance may increase the risk of allergic reactions,<sup>113</sup> advice on avoidance should currently be given with caution.<sup>114</sup> Studies looking at potential aeroallergens show that ownership of cats and dogs in early

childhood may protect against rather than promote the later development of asthma. In one study of 224 28-year-olds, those who owned a cat prior to the age of 18 years had a relative risk of having asthma of 0.08 (0.01–0.46) while those who acquired a cat after the age of 18 years had a relative risk of asthma of 2.62 (0.34–19.97) compared with participants who had never owned a cat.<sup>115,116</sup>

The induction of oral tolerance to food allergens may be augmented by certain bacterial (e.g. environmental mycobacteria) and viral (hepatitis A virus) antigens in the gut, a concept that may help to explain the epidemiological data leading to the development of the Hygiene hypothesis.<sup>8</sup> There is growing interest in supplementing people's diet with normal bacterial flora, particularly *Lactobacillus* and *Bifidobacterium* strains in the form of 'probiotics' to try and prevent or treat atopic diseases. Most studies to date using probiotics have looked at their effect in children with established atopic eczema rather than the prevention<sup>117</sup> of the condition and therefore it is not possible to draw any firm conclusions as to the usefulness of probiotics in the prevention of atopic disease.<sup>118</sup> However, overall the studies detailed earlier suggest that augmentation of intestinal regulatory cell activity in early infancy might possibly help to protect against immune hypersensitivity diseases in later life.

## INTRODUCTION

Child psychiatry is concerned with the assessment and treatment of children's emotional and behavioral problems. These problems are common with prevalence rates of 10–20% reported in community studies. The majority of disturbed children are not seen by specialist psychiatric services, but by general practitioners, community doctors and pediatricians along with other professionals such as teachers and residential care staff. Consequently, knowledge about the range and variety of emotional

and behavioral problems shown by children is important for all doctors involved in the care of children. The everyday work of the pediatrician provides clear evidence of the stressful effects of illness on the children and family's psychological well-being and adjustment.

Psychiatric disturbance in childhood is most usefully defined as an abnormality in at least one of three areas: emotions, behavior or relationships. It is *not* helpful to regard these abnormalities as strictly defined disease entities with a precise etiology, treatment and prognosis. Rather, it is preferable to regard them as deviations or departures from the norm,

which are distressing to the child or to those involved with his care (the male gender is used throughout the chapter for ease of presentation rather than from any bias or discrimination). Although child psychiatric disorders do not conform to a strict medical model of illness, it does not mean that these disorders are trivial or unimportant. Some disorders such as autism or conduct disorder have major implications for the child's development and adjustment in adult life.

In childhood, the distinction between disturbance and normality is imprecise. Isolated symptoms are common and not pathological. For example, many children will occasionally feel sad, unhappy or have temper tantrums. This does not mean that they are disturbed. Disturbance is characterized by the number, frequency, severity and duration of symptoms rather than by the type of symptomatology. In addition, disturbed children rarely present with unequivocal pathological symptoms such as hallucinations or delusions, whereas symptoms such as unhappiness and lying are common and not diagnostic. In clinical practice, it is often more important to establish why the child is the focus for concern rather than to adopt the more narrow perspective of whether the child is disturbed or not.

Another important feature of psychiatric disturbance in childhood is that several, as opposed to single, factors contribute to the development of disturbance. This makes assessment and treatment more difficult, so that an essential prerequisite for successful treatment is the correct evaluation of the relative contribution of the different etiological factors. Etiological factors are usually categorized into two groups: constitutional and environmental. The former includes heredity factors, intelligence and temperament. The three major environmental influences are the family, schooling and the community. Another factor, physical illness or disability, if present, can have a profound effect on the child's development and on his vulnerability to disturbance.

Three other considerations are of general importance in understanding children's behavior: the situation-specific nature of behavior, the impact of current stressful events, and the role of family. Children's behavior varies markedly in different situations, that is, it is situation specific. For instance, a child may be a major problem at school but not at home, or vice versa. Consequently, there may well be an apparent discrepancy between accounts of the child's behavior from the parents and from the teachers. The most likely explanation for this discrepancy is that the demands and expectations upon the child in the two situations are different. It is therefore essential to obtain several independent accounts about the child's behavior wherever possible in order to derive a more accurate and realistic assessment of the problem. This situation-specific nature of the behavior has implications for treatment, as it is important to explain to parents and to teachers the reasons for the discrepancy, thereby lessening the likelihood of misunderstanding.

Children are immature and developing individuals whose capacities and coping skills change markedly during childhood. Childhood is also a period of life characterized by change, challenge and the necessity for adaptation. Consequently it is not surprising that symptoms of disturbance may arise at times of stress when the demands on the child are excessive. Research has shown that life events are associated with an increased psychiatric morbidity among children,<sup>1</sup> a finding similar to that reported for adults. Some stresses such as the birth of a sibling or starting school are of course normal and inevitable, whereas others, such as marital break-up or life-threatening illness, are serious with long term implications for the child's well-being.

The child may, however, cope successfully with the stress, thereby enhancing their self-esteem and confidence. Alternatively, the child may be overwhelmed, responding with the development of symptomatic behavior. The latter may involve regressive behavior (i.e. behaving in a more immature, dependent fashion), or more specifically maladaptive (e.g. aggression, excessive anxiety or withdrawal). A crucial feature of assessment is the identification of stressful factors that may be contributing to the problem, as this will influence treatment strategies and the prognosis.

The family is the most potent force for the promotion of health as well as for the development of disturbance in the child's life. Assessment of parenting qualities, the marital relationship and the quality of family

interaction are essential components of child psychiatric practice. It is a frequent observation that it is the parents who are disturbed and not the child. One consequence of this observation is that in many cases the focus of treatment is likely to be the parents, or the whole family, rather than the child. Indeed, in many instances the main emphasis of treatment is the promotion of normal healthy family interaction as much as in the amelioration of disturbed behavior.

Finally, many disturbed children do not complain about their distress nor admit to problems, but rather it is their parents or other adults involved with their care who bring the child to the attention of professionals. Disturbed children more commonly manifest their distress or unhappiness indirectly through symptoms such as abdominal pain, aggression or withdrawal. Direct questioning of the child during the initial interview is unlikely to reveal the true extent of the child's feelings or the degree of his distress. Sensitive observations during the interview and the use of indirect techniques such as play are necessary to elicit a more accurate view of the child's feelings. This is only likely to be successful once a relationship of trust has been established between the child and the clinician.

## NORMAL AND ABNORMAL PSYCHOLOGICAL DEVELOPMENT

Children are developing individuals. They are not small adults. A 2-year-old is very different to a 12-year-old, whereas an adult aged 25 may not differ that much from a 35-year-old. During childhood, the child undergoes a remarkable transformation from a helpless, dependent infant to an independent self-sufficient individual with his own views and outlook, capable of embarking on a career and living separately from his family. Knowledge about the *mechanisms*, *processes* and the *sequences* underlying these events is necessary in order to understand the nature of psychological disturbance in childhood. This knowledge also helps to define more clearly what age-appropriate behavior is and to distinguish the pathological from the normal. This section has three parts: developmental theories, developmental psychopathology and personality development.

### DEVELOPMENTAL THEORIES (Table 34.1)

It is useful to define some terms at the outset, as they are often used interchangeably. *Growth* refers to the incremental increase of a characteristic; *maturation* is those phases and products of development that are mainly due to innate or endogenous factors; *development* is those changes in the nature and organization of an organism's structure and behavior that are systematically related to age. Many behaviors (for example walking and talking) have a substantial maturational component, whereas others (for instance emotional and social development) are strongly influenced by environmental factors. The continuous interaction between maturational and environmental factors throughout childhood helps to mold the personality development of the child.

Developmental theories tend to focus on at least one of the following areas: cognitive, emotional or social. They differ widely in theoretical orientation, in supporting empirical evidence and in the relative importance attributed to experience in influencing development. No single theory is satisfactory, so that most clinicians utilize some parts of the various theories to explain different aspects of development. The theories are usually described as stage theories, implying that they regard development as a series of recognizable phases of increasing complexity through which the child progresses.

### COGNITIVE DEVELOPMENT

In 1929, the Swiss psychologist Piaget proposed a comprehensive theory of cognitive development. Many of his conclusions were based on experiments conducted on his own children over a number of years. Piaget has had a tremendous impact on educational concepts and teaching, particularly in primary schools over the last 30 years. More recently, the

Table 34.1 Summary of cognitive, emotional and social development

	Age in years				
	0	2	6	9	12+ upwards
Cognitive (Piaget)	<i>Sensori-motor</i> Differentiates self from objects  Begins to act intentionally  Achieves object permanence	<i>Pre-operational</i> Learns to use language and to represent objects by image and words  Thinking is egocentric (unable to see other viewpoint) and animistic (everything has feelings including inanimate objects)		<i>Concrete operational</i> Thinking is more logical and less egocentric  Achieves conservation of number (age 6), volume (age 7) mass (age 8) Able to arrange objects in rank order	<i>Formal operational</i> Able to think in abstract manner about propositions and hypotheses
Emotional (Freud)	<i>Oral</i> Main concern is initially with satisfaction of basic needs such as hunger Later on, attachment to care giver	<i>Anal</i> Co-operative activity with caregiver  Satisfaction with increased self-control and achievement	<i>Phallic</i> Learns to interact with peers, often leads to rivalry  Aware of own sexuality causing Oedipal conflict, resolved by identification with the same sex parent Conscience begins to form	<i>Latency</i> Reduced sexual interest with main concerns about peer relationships and position within peer group	<i>Genital</i> Revival of earlier conflict, especially sexual conflict  Four main tasks: separation from parents, sexual role, career choice, identity
Social & personality development	Social smiling (8 weeks) Attachment (6 months) Stranger anxiety (10 months)  <i>Erikson's stage of trust vs. mistrust</i>	Cooperative play (3 years)  <i>Erikson's stage of autonomy vs. shame and doubt</i>	Strong preference for same-sex friends with stereotyped expectations (6–7 years)  <i>Erikson's stage of initiative vs. guilt</i>	Enduring relationships (8 years onwards)  <i>Erikson's stage of industry vs. inferiority</i>	<i>Erikson's stage of identity vs. role diffusion</i>

theoretical basis and validity of Piaget's conclusions have been questioned by further empirical studies.<sup>3</sup> Despite these criticisms, his views remain the most useful account of cognitive development.

Piaget's theory is set within a biological framework. In order to survive, the individual must have the capacity to adapt to the demands of the environment. Cognitive development is the result of interaction between the individual and the environment. Four factors influence cognitive development: increased neurological maturation, enabling the child to appreciate new aspects of experience and to apply more complex reasoning as he gets older; the opportunity to practice newly acquired skills; the opportunity for social interaction and to benefit from schooling; and the emergence of internal psychological mechanisms or structures that allow the child to construct a successively more complex cognitive model based on maturation and experience.

Piaget describes two types of intellectual structure: *schemas* and *operations*. The former are present at birth, the latter arise during childhood. *Schemas* are internal representations of some specific action, for instance sucking or grasping, whereas *operations* are internal rules of a higher order that have the distinctive feature that they are *reversible*, as, for example, multiplication is reversible by division. There are two ways whereby the child adapts his cognitive structure to the demands of the

environment: *assimilation* and *accommodation*. The former refers to the incorporation of new objects, thoughts and behavior into existing structures, whereas the latter describes the change of existing structures in response to novel experiences. The child attends and learns most when his environment has a degree of novelty that challenges his curiosity but is not so strange that it becomes too confusing.

Piaget describes four main phases: *sensorimotor*, *pre-operational*, *concrete operational* and *formal operational*. The age range given for each stage is the average, though this can vary considerably depending upon intelligence, cultural background and socioeconomic factors. However, the order is assumed to be the same for all children. Schemas predominate in the sensorimotor and pre-operational stages, whereas operations predominate in the concrete operational and formal operational stages.

**Sensorimotor** (birth–2 years). Initially, behavior is dominated by innate reflexes such as feeding, sucking and following, hence the name for this period. Gradually, the infant realizes the distinction between *self* and *non-self*, namely where his body ends and the world outside begins. The infant also realizes that his behavior can influence the environment, so that intentional and purposeful behavior begins. Finally, the infant achieves *object permanence* whereby he recognizes that an object still exists even although it is no longer visible.

**Pre-operational period** (2–7 years). Language development greatly facilitates cognition, so that the individual begins to represent objects by symbols and words. Thinking is, however, *egocentric* and *animistic*. The former refers to the child's tendency to regard the world solely from his own position along with an inability to see a situation from another point of view. Animistic thinking describes the child's tendency to regard everything in the world as endowed with feelings, thoughts and wishes. For instance, the moon is watching over you when you sleep, the child says 'naughty door' when he bangs into the door.

The child has problems with the principles of conservation for number, volume and mass. The essential principle underlying conservation is that the number, volume or mass of an object are not changed by any visual alteration in their display or appearance. For instance, the child readily believes that the more widely spaced of two rows of counters has more counters than a denser packed row, or that there is more water in a tall beaker when it has been poured there from a shorter, more squat beaker.

The child also believes that every event has a preceding cause, rejecting the concept of chance or coincidence. Again, the child's moral sense is rigid and inflexible, so that punishment is invariable, irrespective of the circumstances. The child's concept of illness is radically different to that of the adult, with illness seen as a consequence for misdeeds, a punishment for a misdemeanor.

**Concrete operational** (7–12 years). Thinking becomes more logical and less dominated by immediate perceptual experience or by changes in appearance. Conservation of number, volume and mass is successively achieved during this period. The child becomes less egocentric, capable of seeing events from another person's standpoint. The child is able to appreciate and utilize reversibility, for example if 2 and 2 equals 4, then 4 minus 2 must equal 2.

**Formal operational** (12 years and upwards). This stage represents the most complex mode of thinking. Its main characteristics are the ability to think in an abstract fashion, to formulate general rules and principles and to devise and test hypotheses, an approach similar to that used in mathematics or in a scientific investigation. An example of such reasoning is the following: Joan is fairer than Susan; Joan is darker than Anne. Who is the darkest? (Answer: Susan). Prior to the formal operational stage, the child would require the aid of dolls to solve this problem. It should be pointed out that not everyone achieves this stage of thinking, even as an adult! The content of thinking also alters markedly with an emphasis on the hypothetical, the future and ideological issues.

## CRITICAL COMMENT ON PIAGET

Recently, the Piagetian model has been criticized extensively for the lack of evidence to support the existence of the internal structures necessary for the concrete and formal operational stages. Alternative nonPiagetian explanations for a child's inability to carry out conservation tasks successfully before a certain age have also been put forward.<sup>3</sup> These criticisms are substantial, but they do not detract from the major conceptual contribution that Piaget has made to knowledge about cognitive development in children.

## RECENT DEVELOPMENTS IN COGNITIVE THEORY

Psychologists and psychiatrists have become increasingly interested in the development and application of cognitive theory to the understanding and treatment of psychiatric disorders.<sup>4,5</sup> The main principles underlying this theory are that an individual's beliefs about (1) himself, (2) the future and (3) the world influence his mood and behavior, an idea similar in some ways to the Piagetian concept of schemas. When a person is depressed, his thoughts are self-defeating and he commits certain cognitive errors. Two common types of cognitive error are *personalization* and *dichotomous thinking*. The following two statements are examples of these two errors, respectively: 'The reason my parents separated is all because of me' and 'I'm no good at tennis, so I'm bound to be useless at any other sport'.

A major extension of these ideas in childhood is the notion of the *self-concept*. By the age of 6 or 7 years, most children have very definite and clear ideas about themselves and their qualities. For example, they are able to compare themselves to other children with respect to popularity, attractiveness, scholastic ability, and so on. Self-concept is a construct similar to that of a schema in Piaget's theory. Another important facet of self-concept is the favorable or unfavorable evaluation that the child makes of himself, an aspect called *self-esteem*. Children with high self-esteem appear to do better in school, regard themselves as in control of their own destiny, have more friends and get along better with their families.<sup>2</sup>

## EMOTIONAL AND SOCIAL DEVELOPMENT

Sigmund Freud developed the most comprehensive theory about emotional development while Erikson,<sup>6</sup> also a psychoanalyst, applied psychoanalytic concepts within a social and cultural framework. Freudian theory emphasizes the biological and maturational components of development with an invariable sequence to development for everyone. Like Piaget, it is a stage or phase theory with the individual progressing successively through each phase. A major criticism of Freudian theory is that its concepts do not lend themselves readily to scientific investigation, so that it is difficult to prove or disprove the validity of the theory.

Freud proposed that an individual goes through five stages prior to adulthood, namely *oral*, *anal*, *phallic*, *latency* and *genital*. These terms refer to the major developmental task or potential conflict that the individual has to achieve or resolve during this period. Table 34.1 describes the important features of the different stages, e.g. during the phallic stage, the Oedipal crisis arises. At this time (around 3–4 years), the child becomes aware of his own sexual feelings and also that he is attracted in a sexual manner to the parent of the opposite sex. Moreover, the child is simultaneously aware that the parent of the same sex is a rival for the attention of the other parent. The conflict arises because the child is caught between the desire for one parent and the wrath of the other. The conflict is successfully resolved by the child identifying with the parent of the same sex, thereby eliminating the rivalrous feelings.

Erikson's major contribution has been to place psychoanalytic concepts in a social and cultural dimension (see Table 34.1). For Erikson, the most important task for the individual is to achieve a coherent sense of identity, a balanced and mature appraisal of one's abilities and limitations, with recognition of the importance of previous experience and with realistic expectations for the future. Such a task occupies the individual throughout his lifetime. The individual passes through a series of developmental stages, all of which are polarized into two extremes, one successful and adaptive and the other unsuccessful and maladaptive. The two poles of the first stage are *trust* and *mistrust*. The former refers to the child's belief that the world is safe, predictable, and that he can influence events towards a favorable outcome, whereas a sense of mistrust implies a world that is cruel, erratic and unable to meet his needs. The role of the caregiver, usually the mother, is crucial to the achievement of a successful outcome. Erikson also believed that the individual carries forward the residues of earlier stages into the present, thereby giving the past an influence on contemporary behavior. Erikson's writings are a compelling and coherent account of development. A major weakness is, however, the lack of empirical evidence to support the conclusions.

## Development of social relationships<sup>2</sup>

A characteristic of human beings is their predisposition to establish and maintain social relationships. Although Freud and Erikson refer to social relationships, it is only with the recent elaboration of *attachment theory* by Bowlby<sup>7</sup> and by Ainsworth<sup>8</sup> that a plausible theory for this phenomenon has been described. Attachment theory proposes that social relationships develop in response to the mutual biological and psychological needs of the mother and the infant. Mother–infant interaction promotes social relationships. Each member of the dyad has a repertoire of behavior that facilitates interaction: (1) the infant by crying, smiling and vocalization; (2) the mother by facial expression, vocalization and

gaze. A mother can regulate the infant's state of alertness, for instance rocking or stroking to soothe the child, whilst talking or facial expressions stimulate the child.

The term *attachment* describes the infant's predisposition to seek proximity to certain people and to be more secure in their presence. Bowlby maintained that there is a biological basis for this behavior, as it has been found extensively in other primates as well as in most human societies. It has considerable survival and adaptive value for the species, as it enables the dependent infant to explore from a secure base and also to use the base as a place of safety at times of distress. From the age of 6 months onwards, infants develop selective attachment to people, usually the mother initially, but not exclusively to her. This first relationship is regarded as the prototype for subsequent relationships, so that its success or failure may have long term consequences. Clinicians distinguish between *secure attachment* and *anxious attachment*, with the former referring to healthy and the latter to potentially unsatisfactory relationships.

*Bonding* refers to the persistence of relationships over time, namely the child's capacity to retain the relationship despite the absence of the other individual. Much of the infant's behavior promotes the development of attachments by ensuring close proximity and interaction with the mother. These ideas have many implications for obstetric and pediatric practice, for the reduction of stress associated with hospitalization and for possibly explaining the origins of non-accidental injury to children.

## Other aspects of development

### *Gender and sex role concepts*

Gender identity is a part of self-concept, but the development of the child's understanding about 'boyiness' or 'girliness', the sex role concept, is a more elaborate process. Children usually acquire *gender identity* (correctly labeling themselves and others) by about age 2 or 3 followed by *gender stability* (permanence of gender identity) by about 4. *Gender constancy* (gender identity unalterable by change in appearance) appears around 6 years, similar to other conservation-like concepts. Children show clear evidence of sex role stereotyping from an early age, with an excessively rigid concept for a brief period around 6 or 7 years. Freudian theory explains these findings on the basis of identification whereby the child imitates the same-sex parent, thus acquiring appropriate sex-typed behavior. Alternative explanations emphasize the importance of social reinforcement and of cognition whereby the child acquires a schema about the respective roles and behavior of boys and girls.

### *Moral development*

The acquisition of moral or ethical values is an important aspect of the socialization of children. Freud and Piaget have both described how this process happens. Freudian theory maintains that the superego or conscience develops during the phallic stage around 4–5 years. At this time, the child is identifying strongly with the same-sex parent in order to resolve the Oedipal conflict and in consequence acquires parental values and prohibitions. In contrast, Piaget hypothesizes a much more gradual or stage-like sequence to the acquisition of moral values. The child around 3 years old bases his judgment on the outcome rather than the intention of an act, with an emphasis on punishment following on from a misdemeanor. Subsequently, the child adopts a more conventional morality based upon conformity with family values. Finally, the adolescent derives a personal value system that combines his own idiosyncratic values with those of his family and of society with the intention of achieving the 'greatest good for the greatest number'.

## DEVELOPMENTAL PSYCHOPATHOLOGY

This long-winded phrase refers to two important dimensions necessary to evaluate children's behavior: first, whether the behavior is age appropriate (the developmental aspect); and second, whether the behavior is abnormal (the psychopathological). For example, separation anxiety is a normal phenomenon among children between 9 months and 4 years approximately, whereas it would be abnormal in a child aged 6 years.

The threefold division of disturbance into abnormalities of behavior, emotions or relationships provides a useful way to analyze disturbance. Many behavioral problems can be conceptualized in terms of deficits or excesses. For instance, children with encopresis or enuresis can be regarded as having failed to acquire the skills necessary for toileting. Similarly, the aggressive child is showing excessive belligerent or assertive behavior at an inappropriate time. This approach also has implications for treatment, as the latter is often based on behavioral techniques designed to increase certain behaviors or alternatively to eliminate others.

Anxiety is central to the understanding of emotional disturbance. It has physical manifestations such as palpitations or dry mouth as well as psychological such as fear or apprehension. Anxiety is a normal, indeed essential, part of growing up. It may occur in many situations: in response to external threat, new or strange situations, and in response to the operation of conscience. Anna Freud<sup>9</sup> developed the concept of *defense mechanisms* to explain how an individual dealt with excessive anxiety. This response is entirely healthy and appropriate in many situations, only becoming maladaptive when it is used exclusively or excessively, thereby preventing the individual from learning how to cope with a normal amount of anxiety. Common defense mechanisms include *denial*, *rationalization*, *regression*, and *displacement*. Denial is the process where the child refuses to accept the psychological implications of a particular event or situation. For instance, a child refuses to admit to stealing, even when the theft is obvious, as the resultant loss of self-esteem and the sense of guilt make this impossible. Rationalization is when the child attempts to justify or minimize the psychological consequences of an event. 'I don't really like football, so that I am not bothered about playing for the team' is an example of the way in which the child may deal with a failure to gain selection for the school team. Regression occurs when a child behaves in a more developmentally immature manner, often at times of stress, for example becoming enuretic at the start of primary school. Displacement is the transfer of hostile or aggressive feelings from their original source on to another person, for instance getting angry with a sibling rather than with an adult.

Social relationships are often impaired among disturbed children. This may be a primary failure in some instances, such as autism, or more commonly a secondary phenomenon. Children with neurotic or conduct disorders are usually isolated and unpopular with their peer group as they have either excluded themselves or have alternatively been excluded as a result of their deviant behavior. In addition, the behavior usually brings them into conflict with parents or other adults such as teachers.

## PERSONALITY DEVELOPMENT

Childhood is the time during which personality is formed. Wordsworth's aphorism 'the child is father to the man' is substantially true. Personality is a broad concept referring to the enduring and uniquely individual constellation of attributes that distinguish one person from another. It comprises cognitive, emotional, motivational and temperamental attributes that determine the individual's view about himself, his world and the future. Throughout childhood, the various elements interact with each other to mold the child's personality. Moreover, this process occurs in the context of the child's life experiences, particularly within the family, and also subsequently in the world outside the family. Healthy personality formation is an important prerequisite for satisfactory adjustment during childhood and also during adult life.

Personality is influenced by two main factors – constitutional and environmental – whilst a third, illness or disability, if present, can have a profound effect on the child. Constitutional factors include intelligence and temperament. The former describes the individual's ability to think rationally about himself and his environment, while the latter refers to the individual's characteristic style or approach to new people or situations, his level of activity and prevailing mood. These temperamental traits influence the child's response to his environment and also shape the range and variety of his experiences.

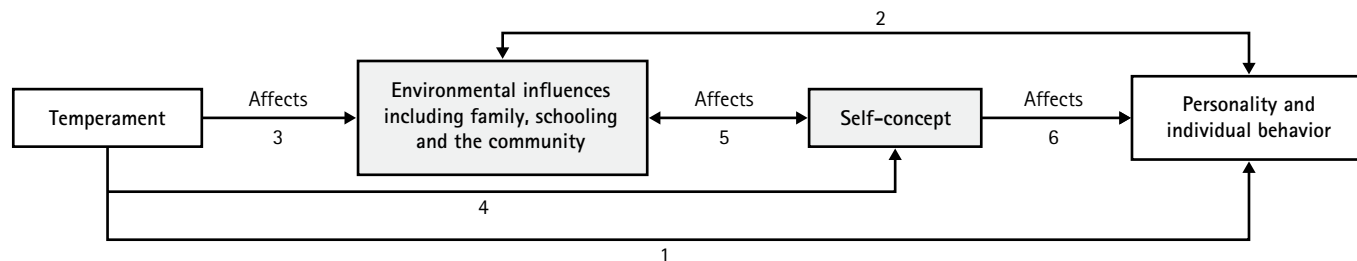

Fig. 34.1 Interactive model of personality development.

The main environmental influences are the family, schooling and the community. The family is the most powerful force for promoting healthy development as well as for causing severe disturbance in a child's life. Families fulfil many functions for children including: (1) the satisfaction of basic physical needs such as food and shelter; (2) the provision of love and security; (3) the development of social relationships with adults and peers; (4) the promotion of cognitive and language skills; (5) the experience of appropriate role models and socialization; and (6) the acquisition of ethical and moral values.

Schooling has three main roles for children: (1) the attainment of scholastic skills; (2) the promotion of peer relationships; and (3) the acceptance of adult authority outside the family. The community through the quality of housing and the availability of resources also has a considerable influence on the child's development. Finally, physical disability or illness, when present, exerts a major effect on personality development. This arises not only from the direct restrictions or limitations that they may impose on the child's abilities or activities, but more commonly and importantly, through indirect effects on the child's self-esteem, from overprotectiveness by the parents and from poor social relationships with siblings and peers.

Figure 34.1 is a diagrammatic representation of an interactive model of personality development that incorporates these ideas discussed in this section. As shown in Figure 34.1, constitutionally determined temperamental traits have a direct effect on personality and behavior, with the environment also exerting a similar impact. Environmental and temperamental factors have direct effects on the self-concept, which in turn shapes and modifies the personality as well as the environment. These interactive processes continue throughout childhood in a dynamic manner to produce a final product, an individual.

## GENERAL FEATURES OF PSYCHIATRIC DISTURBANCE

### DIAGNOSTIC CLASSIFICATION

A single cause is rarely responsible for the development of disturbance. The usual pattern is for several factors to be involved with a broad distinction into constitutional and environmental factors. The important constitutional factors are intelligence and temperament, whilst current life circumstances, the family, schooling and the community are the major environmental influences. One consequence of this multiple causation is that it is not possible to devise a diagnostic classification on the basis of etiology, as the relative contribution of each factor is often unclear.

Diagnostic practice is therefore descriptive or phenomenological, with three main categories of abnormality: *emotions*, *behavior* and *relationships*. In addition, these abnormalities should be of sufficient severity that they impair the individual in his daily activities and/or cause distress to the individual or to those responsible for his well-being. A commonly used definition of disturbance is as follows: an abnormality of emotions, behavior or relationships that is sufficiently severe and persistent to handicap the child in his social or personal functioning and/or to cause distress to the child, his parents or to people in the community.

The two commonest systems are the ICD-10<sup>10</sup> and DSM-IV.<sup>11</sup> DSM-IV is used extensively in North America, whereas ICD-10 is popular in the

UK. The two systems have similar underlying principles with an emphasis on a clinical-descriptive approach to diagnosis. An important difference between ICD-10 and DSM-IV is that the latter allows for more than one diagnosis, whereas ICD-10 prefers a single diagnosis. The following list shows a convenient way to classify the important psychiatric syndromes in childhood:

1. conduct disorders;
2. emotional disorders;
3. mixed disorders of conduct and emotions;
4. hyperkinetic disorders (ICD-10) or attention deficit hyperactivity disorder (DSM-IV);
5. disorders of social functioning;
6. tic disorders;
7. pervasive developmental disorders;
8. Miscellaneous disorders – encopresis, enuresis, sleep disorders and eating disorders.

Conduct disorder is characterized by severe, persistent, socially disapproved of behavior such as aggression or stealing that often involves damage to or destruction of property and is unresponsive to normal sanctions. The main feature of emotional disorder is a subjective sense of distress, often arising in response to stress. This group is further divided into phobic, anxiety, obsessional, conversion states and severe reactions to stress. Many disturbed children show a mixture of emotional and behavioral symptoms, so that a mixed category is clinically useful. An important source of confusion between the two classification systems is the terminology relating to hyperkinetic disorders in ICD-10 and attention deficit hyperactivity disorder (ADHD) in DSM-IV. Although both systems have the same core features (overactivity, impulsivity and inattention), the different names imply the two systems regard the main abnormality differently, namely hyperactivity for ICD-10 and inattention for DSM-IV. The situation is further complicated by the popular usage of another term to describe this group of disorders: ADHD. Disorders of social functioning comprise conditions such as selective mutism and attachment disorders. Pervasive developmental disorders include autistic spectrum disorder, Rett syndrome and childhood disintegrative disorder. The miscellaneous group contains a diverse group of problems such as encopresis, enuresis and developmental disorders. Other important but uncommon conditions such as schizophrenia and mood disorders are categorized in a similar fashion to that for adults, providing that the diagnostic criteria are fulfilled.

### EPIDEMIOLOGY OF DISTURBANCE

Epidemiological research has been an important research interest in the UK for the past 30 years. It has provided accurate information about the frequency and distribution of disturbance throughout childhood and adolescence,<sup>12</sup> the differences between urban and rural areas,<sup>13</sup> the effects of illness and disability on vulnerability to disturbance<sup>14</sup> as well as providing clues about the relative importance of various etiological factors.<sup>13</sup>

Most studies have shown prevalence rates of between 10% and 20% depending on the criteria for deviance. The first and most influential study was the Isle of Wight (IOW) study carried out by Rutter and colleagues.<sup>12</sup> Using a strict definition of disorder, they found rates of approximately 7% among 10–11-year-old children. Follow-up of these children into adolescence indicated a prevalence rate of around 7% with

more than 40% of the children with conduct disorder still having major problems. Disorders arising for the first time during adolescence were more adult like in presentation, with a preponderance of females. Over 80% of the disorders were in the emotional, conduct or mixed categories. Emotional disorders were more common among girls, with anxiety the commonest type. By contrast, conduct disorders, and to an important extent mixed disorder, were more common among boys with an association with specific reading retardation. A comparative study of 10-year-olds living in London<sup>13</sup> showed a rate of disturbance over twice that on the IOW. This study also showed that the difference in prevalence rate was entirely accounted for by the increased frequency of predisposing factors among children and their families in London compared with those on the IOW. These factors were family discord, parental psychiatric disorder, social disadvantage and inferior quality of schooling.

The IOW study<sup>14</sup> also showed that children with chronic illness or disability had much higher rates of disturbance than healthy children. For instance, children with a central nervous disease such as epilepsy or cerebral palsy had a rate over five times that of the general population, while children with other illnesses such as asthma or diabetes were twice as likely to be disturbed as healthy children. A more recent epidemiological study carried out by the Department of Health in the UK<sup>15</sup> on 10 000 children aged 5–15 years found a very similar prevalence rate and range of disturbance as the IOW study, namely an overall prevalence rate of 10% with conduct disorder (5%), emotional disorder (4%) and attention deficit disorder (ADD) (1%) the main diagnostic categories. The survey also confirmed that adverse social circumstance, chronic illness and learning difficulties were still important risk factors for disturbance.

Studies of pre-school children, most notably by Richman et al,<sup>16</sup> have found that about 20% of children have significant behavior problems, with 7% classified as severe. Follow-up studies of these children indicated that about 60% persisted, most commonly among overactive boys of low ability. An important association was found between language delay and disturbed behavior. Finally, problems were more likely to persist when there was marital discord, maternal psychiatric ill health and psychosocial disadvantage such as poor housing or large family size.

## ASSESSMENT PROCEDURES

Assessment is more time consuming in child psychiatry than in other branches of pediatrics. It has three components: history taking and examination, psychological assessment, and information about the child and family from other professionals.

### HISTORY TAKING AND EXAMINATION

This has many similarities to traditional methods, though with important modifications. Interview skills are essential to the elucidation, understanding and treatment of emotional and behavioral problems in children. Points of general importance include: (1) clarification about the nature of the problem and the reason for referral; (2) obtaining adequate factual information; (3) observing and eliciting emotional responses and attitudes about past events and about behavior during the interview; (3) establishing trust and confidence of the child and family; and (4) providing the parents with a summary of problems and a provisional treatment plan at the end of the initial interview.

There are no absolute rules about interviewing, indeed flexibility is essential. However, the following guidelines are useful:

1. The interview room should be large enough to seat the family comfortably and also to allow the children to use the play material in a relaxed manner.
2. Avoid having a desk between the interviewer and the family, i.e. put the desk against the wall of the interview room.
3. Do not spend the interview writing down notes but rather encourage eye-to-eye contact, taking the minimal notes necessary.
4. The play material must be suitable for a wide age range and include crayons and paper, jigsaws, simple games, books (provides a rough

estimate of reading ability), doll's house, play telephones and miniature domestic and zoo animals.

5. The play material should be gradually introduced as appropriate and not left around in a haphazard manner.
6. Interview parents and young children together.
7. Older children and adolescents like to be seen separately from parents at some point during interview.
8. Older children and adolescents are able to talk about problems openly once trust in the interviewer has been established.
9. Too direct questions usually elicit denial from the child, so that open-ended questions are much more preferable.

The interview should provide information about the following (bold type indicates essential facts):

1. **Presenting problem(s). Frequency. Severity. Onset. Course. Exacerbating/ameliorating factors. Effect on family. Help given so far.**
2. Other problems or complaints:
  - general health: eating, sleeping, elimination, physical complaints, fits or faints;
  - interests, activities and hobbies;
  - **relationship with parents and siblings;**
  - relationship with other children, special friends
  - mood – happy, sad, anxious
  - level of activity, attention span, concentration
  - antisocial behavior
  - **schooling: attainments, attendance, friendships, relationship with teachers**
  - sexual knowledge, interests and behavior (when relevant).
3. **Any other problems not previously mentioned**
4. Family structure:
  - a. **Parents: ages**, occupations, Current physical and psychiatric state. Previous physical and psychiatric history;
  - b. siblings, ages, problems;
  - c. home circumstances.
5. Family function:
  - a. quality of parenting: mutual support and help, level of communication and ability to resolve problems;
  - b. parent–child relationship: warmth, affection and acceptance, level of criticism, hostility and rejection;
  - c. siblings' relationship;
  - d. pattern of family relationships.
6. Personal history:
  - a. pregnancy and delivery;
  - b. early mother–child relationship, postpartum depression, early feeding patterns;
  - c. temperamental characteristics: easy or difficult, irregular, restless baby and toddler;
  - d. developmental milestones;
  - e. **past illnesses and injuries, hospitalization;**
  - f. separations greater than 1 week;
  - g. Previous schooling.
7. observation of child's behavior and emotional state:
  - a. appearance: nutritional state, signs of neglect or injury;
  - b. activity level: involuntary movements, concentration;
  - c. mood: expressions or signs of sadness, misery, anxiety;
  - d. reaction to and relationship with the doctor: eye contact, spontaneous talk, inhibition and disinhibition;
  - e. relationship with parents: affection/resentment, ease of separation;
  - f. habits and mannerisms;
  - g. presence of delusions, hallucinations, thought disorder.
8. observation of family relationships:
  - a. patterns of interaction;
  - b. clarity of boundaries between parents and child;
  - c. communication;
  - d. emotional atmosphere of family: mutual warmth/tension, criticisms.

9. physical examination:
  - a. screening neurological examination:
    - i. note any facial asymmetry;
    - ii. eye movements. Ask child to follow a moving finger and observe eye movement for jerkiness, uncoordination;
    - iii. finger–thumb apposition. Ask child to press the tip of each finger against the thumb in rapid succession. Observe clumsiness, weakness;
    - iv. copying pattern: drawing a man;
    - v. observe grip and dexterity in drawing;
    - vi. observe visual competence when drawing;
    - vii. jumping up and down on the spot;
    - viii. hopping;
    - ix. hearing. Capacity of child to repeat numbers whispered 2 m behind him.
  - b. further medical examination (if relevant).

## FORMULATION

At completion of the assessment, the clinician should be able to make a formulation. This is a succinct summary of the important features of the individual case. The formulation consists of the following: (1) statement of main problems; (2) diagnosis and differential diagnosis; (3) relative contribution of constitutional and environmental factors to the etiology; (4) probable short term and long term outcome; further information required (including special investigations); and (5) initial treatment plan. The formulation should be included in the case notes, thereby providing the clinician with a record of his views at referral.

## PSYCHOLOGICAL ASSESSMENT

Psychological assessment carried out by a child psychologist is a valuable part of the overall assessment of a child's problems in some situations. It can provide information about three aspects of development: general intelligence, educational attainments and special skills. Assessment is usually based upon the administration of standardized assessment tests. These are either norm referenced or criterion referenced. The former compares the child's ability with other children of the same age, whereas the latter is on a pass/fail basis, for instance whether he can tie his shoelaces. Ideally, the test items should have good discriminatory value (distinguish between children of different ability), be reliable (give similar results when repeated) and valid (in agreement with other independent evidence). An important aspect of the assessment is that the tasks are carried out in a standardized fashion, thereby increasing reliability and validity.

## INTELLECTUAL ABILITY

### Developmental assessment in infancy and early childhood

The commonly used tests are the Bailey's Scales,<sup>17</sup> Griffiths Mental Development Scales<sup>18</sup> and the Kaufman Assessment Battery for Children (K-ABC).<sup>19</sup>

### Assessment of general intelligence amongst school-age children

The most popular test is the Wechsler Intelligence Scale for Children – Revised Form (WISC-R).<sup>20</sup> This covers an age range from 6–16 years. Ten sub tests are usually used, measuring different aspects of the child's ability. Commonly, the tests are divided into 'verbal' and 'performance' categories, yielding a 'verbal IQ' and a 'performance IQ'. The 'verbal' subtests commonly used are information, comprehension, arithmetic, similarities and vocabulary, whilst the 'performance' tests are picture completion, picture arrangement, block design, object assembly and coding. Each subtest has a mean score of 10, so that combining the 10 tests gives a 'full scale' intelligence quotient (IQ) of 100 with a standard deviation of 15. The 'normal' distribution of the test scores means that it is possible to state that 66% of children will

be within the IQ range 85–115, 95% within IQ range 70–130, 99% within IQ range 55–145. Other tests used include the Stanford-Binet<sup>21</sup> and the British Ability Scales (BAS).<sup>22</sup>

## EDUCATIONAL ATTAINMENT

There are two commonly used reading tests, the WORD (Wechsler Objective Reading Test)<sup>23</sup> and the Neale Analysis of Reading Ability.<sup>24</sup> The former measures basic reading, comprehension and spelling skills, whilst the latter provides information about speed, accuracy and comprehension of reading. The scores on the Neale test can be transformed into reading ages of so many years and months, for instance 6 years 11 months. The subtest scores of the WISC-R or the BAS can be used as a guide to mathematical ability.

## Specific skills

Reynell development language scale,<sup>25</sup> Bender Motor Gestalt Test and the Vineland Social Maturity Scale are examples of tests to assess the child's acquisition of certain abilities and skills. These are often helpful with some specific problems.

## Limitations of assessment

Caution should always be exercised in the interpretation of test results. It is wrong to attribute undue significance to a single result, most often done with the IQ score. Many factors influence test results including fatigue, poor testing conditions and the use of inappropriate tests. The results should be evaluated in the context of the overall assessment and the report from the child psychologist. A great deal of harm, upset and distress can arise for a child when he is incorrectly classified or labeled as too able or too dull on the basis of an unreliable psychological assessment.

## Additional information

A distinctive feature of child psychiatry practice is the importance attached to obtaining independent evidence about the child's behavior. This is for two reasons: firstly, a child's behavior varies from one situation to another, so that it is helpful to have information about the child's behavior in several contexts; secondly, parental accounts of the child's behavior are likely to be distorted in many cases, as it is the parents who are disturbed rather than the child. Consequently, an important part of assessment is to obtain reports from other professionals involved with the family such as schools, health visitors or general practitioners. Another common practice is the use of questionnaires to supplement information provided by referrers and other more formal reports. Several questionnaires<sup>16,26</sup> have been devised to assess different age ranges and have satisfactory psychometric properties. Until recently, the most extensively used questionnaires for school-age children in the UK have been the Rutter parents' and teachers' scales, also known as Rutter A and Rutter B, respectively. These scales have established reliability and validity as well as classifying children into neurotic or emotional, conduct or antisocial and mixed categories. Over the past 5 years, the Strengths and Difficulties Questionnaire (SDQ)<sup>27</sup> has become more popular, as it assesses pro-social behavior as well as disturbed behavior.

## DISORDERS IN PRESCHOOL CHILDREN

Except for rare but severe disorders such as childhood autism, psychiatric disorders in this age group are mostly deviations or delays from normality rather than a psychiatric illness as such. Moreover, the child's behavior and development are so influenced by the immediate surroundings that it is often the environment rather than the child that is responsible for the problems.

## ETIOLOGY

Four types of factors contribute to problems in varying degrees in the individual case: temperamental factors, physical illness or handicap, family psychopathology and social disadvantage. The New York

Longitudinal Study<sup>28</sup> showed clearly that children with certain types of temperamental characteristics, the so-called 'difficult child' and the 'slow to warm up child' profiles, were more likely to develop problems. Again, physical illness or disability can reduce activity, directly or indirectly affect developmental progress and increase parental anxiety, all of which potentate the likelihood of behavioral disturbance. Parental psychiatric illness, marital disharmony and poor parenting skills are examples when disturbance in the parents adversely affects the child's behavior. Several authors<sup>16,29</sup> have shown high rates of depression among mothers with pre-school children. Social disadvantage such as poor housing or inadequate recreational facilities increases the risk of disturbance among pre-school children.<sup>16</sup>

**FREQUENCY OF PROBLEMS**

Table 34.2 shows the prevalence of common problems among 3- and 4-year-olds in the general population.<sup>30</sup>

Problems are mainly about eating, sleeping and elimination, with a marked decrease in wetting and soiling over the 1-year period. Affective symptoms such as unhappiness and relationship problems are much less common, but probably more significant. Community studies<sup>16</sup> indicate that 20% of children are regarded by their mothers as having problems, with 7% rated as severe.

**COMMON PROBLEMS**

This section discusses those problems that are particularly frequent among the pre-school child, whilst others such as soiling, which occur in older children as well are discussed later in the chapter.

**Temper tantrums**

They usually arise when the child is thwarted, angry or has hurt himself. They can occur in isolation or as part of a wider problem. They comprise a variety of behaviors, including screaming, crying, often with collapse onto the floor and banging of feet. A child can be aggressive towards other people around him, but the child rarely injures himself. Most tantrums 'burn themselves out', so that specific intervention is not necessary. If it is, then the following points are useful: if necessary, restrain from behind by folding arms around child's body; minimize any additional attention to the child; and only respond and praise when behavior is back to normal.

**Feeding problems**

They range in severity from a minor problem such as the finicky child to the severe disabling problem of non-organic failure to thrive. Minor problems will usually respond to patient and attentive listening to the

parents' concerns, counseling and specific advice. Severe non-organic failure to thrive (prevalence 2%) is a complex problem requiring comprehensive assessment and a large amount of time and resources to remedy.<sup>31</sup> Several factors are responsible in most cases including a poor mother-child relationship, often in the context of more widespread emotional and social deprivation, and factors in the child, including temperamental factors and an aversion to feeding. *Pica*, the ingestion of inedible material such as dirt or rubbish, is a normal transitory phenomenon during the toddler period. Persistent ingestion is found amongst mentally retarded, psychotic or socially deprived children. Lead poisoning, though always mentioned, is a possible but uncommon danger from pica.

**Sleep problems (sleep problems in older children are discussed in the miscellaneous disorders section)**

These are common with up to 20% of 2-year-olds, waking at least five times per week.<sup>16,32</sup> The two most frequent problems are reluctance to settle at night and persistent waking up during the night. Several factors contribute to the problem including adverse temperamental characteristics in the child, perinatal problems and maternal anxiety. It is also important to distinguish between those factors responsible for the onset of the problem and those for maintaining the problem. Medication such as trimeprazine and promethazine are frequently prescribed, but side-effects often outweigh any advantages. The only real indication is to provide a brief respite for the parents as well as ensuring that the child has an uninterrupted night's sleep. The most successful management is a behavioral strategy (see Treatment section). Richman & Landsdown<sup>30</sup> provide a useful summary of these techniques. More recently, there have been case reports<sup>33</sup> suggesting the successful use of melatonin to treat sleep disorders among visually and neurologically impaired children and substantial randomized controlled trials are currently underway.

**PSYCHIATRIC ASPECTS OF CHILD ABUSE<sup>34</sup>**

Originally this was restricted to the 'battered baby syndrome', but it has now been extended to include physical abuse, sexual abuse, emotional abuse and neglect. This section will concentrate on the psychiatric aspects in childhood as other sections discuss diagnostic (see Ch. 6) and adolescent issues (see later in the chapter). It is also important to remember that the different aspects of child abuse are frequently present in the same child and family and that many comments about the detection, management and treatment apply equally to all aspects of child abuse.

**PHYSICAL ABUSE**

Diagnostic awareness and suspicion are the key elements in the detection and recognition of physical abuse. The following list summarizes the common characteristics of abused children and their families, although the most important factor to recognize is that child abuse can occur in any family irrespective of social class, ethnic group or religious affiliation.

**Common characteristics of abused children and their families**

Risk characteristics of the abused child:

1. product of unwanted pregnancy;
2. unwanted child in the family;
3. low birth weight;
4. separation from mother in neonatal period;
5. mental or physical disability;
6. habitually restless, sleeplessness or incessantly crying;
7. physically unattractive.

Risk characteristics of the parent(s):

1. single parent;
2. young;
3. abused themselves as a child;

Table 34.2 Problem behaviors in 3- and 4-year-olds<sup>30</sup>

Behavior	3-year-olds (%)	4-year-olds (%)
Poor appetite	19	20
Faddy eater	15	24
Difficulty settling at night	16	15
Waking at night	14	12
Overactive and restless	17	13
Poor concentration	9	6
Difficult to control	11	10
Temper	5	6
Unhappy mood	4	7
Worries	4	1
Fears	10	12
Poor relationships with siblings	10	15
Poor relationships with peers	4	6
Regular day wetting	26	8
Regular night wetting	33	19
Regular soiling	16	3

4. low self-esteem;
5. unrealistic expectations of the child and his development;
6. inconsistent or punishment-orientated discipline.

Risk characteristics of social circumstances:

1. low income or unemployment;
2. social isolation;
3. current stress such as housing crisis, domestic friction, exhaustion or ill-health;
4. large family.

## Management

Most cases of child abuse do not require the involvement of a child psychiatrist, as the principal concerns are the protection of the child, practical support for the family and help with parenting skills. The child psychiatrist can make a useful contribution in two ways: firstly, to act as an outside consultant on various aspects of management and treatment to the other professionals and agencies working with the family; and secondly to provide individual and or family therapy for the child, the parents or the family depending upon the assessment.

In addition to the immediate effects, child abuse may have medium term and long term sequelae. Many abused children continue to be exposed to emotional abuse and neglect throughout their childhood, so that they often show symptoms of disturbance such as unhappiness, wariness, untrusting, low self-esteem and poor peer relationships. This childhood experience in turn predisposes abused children to become abusing parents when adults.

## SEXUAL ABUSE

This has become a major public and pediatric concern over the past decade. Several factors have contributed to the increased concern: it is a common event affecting 12–17% of females and 5–8% males according to several epidemiological surveys.<sup>35</sup> It is traumatic for the child, giving rise to major distress at the time of its occurrence, but equally importantly acts as a predisposing factor for psychiatric disorder later on in life. Indeed, a history of sexual abuse in childhood is a very common finding among women referred to adult psychiatric services.

Complex psychological processes contribute to the development of psychopathology, as attitudes to sexuality are shaped in a dysfunctional manner by the abuse. Also, the individual has a sense of betrayal, powerlessness and stigmatization leading to shame, guilt and low self-esteem. One consequence of this process is that sexual abuse can present in a wide variety of ways from the physical, e.g. vaginal discharge to the psychological such as anxiety, aggression or encopresis. It is therefore crucial to be aware that unexplained or atypical symptoms may be the presenting complaint for a child with a current or past history of sexual abuse.

The child psychiatry team has a more clearly defined role in the management of sexual abuse, as interviewing skills, psychotherapeutic expertise and the use of specialist equipment (anatomically accurate dolls) are often necessary at the detection and also during the treatment stage of management. Detailed accounts of this work, including the use of the anatomical dolls, are well described in the several books (the Great Ormond Street child sex abuse team<sup>36</sup>) and the APSAC Handbook.<sup>34</sup>

## EMOTIONAL ABUSE

This term has been introduced to describe the severe impairment of social and emotional development resulting from repeated and persistent criticism, lack of affection, rejection, verbal abuse and other similar behavior by the parent(s) to the child. Affected children display a variety of symptoms: low self-esteem; limited capacity for enjoyment; severe aggression; and impulsive behavior.

## NEGLECT

This varies markedly, ranging from relative inadequacy and incompetence in providing basic shelter, love and security for the child, to a

severe failure in the provision of basic essentials, often combined with emotional and social deprivation.

## FACTITIOUS OR INDUCED ILLNESS<sup>37</sup>

This remarkable variant of physical abuse (previously called Munchausen syndrome by proxy) often occurs against the same background of parental psychopathology and social disadvantage as other forms of abuse. The role of the child psychiatrist is usually confined in most cases to offering counseling for the parents and/or family therapy when indicated.

## PERVASIVE DEVELOPMENTAL DISORDERS<sup>38,39</sup>

Historically, these disorders were classified under childhood psychoses, as they are severe and disabling with clear-cut abnormalities. However, autistic children do not experience hallucinations or delusions, key features of a psychotic disorder, and moreover have had the abnormalities from early infancy. For these reasons, ICD-10 and DSM-IV have separated out childhood autism and related conditions from other psychotic conditions in childhood into a new diagnostic category called pervasive developmental disorders. In clinical practice, most people recognize that autistic disorders comprise a spectrum of disabilities (autistic spectrum disorders) with childhood autism at the severe end and Asperger syndrome at the mild end. Rett syndrome and disintegrative disorder are also included in the pervasive developmental disorders category.

## CHILDHOOD AUTISM

Kanner's<sup>40</sup> original description of 11 children with 'an extreme autistic aloneness' has not been improved upon with its astute observation of 'inability to relate in an ordinary way to people and to situations' and 'an anxiously obsessive desire for the maintenance of sameness'. Subsequently, opinions have fluctuated about the diagnosis, etiology and treatment. Most authorities now agree that three features are essential to the diagnosis: general and profound failure to develop social relationships; language retardation; and ritualistic and compulsive behavior. Additionally, these abnormalities should be manifest before 30 months.

## Prevalence

Previous epidemiological studies in childhood have found prevalence rates of four per 10 000 increasing to 20/10 000 when individuals with severe mental retardation and some autistic features are included. Boys are three times more affected than girls. However, a more recent study<sup>41</sup> reported a rate of 16 per 10 000 for autistic disorder and 64 per 10 000 for other pervasive developmental disorders. It remains to be seen whether these new findings are replicated elsewhere.

## Clinical features

### *Impaired social relationships*

Parental recollections of infancy often reveal that as an infant the child was slow to smile, unresponsive and passive with a dislike of physical contact and affection. Contemporary social deficits include the failure to use eye-to-eye gaze and facial expression for social interaction, rarely seeking others for comfort or affection, rarely initiating interaction with others, a lack of empathy (the ability to understand how others feel and think) and of cooperative play. The children are aloof and indifferent to people.

### *Language abnormalities*

Language acquisition is delayed and deviant with many autistic children never developing language (approximately 50%). When present, language abnormalities are many and varied, including immediate and delayed echolalia (repetition of spoken word(s) or phrase(s)), poor comprehension and use of gesture, pronominal reversal (the use of the third person when 'I' is meant) and abnormalities in intonation, rhythm and pitch.

### ***Ritualistic and compulsive behavior***

Common abnormalities are rigid and restricted patterns of play, intense attachments to unusual objects such as stones, unusual preoccupations and interests (timetables, bus routes) to the exclusion of other pursuits and a marked resistance to any change in the environment or daily routine. Tantrums and explosive outbursts often occur when any change is attempted.

### ***Other features***

Autistic children often exhibit a variety of stereotypes including rocking, finger twirling, spinning and tiptoe walking. They are often overactive with a short attention span. Of autistic children 70% are in the retarded range of intelligence with only 5% having an IQ above 100. Occasionally, some have remarkable abilities in isolated areas, for instance computation, music or rote memory. About 20% will develop epilepsy during adolescence, though not usually severe.

### ***Association with other conditions***

Autistic behavior occurs in some patients with a diverse group of conditions including the fragile X syndrome, congenital rubella, phenylketonuria, tuberous sclerosis, neurolipoidoses and infantile spasms.<sup>43</sup> More recently, Rett syndrome, with its marked autistic features, has been described.<sup>44</sup>

### ***Etiology***

Most people favor an organic basis as neurological abnormalities are common, the association with epilepsy and various neurological syndromes, the increased rate of perinatal complications and a greater concordance rate among monozygotic compared with dizygotic twins.<sup>43,45</sup> Application of new investigative techniques such as CAT scan, MRI and positron emission tomography are beginning to reveal abnormalities in the frontal lobe region, with distinctive deficits on tests of executive function.<sup>46</sup> The relationship between autism and the fragile X syndrome is also unclear, as the different rates in the various studies may be a reflection of the degree of mental handicap rather than of any etiological significance. A most interesting psychological perspective on the autistic deficit is provided by the work of Baron-Cohen<sup>47</sup> and Hobson.<sup>48</sup> On the basis of sophisticated cognitive experiments with autistic children, they propose that the primary deficit in autism is a lack of empathy, namely an inability to perceive and interpret emotional cues in social situations.

### ***Treatment***

The explanation of the diagnosis is a vital first step in helping parents to accept the presence of handicap with the consequent lessening of the parental guilt about etiology. Counseling and advice are likely to be necessary throughout childhood. Lord & Rutter<sup>43</sup> suggested that treatment aims should have four components: (1) the promotion of normal development, (2) the reduction of rigidity and stereotypes, (3) the removal of maladaptive behavior, and (4) the alleviation of family stress. Behavioral methods, including operant conditioning and shaping (see behavioral treatment section), are the most likely ways to achieve some success with the first three aims, whilst counseling is important for the fourth. Special schooling, where the child's special social and educational needs are recognized, is very beneficial, sometimes on a residential basis. Drugs do not have an important part in management.

### ***Outcome***

Many autistic individuals are unable to live independently with only 15% looking after and supporting themselves as adults. Many were placed previously in institutions for the mentally handicapped, though government policy now favors community care. Autistic children with an IQ of at least 70, receiving proper education and coming from middle-class families do better than those in other groups. In most individuals there is some improvement in social relationships, though many are still handicapped. Parents often find it helpful to join a voluntary society such as the National Society for Autistic Children.

## **OTHER PERVASIVE DEVELOPMENTAL DISORDERS**

### **Asperger syndrome/schizoid personality**

This condition, originally described by Asperger,<sup>49</sup> shows some similarities to childhood autism in that there is an impairment of social relationships with a lack of reciprocal social interaction and a restricted repertoire of interests and activities. However, the children differ diagnostically from those with childhood autism in two important respects: there is no general intellectual retardation, and the language development is normal. Other characteristics include male preponderance and poor motor coordination with marked clumsiness. The condition is now regarded as one of the autistic spectrum disorders<sup>39</sup> with the impairment in social relationships persisting into adult life.

The term 'schizoid' personality of childhood was coined by Wolff & Chick<sup>50</sup> to describe a small number of children with unusual but distinctive personality characteristics, similar in some ways to children with Asperger syndrome. These 'schizoid' children were described as aloof, distant and lacking in empathy. Other features include: obstinate and aggressive outbursts when under pressure to conform, often at school; undue rigidity; sensitivity to criticism; and unusual interests to the exclusion of everything else. More recently, Wolff<sup>51</sup> has argued from follow-up studies of these children that they form a separate diagnostic category, the schizoid personality of childhood, similar to but distinct from childhood autism and Asperger syndrome. As adults, Wolff<sup>51</sup> found that they showed features of the schizotypal disorder.

### **Rett syndrome**

In 1966 Rett described 22 mentally handicapped children, all girls, who had a history of regression in development and displayed strikingly repetitive movements of the hands. He thought that the children were autistic with progressive spasticity, and proposed that diffuse cerebral atrophy was the underlying cause. A more recent review<sup>44</sup> has indicated this syndrome is more common than previously thought with a prevalence rate of 1 per 15 000 girls.

### ***Clinical features***

The condition, which has only been described in girls, shows a characteristic clinical picture: a period of normal development up to around 18 months followed by a rapid decline in developmental progress and the rapid deterioration of higher brain functions.

Over the following 18 months, there is evidence of severe dementia, a loss of purposeful hand movements, jerky ataxia and acquired microcephaly. After this rapid decline, the condition may stabilize with no further progression for some time. Subsequently, more neurological abnormalities appear including spastic paraplegia and epilepsy.

### ***Etiology***

Rett originally believed that high levels of ammonia were responsible for the condition, though subsequent studies have not confirmed this observation. The most commonly proposed explanation is that it is due to a dominant mutation on one X chromosome, and that the condition is nonviable in the male. Genetic studies indicate that the disorder is associated with the MECP2 gene at Xq28.

### ***Prognosis***

The majority of children are left profoundly retarded with severe neurological impairments. Many succumb to intermittent infections or to the underlying neuropathological disorder.

### **Disintegrative disorder**

#### ***Clinical features***<sup>43,52</sup>

This term refers to a group of conditions characterized by normal development until around 4 years of age followed by profound regression and behavioral disintegration, loss of language and other skills, impairment of social relationships and the development of stereotypes. It can

follow on from a minor illness or from more definite neurological disease such as measles encephalitis. The prognosis is poor due to the underlying degenerative pathology in many cases. Most individuals are left with severe learning disability.

### **Other related conditions**

Many children with learning disabilities show some autistic features. In clinical practice, it is often difficult to know whether they fulfil the criteria for pervasive developmental disorder in addition to that for intellectual retardation. It is clear that there is a wide diversity in the severity of these 'autistic features', so that it is often arbitrary whether the label 'childhood autism' is applied to these children. Many of them also show features of hyperactivity and aggression. For these reasons, ICD-10 has made two additional categories: (1) overactive disorder associated with mental retardation and stereotyped movements and (2) pervasive developmental disorder unspecified.

## **EMOTIONAL DISORDERS**

The primary abnormality is a subjective sense of distress due to anxiety that can be expressed overtly as in anxiety disorders or covertly as in somatization or conversion disorders. This group of disorders is similar in many respects to neurotic disorders in adults. They are further divided into the following categories: anxiety and phobic states; obsessional disorders; conversion disorders, dissociative states and somatization disorders; and reaction to severe stress and adjustment disorders. Many children often show a mixed pattern of symptoms, so that a clear-cut distinction into a single category is not possible. The DOH 2000 study<sup>15</sup> found a prevalence rate of 4.0% with an equal gender prevalence. Prognosis is generally favorable as many problems arise from an acute stress, so that the problems should resolve once the stressful effects lessen.

### **ANXIETY STATES**

#### **Clinical features**

This is the commonest type of emotional disorder. Anxiety has physical and psychological components, with the former referring to palpitations and dry mouth, while the latter to the subjective sense of fear and apprehension. Somatic symptoms, particularly abdominal pain, are common. Again, many symptoms represent the persistence or exaggeration of normal developmental fears, ranging in severity from an acute panic attack to a chronic anxiety state over several months. Predisposing factors include temperamental characteristics, overinvolved and overconcerned parents and the 'special child syndrome'. The latter refers to children who are treated differently by their parents. This may arise in several circumstances, for instance the child is much wanted and previous ill health during pregnancy or infancy has resulted in an 'anxious' attachment between the child and parents. In turn, 'anxious' attachment may lead the parents to inadvertently reinforce normal fears and anxieties.

#### **Treatment**

Several approaches, including individual, behavioral and family therapy, are used, often in combination depending upon the assessment and formulation. The newer serotonin re-uptake inhibitors (SRIs) such as buspirone have been shown to be effective in clinical trials, and are preferable to benzodiazepines.

### **PHOBIC STATES**

#### **Clinical features**

Phobias are common and normal among children. For instance, toddlers are fearful of strangers, whereas adolescents are anxious about their appearance or weight. Pathological fears often arise from ordinary fears that are exacerbated by parental and/or social reinforcement. A phobia is defined as 'a fear of specific object or situation', for instance dogs or

heights. Its characteristics are that it is out of proportion to the situation, is irrational, is beyond voluntary control and leads to avoidance of the feared situation. This avoidance behaviour is the main reason the fear is maladaptive as it leads to increasing restriction and limitation of the child's activities.

#### **Treatment**

A behavioural approach using graded exposure to the feared situation is the most commonly used treatment. The rationale for this approach is that continued exposure to the feared stimulus reduces the anxiety associated with the stimulus, thereby decreasing avoidance behaviour. The success of this method often depends on the ability of the therapist to devise a treatment program that combines gradual exposure without inducing too much anxiety. Occasionally, anxiolytic drugs are used in conjunction with this behavioral approach.

### **SCHOOL REFUSAL<sup>53</sup>**

This term, also known as school phobia, refers to the child's irrational fear about school attendance. It is also known as the 'masquerade syndrome' as it can present in a variety of disguises, including abdominal pain, headaches or a viral infection. The child is reluctant to leave home in the morning to attend school, in contrast to the truant who leaves home but not arrive at school. It occurs most commonly at the commencement of schooling, change of school, or the beginning of secondary school.

Most cases can be understood in terms of the following three mechanisms, often in combination: firstly, separation anxiety, whereby the child and/or the parent are fearful of separation, of which school is an example; secondly, a specific phobia about some aspect of school such as traveling to school, mixing with other children, or some part of the school routine, for instance some subjects, gym, or assembly; and thirdly, an indication of a more general psychiatric disturbance such as depression or low self-esteem. The latter is more frequent among adolescents. Typically, most school refusers have good academic attainments and are conformist at school, but oppositional at home. School refusal can present acutely or insidiously, often becoming a chronic problem in adolescence.

#### **Treatment**

The initial essential step is to recognize the condition itself, namely to avoid unnecessary and extensive investigations for minor somatic symptoms or to advise prolonged convalescence following a minor illness. For the acute case, early return to school with firm support for the parents and liaison with the school is the most successful approach. For the more intractable cases, extensive work with the child and parents, along with a graded return to school is advisable. A specific behavioral program for the phobic aspects may be necessary as well as the use of anxiolytic drugs in some instances. The chronic problem often requires a concerted approach, sometimes involving a period of assessment and treatment at a child psychiatric day or inpatient unit. Many clinicians use family therapy to tackle the major relationship problems that exist in some cases.

#### **Outcome**

Two thirds usually return to school regularly, whilst the remainder, usually adolescents from disturbed families, only achieve erratic attendance at school at best. Follow-up studies have found that approximately one third continue with neurotic symptoms and social impairment into adult life.

### **OBSESSIVE-COMPULSIVE DISORDERS<sup>54</sup> (Fig. 34.2)**

#### **Definition**

An obsession is a recurrent, intrusive thought that the individual recognizes is irrational but cannot ignore. A compulsion or ritual is the behavior(s) accompanying these ideas, the aim of which is to reduce the associated anxiety.

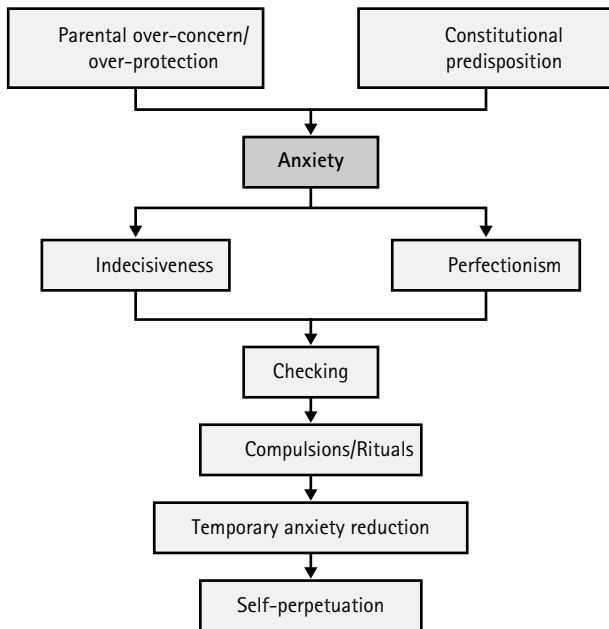

Fig. 34.2 Development of obsessional systems.

### Clinical features

Most children display obsessional symptoms to a minor degree at some time, for instance avoiding cracks on paving stones or walking under ladders. They have no significance. It is when the behavior interferes with ordinary activities that it amounts to a disorder. Common obsessional rituals are hand washing and dressing. Obsessional thoughts often have a foreboding quality, for instance that 'something could happen' to a parent or sibling, that he might die, or get run over. The rituals are maintained, though maladaptive, because they produce a temporary reduction in anxiety. Commonly, the child involves other members of the family in the performance of rituals, so that the child assumes a controlling role within the family. The disorder is rare (community prevalence 0.3%) but commoner among older children and adolescents with an acute or gradual onset. In addition to anxiety symptoms, many children have depressive features.

### Treatment

Behavioral methods, particularly response prevention, are successful in eliminating the obsessive-compulsive behavior. Response prevention consists of training the child to become aware of the cues that trigger the symptom and then using distraction techniques to make the performance of the ritual impossible. Recent clinical trials<sup>34</sup> have shown that SRIs such as paroxetine or sertraline are effective in their own right, but more importantly are very valuable as part of a combined medication – behavioral treatment package. Involvement of other members of the family, whether specifically in family therapy or to assist the child in the elimination of rituals, is necessary. Some cases require inpatient admission.

### Outcome

Two thirds do well and the remainder continue to have problems, usually in a fluctuating fashion.

## CONVERSION DISORDERS AND DISSOCIATIVE STATES

### Clinical features

These are rare in childhood. Conversion disorder is the development of physical symptoms, usually of the special senses or limbs, without any pathological basis in the presence of identifiable stress and/or affective disturbance. The emotional conflict is said to be 'converted' into physical symptoms, which is less threatening to the individual than the under-

lying psychological conflict. A dissociative state is the restriction or narrowing of consciousness due to psychological causes, for example amnesic or fugue states. It is, however, extremely dangerous to diagnose the condition solely by the exclusion of organic disease, as follow-up studies have found that a minority subsequently develop definite organic illness. There should always be positive psychological reasons to explain the development of the symptoms. Common reasons include major life events or stresses for the child, a similar illness among other family members/peers or an underlying depressive disorder.

Minor degrees of these disorders are extremely common and frequently occur as a transitory phenomenon during the course of many illnesses. The more general term 'abnormal illness behavior', similar to the physician's phrase 'functional overlay', has been coined to describe the situation when the individual persists with or exaggerates symptoms following on from an illness.

### Treatment

Successful treatment depends upon the recognition that the symptoms are 'real' for the child. Psychic pain is just as distressing as physical pain. Anger and confrontation are unhelpful. A firm sympathetic approach with little attention to the symptom per se as well as avoiding rewarding the symptom is the best strategy. Allow the child to give up the symptoms with good grace, often providing the child with some face-saving reason for improvement. Identify and treat any affective disturbance. The outcome is good for the individual episode, though other psychological problems may persist.

## SOMATIFORM DISORDERS<sup>55</sup> (see adolescent section for chronic fatigue syndrome)

### Clinical features and management

Many children complain of somatic symptoms that do not have a pathological basis. Common symptoms are abdominal pain, headaches and limb pains with community prevalence rates of approximately 10%. This condition is usually managed by general practitioners, though it sometimes results in a referral for a specialist opinion. Management involves the minimum necessary investigation to exclude any pathology, the identification of any stressful circumstances and a sensitive explanation of the basis for the symptoms. The prevention of restrictions and the active encouragement of normal activities are essential.

When the somatic symptoms are persistent, chronic and involve several systems of the body, ICD and DSM use the term *somatization disorder*. Whilst it is doubtful whether this disorder occurs in childhood, there is no doubt that persistent unexplained physical complaints are a common reason for children being taken to see the doctor. In many cases, there is clear evidence of underlying anxiety or recent stressful events.

## REACTION TO SEVERE STRESS AND ADJUSTMENT DISORDERS

This group of disorders arises in response to an exceptionally stressful event or to a significantly adverse life change. The clinical features of the different syndromes vary considerably with a preponderance of affective symptoms in most cases.

### Adjustment disorder

#### Definition

This is a maladaptive response occurring within 3 months of an identifiable psychosocial stressor. The maladaptive response must be of sufficient severity to impair daily activities such as schooling, hamper social relationships and be greater than expected given the nature of the stressor. Finally, the reaction must not last longer than 6 months.

#### Clinical features

By definition, the symptoms vary with ICD and DSM recognizing more than six categories. Clinical practice shows that anxiety and depressive

symptoms, often combined, are the most frequent categories. Common stressors include parental divorce, unemployment, family illness or family move.

### **Predisposing factors**

Age has different effects depending on the type of stressor. For instance, separation is more upsetting for a younger child than for an adolescent, whereas a loss of or change in a heterosexual relationship is far more important for an adolescent than for a younger child. Boys are also more vulnerable to the adverse effects of stress than girls. Temperamental characteristics such as 'difficult' or 'slow to warm up' style probably influence susceptibility as well. Again, the child's previous experience and repertoire of coping skills affect the response to the current stressor. For instance, if the child has successfully coped with adversity in the past, resilience and ability to withstand the present situation are enhanced. Finally, the family, particularly the parents, can magnify or minimize the impact of a stressor, dependent on their resourcefulness and coping style.

### **Outcome**

By definition, the disorder can only last for 6 months, after which time the diagnostic category must change. The more important clinical consideration is not the change in diagnostic category, but the adverse effect that chronic or repeated stresses can have on the child's long term adjustment.

### **Post-traumatic stress disorder (PTSD)<sup>56</sup>**

The 'epidemic' of disasters that some British children have been involved with over the past 20 years (the capsizing of the *Herald of Free Enterprise*, the sinking of the cruise ship *Jupiter*, the PanAm Lockerbie air crash and the crushing disaster at the Hillsborough football stadium) have made clinicians acutely aware of this syndrome. Clinicians are now familiar with the wide symptomatology often found, and have also become involved in treatment programs to reduce the distress both in the immediate aftermath and also in the long term.

### **Definition**

This disorder arises following exposure to a stressful event of an exceptionally threatening or catastrophic nature that would cause pervasive distress in almost anyone. The events include accidents or disasters as well as more personal traumas such as witnessing a murder, a rape or torture. In clinical practice, children who have been sexually abused commonly present with symptoms falling within the diagnostic category of PTSD.

### **Clinical features**

These include 'flashbacks' (the repeated re-enactment of the event with intrusive memories, dreams or nightmares); a sense of detachment, 'numbness' and emotional blunting; irritability, poor concentration and memory problems. Following disasters, many survivors often experience an increased awareness of danger, a foreshortened view of the future ('only plan for today'), a feeling of 'survivor' guilt (self-reproach about own survival, whilst companions died) and acute panic reactions.

Yule<sup>56</sup> indicates that 30–50% of children show significant psychological morbidity following disasters with symptoms persisting for several months.

### **Individual vulnerability factors**

Important modifying factors are probably age, previous experiences, current life situation and the availability of help. Though cognitive immaturity may protect the child from appreciating the implications of a disaster, it may also be a disadvantage, as the child may not be given the opportunity to talk about the event. The child's previous experience of stressful events and their outcome, successful or otherwise, are likely to influence the response to the disaster.

Similarly, co-existing adverse circumstances such as family disharmony or school problems reduce the child's capacity to cope with the new situation.

### **Management**

Though most research is anecdotal rather than systematic, the available evidence<sup>56</sup> suggests that post-disaster 'debriefing' sessions on an individual or group basis are helpful. Specific counseling sessions to help a child deal with phobic, anxiety or depressive symptoms are frequently necessary as well. Cognitive/behavioral approaches are particularly suitable for this pattern of symptoms.

## **MOOD DISORDERS (See adolescent section)**

### **CONDUCT DISORDER**

#### **Clinical features**

This is usually defined as persistent antisocial or socially disapproved of behavior that often involves damage to property and is unresponsive to normal sanctions. The IOW study<sup>14</sup> found a prevalence rate of 4% when the mixed disorder category was included as well, with a marked male predominance (at least 3:1). There is no independent criterion for deviancy as social and cultural values determine the seriousness or otherwise attached to antisocial behavior. Consequently, most clinicians would include the criterion of impairment, namely an adverse effect on the child's daily life or development, before applying the diagnostic label of 'conduct disorder'.

Common symptoms include temper tantrums, oppositional behavior, overactivity, irritability, aggression, stealing, lying, truancy, bullying and wandering away from home/school. Delinquency (a legal term for someone committing an offence against the law) is a frequent feature among older children and adolescents. Stealing, vandalism, arson and fire setting are common forms of delinquency (male:female 10:1).

Traditionally, a distinction has been made between socialized and unsocialized behavior. The former describes behavior that is in accord with peer group values, but contrary to those of society, for instance antisocial gang behavior such as stealing and vandalism. Unsocialized antisocial behavior implies more disturbed behavior as it is often done alone against a background of parental rejection or neglect and poor peer relationships. Learning difficulties, especially specific reading retardation, occur more commonly among children with conduct disorders. This is a further reason why schooling is unpopular and a source of discouragement for these children. Additionally, many children with conduct disorder have affective symptoms such as anxiety or unhappiness, as well as low self-esteem and poor peer relationships. When these symptoms are prominent, it is often appropriate to classify the disorder as mixed, implying both emotional and behavioral symptomatology.

#### **Etiology**

Four factors – the family, the peer group, the neighborhood and constitutional – make some contribution in most cases, but the family is usually the most important. Families of children with conduct disorder are characterized by having a lack of affection and rejection, marital disharmony, inconsistent and ineffective discipline, parental violence and aggression. The families are often of large size, which aggravates the problems of supervision and care. Constitutional factors present in some cases include low intelligence and learning difficulties, along with adverse temperamental features such as overactivity and impulsiveness. Oppositional peer group values are an important feature in older children and adolescents. Many children with conduct disorder live in areas of urban deprivation with poor schooling. The intractable and chronic nature of these problems is a major reason for the continuation of conduct disorder into adolescence and adult life.

#### **Treatment**

Help for the family, either by counseling for the parents or by family therapy, is often used. More recently, specific intervention programs aimed

at promoting positive parenting have been developed with good outcomes in the short term at least.<sup>57</sup> Educational support through remedial teaching or the provision of special education can be important in some cases. For many families however, the role of psychiatric services is limited, with practical support with rehousing in order to alleviate social disadvantage the most important contribution.

### Prognosis

Continuity into adult life is common, with over 50% having problems as adults. Bad prognostic features are many and varied symptoms, problems at home and in the community, and anti-authority and aggressive attitudes.

## HYPERACTIVITY AND ATTENTION DEFICIT SYNDROMES<sup>39,58</sup>

### Clinical features

Considerable controversy surrounds the diagnostic terms hyperkinetic disorder (HKD), ADHD and ADD. HKD is the category used by ICD-10, which is the diagnostic system mainly used in the UK. This emphasizes the importance of pervasive overactivity (i.e. present in all situations) as a diagnostic feature. By contrast, North American psychiatrists use DSM-IV, which has the diagnostic category of ADHD. The latter stresses inattentiveness as a key symptom rather than overactivity. The different diagnostic practices probably explain the wide variation in prevalence rates (1–10%) found in epidemiological studies. Despite the difference in terminology, the two systems agree upon the same three core features: *overactivity, impulsivity and inattentiveness*.

Current UK practice has changed radically over the past 10 years, so that most UK psychiatrists use the term ADHD rather than HKD. One consequence of this change has been the dramatic increase in the prescription of methylphenidate with the annual rate in England rising from 220 000 in 1998 to 418 000 in 2004.<sup>59</sup>

Another controversy concerns the existence of co-morbidity among children with ADHD symptoms, which in turn is linked to the conceptual argument about whether disorders are categorical or dimensional. Traditional UK clinical practice prefers a single as opposed to several concurrent diagnoses. For instance, if a child was overactive, they would be classified as having HKD or conduct disorder, but not both. By contrast, North American practice allows, or even encourages, more than one diagnosis, namely the overactive child could have ADHD and conduct disorder. Unfortunately, current evidence is unable to provide a definite answer about the best approach. This difference in diagnostic approach is another reason for the divergent prevalence rates in epidemiological studies.

In conclusion, it is probably best to regard overactivity as a symptom rather than a diagnostic term that can occur in many clinical situations: a symptom of ADHD, HKD or ADD; a feature of many children with conduct disorder; a reflection of developmental delay on its own or in association with general intellectual retardation; one extreme of normal temperamental variation; an uncommon response to high anxiety or tension; a symptom of childhood autism; and rarely, as a reaction to some drugs, for example barbiturates or benzodiazepines.

### Treatment of attention deficit hyperactivity disorder

The recent MTA Study<sup>60</sup> and the NICE Report<sup>59</sup> have provided the clearest evidence and guidance, respectively, about the most effective treatment package. Most people would advocate a multi-modal approach involving drug treatment, psycho-educational, parenting skills program and individual or group work with the child. The MTA Study showed that 80% of children improved significantly on methylphenidate with improvement persisting over the 14-month trial period. There appeared little convincing evidence that a combined approach involving drug and behavioral treatments significantly improved the outcome, but it must be remembered that the MTA study was carried out in the USA, where diagnostic practices are different.

Methylphenidate (up to 60 mg/d in divided doses) is the commonest prescribed drug in the UK, whereas dexamphetamine (up to 30 mg/d) is

more popular in the USA and Australasia. Both drugs are equally effective with a similar side-effect profile, but dexamphetamine has a longer time course of effect. Stimulant drugs seem to work through an increase in dopamine levels in the frontal lobes. The common side-effects of both drugs are loss of appetite and night-time insomnia, with abdominal pain, headache, tearfulness and tics less common. It is debatable whether stimulants have any long term effect on growth or the exacerbation of tics, but careful monitoring is advisable. The last 5 years have seen important advances in the range of medications available with the licensing of extended-release preparations of methylphenidate such as Concerta XL or Equasym XL and also the availability of a once-a-day noradrenergic compound, atomoxetine. Comparative trials with these new preparations are currently underway in the UK.

Tricyclic antidepressants such as imipramine or nortriptyline are also an effective alternative treatment, and are used when the child is unresponsive to stimulants, side-effects are disabling or there is a depressive component to the child's symptoms. There are also open-label studies with clonidine, particularly for aggressive symptoms, but there have been case reports of sudden death due to cardiac arrhythmias, so that an ECG prior to commencement of treatment is essential. Pemoline, which has the considerable advantage as a once-daily dosage, has now been withdrawn in the UK on account of fears about hepatic toxicity.

Behavioral techniques, parental counseling and the alteration and manipulation of the child's environment, particularly at school, to reduce and minimize distraction are important components of most treatment programs. An alternative approach adopted by some clinicians has been the use of exclusion diets on the basis that the child is allergic to certain substances, commonly tartrazine. Evidence for the efficacy of these exclusion diets other than as a placebo response is unconvincing, though Egger et al,<sup>61</sup> using a sophisticated methodological design, showed that children with severe hyperactivity and mental retardation did respond. It is, however, unclear whether these results would apply to children of normal intelligence with less severe problems, who make up the majority of children with ADHD.

### Outcome

Hyperactivity and attention deficits lessen considerably by adolescence, though other major problems such as learning difficulties and behavior problems persist. A substantial minority continue to have problems in adult life, mainly of an antisocial nature. There is also increasing evidence for the efficacy of methylphenidate in adults in whom the diagnosis of ADD had been missed in childhood or who have continued on treatment from childhood.<sup>62,63</sup>

## DISORDERS OF ELIMINATION

### ENURESIS

This term refers to the involuntary passage of urine in the absence of physical abnormality after the age of 5 years. It may be nocturnal and/or diurnal. Bed wetting continuously, though not usually every night, since birth is termed *primary enuresis*, whereas when there has been a 6-month period of dry beds at some stage, recurrence of bed wetting is termed *secondary* or *onset enuresis*. Diurnal enuresis is much less common than nocturnal, but more common among girls and among children who are psychiatrically disturbed. Depending upon definition, approximately 10% of 5-year-olds, 5% of 10-year-olds and 1% of 18-year-olds will have nocturnal enuresis. The majority of children with nocturnal enuresis are not psychiatrically ill, though a substantial minority, approximately 25%, have signs of psychiatric disturbance.

### Etiology

A combination of individual factors such as positive family history (approximately 70%), low intelligence, psychiatric disturbance and small bladder capacity along with environmental factors such as recent

stressful life events, large family size and social disadvantage are present in most cases.

### Treatment

It is important to exclude any physical basis for the enuresis by history, examination and, if necessary, investigation of the renal tract. Assuming no physical pathology, the most important initial step is to minimize the handicap, namely to point out to the parents the very favorable natural outcome of the condition, and to re-label the child's enuresis as immaturity rather than laziness or wilfulness. A star chart, the accurate recording of enuresis plus positive reinforcement for dry nights, provides an accurate baseline as well as a successful treatment in its own right. An enuresis alarm is successful with older cooperative children. The success of this approach is probably because the child becomes more aware of the sensation of a full bladder along with the encouragement from parents for dry nights. The modern alarms are extremely compact and do not require a pad placed between the sheets, thereby increasing patient compliance considerably. It is useful to combine a buzzer with a star chart. Drugs such as desmopressin and imipramine are very effective at stopping enuresis, though their major limitation is that the enuresis returns when they are stopped. Most pediatricians believe it is wrong to prescribe potentially lethal drugs such as imipramine for a benign condition such as enuresis, so that desmopressin is the preferred drug treatment.

### SOILING AND ENCOPRESIS

Most children are continent of feces and clean by their 4th birthday. Encopresis is usually defined as the inappropriate passage of formed feces, usually onto the underwear, in the absence of any physical pathology after 4 years of age. Soiling, the passage of semi-solid feces, is often used synonymously with encopresis. Symptoms vary widely in severity, ranging from slight staining of underwear to encopresis with the smearing of feces onto the walls. It is uncommon with a community prevalence among 8-year-olds of 1.8% for boys and of 0.7% for girls. Psychiatric disturbance is common among children with encopresis. Enuresis may also be present.

### Clinical features

Figure 34.3 shows a convenient way to classify encopresis with a broad distinction between children who retain feces with eventual overflow incontinence and those who deposit feces inappropriately on a regular basis. Some children have never achieved continence, a situation called 'continuous' or 'primary encopresis', whilst others have had periods of cleanliness followed by relapse, the so-called 'discontinuous' or 'secondary encopresis'. Figure 34.3 also lists the common different patterns of interaction found among children with encopresis and their parents. For instance, children with retentive encopresis have often been subjected to coercive and obsessive toilet training practices, so that the encopresis is seen as a reaction, often of anger or aggression, towards this practice. Similarly, many children with continuous nonretentive encopresis come from disorganized, chaotic families where regular training and toileting are not the norm. Again, encopresis can arise in some children as a response to a stressful situation. Finally, encopresis can reflect poor parent-child relationship, often longstanding and usually associated with other aspects of psychiatric disturbance. The clinical picture is often, however, not as clear-cut, with the different elements each making some contribution. There may be a previous history of constipation and occasionally of anal fissure.

### Treatment

A physical etiology such as Hirschsprung disease must be excluded before commencement of psychiatric treatment. The assessment must include an account of previous treatments and most importantly, the current attitude of the parents and the child to the problem. Treatment has two aims: the promotion of a normal bowel habit and the improvement of the parent-child relationship. Initially, a bowel washout and/

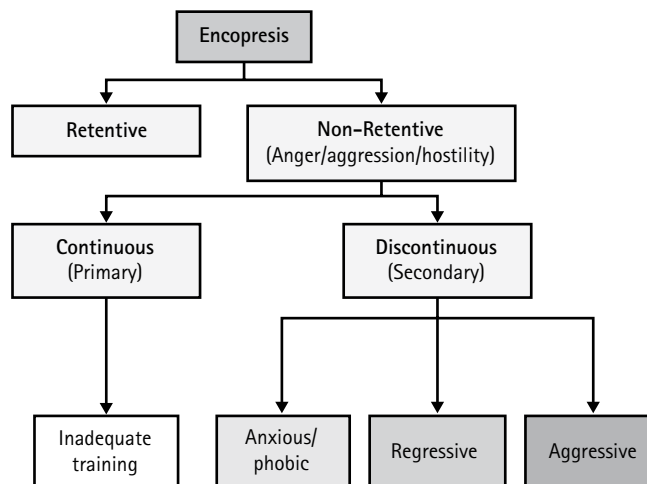

Fig. 34.3 Types of encopresis and their psychopathology. Three patterns are common in children: primary encopresis, retentive encopresis and secondary encopresis.

or microenemata may be necessary to clear out the bowel. Judicious use of bowel smooth muscle stimulants (Senokot), stool softeners (Dioctyl) and bulk agents (macrogol, lactulose) is helpful for the child with retention. Again, suppositories may be useful from time to time. This should also be combined with parent and child education about the dietary importance of fiber. The psychological component includes behavioral (star chart) and individual psychotherapy to gain the cooperation and trust of the child along with parental counseling or family therapy to modify attitudes and hostile interactions between the child and his parents.

### Prognosis

It usually resolves by adolescence, though other problems may persist. Occasional case reports of persistence into adult life have been published.

## MISCELLANEOUS DISORDERS

### DEVELOPMENTAL DISORDERS

#### Language disorders (see also Ch. 23)

Children with language disorders are more vulnerable to disturbance, mainly because of the associated anxiety and embarrassment caused by the disorder. Specific language delay (5–6/1000) is twice as common in boys as in girls, with a strong association with large family size and lower social class. Richman et al<sup>16</sup> found that approximately 25% of 3-year-olds with specific language delay had behavioral problems.

Stuttering, an abnormality of speech rhythm consisting of hesitations and repetitions at the beginning of syllables and words is a normal, though transitory phenomenon, occurring at around 3–4 years of age. When it persists (approximately 3% of the general population), often due to inadvertent parental attention, it leads to anxiety and low self-esteem.

#### Selective mutism

This is not strictly a language disorder, as the main problem is the child's refusal to talk in certain situations, most commonly at school, rather than an inability to speak. Mild forms of the disorder are common but transitory, usually at the commencement of schooling, while the severe form has a prevalence rate of about 1 in 1000. Other features include a previous history of speech delay, excessively shy but stubborn temperament and parental overprotectiveness.

A combination of behavioral and family therapy techniques to promote communication and the use of speech is most commonly used, though some cases require inpatient assessment. Fluoxetine had been shown to be effective in an open trial of children with selective mutism and co-morbid anxiety disorder.<sup>64</sup> Prognosis is good for approximately 50%, with failure to improve by the age of 10 years a poor prognostic sign.

### Reading difficulties

Though mainly of educational concern, the pediatrician or child psychiatrist may get involved because of the associated behavioral or emotional problems. The two main types are first, general reading backwardness, when the retardation is a reflection of generalized intellectual delay, and second, specific reading retardation when the attainment in reading is significantly behind the expected level after controlling for age and intelligence. The problem is 'significant' when the delay is at least 2 years. Dyslexia is a concept similar to specific reading retardation, implying a neuropsychological substrate for the specific reading difficulties. The use of this term is contentious, so that the more bland expression, 'specific reading retardation', is preferred by many clinical psychologists.

The etiology is multifactorial, involving genetic, social, perceptual and language deficits. A noteworthy feature is the strong association between specific reading retardation and conduct disorder with the behavior problem most likely arising secondary to the frustration and disillusionment associated with the reading difficulty. Treatment involves detailed psychometric assessment of the problem by a psychologist followed by an individualized remedial program carried out by a specialized teacher in collaboration with the psychologist. Help with the behavioral problem is also necessary in order to prevent more serious problems arising during adolescence.

## HABIT DISORDERS

### Tics and Tourette syndrome

Tics are rapid, involuntary, repetitive muscular movements, usually involving the face and neck, for instance blinks, grimaces and throat clearing. Simple tics occur as a transitory phenomenon in about 10% of the population with boys outnumbering girls three to one and with a mean age of onset around 7 years. They range in severity from simple tics involving head and neck through to complex tics extending to the limbs and trunk and finally to Tourette syndrome. The latter comprises complex tics accompanied by coprolalia (uttering obscene words and phrases) and echolalia (the repetition of sounds or words). Like stammering, tics are made worse at times of stress and may be exacerbated by undue parental concern. The differential diagnosis of tics in childhood is principally from chorea, where the movements are less coordinated and predictable, not stereotypic in form and cannot be suppressed.

Other features of tics are a positive family history and a previous history of neurodevelopmental delay. Many tics resolve spontaneously, but those that persist can be extremely disabling and difficult to treat.

#### Treatment

Several approaches are used singly or in combination, depending on assessment. Medication is effective, but should be reserved for severe cases. Haloperidol is the most common drug used for Tourette syndrome, but pimozide and clonidine are alternative drugs. Many children with simple tics respond to explanation and reassurance along with advice for the parents. Individual and/or family therapy may be indicated when anxiety and tension are clearly making important contributions to the problem. Behavior therapy in the form of relaxation and/or massed practice can also be helpful.

#### Prognosis

Simple tics have a good outcome with complete remission, whereas in Tourette syndrome the condition fluctuates in a chronic manner with 50% continuing with symptoms into adult life.

## SLEEP DISORDERS (see preschool children section)

### Night terrors

The usual pattern is for the child to wake up in a frightened, even terrified state, not to respond when spoken to, nor appear to see objects or people. Instead, he appears to be hallucinating, talking to and looking at people/things not actually present. The child may be difficult to comfort with the period of disturbed behavior and altered consciousness lasting up to 15 min, occasionally longer. Eventually the behavior settles, with or without comfort, and the child goes back to sleep, awakening in the morning with no recollection of the episode. The latter point is invaluable in helping to allay parental anxiety about the episodes. Night terrors arise from stage 4 or deep sleep. The peak incidence is between 4 and 7 years with a continuation of 1–3% into older children. It is also helpful to identify and ameliorate any identifiable stresses that may occasionally contribute to the problem. Lask<sup>65</sup> has described an apparently successful novel behavioral approach relying on waking the child 15 min prior to the expected time of the night terror. Drugs such as benzodiazepines or tricyclics have also been used successfully.

### Nightmares

These are frightening or unpleasant dreams, occurring during REM (rapid eye movement) sleep. The child may or may not wake up but there will be a clear recollection of the dream if he does wake up and also in the morning. There is no period of altered consciousness or inaccessibility as in night terrors. Again, daytime anxieties and/or frightening television programs in the evening may be contributory factors.

### Sleep walking (somnambulism)

The child, usually aged between 8 and 14 years, calmly arises from his bed with a blank facial expression, does not respond to attempts at communication and can only be awakened with difficulty. The child is in a state of altered consciousness at the deep level of sleep (stages 3 or 4). Any contributory anxiety should be treated as well as giving the parents some advice about the safety and protection of the child during these episodes.

## PSYCHOLOGICAL EFFECTS OF ILLNESS AND DISABILITY

Approximately 15% of children have some form of chronic illness or disability. The IOW study<sup>14</sup> showed clearly that this group of children was much more at risk for disturbance, namely a rate of 33% for children with chronic illness affecting the central nervous system and of 12% for children with chronic illness not affecting the central nervous system compared with 7% among the general population. The IOW study also reported that children with chronic illness or handicap had the same range of disorders as other disturbed children, thereby implying that the mechanisms involved with this increased morbidity are probably indirect and nonspecific rather than direct and specific to each illness or disability. Illness or disability imposes psychological stress on the child and family not only at the time of diagnosis but also in the long term. These effects are now discussed with regard to the child himself and to other family members, though the two effects interact with each other.

### Effects on the child

Three aspects are important: the acquisition of skills and outside interests, the development of self-concept, and the development of adaptive coping behavior. Many illnesses or disabilities inevitably restrict the child's ability or opportunity to acquire everyday skills and to develop interests and hobbies. For example, the child with cerebral palsy is by definition motor impaired, having the dietary restrictions of diabetes, the exercise limitations of asthma and the avoidance by children with epilepsy of some activities such as cycling or swimming. Additionally, educational problems are common among this group of children for a variety of reasons including increased absence from school, specific

learning difficulties, especially among children with epilepsy, and low expectations of parents and teachers.

Illness and disability can adversely affect the child's self-concept in several ways through the effects on the child's body image and self-esteem. Many children have a distorted view of their body, believing the disability to be very prominent or disfiguring. These ideas can be reinforced by comments from parents or peers. Self-esteem can also be impaired due to a faulty cognitive appraisal of the situation and to a pessimistic attitude to the situation. This leads the child to have low self-esteem with a gloomy view about his illness and the outlook for the future. This is particularly likely and also potentially very disabling among older children and adolescents.

Successful adaptation to a disability depends on the acquisition of a range of coping behaviors and defense mechanisms to lessen anxiety to an acceptable level. Effective coping strategies include regulating the amount of stress into containable amounts, obtaining information, rehearsing the possible outcomes of treatment and assessing the situation from several viewpoints. Parents, nursing staff and pediatricians have an important role in promoting this repertoire of skills for children with a disability. Additionally, defense mechanisms such as denial, rationalization and displacement can be helpful for the child during the initial stages of adjustment to the illness or disability.

### Effects on the parents

The parents can respond in various ways in the short term and also in the long term. Most parents eventually achieve some degree of adaptation, though for a minority maladaptive behavior patterns emerge and are prominent. The common reaction is overprotection whereby the parent(s) is unable to allow the child to experience the normal disappointments and upsets inevitable during childhood, so that the child leads a 'cotton wool' existence. Less frequently, the parent(s) may be rejecting and indifferent to the child because the child's disability is so damaging to the parents' self-esteem or because the disability has exacerbated an already precarious parent-child relationship. Overprotection and rejection are sometimes combined in the parental reaction.

The parents may also find it difficult to provide appropriate discipline and control, as they irrationally fear that such control may aggravate the child's illness. For example, parents of children with epilepsy may think that thwarting the child's wishes may induce an epileptic fit.

Finally, the stress of coping with the child's illness may exacerbate parental marital disharmony, though in a minority it may paradoxically unite them as they face the adversity together.

### Effect on siblings

This can manifest itself in several ways: the oldest sibling may be given excessive responsibility such as looking after the disabled sibling; the siblings may lose friendships because they are reluctant to bring their friends home in case their disabled sibling is an embarrassment; and finally, the sibling's own developmental needs may be neglected with consequent resentment and frustration.

## BREAKING BAD NEWS TO PARENTS

This distressing but inevitable aspect of pediatrics comes in various guises such as the birth of a child with Down syndrome or with the diagnosis of cystic fibrosis. Unfortunately, most undergraduate and postgraduate training includes very little teaching about this important subject. Though the details vary for each case, the following general principles are important:

1. Information should be given by the most senior and experienced doctor involved with the child's care.
2. Both parents must be seen together if at all possible, as this reduces misinformation and allows the parents to be mutually supportive from the outset.
3. Allow adequate time for the interview (not 10 min at the end of a ward round).

4. Privacy is essential not only as a matter of courtesy and dignity but also because it allows parents to express their emotions more freely.
5. Begin the interview by asking the parents to tell you what they know about the problems.
6. Tell parents frankly and honestly in simple and non-technical language the nature of the problem, explaining the reasons for the investigations and the basis for the diagnosis.
7. Encourage the parents to ask questions (by asking them some open-ended questions).
8. Emphasize the positive as well as the negative aspects of the diagnosis, for instance the child will be able to have physiotherapy and special equipment, will be able to go to school and to receive effective control for pain.
9. Facilitate the expression of emotions by the parents, namely respond sympathetically and sensitively to the parent(s)' distress and crying.
10. Make a definite offer of a further appointment to talk things over again.
11. Many parents find it helpful to continue the discussion with a nurse or social worker after the interview.

## REACTIONS TO HOSPITALIZATION

Admission to hospital is a common experience during childhood with approximately 25% admitted by the age of 4 years. For most children, this is a short admission for a brief treatable illness, whilst a minority (approximately 4%) remains in hospital for at least 1 month. While most parents and their children cope successfully with the admission, some, particularly those with repeated admissions for minor illnesses, show evidence of disturbance that may in turn have been the reason why the child was admitted in the first place.

Admission to hospital can have adverse short term and long term effects. The contributory factors can be grouped under three headings: (1) the child and family, (2) the nature of the illness, and (3) the attitudes and practices of the hospital and its staff. Important factors within the child and family include age, temperament of the child, previous experience of hospital, previous parent-child relationship and current family circumstances. Children aged between 1 and 4 years are particularly stressed by separation from familiar figures. Similarly, children with adverse temperamental characteristics, such as poor adaptability or irregularity of habits, are more vulnerable. If the child had a favorable experience when in hospital previously, this will ease the burden for any subsequent admission. If the parent-child relationship was poor prior to admission, hospitalization is likely to exacerbate this problem because of the additional stress. Adverse family circumstances, for instance financial, may also be aggravated by admission.

The nature of the illness, particularly the associated pain or the necessity for painful procedures, influences the child's response. Again, an acute admission is likely to be more stressful than an elective procedure.

The attitudes of the staff and hospital practices can minimize the distress for the child. Helpful and favorable aspects include good rooming-in facilities, adequate preparation for painful or unpleasant procedures, and nursing and medical staff trained to minimize distress and to offer comfort when required. The ward should be organized so that parents and siblings are encouraged to visit as well as ensuring the ready availability of play leaders and teachers. Medical and nursing staff should also have access to social work resources as well as to psychological and psychiatric services. Finally, joint liaison between the medical and psychiatric team and the establishment of a staff support group to enable staff to discuss their own anxieties about working in a stressful environment are likely to be beneficial.

## TREATMENT METHODS

Several factors are usually responsible for the development of disturbance, so that it is unlikely that one treatment method will resolve the problem. All treatment approaches also rely upon common elements that are not only necessary but also essential for a successful outcome.

Table 34.3 Drug treatment in child psychiatry

Drug	Usage	Comment
<i>Anxiolytics</i>	Anxiety / phobic conditions	Short-term adjunct to behavior treatment
<i>Neuroleptics</i>	Phenothiazines (e.g. chlorpromazine)	Butyrophenones (e.g. haloperidol)
Newer antipsychotics (e.g. risperidone/olanzapine)	Schizophrenia/ADHD Complex tics/Tourette syndrome Schizophrenia	Extrapyramidal side-effects common Extrapyramidal side-effects common Fewer side-effects
<i>Tricyclics</i>		
Imipramine / nortriptyline clomipramine	Second-line treatment for ADHD Obsessional-compulsive disorder	Useful when an affective component present Long-term usage often necessary
<i>SRLs</i> (fluoxetine, paroxetine, sertraline)	Probably first choice for depressive disorder	Better compliance with fewer side-effects
<i>Stimulants</i>		
Methylphenidate/dexamphetamine	ADHD	80% effective. Side-effects closely monitored
<i>Hypnotics</i> (melatonin) with ADHD	Persistent sleep disorder	Sometimes used for sleep problems associated
<i>Lithium</i>	Recurrent bipolar affective disorder	Close supervision of blood level and for signs of toxicity
<i>Laxatives</i> (e.g. bulk-forming (methylcellulose), stimulants (senna), softener (dioctyl))	Encopresis with constipation	Facilitates formation and passage of feces
<i>Central <math>\alpha</math>-agonist</i> (e.g. clonidine)	Unresponsive Tourette syndrome	Sedation and rebound hypertension

SRLs, serotonin reuptake inhibitors.

These elements include active cooperation between the therapist and the child and family, agreement between them about the aims of treatment, and a mutual trust to enable these aims to be achieved. Again, the relative efficacy of different treatments is not clearly established, so that the choice of treatment is often a reflection of the therapist(s)' training and experience rather than an absolute indication in any particular instance. Careful analysis of the following elements is therefore necessary in order to devise an effective treatment program:

1. Individual:
  - physical illness or disability;
  - intellectual ability;
  - type of symptomatology.
2. Family
  - developmental stage (for instance a family with pre-school children or one with adolescents);
  - psychiatric health of parents;
  - marital relationship;
  - parenting qualities;
  - communication patterns within the family;
  - ability to resolve conflict;
  - support network, for instance availability of the extended family.
3. School:
  - scholastic attainments;
  - child and parents' attitude to the authority of the school;
  - peer relationships.
4. Community:
  - quality of peer relationships and of role models;
  - neighborhood and community resources.

The formulation of the problem along these four dimensions provides the basis to decide the suitable treatment program.

The three main types of treatment approach available are: (1) drug treatment, (2) the psychotherapies and (3) liaison or consultation work. The latter refers to the common practice whereby the child psychiatrist or a member of the psychiatric team does not have direct contact with the referred child, but rather helps those involved with the child to understand and modify the child's behavior. Psychotherapies are those treatments that use a variety of psychological techniques to ameliorate disturbance. They include individual therapy, behavior therapy, family therapy and group therapy as well as counseling and advice for parents.

## Drug treatment<sup>66</sup>

This has increasing importance in child psychiatry. Table 34.3 summarizes the important indications and side-effects of various drugs used in child psychiatry.

## Psychotherapies

These are a very common treatment approach in child psychiatric practice.

### Individual psychotherapy<sup>67</sup>

Though there are several theoretical orientations, including psychoanalytic<sup>68</sup> and Rogerian,<sup>69</sup> the therapist has nevertheless the same therapeutic tasks. These are: (1) to develop a trusting, nonjudgmental relationship with the child; (2) to enable the child to express his feelings and thoughts; (3) to understand the meaning of the child's symptoms, including his behavior during the therapeutic session; and finally (4) to provide the child with some understanding and explanation for his behavior. The indications for individual psychotherapy are not clearly established, though most usually it is for children with a neurotic or reactive disorder rather than for those with a constitutionally based disorder. For younger children the medium for communication is play such as sand play or through drawing, whilst for older children verbal exchange and discussion are possible.

### Behavioral psychotherapy<sup>70</sup>

This approach is based upon the application of the findings from experimental psychology, particularly learning theory, to a wide range of problems such as enuresis, encopresis, tantrums and aggression. Its characteristics are as follows:

1. Define problem(s) objectively with reference to the Antecedents, the Behavior itself and the Consequences (the ABC approach).
2. Place emphasis on the current behavior rather than on past events.
3. Set up hypotheses to account for the behavior.
4. Set pre-treatment baseline to determine the frequency and severity of the problem.
5. Devise behavioral program on an individual basis to test the hypothesis.
6. Evaluate outcome of treatment program.
7. Tackle one problem at a time.

As with other psychotherapies, success depends upon the establishment of a trusting relationship with the patient and the close supervision of the treatment program together with the involvement of teachers and parents in many cases.

### Cognitive behavioral therapy (CBT)<sup>71</sup>

This is used increasingly with older children and adolescents for a variety of conditions including anxiety, depression and anorexia nervosa. The central premise is that the individual's cognitive distortions are responsible for the symptoms and the disorder, so that therapy is designed to change cognitions through a collaborative approach between the therapist and the patient. Usually the treatment lasts about 12 sessions. The early part of the treatment is devoted to teaching the patient to recognize their cognitive distortions, and then training them to devise alternative and more healthy interpretations of the situation. This is combined with 'homework tasks' between sessions in order to put into practice the new ideas or responses to situations that they find difficult.

### Family therapy<sup>72</sup>

This is a popular treatment approach now. The rationale underlying family therapy is that the child's disturbed behavior is symptomatic of the disturbance within the family as a group. There are many different theoretical approaches and techniques,<sup>72</sup> but all usually involve interviewing the whole family on each occasion for about 1 h. Most family work is short term, lasting about 6 months, with approximately monthly sessions. The emphasis is on current behavior, verbal and nonverbal, observed during the session rather than on past events. The main aim is to improve communication within the family, so that dysfunctional patterns of behavior are replaced by more healthy and adaptive behavior.

### Group therapy

Older children and adolescents often benefit from group therapy when the aim is to improve interpersonal relationships, particularly with the peer group, using a variety of theoretical models (for instance psychodynamic and social skills).

### Supportive psychotherapy and counseling

The former is frequently used for the child with chronic illness or handicap when the focus may be the child or the parents. It is especially beneficial at the time of diagnosis and also in the long term, when the implications of the disability become more evident. Parental counseling is also used to help the parents understand their child's behavioral problems, the factors that may have led to them and that are responsible for their continuation, along with an emphasis on the parent-child relationship and the improvement of parenting skills. Counseling may therefore help the parents to devise and implement a behavioral program to modify the child's behavior as well as to promote normal development.

### Liaison and consultation psychiatry<sup>73</sup>

This is a collaborative approach between the child psychiatry team and the professionals directly involved with the child, for instance hospital staff, teachers or residential care staff, in order to help these professionals to understand the child's disturbed behavior, their own possible contribution to the problem and to suggest ways to improve the situation. Although the child psychiatrist may see the referred child in the first instance, subsequent contact is usually with the staff rather than with the child. This approach can also include the establishment and supervision of a staff support group whose aim is to look at the attitudes and emotional responses of the staff towards the behavior shown by the children under their care.

## PSYCHIATRIC DISORDERS IN ADOLESCENCE

This section has two parts: adolescent psychological development and adolescent psychiatric syndromes.

## ADOLESCENT DEVELOPMENT

Adolescence is the transition between childhood and adult life. Four maturational tasks must be accomplished successfully to ensure a favorable outcome:

- attainment of independence;
- establishment of a sexual role and orientation;
- self-control of aggressive and oppositional impulses;
- achievement of self-identity.

Though these tasks are not necessarily complete nor entirely resolved by the end of adolescence, the adolescent should have made substantial progress with these tasks. Three tasks – independence, sex role and orientation, self-control of aggressive and oppositional impulses – refer to specific aspects of psychological development, whereas the fourth – self-identity – is a global term referring to that sense of uniqueness or individuality that distinguishes one person from another. Erikson<sup>6</sup> believed that the attainment of a stable self-identity during adolescence is the prerequisite for successful adult adjustment. Important components of self-identity for Erikson are 'sexual identity' and 'career identity'. The Eriksonian unsuccessful outcome of adolescent conflict is 'identity diffusion', with the person lacking clear goals and direction in the fulfilment of individual ambition.

Adolescent development is commonly divided into four phases:

- pre-adolescent phase (11–13 years);
- early adolescence (13–15 years);
- mid adolescence (15–17 years);
- late adolescence (18 years onwards).

The main features of the pre-adolescent phase are the onset of biological puberty and an increased interest in peer relationships and teenage pursuits. Early adolescence is characterized by the critical questioning of parental values combined with an uncritical acceptance of peer group views. The establishment of a separate sexual and social identity occurs during mid-adolescence. The individual explores and develops their own gender and sexual role. The development of social relationships outside the family enables the individual to have their own social network as well as altering the basis of their relationship with their parents. Later adolescence is focused on the career or work choice along with the expression of the sexual role through more satisfying and enduring relationships.

## DETERMINANTS OF ADOLESCENT ADJUSTMENT

Though the same general factors influence development and adjustment in adolescence as in earlier periods, brief mention will be made of those that are of particular relevance.

### Previous childhood experience(s)

Unsatisfactory earlier experience(s) and relationships, particularly the child-parent(s) relationship, are major factors affecting predisposition to adjustment during adolescence. The individual's capacity to withstand the inevitable stresses of adolescence and also their resilience are greatly impaired when the outcome of earlier experiences was unsatisfactory. Adverse childhood experience is an important vulnerability factor in adolescent breakdown.

### Family psychopathology

Parental psychopathology such as marital disharmony or parental psychiatric illness has a powerful influence on children's behavior throughout childhood, but even more so during adolescence, when conflicts over discipline, control and autonomy are normal and unavoidable. Parental disagreements and disunity on these matters greatly exacerbate the difficulties.

### Schooling

Common problems are: academic failure with scholastic subjects, poor motivation and disillusionment with schooling, conflicts over authority with teaching staff.

### Peer group

Peer group values and pressure exert enormous influence on the adolescent, so that contact with and membership of a deviant peer group can lead to major problems in school, for instance truancy, or in the community, for instance delinquency or vandalism.

### Chronic illness or disability

The normal adolescent drive for self-appraisal and self-identity leaves the disabled or disabled adolescent feeling isolated and different from their peers, a most distressing experience. Early childhood feelings of acceptance and tolerance by peers are replaced by those of exclusion and separateness with a reluctance or inability to gain peer group acceptance. The adolescent often deals with these feelings of anger and frustration by denial or minimalization of the seriousness of his condition. This can result in poor compliance with medication or reckless exposure to dangerous situations.

## INTERVIEWING AND ASSESSMENT OF ADOLESCENTS

Though the earlier part of the chapter discussed the general principles of interviewing and assessment, it is helpful to mention some specific points relating to adolescence. Flexibility in approach is essential for successful interviewing. In general, the older the adolescent and the more serious or intimate the problem, the greater the necessity for a separate interview with the adolescent. Usually, this is combined with a family interview in order to complete the assessment.

Many adolescents are reluctant, confused or anxious attenders, so that the clinician must clarify and explain the purpose, sequence and duration of the assessment procedures at the outset. Respect for the adolescent's maturity, the right to privacy and confidentiality must be acknowledged clearly. The distinction between 'family business' and 'individual business' must be emphasized to the adolescent and to the parents. Adolescent anxieties about 'seeing the shrink' or being 'treated like a child' must be addressed and talked through. The individual interview may allow the clinician to conduct a thorough assessment of the mental state, though careful phrasing of questions about sexual or psychotic phenomena is essential in order to avoid a dismissive denial and a further increase in anxiety and confusion.

Silence and refusal to talk during the interview are common and often difficult to overcome. The clinician can use three tactics to deal with this problem: (1) it can be pointed out that the silence is just as difficult for the interviewer as it is for the adolescent; (2) there will be the opportunity and time to talk through difficult topics now or alternatively on another occasion; and finally, (3) to terminate the interview when necessary to prevent prolonged or undue tension.

Family interviews are often not only part of the assessment procedure but also of the treatment plan. Sometimes however, it is more appropriate to interview the parents and the child together rather than the whole family.

## ADOLESCENT PSYCHIATRIC SYNDROMES

These are divided into three categories: those disorders persisting from earlier childhood; new disorders arising during adolescence; and those disorders with features special to adolescence. Prior to the discussion of these topics, brief comment will be made about the prevalence of psychiatric disorders in adolescence.

### Prevalence

This varies widely from 10–20% depending upon the population studied, the diagnostic criteria and the age group. Most studies do however show a consistent pattern with respect to gender ratio, urban vs. rural differences and the range of clinical syndromes. In contrast to earlier childhood, when psychiatric disorder is more common among boys, the adolescent period shows a shift towards an equal gender ratio in early adolescence followed by a subsequent female preponderance in late

adolescence and adult life. Prevalence rates in urban populations are at least twice that for rural populations. Schizophrenia, major affective disorder, suicide and attempted suicide, anorexia and substance abuse all begin to appear with some frequency during adolescence, whereas encopresis or enuresis decrease markedly.

## PERSISTENT CHILDHOOD DISORDERS

Childhood disorders are more likely to continue into adolescence when one or more of the following are present: a major constitutional factor to the syndrome, the adverse circumstances responsible for the onset of the disorder are still present and perpetuating or maintaining factors are prominent. The follow-up study of 10-year-old children in the IOW study<sup>13</sup> showed that 40% of the disorders had persisted into adolescence with a strong continuity for boys with conduct disorder and associated educational problems. This section now discusses the factors responsible for the persistence of some disorders into adolescence from earlier childhood.

### Conduct disorder

The oppositional and defiant character of conduct disorder means that it is very likely to be exacerbated by the rebellious and anti-authoritarian nature of ordinary adolescent behavior. Childhood predictors of persistent conduct disorder are: early onset of symptoms, extensive and varied symptomatology, and the severity of aggressive behavior. Adverse temperamental characteristics combined with continued exposure to deviant family psychopathology such as deficient and ineffective parenting, marital disharmony or parental psychiatric illness are thought to be important factors maintaining the conduct disorder. The persistence of the frequently associated learning disorders is another source of frustration and disillusionment for the adolescent, producing conflict with the teachers and reluctance to attend school.

### Emotional disorders

Generally, emotional disorders have a good prognosis, often because they arise in response to some identifiable but remedial stress. Consequently, emotional disorder persisting into adolescence implies a more serious underlying cause. The school refusal syndrome is the most likely condition to show continuity from early childhood. It may reappear at the transfer from primary to secondary school, or early on during secondary schooling. Previous history of separation difficulties, for instance at the start of nursery or primary school and/or an overdependent relationship between the child and parent(s), are commonly found. The increased necessity for independence, autonomy and assertiveness at secondary school may prove too much for the vulnerable adolescent.

### Childhood autism

The overt autistic-like behavior and overactivity prominent in younger children with the disorder often decrease during adolescence, but the majority are still profoundly impaired in social and communication skills with a marked apathy and lack of empathy. Educational and learning disabilities are very evident. Epilepsy also develops in about 15% of individuals with a greater risk when severe mental retardation is also present.

### Attention deficit hyperactivity disorder

The overactivity usually decreases during adolescence, but persistent problems with antisocial behavior, impulsivity, recklessness, distractibility and learning disorders mean that the adolescent with ADHD is likely to remain disturbed.

## NEW DISORDERS ARISING DURING ADOLESCENCE

These can be divided into two categories: those related to the stress of adolescence and major adult-like disorders arising in adolescence.

### Stress-related adolescent disorders

During adolescence, the distinction between normal and abnormal behavior is often imprecise, so that it is more important to understand

why the adolescent's behavior is such a cause of concern rather than whether the behavior fulfils the criteria for a disorder in a diagnostic classification system. In many cases, conflict often arises between the adolescent and the parents' overdependence and control issues. Allied with the pressure from peers, this often leads the adolescent to engage in antisocial or conduct-disordered behavior. Delinquency, vandalism and out-of-control behavior are common, sometimes mixed with a pattern of alcohol or drug abuse. Persistent antisocial disorder often culminates in criminal behavior and arrest by the police. Co-existent family problems with a limited capacity to resolve issues also contribute to the severity of the disorder. Eventually, it may be necessary for the adolescent to leave the family home and to provide him with alternative care arrangements, for instance with foster parents or community carers. Another solution sometimes adopted by the adolescent is to run away from home. Although the majority of runaways eventually return home, a minority stay away and become involved with the homeless subculture found in large cities.

The common neurotic or emotional responses to adolescent stress are affective symptoms such as irritability, lability of mood and anxiety symptoms, particularly related to social situations or mixing with peers. The latter may sometimes lead to marked social withdrawal. School refusal may sometimes present for the first time during early adolescence, when it represents a combination of adolescent stress and the revival of an earlier overdependent parent-child relationship. The increased need for independence and autonomy posed by the demands of secondary school precipitates an avoidance response to school attendance from the adolescent. The anxiety symptoms often masquerade themselves as physical complaints such as headaches or abdominal pain. The prompt exclusion of organic pathology with a minimum amount of investigation is essential in order to prevent the secondary elaboration of physical symptomatology. Delay in the recognition of the underlying psychological basis for the problem greatly exacerbates the difficulties. The prognosis is not good for a significant minority of adolescents with up to one third failing to maintain regular school attendance. Poor prognosis is usually a sign of more serious underlying family psychopathology. Follow-up studies into adult life have shown that anxiety or agoraphobic symptoms are present in about 20%.<sup>53</sup>

Obsessive-compulsive disorder sometimes begins during adolescence, when its occurrence can be seen as a maladaptive response to the stress of adolescence. There is often a history of earlier childhood obsessional and anxiety traits. The key element in the maintenance and exacerbation of the disorder is usually the willingness of the family to participate in the ritualistic behavior. SRIs such as sertraline and fluvoxamine have been shown to be effective in reducing OCD symptoms, but more importantly are particularly effective when combined with cognitive-behavior therapy.<sup>74</sup>

### Major adult-like disorders arising in adolescence

Three categories of disorder – schizophrenia, mood disorders and anorexia nervosa – begin to occur with increasing frequency during adolescence.

#### Schizophrenia<sup>75</sup>

This is a rare disease during childhood. Even during adolescence, it has a frequency of less than 3 per 10 000. Symptoms are usually classified into two groups: positive and negative. Positive symptoms comprise delusions (fixed, false beliefs), hallucinations (a perceptual experience in the absence of the relevant sensory stimulus) and distortions of thinking (thought insertion and withdrawal). Negative symptoms include social withdrawal, emotional blunting, apathy, lack of motivation, poverty of speech and slowness of thought. The usual presentation is insidious rather than florid with a gradual social withdrawal and increased internal preoccupation. Dysphoric symptoms are common, so that a diagnosis of affective disorder is sometimes made. The adolescent is often able to conceal his bizarre ideas from parents and peers. However, it is the presence of increasingly unpredictable and

erratic behavior that indicates something more serious is occurring. The possibility of drug misuse is an important alternative diagnostic possibility.

#### Etiology

There is good evidence of a genetic component with approximately 20% of relatives having the disease.<sup>75</sup> The Maudsley long term follow-up study of early-onset psychosis<sup>75</sup> showed that one third had significant premorbid social difficulties affecting the ability to make and retain friends. There was also a downward shift in intelligence with a mean IQ of 85. The disorder tends to run a chronic course with only a minority making a full symptomatic recovery – only 12% of patients in the Maudsley study were in remission at 6 months. The best prognostic indicator was the clinical state at that time.

#### Treatment

It must be comprehensive including drug treatment with antipsychotics, individual and family therapy as well as help with education. Traditional antipsychotics such as chlorpromazine and haloperidol are effective, particularly for positive symptoms, but side-effects such as extrapyramidal side-effects and drowsiness adversely affect compliance. Consequently, the newer antipsychotics such as risperidone and olanzapine, with their low side-effect profile, are now the drugs of first choice. When treatment with first-line drugs is ineffective, serious consideration should be given to clozapine. This drug has been shown to be effective for treatment-resistant schizophrenia in adults, and promising case reports have been published for adolescents. There must be careful screening and monitoring for side-effects, particularly for blood dyscrasias, when clozapine is used.

Finally, bad prognostic features include poor premorbid functioning, negative symptoms and a long period of untreated illness.

### MOOD DISORDERS<sup>76,77</sup>

This section has the following parts: depression as a symptom, depressive disorders, bipolar affective disorder, and suicide and attempted suicide.

#### Depression as a symptom/syndrome

Depression has been recognized as a syndrome in adults for a long time because of its characteristic constellation of symptoms, response to treatment and outcome. The depressed mood or dysphoria has qualities other than just simple sadness or unhappiness. Rather, it is the inability to derive pleasure or satisfaction from daily life (anhedonia) or to be able to respond emotionally to ordinary events. Other features of the syndrome are cognitive disturbances, behavioral changes and alterations in physiological functions. The cognitive disturbances are primarily cognitive distortions around oneself (self-blame, self-reproach, guilt and worthlessness), the world (helplessness and despair about one's life situation) and the future (hopelessness and despondency about the future). The behavioral changes range from marked agitation to withdrawal and stupor, while the physiological changes are poor appetite, weight loss and disturbed sleep pattern.

In adolescence, depression can present in the following ways: as a transient mood state; as a symptom in other psychiatric disorders, for instance anxiety states; as a symptom in physical illnesses, for instance infectious mononucleosis; and as part of a symptom complex in major depressive disorder. Epidemiological studies have shown an increasing prevalence of depressive symptomatology from childhood to adolescence. Rutter et al<sup>78</sup> found that many adolescents had experienced feelings of misery and depression (40%), self-deprecation (20%) and suicidal thoughts (7%) at one time or another.

#### Depressive disorders

Both the ICD and DSM classifications now state that depression in children and adolescents should have the same features as that in adults. They recognize the following core features: abnormal depressed mood for at least 2 weeks, marked loss of interest or pleasure in almost all activities,

decreased energy or increased fatigue. Additional features include: loss of confidence and self-esteem, unreasonable feelings of guilt or self-reproach, suicidal thoughts, poor concentration and indecisiveness, psychomotor agitation or retardation, sleep disturbance, and loss of appetite.

### **Etiology**

The etiology of child and adolescent depression is not clear but there is some support for the two main theories: genetic and environmental. Evidence for a genetic component comes from twin studies, adoption and family studies, though the size of the effect is not known. Environmental theories range from the traditional psychoanalytic perspective, to the adverse impact of life events and to the cognitive theory of Beck et al.<sup>79</sup> The latter regards the individual's negative view of himself, the world and the future as the cause of the depression, though clearly these cognitions could be seen as a consequence of the depressed mood rather than the cause.

### **Assessment**

This involves detailed and sensitive interviewing of the adolescent, usually alone, as well as assessment of the adolescent and the family. Family assessment is useful for two reasons: the adolescent's behavior can be seen in the context of current family functioning, and other sources of stress for the adolescent or family may be identified. Physical symptoms are frequently found among depressed adolescents, though the findings are not specific as anxious adolescents often have physical symptoms as well. The differential diagnosis must involve the distinction between normal sadness or unhappiness, other psychiatric conditions with depressive symptomatology, for instance anorexia nervosa, or physical illnesses such as infectious mononucleosis or influenza.

### **Treatment**

A comprehensive treatment package is most likely to be most effective. Components include drug treatment, individual and family therapy and the reduction or lessening of stressful circumstances. The relative emphasis and sequence of treatments are dependent upon assessment.

Drug treatment is most likely to be effective for adolescents who are most severely affected and have a disturbance of physiological functions such as appetite, sleep or weight. Emslie et al<sup>80</sup> have reported the superiority of fluoxetine to placebo in a well-conducted randomized control trial. Fluoxetine is currently the only recommended SRI for the treatment of depression. This advice arose from a review of published clinical trial data of SRIs that reported that evidence of efficacy was lacking for most SRIs in this age group and they were associated with increased suicidality, namely suicidal thoughts and behavior.

The purpose of individual therapy varies widely depending on the assessment and therapeutic style of the clinician. The common aims of an individual approach are: to establish a trusting relationship with the adolescent, to enable the adolescent to feel understood and accepted, and to allow the adolescent to disclose their concerns and anxieties including suicidal thoughts. Beyond these core aims, the therapeutic approach is varied, ranging from the psychodynamically insight-orientated psychotherapy to the cognitive-behavioral.

Work with the family is often undertaken more to improve communication between members of the family rather than to specifically treat family dysfunction. Family sessions are extremely useful at the start of treatment as a way to discuss events of emotional significance that may have happened recently but have not been talked through, for instance a family illness or a bereavement. These sessions also provide the opportunity to discuss ways to reduce any overt source of stress or anxiety for the adolescent. Common sources of stress include lack of friends, bullying or teasing at school and the adolescent's sense, usually distorted, of academic failure.

### **Bipolar disorder or manic-depressive psychosis**

ICD and DSM use similar criteria for the diagnosis of bipolar disorder whether in adolescents or adults. The following points summarize the main diagnostic criteria of ICD and DSM:

- A disorder characterized by repeated episodes (two or more) in which the subject's mood and activity are significantly disturbed. This disturbance consists on some occasions of an elevation of mood with increased energy and activity (mania or hypomania), and on others of a lowering of mood with decreased energy and activity (depression).
- Recovery is characteristically complete between episodes.
- Manic episodes usually begin abruptly, lasting from 2 weeks to 4 or 5 months, whilst depressive episodes often last longer.

### **Clinical features**

A hypomanic or depressive episode is equally common as the first manifestation of a bipolar illness with subsequent episodes more likely to be hypomanic than depressive. A depressive episode shows similar features to other depressive illnesses except that it tends to be more severe with a pronounced disturbance in physiological functioning and frequent suicidal thoughts.

The main feature of the hypomanic episode is an elevated, expansive or irritable mood with the other aspects understandable in terms of the elevated mood. The common features are: increased physical activity or physical restlessness, increased talkativeness, difficulty in concentration and distractibility, less need for sleep, increased sexual energy, mild spending sprees or other types of reckless behavior, and increased sociability or overfamiliarity. A manic episode causes severe disruption to the individual's life. The increased talkativeness becomes a 'pressure of speech' with flight of ideas (rapid switching of ideas based on a literal rather than a logical association, for instance rhyming or punning). The social disinhibition and recklessness can have a devastating effect on the individual's life. Cases with early onset have a worse prognosis with more frequent episodes, rapid cycling and a greater risk of suicide.

Though uncommon, several organic conditions can mimic a hypomanic episode. These include infections (encephalitis), endocrine (hyperthyroidism), neurological (repeated seizures, head trauma), brain tumor (meningioma, glioma), medication (steroids) and substance misuse (alcohol and amphetamine/LSD misuse).

### **Management**

A depressive episode should be managed in a similar manner to other depressive episodes: that is SRIs, individual and family support. ECT may need to be considered for a severely depressed and/or suicidal patient.

The hypomanic episode is often harder to manage, as it usually requires inpatient admission, measures to ensure the safety and protection of the patient and drug treatment. The most useful drug for an acute episode is haloperidol (dosage 0.05 mg/kg/d in three divided doses). It is usually necessary to supplement this medication with anti-parkinsonian drugs such as benzhexol or orphenadrine. An acute dystonic reaction such as an oculogyric crisis or acute torticollis can occur when treatment is commenced. Consequently, it is essential to observe closely the initiation of the medication.

Lithium carbonate is also effective in the acute episode, though its effect has a slower onset. Lithium is more useful as a prophylactic medication for individuals who have had several episodes. Its introduction should be carefully supervised and monitored. There have however been no controlled trials of the effectiveness of lithium in the prevention of further episodes in children or adolescents. Lithium has however been shown to be less effective among individuals with a rapid cycling disorder, features common among adolescents with bipolar disorder. Other drugs such as carbamazepine and sodium valproate have been used in the treatment of previously drug-resistant manic episodes in adults, but there is insufficient evidence to evaluate their efficacy for adolescents with bipolar disorder.

### **Prognosis**

Most individuals usually recover from an acute episode. For individuals with repeated episodes, poor prognostic features include the absence of a precipitating factor, a family history of recurrent illness and the continuation of some symptoms between acute episodes.

## SUICIDE

This is extremely rare below the age of 12 years with an increase during adolescence to approximately 30 cases per million per year.<sup>81</sup> It is more common in males with no trend in social class. Males tend to use violent methods such as hanging or jumping from high buildings or bridges, whilst females have a preference for self-poisoning. Shaffer & Piantonini<sup>81</sup> identified four types of personality characteristics among adolescents who commit suicide: irritable and oversensitive to criticism; impulsive and volatile; withdrawn and uncommunicative; and perfectionist and self-critical. They also found that some evidence for an increased psychiatric disturbance in the family and that a 'disciplinary crisis' was the most common reason precipitating the suicide.

### Attempted suicide

This is common with a rate of 4 per 1000 per year among 15–19-year-olds. Females are three times more likely than males to make an attempt with an excess among lower socioeconomic groups. Not surprisingly, the families show evidence of marital disharmony, maternal psychiatric ill health, particularly depression, and paternal personality disorder. About 50% of adolescents show some evidence of psychiatric disorder, usually depression. In older adolescents, there is often a history of alcohol or drug misuse and running away from home. Social isolation and poor peer relationships are also common.

The most common method is an overdose of non-opiate analgesics such as aspirin or paracetamol, probably related to their easy availability. The severity of the overdose varies markedly from a few tablets taken impulsively to swallowing the contents of a bottle of analgesics. The attempt often follows a row with a boyfriend or a serious dispute with the parents over discipline. The adolescent may have threatened to take an overdose on previous occasions, and about 50% have consulted their general practitioner in the month prior to the overdose.

A crucial part of management is the assessment of future suicide risk. This depends on three factors: the circumstances of the attempt, the patient's current mental state and their attitude to the future. Detailed questioning about events prior to the attempt are necessary as well as a 'blow-by-blow' account of the attempt. The latter includes information about the degree of planning, whether anybody else was present and any action taken after the attempt. The identification of any difficulties at home or at school is also important.

The presence of significant depressive symptoms and pessimism about the future are predictors of continued suicide risk. It is important to enquire whether the overdose has altered the adolescent's or family's attitude to their current difficulties and their resolve to improve the situation. An assessment of the coping strategies and the capacity for change within the family is important in order to make a more realistic judgment about the future. Finally, there should be some agreement about future plans and any further contact between the adolescent, the family and the relevant professional agencies.

Treatment depends on the assessment and clinical judgment. The majority of adolescents do not require specialist psychiatric follow-up, though clearly they must know how to access psychiatric services in order to arrange further help when necessary. The indications for more specialized help include: (1) the seriousness of the attempt; (2) the presence of definite depressive disorder or persistent suicidal ideas; (3) poor family circumstances and social support; and (4) the limited capacity of the family for change. A small number may require inpatient psychiatric care, particularly the older adolescent. Follow-up psychiatric contact often involves individual counseling for the adolescent as well as family sessions to improve communication and the capacity to resolve disagreements.

There have been few systematic follow-up studies, though clinical impression suggests that those with definite psychiatric disorder or adverse social or family circumstances are more likely to be 'repeaters'.

## ANOREXIA NERVOSA AND RELATED DISORDERS<sup>82</sup>

Anorexia nervosa is a disorder of older female adolescents with a prevalence rate of 1% among 15–19-year-olds. It does however occur among prepubertal children. The core features are:

- self-induced starvation and weight loss;
- a strong desire to be thinner with a marked fear of weight gain;
- a distorted body image (for instance feeling fat when emaciated);
- a body mass index (BMI) < 17.5.

### Clinical features

The presentation is varied, sometimes mimicking physical illness or the consequences of weight loss and starvation. The history is of prolonged self-imposed starvation. Dieting often begins following a chance remark about size or shape, or alternatively as a group behavior with other adolescent girls. Food portions at mealtimes are reduced, and some meals such as breakfast or lunch are skipped entirely with the total elimination of high calorific foods such as sweets, puddings or cakes. The individual derives satisfaction from the weight loss, which in turn is a further incentive for weight loss. Parents and other adults are often complimentary and pleased at this initial weight loss. More extreme and rigid dieting is then self-imposed to meet the target for further weight reduction. Appetite and hunger pains are prominent, but the prospect of further weight loss is a powerful motivator. Only when the illness is well established does the anorexia and nausea over food become apparent. Interest and participation in exercise and athletic activities often parallel the dieting in the belief that these activities will enhance weight loss. Later on, excessive laxative use begins in order to reduce weight further.

Despite an increasingly thin physique, the adolescent refuses to accept her emaciated status, still believing and perceiving herself as fat or overweight. The distorted body image is often the first indication to the parents that the adolescent has a serious illness. Increasing arguments over food and its consumption combined with an implacable refusal to eat convince the parents that urgent medical help is required. Often, the adolescent is initially referred to a pediatrician or an endocrinologist in order to exclude a physical basis to the problem rather than accepting a psychological basis for the weight loss.

Physical examination usually shows an individual who is bright and alert despite the evident emaciation. Prominent cheekbones, sunken eyes, bones protruding through the skin, dry skin and hair with blue cold hands and feet are common features. Severe emaciation is accompanied by the appearance of fine downy hair or lanugo hair on the face, limbs and trunk with a slow pulse rate, low blood pressure and hypothermia. Most biochemical investigations are normal, but low gonadotrophin levels with high growth hormone and cortisol levels are sometimes found. Although anorexia is the most likely diagnosis, other psychiatric such as depression, obsessive-compulsive disorder or schizophrenia may need to be excluded.

### Etiology

Almost as many theories have been proposed as the number of people who have researched the condition with individual, family or societal factors prominent in most explanations. Review of the premorbid personality characteristics of anorexics shows them to be conformist, conscientious, compliant and high achieving. Issues over autonomy and independence are core issues for anorexics with control over food intake the only available means to preserve self-identity and independence. Similar conflicts over autonomy and independence have been observed among families with an anorectic member, but whether this is cause or effect is unclear. Again, over the past 40 years, society's view about female attractiveness has veered towards the thin end of the spectrum, so that the 'pursuit of thinness' is a major issue for many women.

### Management

The severity of the condition varies widely, so that treatment includes outpatient and inpatient management with an emphasis on a 'multimodal' approach. The latter implies that a variety of treatment strategies such as individual, family or cognitive therapies are used, often concurrently or sequentially, dependent on assessment. Recognition and acknowledgement of the problem are the first crucial steps in management. The nature and seriousness of the condition highlighted by the avoidance of food and the irrational ideas about eating must be explored

thoroughly in order to establish a therapeutic alliance with the adolescent and the family. Only when the latter has occurred is it possible to commence a specific treatment program.

The next stage is the alteration of eating habits in order to restore weight loss and to correct nutritional deficiencies. Advice and collaboration with the dietician are important from the outset, particularly for any nutritional deficiencies. A target weight, usually around the average for the age and height, should be agreed upon along with the appropriate daily calorific intake to ensure its attainment. Only minimal concessions to food fads or preferences should be allowed with a standard protocol for regular weight checks.

If the patient is in hospital, the nursing care and support are the most important aspects of management. The nursing staff members have to win the cooperation of the adolescent for the treatment plan. They must also be vigilant about food hoarding and surreptitious vomiting. Treatment programs usually involve a graded series of privileges dependent upon satisfactory weight gain. Once the target weight is attained, the diet should be modified, so that age-appropriate weight gain continues. Inpatient programs often involve nursing staff supervising family meals at home during weekend leave.

Working with the family has two aims: to provide educational advice about the disorder and to improve communication patterns within the family. Individual and group work is also useful, but drug treatment is not indicated unless there is a specific treatable disorder such as co-morbid depression. Russell et al<sup>83</sup> in a randomized intervention study reported that family therapy was better than individual therapy in the prevention of relapse among anorexics under 18 years of age who had had the illness for less than 3 years. An important limitation of this study was that only 65% of the 80 patients completed the intervention program.

In many ways, the easiest part of the treatment program, particularly with inpatients, is the restoration of weight loss. A more challenging aspect is the restructuring of the adolescent's and family's attitude to food and their pattern of interaction. Regular supervision, support and contact are essential to maintain progress and keep up morale. Very often a compromise has to be made between an ideal resolution of the problem and a realistic appraisal of the adolescent's and family's capacity to change.

## Outcome

Results from follow-up studies vary widely according to inclusion criteria, outcome measures and length of follow-up. Despite these problems, outcome appears to fall into three categories, one third good, one third intermediate and one third poor. There is a 10% mortality in the long term with malnutrition and suicide accounting for most deaths. Poor prognostic factors are an early age of onset, co-existent psychiatric disorder and poor family functioning.

## BULIMIA NERVOSA

This has three key features: (1) recurrent binges and purges, (2) a lack of control and (3) a morbid preoccupation with weight and shape. It is rare in the prepubertal period, but becomes increasingly common in older adolescents and young adults, when it is often associated with depression. Most patients are of normal weight. The most serious medical concern is potassium depletion from frequent vomiting. The patient's lifestyle is often chaotic, so that the first aim of treatment is to establish some structure and boundaries for the patient. Dependent on assessment, a combination of individual, cognitive – behavioral and family work is appropriate in most cases.

Two new types of eating disorder have recently been described: *food avoidance emotional disorder* and *pervasive refusal syndrome*. The former is a disorder of emotions in which food avoidance is a prominent symptom along with other affective symptoms such as depression, anxiety or phobias. There is often a previous history of food fads or food restrictions, but the symptoms do not meet the criteria for anorexia nervosa. The validity and independence of this syndrome has however not yet been established.

Pervasive refusal syndrome is a severe life-threatening syndrome characterized by pervasive refusal to eat, drink, talk, walk or engage in any self-care skills. The patients are markedly underweight with an adamant refusal to eat or drink, which ultimately becomes life threatening. Although they fulfil some criteria for anorexia nervosa, the pervasiveness of the symptomatology makes this diagnosis inappropriate. They require prolonged and extensive inpatient nursing care in order to maintain vital body functions. Most patients have been girls with some suggestion that previous traumatic sexual abuse, often involving violence, may have been responsible for the precipitation of the disorder. Most make a satisfactory physical recovery, but the long term psychiatric adjustment is not yet known.

## SPECIAL TOPICS

### CHRONIC FATIGUE SYNDROME<sup>84</sup>

This has attracted widespread media coverage because of the controversy surrounding etiology and treatment. It is usually defined as a severe disabling fatigue affecting physical and mental functioning accompanied by myalgia, mood and/or sleep disturbance. Accurate prevalence figures are difficult to obtain, but are probably about 1 in 2000. Clinic samples tend to be adolescents aged between 11–15 years, with more girls and from a higher socioeconomic grouping.

Two thirds of patients have had a previous viral infection, but not usually of the Epstein–Barr type. This leads to fatigue, which results in a reduction in physical activity, leading to more fatigue on undertaking any physical activity. The situation is reinforced by parental and personal beliefs about causation, so that a state of inactivity and fatigue become established.

Management involves a thorough assessment to exclude co-morbid psychiatric disorder such as depression, but keeping investigations to an agreed minimum. The establishment of mutual trust and a collaborative approach with the adolescent and the parents are essential to a good outcome. Individual cognitive and family work combined with a structured incremental rehabilitation strategy (a graded exercise program) are the best way to make progress and limit further incapacity. A coordinated plan for school and social reintegration is also necessary.

Outcome varies depending on the initial severity, but three quarters have made a reasonable recovery after 2 years.

### SUBSTANCE MISUSE

This ranges from the readily available and legal substances such as tobacco or alcohol to the more uncommon and illegal substances such as heroin or cocaine. Though the latter give rise to more public concern, there is little doubt that cigarette smoking and excessive alcohol consumption have a far more deleterious effect on the health of the population as a whole. A recent survey of over 7000 15- and 16-year-olds in the UK<sup>85</sup> found that almost everyone had drunk alcohol, 30% had smoked cigarettes in the previous 30 d and 43% had at some time used illicit drugs. High levels of smoking were associated with a poorer school performance, and smoking was more common among girls. Adolescents are however only rarely referred to psychiatric services because of their smoking or alcohol habits.

### Solvent abuse (glue sniffing)

Ashton<sup>86</sup> reviewing the available literature, estimated that 5–10% of adolescents have at some time inhaled solvents, with 0.5–1% regular users. Since 1971, the death rate from solvent overdose has risen from 2 per annum to over a 100 per annum recently. Solvent abusers have the following characteristics: male gender; peak adolescent usage between 13–15 years; and more common among lower socioeconomic groupings, minority ethnic groups and disrupted families.

Inhaled substances include many everyday items such as adhesives, aerosols, dry cleaning fluids and cigarette lighter fuel. The substances are inhaled through paper bags, saturated rags or direct inhalation. It is often done as a group activity in the socioeconomically disadvantaged

areas of large cities, with regular solitary sniffing a cause for more serious concern. The immediate effect is euphoria followed by confusion, perceptual distortion, hallucinations and delusions. The regular user is often able to titrate the 'sniffs', so that a pleasantly euphoric state is maintained for several hours. The characteristic appearance of red spots around the mouth is highly suggestive of solvent abuse.

Sudden death during inhalation can occur from anoxia, respiratory depression, trauma or cardiac arrhythmia. The latter accounts for over half the deaths, whilst anoxia, usually from inhalation of vomit, is responsible for over 10% of deaths. Accidents or suicide attempts during the intoxication are another cause of death, particularly with toluene adhesives. Long term effects include neurological damage (peripheral neuropathy, encephalopathy, dementia and fits) as well as renal and liver damage.

Most solvent abusers do not come into contact with psychiatric services, unless they are referred following hospital admission with acute intoxication. School-based educational program and community-resource initiatives are more likely to be beneficial in the long term. The encouragement of retailers and shop owners to enforce the restrictions on the sale of solvents is also useful. A number of solvent abusers are referred for psychiatric assessment, usually when the abuse is seen as part of more widespread individual or family psychopathology. In the long term, most adolescents do not persist with the habit, but a minority progresses onto more addictive drugs such as heroin or cocaine.

### Other substances

These include 'soft' drugs such as cannabis (marijuana) or 'hard' drugs such as amphetamines, cocaine, heroin, lysergic acid diethylamide (LSD) and designer drugs such as 'Ecstasy'. The effects are euphoric and relaxing in the short term, but apathy and inertia occur with chronic use. Most individuals do not progress from cannabis to other more seriously addictive drugs, and its consumption is not indicative of underlying psychological disturbance.

Hard drug consumption is a far more serious problem with deleterious effects on physical and psychological well-being and also from the risk of physical or psychological dependence. In addition to euphoric and pleasurable effects, most of these drugs can produce acutely distressing symptoms such as panic, fright or hallucinations. This can result in suicidal behavior or an increased risk of accidents. Long term use, for example with amphetamine or cocaine, can precipitate a florid psychotic episode with hallucinations, usually visual, and paranoid delusions. Psychological withdrawal symptoms such as an unbearable craving for a 'fix' and physical withdrawal symptoms such as nausea, vomiting and diarrhea make stopping the drug extremely difficult. Physical neglect and malnutrition are also common and exacerbate the problems. The necessity for a regular supply of the drug means that the individual resorts frequently to stealing or crime to support the addiction. The practice of needle-sharing is a major health hazard with human immunodeficiency virus (HIV) infection a strong possibility. Referral of the adolescent to a specialist treatment center and support for the parents are essential to prevent the serious social and psychological problems inevitable with long term drug misuse.

### SEXUAL PROBLEMS

Two topics are discussed: sexual abuse and sexual offenders in adolescence; and gender identity disorders.

#### Sexual abuse and sexual offenders in adolescence<sup>34</sup>

Sexual abuse can present in two ways, direct disclosure of abuse or indirect manifestations of abuse. The same principles of practice and management apply to adolescents as to children (see child section of the chapter), but some special features are important. Open disclosure by the adolescent is often accompanied by the plea for complete confidentiality and no further action. Clearly this guarantee cannot be given, and the adolescent must be counseled about the necessity for an open investigation and the need for a child protection conference.

Indirect manifestations of abuse are twofold, sexually related behavior and psychiatric symptomatology. Sexually related manifestations include pregnancy, venereal disease and promiscuity. The latter often arises because the adolescent relates too readily to adults in a sexual manner as a result of the earlier experience of sexual abuse by an adult. Paradoxically, the promiscuous behavior may also lead some adults to disbelieve the adolescent's claims of abuse or believe that the adolescent was responsible for the initiation of the sexual contact. Psychiatric presentations of abuse are numerous with distress a prominent feature. Common presentations include depression, deteriorating school performance or attendance, suicidal behavior and running away from home.

Help for the sexually abused adolescent has two aims: the protection of the adolescent from further abuse and the provision of therapy to lessen the psychological trauma of the abuse. The first aim is usually achieved by ensuring that the perpetrator is no longer living at home and/or does not have contact with the adolescent. A wide range of therapies is used including individual counseling and support, family therapy or group therapy. Group therapy has become extremely popular recently. This approach has several advantages: the adolescent realizes that other adolescents have had a similar experience, the adolescent has the opportunity to discuss and share their feelings with other adolescents who are in a similar predicament, and they may feel less stigmatized. The group approach is probably less successful when the predominant feeling of the adolescent is betrayal. In this instance, it is more useful to offer individual psychotherapy to enable the adolescent to establish trust with the therapist, so that disclosure and discussion can occur in a confidential setting.

A more recent development has been the provision of treatment strategies for adolescents who have committed sexual offences. The latter include exhibitionism or indecent exposure as well as sexual abuse of other, usually younger, children. The treatment program involves an assessment of the offender's sexual knowledge and attitudes as well as their social skills and relationships. Treatment programs use a variety of approaches, often in combination, including social skills training, sex education and cognitive – behavioral approaches.

### GENDER IDENTITY DISORDERS<sup>87</sup>

Society's attitudes towards sexuality have been changing in recent years, so that a more open discussion about sexual values and behavior is possible with greater tolerance and less stigma associated with homosexuality whether in males or females. Homosexual behavior in some form or another is quite common during the pre-adolescent and adolescent years, occurring in approximately 20% of boys and 10% of girls. It appears to be a transitory pattern of behavior as adult estimates of male and female homosexuality are 3% and 1.5%, respectively. Whilst homosexuality per se is most unlikely to be a reason for psychiatric referral, occasionally anxiety and depression associated with doubts about the homosexual role are sufficiently severe to warrant referral.

Clinicians are more likely to be involved with children or adolescents who have a gender identity disorder. A core distinction is made between individuals who display anomalous gender role behavior and those with gender identity disorder. Anomalous gender role behavior is the individual's preference for interests, activities and clothes normally associated with the opposite gender. For example, effeminate boys prefer girls' style of clothing and to play with dolls, whilst 'tomboy' girls like aggressive contact games and boys' style of clothing.

By contrast, the essential feature of the gender identity disorder is the persistent wish to be of the opposite gender. This is confirmed by the frequent expression of this wish and by extensive anomalous gender role behavior including cross-dressing. During adolescence, referral is often sought for problems associated with cross-dressing, homosexual behavior and social ostracism from peers. Trans-sexualism or the wish for permanent change of gender assignment can also become an issue.

The search for etiological factors in gender identity disorder has not been fruitful with no convincing evidence for chromosomal, physiological

or endocrine abnormalities. Most clinicians believe that several psychosocial factors acting in combination are responsible. The initial parental tolerance of the anomalous sexual behavior followed by subsequent acceptance and reinforcement is a common finding among referred patients together with an overdependent mother–child relationship.

Treatment strategies for gender identity disorder include individual and family therapy, parental counseling and behavior therapy. The most important aspect of treatment is to define and agree goals with the parents and the child. Clinic studies<sup>88</sup> indicate that the earlier treatment is commenced the better the prognosis. Behavioral programs with attainable short term goals are much more likely to be successful than more ambitious plans. Minimizing anomalous gender behavior such as cross-dressing and the promotion of gender-appropriate behavior are the basis for intervention strategies. Treatment of co-existing individual and family psychopathology is also beneficial. Finally, the long term follow-up of 66 effeminate boys<sup>88</sup> found that three quarters were bisexual or homosexual as adults.

## PSYCHIATRIC ASPECTS OF LEARNING DISABILITY IN CHILDHOOD

### INTRODUCTION

Child psychiatrists are likely to become involved with children who have learning disability in several different ways. Sometimes they are responsible for the provision of the specialist medical care for these children, but more commonly they are asked for advice from other professionals about the emotional and behavioral problems that are quite frequent in this group of children.

### TERMINOLOGY

Many terms such as mental *subnormality* or/and *mental handicap* have been used in the past. ICD and DSM use IQ or mental age as the basis for classification. IQ is defined as: mental age/chronological age  $\times$  100. The mean or average IQ is therefore 100 with a standard deviation of 15. The normal or Gaussian distribution of intelligence means that approximately 2.5% of individuals are two standard deviations below the mean, corresponding to an IQ of 70. This is usually taken as the dividing point between the normal range of intelligence and learning disability/mental retardation. ICD and DSM have four categories of mental retardation: mild (IQ 50–69 approximately); moderate (IQ 35–49 approximately); severe (IQ 20–34 approximately); profound (IQ less than 20). The other important defining criterion is that there should be evidence of social impairment and limitation in the individual's daily activities and self-care skills.

## PSYCHIATRIC DISORDER IN CHILDREN WITH LEARNING DISABILITY

### Prevalence

The IOW study<sup>14</sup> found that approximately one third of children with learning disability showed signs of disturbance with the rate rising to 50% among moderate to severely learning disabled children. The children exhibited the same range of disturbance as children of normal ability but in addition three disorders were much more frequent: childhood autism, pervasive hyperkinetic disorder and severe stereotyped movement disorder. Self-injurious behavior and pica were also more frequent.

### Etiology

It is important to distinguish between the factors responsible for disorders occurring in mildly learning-disabled children and those with moderate to severe learning disability. The former probably have the same risk factors as children of average ability, but to a greater extent, that is adverse temperamental characteristics, specific learning disorders and family psychopathology. The latter is particularly important, as parents of children with mild learning disability are also likely to be within the lower range of intellectual ability. Consequently, their parenting capacity may be limited with inconsistent discipline and control prominent features. In addition, this may be combined with marital disharmony

and socioeconomic disadvantage, so that the vulnerability to psychiatric disturbance is considerably increased among this group of children.

By contrast, brain damage is an important causative factor among children with severe learning disability. Several studies<sup>12,14</sup> have reported that half the children with moderate to severe learning disability have demonstrable brain damage. This increases the risk of psychiatric disturbance in several ways: loss of specific functions or skills; active disruption or dysfunction of normal brain activity; and the increased risk of epilepsy. These children are also more likely to have specific learning difficulties that further increase vulnerability. In addition, adverse temperamental characteristics such as impulsivity, distractibility or overactivity are more common among this group of children. The psychosocial consequences of disability for the child and the family also make a factor in some cases, though its importance is difficult to quantify.

## PSYCHIATRIC SYNDROMES SPECIFICALLY ASSOCIATED WITH MODERATE TO SEVERE LEARNING DISABILITY

### Childhood autism

80% of children with childhood autism have an IQ less than 70. Many clinicians distinguish between individuals who have classical childhood autism from those with severe learning disability and some autistic features. The latter include stereotypies, mannerisms and deficits in comprehension and expressive language. These symptoms, which are quite common among many retarded children, tend to occur in isolation, so that the individual does not fulfil the diagnostic criteria for childhood autism. Clinical practice and research findings do not however provide clear-cut criteria to decide the dividing line between childhood autism and severe learning disability with autistic features. Consequently, clinicians tend to have their own personal preferences in terminology and classification.

Autistic behaviors are also features of some syndromes associated with learning disability such as tuberous sclerosis, congenital rubella, fragile X syndrome and infantile spasms. In some cases, for instance congenital rubella, the autistic behavior seems to be a response to the co-existing sensory deficit rather than the separate occurrence of childhood autism. Finally, individuals with the extremely uncommon neurodegenerative diseases such as subacute sclerosing panencephalitis or with disintegrative disorder often show autistic-like stereotypic behavior.

### Hyperkinetic syndrome/attention deficit hyperactivity disorder

Like autistic behavior, overactive or hyperkinetic behavior is common among children with severe learning disability. In most cases, the overactivity occurs in some situations but not others with the overactivity reflecting an immaturity in behavior and language skills. A much smaller but nevertheless significant number do show pervasive hyperactivity with other features of that syndrome including distractibility, impulsivity and aggressive behavior.

### Stereotypic and self-injurious behavior

Stereotypic movements such as body rocking or hand-flapping have been reported as frequently as 40% in mild to severely learning-disabled children. Self-injurious behavior such as head banging, biting of limbs or eye gauging is much less common but more potentially harmful and also difficult to eradicate. It often arises in an individual of very limited ability whose surroundings and immediate environment provide little or minimal stimulation. The Lesch–Nyhan syndrome is particularly associated with the development of self-mutilating behavior.

Murphy<sup>89</sup> reviewed the treatment methods for these intractable and destructive behaviors. Protective devices such as helmets, treatment with major tranquillizers such as haloperidol and behavioral approaches have all been used with some success. A real disadvantage with drug treatment is that once started it is difficult to stop, so that the individual can remain on a drug for several years, often with an increasing dose over time. A behavioral approach is more likely to produce long-lasting benefits, but it is more time consuming to carry out and more demanding of staff cooperation.

## Pica

The ingestion of inedible substances is a transitory phenomenon among normal toddlers and is even more common among children with severe learning disability. The main adverse consequence of this behavior is lead intoxication from the licking of objects. Fecal smearing and ingestion can occur among some children, particularly those with an additional sensory handicap such as blindness.

## LEARNING DISABILITY SYNDROMES ASSOCIATED WITH SPECIFIC BEHAVIORAL CHARACTERISTICS

Traditionally, children with certain learning disability syndromes have been said to show a characteristic behavioral or personality profile, though contemporary opinion is more sceptical about such association.

### Down syndrome

Children with this syndrome are often described as sociable, musical, contented and easy going, features they share with their siblings. Overall, these children have a slightly increased rate of disturbance with a minority showing aggressive and oppositional behavior, usually associated with Down syndrome due to a translocation trisomy.

### Phenylketonuria

Untreated, these children develop severe learning disability with autistic and hyperkinetic behavior prominent. Successful dietary treatment usually results in normal growth and development, but treated children have a greater risk of psychiatric disturbance with overactivity, distractibility and restlessness common.

### Lesch – Nyhan syndrome

This sex-linked disorder of purine metabolism, occurring only in boys, is associated with an extrapyramidal movement disorder including chorea and athetosis, severe mental retardation and self-injurious behavior. The latter is extremely difficult to treat and eliminate.

### Prader–Willi syndrome

The main behavioral feature is the explosive outbursts associated with dietary restriction frequently imposed to control the voracious appetite and accompanying obesity.

### Hydrocephalus

Children with hydrocephalus were previously described as showing the 'cocktail party' syndrome. This is characterized by a verbosity to their speech and a superficiality or shallowness to the content of their conversation. The early detection and treatment of hydrocephalus has now produced a reduction in morbidity, so that these features are less commonly seen.

### Management

Many professionals including pediatricians, teachers and psychologists are likely to be involved in the provision of care for children with learning disabilities and their families. A multidisciplinary approach to assessment and treatment is vital. Different aspects of management are important at various stages during the child's life.

## Breaking the news

This topic is discussed more fully in the child section of the chapter, so that only brief comments are made here. The ability to communicate bad news in a sensitive manner is a skill rarely taught to medical students or junior doctors. Many parents complain justifiably that the initial interview with the doctor was unsatisfactory and distressing. Tact, sympathy and time are essential to enable the parent(s) to begin to grasp and understand the implications of the situation. Honest discussion combined with an emphasis on the hopeful aspects are the important prerequisites for a satisfactory interview.

## Promotion of normal development

Parents should be encouraged from the outset to develop the social, self-care and educational skills of their child to the maximum. A 'normalization' and 'optimalization' strategy is the basis to the approach. Specific treatment packages, for example the Portage scheme, are helpful in enabling the parents to set realistic targets for their child.

## Treatment of medical and behavioral problems

Advice from neurologists, physiotherapists and occupational therapists is important in the management of the neurological deficits frequently present among this group of children. Behavioral problems are managed in a variety of ways including medication (for hyperactivity and aggressive outbursts), protective devices (for excessive head-banging) and operant or time-out procedures (for maladaptive behavior).

## Educational needs

Parents need advice from an early stage about the most appropriate educational provision. A specialized pre-school nursery is vital, and should be combined with a plan for later special educational placement. Some children may benefit from attendance at schools for children with communication or autistic-like disorders.

## Genetic counseling

This is clearly essential for all parents, especially when a specific syndrome is identified.

## Long term casework and support

Clinical experience and practice suggest that many families find this type of help invaluable in the long term. The identification of a key professional worker who coordinates the care plan for the child is very useful. A social worker or a professional from a voluntary organization with counseling skills is often the person best placed to fulfil this role.

## Outcome

Treatment programs with an emphasis on maximizing potential, minimizing adverse effects and integrating the child into the community are the best approach. Despite cognitive impairment, behavioral problems can be reduced by the treatment program, and families learn to adapt satisfactorily. The policy of the UK Government is to close institutions for individuals with learning disability and to integrate them into the community in order to promote better long term adjustment.

## WHAT IS ADOLESCENCE?

Strictly speaking, adolescence is the period between childhood and adulthood. But finding a useful definition of adolescence is difficult. Biologically it is the time of sexual maturation and the completion of growth. More than mere biology, adolescence is psychosocially the period between childhood dependency and being a functionally independent autonomous adult. Theorists have viewed adolescence in different ways; Freud saw adolescence as the period of recapitulation of the childhood Oedipal complex, while Erickson claimed that the struggle between Identity and Role Confusion typified the adolescent stage of development.<sup>1</sup>

Chronological definitions abound and are more pragmatic for allowing us to identify who is or is not an 'adolescent'. The World Health Organization for example defines adolescence as the second decade of life, from 10 to 20 years of age, but also defines a category of 'youth' as being 10–25 years.<sup>2</sup> However, chronological definitions take little account of the developmental changes of adolescence and their temporal variation, failing to apply to certain cultures or to those who are early or late developers. Because of this, some have suggested that adolescence is merely a social construct, a rite of passage that is culturally and socially invented.<sup>3</sup> These claims ignore the biological changes of puberty and the psychological developments driven by increasing CNS maturation and myelination. The most useful definition of adolescence is that it is a period of biopsychosocial maturation between the ages of 10 and 20 years, leading to functional independence in adult life. This definition has been adopted by the Royal Medical Colleges in the UK.<sup>4</sup>

## WHY IS A SPECIAL MEDICAL APPROACH NEEDED FOR ADOLESCENTS?

Adolescence, the period between childhood and adulthood, is increasingly recognized as a life period that poses specific challenges for treating disease and promoting health. In working with adolescents, the treatment of disease, the prevention of ill-health and the promotion of healthy behaviors are played out against a background of rapid physical, psychological and social developmental changes – changes that

produce specific disease patterns, unusual symptom presentations, and above all, unique communication and management challenges. At no other time of life are the physical and the psychosocial elements of illness and behavior so inextricably intertwined as in adolescence. This can make working with adolescents difficult. However given the right skills (which can be learned!), practicing medicine with young people can be extremely rewarding and fruitful. These skills are not only for those who deal solely with young people, but are needed by all in pediatric practice. Specific skills in adolescent health are recognized as being necessary for the practice of pediatrics in the UK,<sup>5</sup> the USA and other countries.

The reasons for a distinct approach to medicine with adolescents are outlined below.

## ADOLESCENTS ARE A LARGE CLIENT GROUP

One argument for considering adolescents differently to children is sheer numbers; young people between 10 and 20 years of age make up between 12% and 15% of the population in most resource rich countries (13% in the UK), a client group as large as children under 10 in the UK. Projections suggest that the adolescent population will grow by 8.5% between 1998 and 2011.<sup>6</sup> While adolescence is generally considered to be a healthy period, health resource use by young people is higher than in late childhood.<sup>7</sup> Most adolescents visit their general practitioner (GP) each year,<sup>8</sup> around 30% have a chronic condition that requires some health resource utilization,<sup>9</sup> mental health resource use is higher than in childhood<sup>10</sup> and hospital bed use is higher during adolescence than in late childhood.<sup>11</sup>

## ADOLESCENTS HAVE A UNIQUE EPIDEMIOLOGY OF DISEASE AND HEALTH RISK

The second argument for a special approach to adolescent health is that young people have a distinct epidemiology of disease and health risk. The diseases that are unique to adolescence are small in number (Table 35.1). But both disease and health behaviors in adolescents present a unique constellation of symptoms and problems not found in children or adults.

**Table 35.1** Disorders unique to adolescence or with onset predominantly in adolescence

Disorders of puberty and pubertal growth
Adolescent idiopathic scoliosis
Juvenile idiopathic arthritis – subtypes
Adolescent acne
Eating disorders (anorexia nervosa; bulimia nervosa)
Mental disorders, e.g. conduct disorder; adolescent psychosis

Those practicing with adolescents must be familiar with both persistent or late-onset ‘pediatric’ diseases and with early-onset ‘adult’ diseases. In each, ongoing adolescent development produces characteristic symptom patterns and management problems that meld the biological with the psychosocial in unique ways. For example, type 1 diabetes has its peak age of incidence around 12–14 years, and the growth hormone excess of puberty and the psychosocial challenges of chronic illness self-management produces poorer metabolic control during adolescence than at any other age.<sup>12</sup> Furthermore, puberty itself accelerates the progression of diabetic complications such as nephropathy.<sup>13</sup> Cancer during adolescence is remarkable for its threats of mortality to a personality with a newly developing sense of identity and place in the world, but also in its combination of ‘late’ presentations of pediatric type cancers (e.g. rhabdomyosarcoma, medulloblastoma), ‘age-specific’ cancers of adolescence (e.g. bone tumors) and early onset ‘adult-type’ carcinomas.<sup>14</sup>

### INCREASING SURVIVAL FROM AND INCIDENCE OF CHRONIC ILLNESS IN YOUNG PEOPLE

The increase in the prevalence of chronic illness among adolescents is changing the pattern of pediatric practice, and it is likely that young people will in the future make up a larger part of the pediatric workload. This has been driven by an increasing incidence of common chronic illnesses such as asthma and diabetes, but also by increasing survival from congenital diseases previously fatal in childhood. Cohort studies in the UK report a 70% increase in the prevalence of wheezing illness at age 16 years between 1974 and 1986, with further rises apparent in the 1990s.<sup>15</sup> It has been reported that almost 20% of UK 12–14 year olds used asthma medications in the past 12 months.<sup>15</sup> Diabetes in 10–14 year olds has increased by almost 24% Europe-wide during the past 10 years,<sup>16</sup> and the incidence of type 2 diabetes has risen dramatically in adolescents, particularly in minority ethnic populations.<sup>17</sup>

Advances in the last 20 years in the treatment of metabolic conditions, cystic fibrosis and congenital heart disease has produced new cohorts of young people surviving into adolescence and early adulthood.<sup>18–21</sup> The prevalence of cystic fibrosis over 15 years of age in the UK more than doubled between 1977 and 1985,<sup>21</sup> and currently over 85% of children with chronic illness survive to adult life.<sup>20</sup>

### HEALTH BEHAVIORS ARE LAID DOWN IN ADOLESCENCE AND CONTINUE INTO ADULT LIFE

One of the most compelling arguments for a focus on adolescent health is that adolescence is a time when new health behaviors are laid down, behaviors that track into adulthood and will influence health and morbidity life-long. Health behaviors in childhood are dominated by parental instruction and shared family values. During adolescence young people begin to explore alternative or ‘adult’ health behaviors, including smoking, drinking, drug use, violence and sexual intimacy. The continuities between adolescent initiation of health behaviors and adult behavior are well documented. Regular smoking rates rise from 1% at 11 years to 24% at 15 years,<sup>22</sup> and over 90% of adult smokers began in the teenage years.<sup>23</sup> Depression and its related mental health problems are rare in childhood, but rise through puberty to adult levels in late adolescence.<sup>24</sup>

Equally importantly, health behaviors around exercise and food are laid down in adolescence and track into adult life. Adolescent obesity

predicts adult obesity,<sup>25</sup> which is strongly and independently predictive of cardiovascular risk,<sup>26,27</sup> and cardiovascular risk in young adulthood is highly related to the degree of adiposity as early as age 13 years.<sup>25</sup>

### ADOLESCENTS HAVE UNIQUE NEEDS IN THE MANAGEMENT OF HEALTH AND ILLNESS

Dynamic and continued development in every aspect of a young person's life during adolescence means that young people have distinct needs in the management of illness and health. In clinical interactions with younger children, management decisions are made ‘adult to adult’ by health professionals in consultation with parents, and day-to-day disease management is generally undertaken directly by parents. When working with adolescents, the wishes, desires, knowledge base, capabilities and rights of the young person involved must also be taken into account – as must the fact that these wishes, desires, knowledge, capabilities and rights are constantly evolving and changing! Different approaches are required to all aspects of the doctor–patient relationship. Specialized clinical communication skills are needed to take an accurate history, bearing in mind new life domains not applicable to children (sex and drugs) and adding communication and engagement of the young person to the standard pediatric communication with the family. Physical examinations of adolescents require consideration of privacy and personal integrity as well as requiring additional skills such as pubertal assessment, breast examination and possibly genital examinations. The effective treatment of illness in adolescence requires adept management of the issues regarding adherence (compliance), consent and confidentiality, and relationships between the young person and their family.

### INCREASING SOCIAL MORBIDITIES AND MORTALITY LEVELS

Perhaps the most cogent argument for specific attention to adolescent health lies in the public health arena. The causes of mortality and morbidity in adolescents are distinct from both children and adults, as environmental or social causes of mortality (e.g. accidents and suicide) make up a larger proportion of total adolescent mortality than at any other age. In most public health priority areas, including cardiovascular risk (obesity, diabetes, smoking), mental health (suicide) and sexual health (teenage pregnancy and sexually transmitted diseases (STI)), the extent of problems in young people is stable or increasing rather than diminishing (Table 35.2).

Suicide rates among older male teenagers doubled over the last three decades of the 20th century and remain high.<sup>28</sup> Obesity has doubled among teenagers in the past 10 years, leading to the emergence of type 2 diabetes as a significant clinical and public health problem.<sup>29,30</sup> While smoking rates have fallen among teenage boys, rates among teenage girls have risen over the past 20 years. Earlier sexual debut and increased rates of high-risk sexual activity have led to high rates of teenage pregnancy and STIs in countries with poor sexual and relationship education such as the UK and USA. Given explicit evidence of the continuities between adolescent and adult health risk behaviors, adolescent morbidity trends argue strongly for urgent attention to adolescent health and the development of targeted adolescent-specific interventions.

### ADOLESCENT DEVELOPMENT

All clinical interactions with adolescents must be seen against the dynamic background of continued development. For example, chronic illness management issues can be quite different between a 13-year-old boy in very early puberty who has poorly developed abstract thinking and a 16-year-old girl who is sexually mature, at final height and has well-developed adult cognitive skills. The developmental tasks or events of adolescence are outlined in Table 35.3. While we group development for convenience into early, mid- and late adolescence, it

Table 35.2 Trends in indicators of adolescent health over the past two decades. (Adapted from Viner & Barker 2005<sup>76</sup>)

Key indicator area	Outcome	Direction of change in past 30 years	Detail
Cardiovascular risk	Obesity	↑	The prevalence of adolescent obesity (defined as BMI ≥95th centile) has quadrupled in representative samples since 1970s, rising from 4–5% in 1972 <sup>72</sup> to 8% in the mid-1990s <sup>73</sup> and 21–23% in 2002
	Smoking	←	There has been no significant change in prevalence of regular smoking among adolescents aged 11–15 years since 1982, <sup>74</sup> while smoking among adults declined significantly during the 1980s and early 1990s <sup>75</sup>
Sexual health	Teenage pregnancy	←	Live birth rates to women aged 15–19 years in the UK have changed little since the late 1970s, while rates have declined markedly in the same period in other European countries such as Germany and the Netherlands <sup>76</sup>
	STIs	↑	Rates of uncomplicated <i>Chlamydia</i> infections among 16- to 19-year-old females doubled during the 1990s in the UK (PHLS)
Mental health	Suicide	↑	In contrast to dramatic declines in suicide rates among men and women over 45 years of age between 1950 and 1998, among 15–24 year olds, suicide rates doubled in young men and remained stable in young women <sup>28,77</sup>

is important to remember that the timing and tempo of biological, psychological and social development each proceed independently in each individual, although each strand can influence the others. Those who are pubertally early developers may be late in developing cognitive skills or vice versa, and it is imperative to assess biological and psychosocial maturity separately. Gender issues are important here, as the timing of biological and psychosocial maturation is subtly different in boys and girls.

### BIOLOGICAL CHANGES

The biological changes of adolescence are puberty, the pubertal growth spurt, and accompanying maturational changes in other organ systems. The processes and timing of puberty and pubertal assessment skills are outlined in Chapter 15. The defining event of puberty in girls is menarche. The mean age at menarche showed a dramatic decline in most resource rich countries through the first half of the 20th century, stabilizing in the 1960s at 12.8 years in the USA and 13.2 years in the

Table 35.3 Developmental tasks of adolescence

	Biological	Psychological	Social
Early adolescence	<p>Early puberty</p> <p><i>Girls:</i> Breast bud and pubic hair development (Tanner Stage II); initiation of growth spurt</p> <p><i>Boys:</i> Testicular enlargement; beginning of genital growth (Stage II)</p>	<p>Thinking remains concrete but with development of early moral concepts</p> <p>Progression of sexual identity development: development of sexual orientation – possibly by experimentation</p> <p>Possible homosexual peer interest</p> <p>Reassessment and restructuring of body image in face of rapid growth</p>	<p>Realization of differences from parents</p> <p>Beginning of strong peer identification</p> <p>Early exploratory behaviors (smoking, violence)</p>
Mid-adolescence	<p><i>Girls:</i> Mid to late puberty (Stages IV–V) and completion of growth</p> <p>Menarche (Stage IV event)</p> <p>Development of female body shape with fat deposition</p> <p><i>Boys:</i> Mid-puberty (Stages III and IV)</p> <p>Spermarche and nocturnal emissions</p> <p>Voice breaking</p> <p>Initiation of growth spurt (Stages III–IV)</p>	<p>Emergence of abstract thinking although ability to imagine future applies to others rather than self (self seen as 'bullet-proof')</p> <p>Growing verbal abilities; adaptation to increasing educational demands</p> <p>Conventional morality (identification of law with morality)</p> <p>Development of fervently held ideology (religious/political)</p>	<p>Establishment of emotional separation from parents</p> <p>Strong peer group identification</p> <p>Increased health risk behaviors (smoking, alcohol, drugs, sexual exploration)</p> <p>Heterosexual peer interests develop</p> <p>Early vocational plans</p> <p>Development of an educational trajectory; early notions of vocational future</p>
Late adolescence	<p><i>Boys:</i> Completion of pubertal development (Stage V)</p> <p>Continued androgenic effects on muscle bulk and body hair</p>	<p>Complex abstract thinking</p> <p>Postconventional morality (ability to recognize difference between law and morality)</p> <p>Increased impulse control</p> <p>Further completion of personal identity</p> <p>Further development or rejection of ideology and religion – often fervently</p>	<p>Further separation from parents and development of social autonomy</p> <p>Development of intimate relationships – initially within peer group, then separation of couples from peer group</p> <p>Development of vocational capability, potential or real financial independence</p>

UK.<sup>31</sup> Despite recent controversy, the evidence is clear that there has been no change in the age of menarche in the USA or the UK over the past 40 years.<sup>31</sup>

As well as completion of linear growth and sexual maturation, other biological systems develop their final adult form during adolescence. These include maturation of enzyme systems such as cytochrome P450 systems, accretion of peak bone mass, and the development of sexually dimorphic adult patterns in blood lipids, haemoglobin and red cell indices.

## PSYCHOLOGICAL DEVELOPMENT

Psychological changes in thought patterns and cognitive ability are driven by increasing maturation and myelination of the adolescent brain.<sup>32</sup> Between the ages of 6 and 11 years, children generally think concretely, understanding only the immediate and short-term consequence of actions or events. Ideas and concepts can only be manipulated through using concrete representations. From the age of 12 years onwards, thought patterns begin to change to formal operational or abstract thought, the ability to manipulate ideas rather than things, imagine the future, and conceive of multiple outcomes of actions. These capacities are important for the development of a settled personal and sexual identity.<sup>33</sup> These psychological changes, like the biological changes of puberty, are universal to all races and cultures. However, the majority of psychological and social development is culture specific, varying with social and cultural norms regarding the roles of children and adults in society.

## SOCIAL DEVELOPMENT

The social changes of adolescence are outlined in Table 35.3. Biological and psychological changes occur within the context of an individual's social environment. The essential social tasks of adolescence are developing a sense of personal identity, moving from dependence to independence, and developing mature relationship with peers. These challenges exist across all cultures; however the timing of changes and the point at which successful completion is expected varies greatly between cultures.<sup>34</sup> In Western societies, adolescence commonly extends over many years, with its endpoints marked by relative financial independence after the completion of education. By contrast, in some societies, the social rights and responsibilities of adulthood are conferred at initiation ceremonies or rites.

## IMPLICATIONS OF ADOLESCENT DEVELOPMENT FOR HEALTH

It is the reciprocal impacts of adolescent development on disease management and health-related quality of life that pose the greatest challenges of adolescent medicine. This is especially true in chronic conditions (Table 35.4). A chronic illness or disability of any type may retard normal adolescent development, producing pubertal and growth delay, delayed social independence, poor body and sexual self-image and educational and vocational failure. Doctors, including both pediatricians and adult physicians, are poor at monitoring growth and pubertal development in adolescents with chronic illness, and attention is required to growth in chronic illness well into the early twenties.<sup>35</sup>

Being chronically ill, having a visible disability or being required to adhere to difficult treatment regimens is difficult at all ages – but particularly so during adolescence. Alienation from the peer group and absence from school cause social isolation, failure of socialization and ultimately, educational and vocational failure. The importance of thinking proactively about helping young people with chronic illness or disability develop independent adult living and vocational skills has been shown in longitudinal follow-up studies.<sup>36</sup>

Conversely, adolescent development issues impact upon the management of illness and disability. Poor adherence to medical regimens and poor disease management are virtually developmentally 'appropriate' in adolescence. Immature abilities to imagine future consequences allied with a concept of themselves as 'bullet-proof' means that the prevention of long-term complications of illness is a poor motivator for compliance. Additionally, medical advice may be rejected as part of a young person's growing independence from parents, particularly in chronic pediatric illnesses where medical staff have become medical 'parents'. Adherence and disease control are also put at risk by the developmental need to explore possible modes of future behavior, no matter how dangerous (usually derogatively referred to as 'adolescent risk-taking'). Health risk behaviors such as smoking, alcohol and drug use are as common in adolescents with chronic illness or disability as in the general population.<sup>37</sup>

Developmental issues in adolescent medicine are becoming more important, as the burden of chronic illness in adolescence increases as larger numbers of chronically ill children survive into the second and third decades.

**Table 35.4** Reciprocal effects of chronic illness or disability and adolescent development

Effects of chronic illness or disability on development	Effects of developmental issues on chronic illness or disability
<p><i>Biological:</i> Delayed puberty Short stature Reduced bone mass accretion</p> <p><i>Psychological:</i> Infantilization Adoption of sick role as personal identifier Egocentricity persists into late adolescence Impaired development of sense of sexual or attractive self</p> <p><i>Social:</i> Reduced independence at a time when independence is normally developing Failure of peer relationships then intimate (couple) relationships Social isolation Educational failure and then vocational failure; failure of development of independent living ability</p>	<p><i>Biologically:</i> Increased caloric requirement for growth may negatively impact on disease parameters Pubertal hormones may impact upon disease parameters (e.g. growth hormone impairs metabolic control in diabetes)</p> <p><i>Poor adherence and poor disease control due to:</i> Poorly developed abstract thinking and planning (reduced ability to plan and prepare using abstract concepts) Difficulty in imagining the future; self-concept as being 'bullet-proof' Rejection of medical professionals as part of separation from parents Exploratory (risk-taking) behaviors</p> <p><i>Associated health risk behaviors:</i> Chaotic eating habits may result in poor nutrition Smoking, alcohol and drug use often in excess of normal population rates Sexual risk-taking, possibly in view of realization of limited life span</p>

## RESILIENCE AND RISK IN ADOLESCENT HEALTH

Morbidity in adolescence is generally understood to result from ‘risk-taking’, impulsivity, the rejection of parental values and the testing of boundaries. But the standard conceptions of adolescents as risk-takers with poor future thinking abilities have been shown to be largely false.<sup>38</sup> Most adults take as many risks and have equally poor future thinking abilities as the majority of young people. Indeed, mental health problems, drug use and sexual risk-taking is co-morbid in the same way in adults as occurs in adolescents.<sup>39,40</sup> That adults seem to take fewer risks is largely because they have learned to more effectively manage the consequences of their risk-taking. It is more helpful to understand so-called ‘risk-taking’ behaviors in young people as developmentally appropriate ‘exploratory behaviors’; i.e. young people exploring the diversity of possible adult behaviors open to them – behaviors that they may or may not continue as adults.

Once these behaviors are understood to be largely developmentally motivated, it becomes unsurprising that interventions based upon education about ‘risk’ behaviors show very poor results.<sup>41</sup> Large studies of adolescent behavior and health show convincingly that health risk behaviors of all types (substance misuse, sexual risk, suicide, injuries and violence) occur together, and are strongly associated with deprivation and ethnicity.<sup>42</sup> Conversely, high family, community and school support (‘connectedness’ or ‘social capital’) are protective against most health risk behaviors in adolescents.<sup>42</sup> Identifying such ‘resilience’ or protective factors is now the focus of public health interventions with young people, and known protective factors for different behaviors are outlined in [Table 35.5](#).

The search for protective factors applies equally to clinical management of acute or chronic illness in young people. In young people with poor control of a chronic illness, it is traditional to search for causes of poor control and why things go wrong. In a young person with recurrent hospital admissions with asthma, for example, causes of exacerbations may be a lack of education or lack of a crisis plan, or psychological problems including non-adherence and manipulation of the treatment regimen. In some cases, it may be more fruitful to examine ‘what has helped’ and what has kept the young person out of hospital between admissions. This ‘solution-focused’ approach, asking young people what resources they have used to stay well between

exacerbations, can be very effective in treating poor chronic illness control.<sup>42</sup>

## THE MANAGEMENT OF ILL-HEALTH IN ADOLESCENCE

Most doctors (with the notable exceptions of neonatologists and geriatricians) have adolescents in their practice. But many are not comfortable or skilled in dealing with adolescents. American studies suggest that only around a third of physicians and pediatricians actually like working with adolescents and that around another third have very little interest in adolescent care.<sup>43</sup>

The effective management of young people with acute or chronic illnesses requires a nonjudgemental communication style, knowledge of adolescent development and an awareness of consent and confidentiality issues, and an ethnographic approach which aims at understanding the health beliefs and contexts in which the young person manages their disease.

## COMMUNICATION WITH YOUNG PEOPLE

Consultations with adolescents differ from pediatric consultations in that the young person forms a more important and more problematic third party in the decision-making process. In working with young people, we must communicate not with another adult, but with a personality undergoing rapid psychological and social changes who may or may not share an adult’s understanding of society nor adult cognitive abilities to decide between treatment alternatives in the light of future risk.

Effective clinical communication is a basic health right for young people, as well as being necessary for effective disease management. Yet adolescents report that they frequently find communication with doctors unsatisfactory, with doctors often seen as remote and judgmental figures whose confidentiality cannot be trusted.<sup>44</sup> Communication with adolescents requires an understanding of the cognitive and social developmental level of the young person and a nonjudgmental understanding of the social contexts of that individual’s health behaviors. Important elements of effective communication with young people are outlined in [Table 35.6](#).

**Table 35.5** Identified risk and protective factors for adolescent morbidities and health behaviors

Behavior	Risk factors	Protective factors
Smoking	Depression <sup>61</sup> Alcohol use <sup>59</sup> Disconnectedness from school or family <sup>59</sup> Difficulty talking with parents <sup>59</sup> Minority ethnicity <sup>62,63</sup> Low school achievement <sup>42</sup> Peer smoking and high peer popularity <sup>64</sup>	Family connectedness <sup>42</sup> Perceived healthiness <sup>59</sup> Higher parental expectations <sup>42</sup> Low school smoking prevalence <sup>64</sup>
Alcohol and substance use	Depression <sup>62</sup> Low self-esteem <sup>42</sup> Easy family access to alcohol <sup>42</sup> Ethnicity <sup>62</sup> Working outside school <sup>42</sup> Difficulty talking with parents <sup>59</sup> Risk factors for transition from occasional to regular use are cigarette smoking, availability, peer use and other risk behaviors <sup>65</sup>	Connectedness with school and family <sup>42</sup> Religious affiliation <sup>42</sup>
Teenage pregnancy	Disadvantage Urbanicity Low educational expectations <sup>66,67</sup> Lack of access to sexual health services <sup>68,69</sup> Drug and alcohol use <sup>70</sup>	Religious affiliation <sup>71</sup> Parental connectedness and expectations <sup>42,67,68</sup>
Sexually transmitted infections (STI)	Psychological disturbance <sup>40</sup> Substance use <sup>40</sup>	

**Table 35.6** Practical points for communicating and working with adolescents

---

Assure confidentiality – both in the clinical interaction and in the clinical/hospital set up

See young people by themselves as well as with their parents. The best strategy for getting the parents out of the room is warning families when you first see them that you routinely see adolescents by themselves as a way of respecting their rights as a young person

Be empathic, respectful and nonjudgemental and try to avoid taking the 'expert' position. Treat the young person as the expert in their own condition, with the doctor as the medical advisor. Find out what the young person's goals are for their treatment and health, and negotiate matching treatments to their health goals

Try to communicate and explain concepts in a developmentally appropriate fashion. This is particularly important in health promotion. For young adolescents, concentrate on concrete 'here-and-now' issues and avoid abstract discussions, particularly about possible future health risks. You may need to repeat the information in a different form as they mature cognitively

Be yourself and don't be 'cool' or use youth language. Young people don't want you as a friend, they want a knowledgeable doctor whom they can respect and trust

Provide an emotionally and physically safe environment. A gender balance among staff is important, particularly where physical examinations are undertaken

Take a full psychosocial history when seeing young people for the first time, for example using the HEADSS protocol (see [Table 35.7](#))

---

The standard pediatric consultation (doctor communicates with parents) and the standard adult consultation (doctor communicates solely with patient) are both inappropriate in dealing with adolescents. Best practice is to see young people both together with their parents and by themselves. While this is time consuming, it is essential for taking an accurate history, understanding the young person's motivations and goals, and for getting accurate information on health risk behaviors such as smoking, drinking, drugs and unsafe sex.<sup>45</sup>

Frameworks have been developed for best practice in clinical settings with young people, the most well known being the HEADSS approach which reminds clinicians to cover the important domains of Home life, Education, Activities, Drugs, Sexuality and Suicide (depression and self-harming) when interviewing any young person ([Table 35.7](#)).<sup>46</sup> But having a framework is not enough; the key skills required for effective communication with young people are to understand adolescent development, to be empathic, respectful and nonjudgmental, to understand the link between physical and emotional well-being, and to provide a physically and emotionally safe environment for the clinical interaction. The good news is that these skills can be learned.<sup>47</sup>

## EXAMINING YOUNG PEOPLE

While the bulk of physical examination of adolescents is similar to that of children, new types of examinations may provide a challenge to the pediatrician, including pubertal assessments, pelvic examinations and breast and testicular examinations. Regardless of the examination, adolescents require more attention to privacy and confidentiality than children. Ensuring personal privacy is essential, and it is appropriate to ask all young people whether or not they wish their parents to be present during physical examination, especially of the genitals. Be sensitive that they may not wish their parent to be present but may have difficulty saying this in front of their parent. This can be dealt with by suggesting to the parent that the young person may now be old enough to want their privacy and then asking the young person what they wish.

**Table 35.7** HEADSS psychosocial assessment interview<sup>46</sup>

---

H	Home life including relationship with parents
E	Education or employment, including achievements and financial issues
A	Activities: particularly friendships and social relationships and the existence of close friends that the young person can rely on and talk to. Also participation in sports and exercise
D	Drug use, including cigarettes and alcohol
S	Sex: information on intimate relationships and sexual risk behaviors may be important in both acute and chronic illnesses in adolescents
S	Suicide: this is short-hand for depression and other mood disturbances and self-harming behavior

---

The issue of the gender of the doctor and chaperones for intimate examinations is important. Many but not all adolescents prefer to be examined by a same-sex doctor, and providing a gender balance and choice of examiner is useful if this is possible. Having a chaperone for examination of adolescents of the opposite sex is obviously mandatory to protect both the patient and the doctor.

Assessment of pubertal stage is important for the management of all chronic illnesses in adolescents as well as in the assessment of endocrine disorders. These skills are easily learned, and pubertal stage should be assessed at least annually in young people with chronic illnesses during early adolescence. For those who refuse direct genital examination, pubertal self-assessment using standard Tanner photographs or drawings offers a less accurate alternative.<sup>48</sup> Pediatricians in most medical systems will rarely be required to undertake pelvic examinations on adolescents, although in others this is routine.

## CONFIDENTIALITY AND CONSENT ISSUES

Confidentiality and consent issues are central to the management and examination of young people, who are potentially legally underage. Adolescents are very clear that the major things they want from clinicians are confidentiality, respect and clinical excellence.<sup>49,50</sup> Services that are not considered to be confidential are less likely to be used by young people.<sup>51,52</sup> Full confidentiality (including keeping confidentiality from parents) should be assured to young people unless they are found to be at risk from suicide, sexual abuse or reveal plans to harm others.<sup>44</sup>

In relation to issues of consent to treatment, adolescents can fall into a no-mans' land between parental rights over minors and adult rights. In most countries including the UK, adolescents are now deemed to have adult rights to consent to treatment themselves if they are legally competent, regardless of their parents' wishes. The legal criteria for competence differ between countries, but usually require the ability to give informed consent and understand the benefits and risks of treatment or nontreatment. In the UK, competence is presumed over the age of 18 years, and adolescents between 16 and 18 years can consent to treatment but cannot refuse life-saving treatment. Under 16 years of age, adolescents are legally presumed incompetent unless they show otherwise.<sup>53</sup> Of course, many young people under this age are competent, so in a practical sense, it is appropriate to treat adolescents from 12 to 14 years upwards as if they have full adult medical rights and responsibilities.

## ADHERENCE (COMPLIANCE) AND THE CONTROL OF CHRONIC ILLNESS IN ADOLESCENCE

Adolescents are frequently poor clinic attenders and adolescence is a time of poor disease control in many chronic conditions. Because of this,

adolescents are frequently labeled as ‘noncompliant’,<sup>54</sup> although there is very little evidence that young people adhere more poorly to medical regimens than adults. Many young people struggle with the organizational responsibility of managing difficult regimens; others manipulate their regimen as part of ongoing conflict with parents; but most are faithfully adherent, but adherent to a regimen of their own choosing – one that may have little relationship to that prescribed by their doctor!

Practical measures to improve adherence to medical regimens are outlined in Table 35.8. The most important aspect is to ‘decriminalize’ non-adherence by recognizing that some non-adherence is universal, and working with the adolescent to tailor the regimen to meet their health goals. The most effective medical regimen for adolescents is one that ensures its own success by being tailored to meet the health goals of the young person. Finding out what the young person is most worried about, what would motivate them to take their treatments, and what they would like to change about their illness, their appearance and their life, allows doctors to start a negotiation with a young person about a regimen that would maximize adherence.

When thinking about disease ‘control’ in adolescence, we cannot assume that control means the same thing for the young person as it does for health professionals. In diabetes for example, good medical control is defined as a low HbA1c, few hypoglycemic episodes and no admissions to hospital in diabetic ketoacidosis. But from a young person’s point of view, good ‘control’ may mean minimizing the impact and appearance of diabetes in their lives – which may manifest as carefully running blood sugars moderately high to avoid embarrassing ‘hypos’ but not high enough to cause ketosis, eating a normal diet (dietary non-adherence) and doing very few blood sugar levels. Good ‘control’ for the young person may also include withholding insulin to control weight. This phenotype of ‘careful poor control’ is common in many diseases

**Table 35.8** Practical measures to improve adherence and disease control in adolescents

---

‘Decriminalize’ non-adherence. Ask: ‘Most young people have trouble taking medications. How many days a week do you manage to take them all?’
Involve the adolescent as much as possible in planning the regimen, choosing the drugs (if there are alternatives), and deciding on dose timing. Young people are more likely to adhere to programs they feel responsible for
Search for motivating factors that will help the young person stick with treatment. Issues about growth, weight and appearance are often useful in chronic illness
Make a contract with the young person where each side agrees to fulfill certain conditions
Provide written instructions (in adolescent-friendly language) about the treatment regimen
Focus the regimen on the least chaotic time in the adolescent’s daily life. This is usually the morning but is different for different adolescents
For complex regimens, don’t assume adherence is the same for each drug. Adolescents may faithfully adhere to some and never take others because of beliefs about the drug or side-effects. Discuss compliance with each medication separately and explore beliefs and knowledge about the drug
Find ways to involve the family in ways that do not increase parent-adolescent conflict about independence; e.g. assign the parents ‘check-points’ every 2–3 days but forbid constant nagging (which usually reduces compliance!)
Don’t believe that non-adherence is because of ignorance or that education will improve compliance
Take a ‘solution-focused’ approach. Find out when things have gone well and try to work out why. Use these

---

in adolescence, and is a product of young people’s health goals being focused on the here-and-now and on living a normal teenage life rather than on future disease complications. The management of this form of poor control focuses on exploring the motivations and aims of the behavior, and negotiating with the young person to fulfill their aims while also producing good medical control.

Other phenotypes of poor disease control in adolescence may result from psychological problems associated with chronic illness. Perhaps more than at any other time, the developmental changes during adolescence means that the psyche and soma are inextricably interrelated. Many young people with chronic medical conditions suffer adverse psychological sequelae, particularly depression and anxiety and adjustment disorders, as well as delayed psychosocial development.<sup>55</sup> This can manifest as poor disease control, frequent hospital admissions and long term school absence. Assessment and management of the reciprocal psychosocial impacts of adolescence and chronic illness (Table 35.4) are a central part of medicine for adolescents. Severe or chronic illness in adolescence should be managed in the context of multidisciplinary teams that include mental health professionals, social workers, youth workers and teachers, as well as doctors and nurses. As noted above, taking a ‘solution-focused’ approach may help. A young person admitted for an asthma exacerbation every month has 25 days per month when their asthma is well controlled. Find out what helped them do this and identify resiliency factors that can be worked upon to help keep the young person well and their disease better controlled.

## TRANSITION

The transition of adolescents with chronic illness from pediatric to adult services is now a central part of chronic illness management (Table 35.9). This transition means more than just a transfer from one clinic to another.<sup>56</sup> It entails a significant change from the family-centred and developmentally focused pediatric paradigm (which frequently infantilizes the adolescent) to an adult medical culture which acknowledges patient autonomy and reproduction and employment issues but neglects growth, development and family concerns. It also entails the loss of well-known and valued pediatric care-givers and the necessity of trusting new and unknown adult carers. Because this change is so significant for the young person and their family, traditional methods of transfer of care by referral letter can lead to adolescents settling poorly into the new adult service or even dropping out of medical supervision altogether for a period.<sup>57</sup>

This transition period is particularly dangerous in those diseases where adult services or skills are poorly developed, such as in ‘pediatric’ metabolic diseases or congenital heart disease. It is important for all pediatric specialist clinics to have transition guidelines and those where larger numbers of adolescents are transferring should develop an active transition program with the receiving adult service. Preparation for transition should begin in early

**Table 35.9** Transition recommendations

---

Transition preparation must be seen as an essential component of high quality health care in adolescence
Every pediatric general and speciality clinic should have a specific transition policy. More formal transition programs are necessary where large numbers of young people are being transferred to adult care
Young people should not be transferred to adult services until they have the necessary skills to function in an adult service and have finished growth and puberty
An identified person within the pediatric and adult teams must be responsible for transition arrangements. The most suitable persons are nurse specialists
Management links must be developed between the two hospitals
Evaluation of transition arrangements must be undertaken

---

adolescence, and young people should only move to adult care when they have the necessary skill-set to survive independently in the adult service.<sup>58</sup>

## HEALTH PROMOTION FOR YOUNG PEOPLE

The most serious health problems affecting young people are primary care issues including teenage pregnancy, drug misuse, mental health problems and violence. By 15 years of age, around 24% of adolescents in the UK are regular smokers, 38% will be regular alcohol consumers<sup>59</sup> and around 25% are sexually active.<sup>60</sup> While these problems are generally the province of general practitioners and others in primary care, all health professionals who deal with young people should possess basic health promotion skills. Over 70% of adolescents visit a doctor every year<sup>8</sup> and each clinical interaction with an adolescent should provide an opportunity for health promotion.

As noted above, young people with chronic illness have similar rates of risk behaviors to the general population,<sup>37</sup> although few pediatricians address smoking, alcohol or sex in clinical interactions with young people with chronic conditions. Health behaviors begun in adolescence continue into adult life, and health promotion during adolescence can positively influence smoking, drug use and sexual exploratory behaviors. Those looking after young people with chronic illness must begin to

address smoking, alcohol and drug use and sexual health in early adolescence as this is when exploration with health behaviors begins. This is often best done by other members of the multidisciplinary team, or by the inclusion of consultation with sexual health workers, etc. as part of the multidisciplinary management of adolescents with chronic illness.

## CONCLUSIONS

Adolescent health is of increasing importance in both pediatric practice and in public health. Young people require and benefit from a distinct clinical approach based upon knowledge of adolescent development in biological, psychological and social domains and the search for resiliency factors that promote health and healthy behaviors. Although chronic illness control is frequently poorer during adolescence, concepts of the 'non-adherent' or 'difficult' adolescent are based on a lack of understanding of the disparity between traditional medical goals and the health and life goals of the young person. The most effective ways to foster healthy behavior and improve disease control during adolescence are to aim for concordance between the treatment regimen and the health goals of the young person, and to focus on factors the young person finds helpful in maintaining good health/disease control.

## PEDIATRIC INJURY AND EMERGENCY CARE

### A PEDIATRIC EMERGENCY MEDICAL SERVICE (PEMS)

Most children become critically ill or are injured in their own environment. In order to provide optimum care for these children a seamless structure of continuous care, from environment to hospital, is essential. There are few centers in the world where this seamless care exists. Where it has been achieved however, outcomes for critically ill and injured children have been positively influenced.<sup>1,2</sup>

The continuum of pediatric emergency care is best summarized in Figure 36.1. Within this there should be the desire to keep as many children as possible out of hospital and maintain their care within the home and community environment for as much of the time as possible.

### THE HOME SETTING

For the first 5 years of life most children spend the bulk of their time within the home and local community. The majority of children coming into contact with emergency medical services do so as a result of infection or injury.

Most children will experience upper and lower respiratory tract infection with considerable frequency between the ages of 0 and 5 years. After this age it is much less frequent. Much of this illness can be treated within the home providing parents have sufficient confidence and education. Most illness in this age group will be viral and will require little more than supportive measures such as antipyretic therapy and encouraging fluid intake. However, there is an increasing demand for this type of treatment to be obtained from family doctors or emergency departments. The disintegration of the nuclear family is one factor increasing this demand on medical time, particularly in primary care. Recent evidence has indicated that attenders at emergency departments for minor illness and injury come from deprived areas of the community.<sup>3</sup> The reasons for this are complex but probably relate to coping mechanisms and education.

In a small number of cases bacterial infections will be present that require antibiotic therapy. In an even smaller number significant infectious disease such as meningitis, septicemia and osteomyelitis will be present. A small number of children with viral illness will get further complications such as a febrile seizure, or superimposed bacterial infection may supervene. If parents are unaware of these problems they will lose confidence in managing illness within the community.

One way to tackle such issues is to develop an educational program aimed at developing competence in minor illness and injury management. Such an education program must also alert parents to the dangers of significant illness or injury that may require further treatment with or without a stay in hospital. Within this education program it is important to differentiate the needs of the infant younger than 3 months of age from those older than 3 months of age. The response of the younger child to infection is totally different from that of older children and adults and parents should be aware of how to get advice for these children should the need arise.<sup>4</sup> This is a difficult task as even health

professionals using clinical decision tools cannot reliably detect children with significant infection.<sup>5-7</sup> Similarly injury in the infant may be a harbinger of child abuse or neglect.

Despite the frequency of infections, injuries are still the leading cause of morbidity and mortality between the ages of 1 and 5 years. Most of these injuries occur within the home setting, which includes the garden and its surroundings. Burns and scalds, poisonings, falls from a height, finger tip injuries and near drowning account for the majority.

One of the means to tackle the toll wrought by injury in this age group is an integrated injury prevention program within an emergency medical system. The components of such a system include:

1. injury surveillance;
2. data analysis;
3. identification of problems;
4. development of strategies;
5. implementation of strategies;
6. injury surveillance.

In many ways this is a typical audit cycle. It relies on collaboration among emergency physicians, general practice, public health medicine, educationalists and health promotion agencies. Their respective skills should be brought together in a coordinated fashion.

At present injury surveillance is patchy with much information being derived from inpatient databases. These are inaccurate and only reflect 10% of total injuries that occur.<sup>8</sup> Without meaningful measures of injury severity these data are at best a reflection of current medical practice. A good example of this is the documentation of poisoning. Many children who are poisoned can be safely dealt with in the home without ever coming to hospital provided adequate medical advice can be given and monitored by telephone. If this advice is not available then many children will present to hospital. They will present to the emergency room, where their treatment will depend on the experience and confidence of the staff working in that department. Junior staff, insecure or ill taught will tend to admit because they are unsure of what to do. Senior staff, experienced and confident will be able to manage many of these children on an outpatient basis. In an institution staffed in the former manner poisonings determined from inpatient stay will be at a high level whereas those in an institution managed in the latter manner will be lower. This has nothing to do with the incidence of the poisoning but all to do with medical practice. Simply by changing medical practice an apparent fall in the incidence of poisoning can be demonstrated when in fact the incidence remains high. Failure to take cognizance of these matters when developing injury surveillance will lead to inappropriate preventive measures.<sup>9</sup>

Effective data surveillance should start with a minimum data set. This minimum data set should aim to capture a small, important amount of information on every child who presents.<sup>10</sup> If too much information is to be documented staff members will tend not to collect it and parents will get irritated because they feel that their child should be treated rather than them answering questions. Typically it should include age, sex, postcode and proxies for social class and/or deprivation. Some idea as to the causation should also be included. One way of doing this is to use international classification of disease E codes;<sup>11</sup> this is universally accepted and is adequate for most things. This could be further

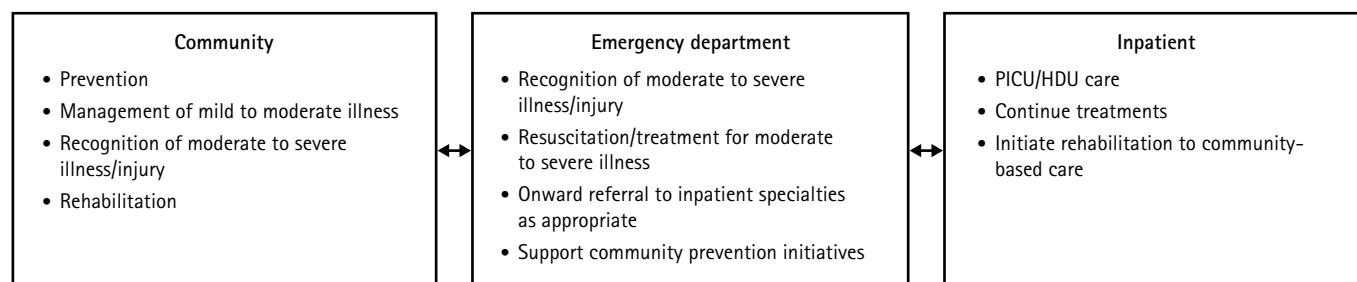

Fig. 36.1 Continuum of emergency care.

refined to having the most common injuries already precoded. Similarly some ideas to the most common diagnoses using a system such as the International Classification of Disease codes (ICD) could also be included on discharge. If this information were to be collected on all children a very suitable injury surveillance system would very rapidly be developed that could be expanded as the need arose.

## DATA ANALYSIS AND PROBLEM IDENTIFICATION

Once an accurate database is in place that gathers details on a substantial proportion of injury occurring within the community then problem areas can be identified. This can be on the basis of deprivation or need; clustering; type of injury, e.g. fall, poisoning; type of injury, e.g. fracture or head injury. Once analyzed this information can then be made available to the relevant health education agencies, who can then implement parts three and four of the audit cycle.

## DEVisING A STRATEGY

Before any strategy can be devised to protect against childhood injury three components have to be addressed:

1. the child;
2. the family;
3. the environment.

Tackling any of these on their own will fail if it does not concomitantly address the problems inherent in the other two areas. It is well recognized that some children are more injury prone than others. Is this because the family is poor or the environment is poor? Or is it that that child is inherently more prone to injury for reasons of clumsiness, poor eyesight/coordination? Attention deficit and hyperactivity disorder is an example of a behavioral problem that might be expected to be associated with injury and this is the case.<sup>12</sup> To date many injury prevention programs have been simplistic with individuals working in isolation without the complete umbrella of a PEMS.

## IMPLEMENTING A STRATEGY

Before a strategy can be successful the lessons from commercial advertisers have to be learned. Simply repeating the same message ad infinitum leads to message fatigue. The message must be appropriate to the target audience and must take note of all the above factors. In addition the audience must be identified and targeted effectively.

## RE-AUDIT

It is important to measure any effect of the prevention campaigns against the initial database. Failure to do so may lead to inappropriate and ineffective campaigning being continued indefinitely. If there has been no diminution in the levels of injury that one has targeted then the strategies need to be re-evaluated in the light of the data analysis and message.

## COMMUNITY EDUCATION

In order for the child to be cared for within the home as effectively as possible, ideally not accessing emergency medical services, a substantial amount of effort must be paid to community education. However, the target audience has not been well defined. Does the practitioner, for instance, tackle children in junior school or senior school in an effort to help future generations? Should the practitioner address the problem at antenatal classes, where there is a substantial chance of reaching an interested mother and perhaps the father? Is it appropriate to address the issue of safety in the postnatal period, when the father is almost certainly not going to be present? These issues need to be addressed as a matter of urgency if child injury prevention is to be taken forward in a meaningful manner.

## COMMUNITY CARE

Within the context of a PEMS, community care should be directed at disease prevention. There will however be a significant proportion of children who have transient episodes of acute illness requiring medical intervention. Interspersed with these will be children with chronic disability who will have more sophisticated needs for emergency care than their able-bodied peers.

To work effectively there needs to be a network of experienced general practitioners and community pediatricians working alongside health visitors, district nurses, midwives and other paramedical staff. The public health system working alongside ensures good sanitation and maintenance of water supplies. Attention to housing and overcrowding is also all-important in the prevention of disease and illness. Surveillance by public health physicians and public health laboratories can identify trends in disease. Many infectious diseases, e.g. *Mycoplasma* infection, occur in a cyclical fashion over a period of years. Croup will present 2–3 times per year, one being significantly greater than the others.<sup>13</sup> Disease reporting can help identify when these infections are imminent and serological testing can help confirm that they have actually arrived. This will alert practitioners to the common disease that may be in the community setting at any given time and may help avoid unnecessary hospital admissions by the correct use of antibiotics.

The health professionals within the community have several roles. The first is disease prevention, primarily in terms of immunization and injury prevention. Where immunization has been effective many diseases have all but been eradicated. This is in danger of disappearing with recent changes in attitude to immunization. The recent scare regarding possible links with autism and bowel disease has led to concern about the safety of the combined measles/mumps/rubella (MMR) vaccination.<sup>14</sup> That this link has been convincingly disproven has not yet convinced a section of the public. This has led to a small but significant decrease in herd immunity, opening the way for a measles epidemic in particular.<sup>15–17</sup>

Health professionals in the community should be able to give advice to parents on disease and injury prevention. They should also be able to recognize situations where family dynamics are breaking down, making injury and child abuse more common.

Within the community one of the more vital functions is recognition of the child who has a disease process that is not suitable for treatment in the community but needs further care within a hospital setting. A good example of this is bronchiolitis. Many cases of bronchiolitis will be cared for in the community with children getting supportive care and advice. However, family practitioners should be in the position to identify the child at risk from significant airway distress, e.g. not feeding, a respiratory rate over 55 or apneic attacks.<sup>18</sup> In this situation the child needs to get to hospital for further treatment that may include high-dependency and/or intensive care. Equally the community services should be able to identify the child who may not be so ill but where the family circumstances mean that the child is not going to be capably looked after at home. Situations where this may occur include poverty, a mother who is not coping because of two or three other small children, and single parents or families of drug abusers. In these situations even though the child may not warrant admission for medical reasons, the social factors may indicate the child needs to be transferred for inpatient care. Community practitioners are much better placed to identify these problems than hospital-based staff.

## PREHOSPITAL CARE

Prehospital care is a link between home and the community on one hand and the hospital-based services of emergency and tertiary level care on the other. The function of prehospital care is to transfer ill or injured children to places of either advanced or definitive care. Two issues predominate within the prehospital care setting:

1. access;
2. education.

To be effective prehospital care has to be easily accessed by all members of the community, e.g. in the UK dialling '999' gains access to the ambulance service. This universal national access code available to all and free of charge is probably the most effective component in the prehospital setting.

Education is also vital. The role of practitioners in prehospital care has got to be fully defined. It must be relevant to the PEMS within which the prehospital care is practiced. It will differ between urban and rural areas in terms of decisions to 'stay and play' and 'scoop and run'. It must be remembered that the absolute numbers of true pediatric emergencies (illness or trauma) is relatively rare, particularly compared to the adult population. The skills needed to carry out emergency care effectively require time to attain and practice to maintain.<sup>19</sup> An integrated PEMS can best evaluate the needs of its catchment area and train the prehospital care staff accordingly. Where short distances are envisaged and transfer times are rapid then training needs may be less demanding with concentration on simple airway, breathing and circulation skills. In rural areas where transport times may be prolonged advanced life support skills may be necessary.<sup>20</sup> Where land-based transport is adequate, training in driving skills may be required. However, should air medical transport by helicopter or fixed-wing aircraft be necessary as a routine then training in aviation medicine and the associated problems will need to be included in the training package.

There is increasing evidence that prehospital life support should include effective, simple measures. Gausche et al showed that prehospital intubation had no benefit on outcome, and worryingly might increase mortality and morbidity.<sup>21-23</sup> This poses a dilemma for rural practitioners in particular. Urban and semiurban situations have clear guidance that in an emergency intubation should not be attempted in the field. Rather they should concentrate on bag-valve-mask ventilation with good, simple airway-opening maneuvers and transport of the child to the nearest pediatric unit. In rural and remote areas or in situations where weather or geography make transport impossible, advanced airway care may be needed. The rarities of this, combined with the complexity of skills needed, make maintenance of skills difficult. Innovative and practical solutions have to be found, but there is no doubt that this will lead to increasing costs. Similarly the value of i.v. access has been questioned.<sup>24</sup> In particular the value of delaying at scene must be set against potential benefits. In this study Teach et al found no such benefit and some possible harm, either from delay at scene or inappropriate fluid administration.

Inner city areas with significant drugs problems may well have a high incidence of penetrating trauma, which will require an emphasis to be placed on treatment of such injuries within that setting.<sup>25</sup>

## THE EMERGENCY DEPARTMENT SERVICES

Pediatric emergency departments fall into three broad categories:

1. those attached to specialist pediatric hospitals that treat only children;
2. those attached to large district or teaching hospitals that have combined pediatric and adult populations;
3. those attached to small community or cottage hospitals treating relatively small numbers of patients overall.

Within each of these three settings various problems exist.

The dedicated pediatric unit is usually situated in a large conurbation, often attached to a university or medical school. It will provide child- and family-centered care of an exceptionally high order. Major injury and illness will often be much less than that in a comparable adult population so there will have to be significant emphasis on education directed at the recognition of illness and the development of resuscitation skills to facilitate optimum care of ill and injured children. Retention of these skills is also a major issue that needs to be addressed.<sup>26,27</sup>

In a unit that combines pediatric and adult patients, general resuscitation skills and teamwork will be much more practiced but in contrast recognition of pediatric illness and skill in treatment may be deficient.

The ability to provide a child- and family-centered approach is often more difficult than in the purely pediatric setting.

The cottage hospital may benefit from being able to provide care closer to the patient's home but illness recognition and resuscitation skills may be poor unless teaching programs are available. This may require that staff rotate to busy units at regular intervals to update and recertify in pediatric skills.

A computer-based model of a typical region with various types of hospital postulates that all types of hospital are necessary to enable children to receive optimal care. This presupposes that skills are present and are updated regularly in each setting and that facilities for children are maintained.<sup>28</sup>

In all settings with the regular turnover of staff inherent with movement of junior doctors and nursing staff, regular resuscitation updates (e.g. pediatric advanced life support courses) are essential. Staffing and training in departments that have children attending should build in adequate time for training and staff development to ensure that skills are maintained at an optimum level. Within these settings certain basic concepts need to be addressed.

There should always be dedicated facilities for the reception and treatment of children, removed from the sights and sounds of the adult world. Children are often already frightened and distressed by being in hospital and every effort should be made to keep them as calm and content as possible. An attractive child-friendly environment should facilitate this. Examination rooms should have sufficient toys and pictures to enable efficient distraction therapy to be practiced. Play leaders are an invaluable resource to aid this process.

Resuscitation rooms should be fully equipped with all the various equipment that is required for pediatric resuscitation. Children change shape and size with age. A full knowledge of how this occurs and the clinical implications are important. It is almost impossible to accurately recall all the weights of children at various age groups. Drug and fluid therapy is usually done on a dose-per-weight basis. It is important to avoid calculations in 'the heat of the moment'. It is all too easy to place a decimal point in the wrong place and either over- or underdose children. For this reason charts should be available or tapes laid out on beds so that rapid determination of dosage depending on the weight/length of the child can be established. These charts will also have details of the correct size of endotracheal tube, the length to which the tube should be cut and various other parameters necessary for effective pediatric resuscitation.<sup>29,30</sup>

Typical equipment required in the resuscitation room is shown in Table 36.1.

The staff working within such an environment must be familiar with recognition of the sick child and similarly be comfortable with all aspects of pediatric care.

Parents often arrive at the emergency department with other siblings. The presence of play leaders will help entertain these children and enable the distressed relatives to be with the sick or injured child. Quiet rooms should be laid aside so that bereaved or distressed relatives can be alone in their time of distress though a staff member should always be available for this if required. Facilities should be available to enable nappy changing and breast-feeding to occur in private.

The function of staff in the emergency department is to receive all ill and injured children and to institute treatment in a timely and appropriate fashion depending on the urgency of the condition (triage).

The nursing staff members usually perform triage but medical staff could also perform this task. Objective triage is difficult in the pediatric population. There are few objective pediatric scales that can be related to all types of presenting problems, medical, surgical, trauma or other. Much triage therefore is subjective and will in part depend upon the volume of work. A well child presenting at a quiet time will very often get through the system more rapidly than an ill child presenting at a busy time. It is imperative that staff members working within the emergency department are able to recognize the child who has a disease process which, if left untreated, will lead to serious incapacity or death. Key recognition skills relate to respiratory and circulatory compromise.

Table 36.1 Equipment to provide emergency care for children: equipment for the resuscitation room

<b>Airway</b>		Suture packs
Guedel airways – 000→3		Chest drain packs
Endotracheal tubes – 2.5→8 uncuffed, 7→10.5 cuffed		Urinary catheters
Introducers		Nasogastric tubes
Laryngoscope handles		Clock
Laryngoscope blades – straight and curved		Warmth
Yankauer suction catheters		<b>Drugs</b>
Argyle suction catheters		Epinephrine (adrenaline) – 1:10 000 and 1:1000
Suction device (with backup)		Atropine
Cricothyroid puncture set (this may be commercial or 'homemade')		Lidocaine – 1%, 2%
Jet insufflation system		Sodium bicarbonate – 1.84%, 4.2%, 8.4%
<b>Breathing</b>		Morphine
Round masks		Naloxone
Triangular masks		Glucose – 50%, 25%
Bag–valve–mask device with pressure-limiting device set at 30–40 cmH <sub>2</sub> O		Glucagon
Reservoir bag		Diazepam (as emulsion) or lorazepam
O <sub>2</sub> supply (with backup)		Midazolam
Ayres T-piece circuit (or equivalent)		Phenytoin
Chest drains 10→32G		Adenosine
Drainage tubing and jars for underwater seal		Disopyramide
<b>Circulation</b>		Beta-blocker
I.v. cannulae 24→14F		Thiopental
Central venous cannulae and Seldinger introducer wire		Suxamethonium
Intraosseous cannulae 17F		Atracurium
Giving sets		Mannitol – 10%, 20%
Blood warmer		Beta 2-agonists – nebulizer solution
Infusion pumps		Ipratropium – nebulizer solution
Defibrillator with facility for synchronized DC version capable of variable energy delivery		Beta agonists – i.v. solution
<b>Disability</b>		Aminophylline
Cervical collars		Hydrocortisone
Spinal boards		Procyclidine
Arm and leg splints		<b>Fluids</b>
		Normal saline
		Plasma
		<b>If neonates are expected the following equipment should also be available in addition:</b>
		Resuscitaire
		Heat source
		Warm towels/wraps
		Umbilical catheters
<b>Monitoring equipment</b>		
Pulse oximeter		
Cardiac monitor		
Blood glucose test machines		
Blood gas analyzer		
<b>Other</b>		
Tapes for i.v. lines, ETT tubes, chest drains		
Syringes 1 ml, 2 ml, 5 ml, 10 ml		
3-way taps		
Connection tubing		
Suture material		

In parallel, skills are needed to:

1. open and secure an airway;
2. ensure that oxygenation is maintained;
3. ensure that circulation is maintained.

The frequency with which these skills are practiced will depend on the population served and the effectiveness of the home, community and pre-hospital services. Communities that have poor home safety, poor community immunization rates and primitive public sanitation can expect to deal with large numbers of ill or injured children.

Where numbers are small maintenance of recognition skills can only be maintained by appropriate teaching programs, for example pediatric advanced life support (PALS). PALS courses were introduced into the UK in the early 1990s. Roberts et al<sup>31</sup> have demonstrated increased survival since these were introduced. Cause and effect have still to be reconciled.

Once a child has been received into the emergency department and the airway, breathing and circulation have been stabilized, the child needs to be transferred to a place of definitive treatment. Often this will be via an imaging facility to surgery, and from there to an intensive care setting. To complete the emergency medical system, a system of safe

transfer to and from each of these areas needs to be established. Even if the emergency department is within the tertiary care center, transfer to the scanning suite or the intensive care unit can be fraught with danger if not performed expertly and efficiently. For this reason transfers should be kept to a minimum.

A transport team should be a priority development in any pediatric emergency care system so that there can be safe transfer to the tertiary care center for definitive treatment.

Both within the injury and emergency setting and the tertiary care unit rehabilitation is important. This will enable the ill or injured child to regain his place as effectively as possible within the home/community setting.

## APPROACH TO THE MANAGEMENT OF THE SEVERELY ILL OR INJURED CHILD IN THE EMERGENCY DEPARTMENT

Most ill children will be brought to hospital by the prehospital services. In these situations airway care and circulatory support will have been instituted according to local training and policy guidelines. In addition

there will be an element of warning so that the resuscitation team can be gathered and tasks allocated.

As it is very easy for parents or bystanders to pick up smaller children, children who are severely ill or injured will often be brought to hospital unannounced and unexpected in private transport.

Consequently the components of the resuscitation team should be established in advance. It is important that one doctor is in charge to coordinate the resuscitation and decide on the priorities for care, with other staff in complementary roles.

## INITIAL ASSESSMENT

Rapid assessment of the airway, breathing and circulation is mandatory (primary survey).

## AIRWAY

The airway can be described as open, maintainable or unmaintainable. An open airway is defined as one with no obstruction present. This includes the absence of secretions, stridor, gurgling or other noises. An open airway needs no further management at this stage but this should be kept under review.<sup>32,33</sup>

A maintainable airway is defined as one that can be kept open with simple measures such as positioning; chin lift/head tilt (or jaw-thrust only, if trauma to the cervical spine is a possibility); the use of an oropharyngeal airway or the use of gentle suction.

An unmaintainable airway is one that is still at risk despite these simple measures necessitating either intubation or the creation of a surgical airway (cricothyrotomy).

The airway should be maintained at this stage by the simplest effective measures available. Intubation must only be carried out by experienced operators who can intubate with skill in a timely fashion. Any attempt taking longer than 30s should be abandoned and the child oxygenated with a bag–valve–mask device pending a second attempt.

All sick or injured children require high flow oxygen. This should be administered using a facemask if the airway is open and maintainable. Otherwise artificial ventilation should be established using a bag–valve–mask device (see later).

## BREATHING

The efficacy of breathing can be assessed only after the airway has been opened. The rate, volume and symmetry of respiration should be assessed by observation and auscultation.

Respiratory compromise can be characterized by either an increasing or decreasing work of breathing.

### Increased work of breathing

*Increasing respiratory rate*

*Increasing heart rate*

*Use of accessory muscles in respiration*

*Flared nostrils*

*Intercostal/sternal recession*

*Grunting*

*Decreasing level of consciousness*

### Decreased work of breathing

*Decreasing respiratory rate*

*Poor respiratory effort*

*Poor lung expansion*

If breathing is absent or diminished, ventilation using a bag–valve–mask device should be instituted as soon as possible. Absent breath sounds and hyper-resonance to percussion on one side should lead one to consider a pneumothorax. This should be immediately drained using a needle thoracostomy. The needle should be inserted into the midclavicular line in the second intercostal space pending the insertion of a formal chest drain. Once inserted the needle should be left in place until the chest drain is working properly. If signs of respiratory compromise

are present supplemental oxygen should be administered in the highest rate available.

## CIRCULATION

The adequacy of the circulation should only be assessed when Airway and Breathing are adequate. A central pulse should be palpated at this stage. The carotid pulse should be palpated lateral to the thyroid cartilage and medial to the sternocleidomastoid muscle in a child. In an infant the brachial pulse should be palpated in the upper arm.

If there is no pulse palpable (or pulse is less than 60 beats/min) cardiac massage should be started at a rate of 80–100 b.p.m. If a pulse is palpable look for other signs of circulatory embarrassment.

### Physical signs of circulatory embarrassment

*Rising pulse*

*Tachypnea*

*Weakening peripheral pulses*

*Increasing delay of capillary return (greater than 2 s)*

*Increasing peripheral core temperature difference*

*Decreased urine output*

*Altered level of consciousness*

All children with circulatory embarrassment (and all children who are severely ill or injured) should have i.v. access established as soon as possible. Failure to establish peripheral i.v. access within a few minutes in children who are in circulatory distress should lead one to insert an intraosseous needle into the tibia or femur. If signs of circulatory embarrassment or shock are present, fluid should be administered as a 20 ml/kg bolus. Recent meta-analysis has suggested that crystalloid fluids are to be preferred.<sup>34</sup> Certainly UK practice has been to use colloid, e.g. plasma, but crystalloid has been widely used elsewhere. The quality of the literature makes it difficult to make a definitive decision as to best initial fluid resuscitation, but the Cochrane database review recommends avoiding albumin outwith controlled studies.

Blood pressure (BP) is an unreliable sign of circulatory compromise in children. Up to 40% of the circulating blood volume needs to be lost before the blood pressure will fall. A falling blood pressure is a late sign and indicates a failure of compensatory mechanisms to maintain perfusion to vital areas. Once BP falls, early and urgent treatment is indicated if permanent harm is to be avoided.

While the medical staff are assessing the airway, breathing and circulation, the nursing staff should help get the child undressed and should attach a cardiac monitor and a pulse oximeter.

As a result of this initial assessment, the practitioner should be dealing with one of the following:

1. a child in cardiac arrest;
2. a traumatized child who requires further trauma-orientated resuscitation; or
3. an unstable child with continuing airway, breathing or circulatory compromise associated with underlying pathology.

## CARDIAC ARREST

Cardiac arrest is rare in the pediatric population. Common causes include sudden infant death syndrome, trauma, drowning and asphyxia.<sup>35</sup>

Cardiac arrest in children is primarily asystolic in nature. Occasionally pulseless electrical activity ([PEA] also known as electromechanical dissociation [EMD]) or ventricular fibrillation (VF) is present.<sup>35</sup> It is important to begin resuscitation as above but consider definitive drug and fluid therapies as indicated by the underlying rhythm.

The outcome of cardiac arrest in children is dismal, particularly when it occurs in the community.<sup>36</sup> Children who sustain cardiac arrest in the emergency department have a better outcome than those who arrest in the community, but worse than those who arrest in hospital.<sup>37</sup> Prolonged hypoxia, hypoglycemia and acidosis in addition to the underlying disease process, all contribute to cell death particularly in the myocardium and brain, making restoration of vital functions difficult. Even

if cardiac function is restored the prolonged insult to the brain usually leaves the child with permanent and usually profound neurological deficit.

## ASYSTOLE

Asystole is characterized by a pulseless, apneic child associated with no complexes on the cardiac monitor. It is important to confirm that this is so by going through the following procedure:

1. turning up the gain on the cardiac monitor;
2. ensuring that all the connections are made;
3. checking that the monitor is not connected to 'paddles'.

The recommended sequence for dealing with asystole is found in Figure 36.2.<sup>38</sup>

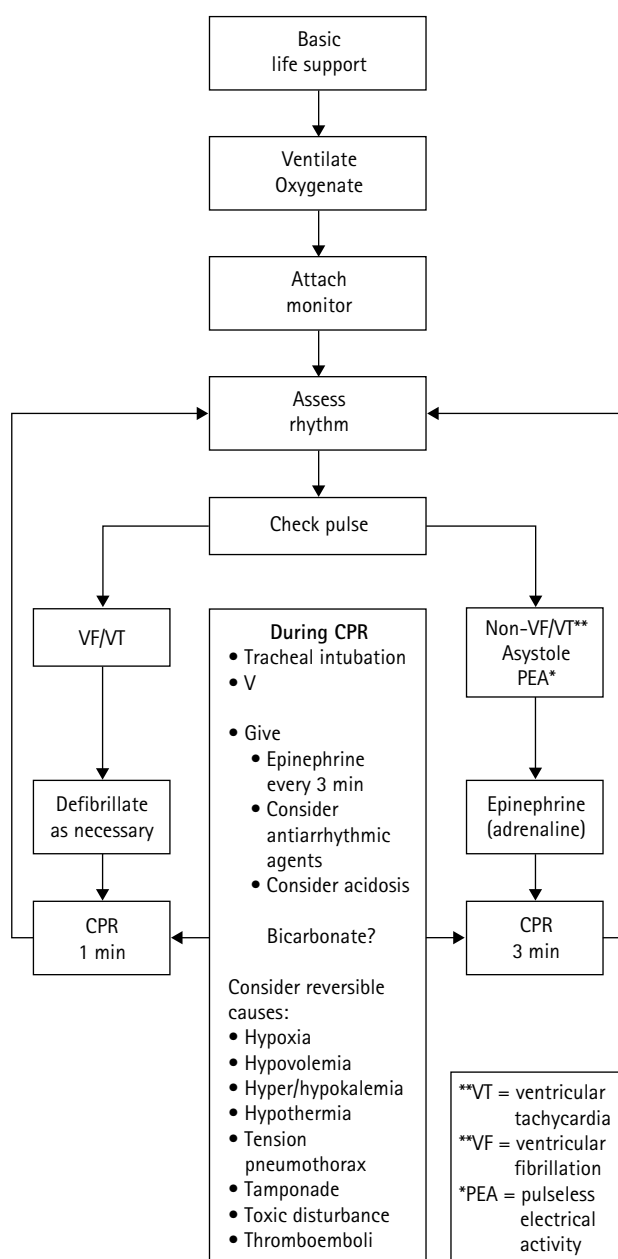

Fig. 36.2 Algorithm for management of pediatric cardiac arrest. (Adapted from Resuscitation Council (UK)<sup>38</sup> with permission)

## PULSELESS ELECTRICAL ACTIVITY (PEA) (PREVIOUSLY KNOWN AS ELECTROMECHANICAL DISSOCIATION [EMD])

PEA is associated with a pulseless, apneic child and often bizarre complexes on a cardiac monitor. This may be associated with underlying pathology such as pneumothorax, cardiac tamponade, electrolyte imbalance, hypovolemia and hypothermia. Treatment should be aimed at correcting these underlying disorders. An algorithm for treating EMD can be seen in Figure 36.2.

## VENTRICULAR FIBRILLATION

VF is much rarer in children than in adults. Recent reports have indicated that it might be more frequent than once suspected.<sup>39,40</sup> An algorithm for treating VF can be found in Figure 36.2.

## STOPPING RESUSCITATION

The decision to terminate resuscitation can be difficult. Children who have been poisoned, drowned or who are hypothermic should have active resuscitation continued for considerable time. This will usually occur within the intensive care setting with continuing resuscitation during transit. Post-traumatic cardiac arrest has a very poor prognosis and prolonged attempts at resuscitation should be avoided. Similarly sudden infant death syndrome should not lead to unduly prolonged resuscitation attempts.

## APPROACH TO THE SEVERELY INJURED CHILD

Major trauma is a relatively rare occurrence in the pediatric population compared to the adult population. Of children who die, 80% will be dead on arrival of the paramedical team at the scene, a fact which makes injury prevention all the more important. The role of paramedical intervention at the scene is crucial.

As with other forms of illness care of the airway, breathing and circulation are of paramount importance. *One of the major differences however, is that traumatized children are at risk of having damage to the spinal column, particularly the cervical spine, without radiological evidence of such injury (SCIWORA – see later).* In particular this means that one has to be able to perform airway-opening maneuvers without excessive movement being involved in the cervical spine area. Measures such as chin lift *without* head tilt are important. Oropharyngeal airways are important adjuncts to the process.

## SCIWORA

SCIWORA is an acronym for Spinal Cord Injury WithOut Radiological Abnormality. This is a rare finding but has a potentially horrendous outcome.<sup>41</sup>

## PATHOPHYSIOLOGY

Relative laxity of spinal ligaments associated with underdevelopment of the articular facets of the vertebrae in the spinal column allow excessive movement to take place during severe hyperflexion/extension injuries. This results in compression of the spinal cord with subsequent damage. The column will return to its normal anatomy without any evidence of fracture or subluxation being present. Normal X-rays therefore in an unconscious child should not lead one to assume that there is no possibility of spinal cord injury.

## IMPLICATIONS FOR CLINICAL PRACTICE

If the child is awake and is able to move all four limbs then SCIWORA is unlikely to be present.<sup>41</sup> However, in those children who have an altered level of consciousness, SCIWORA must be suspected. In these children full spinal column immobilization measures must be implemented until

such time as the spine can be cleared either radiologically or clinically. Simple measures to immobilize the spine will include: use of sand bags or other similar sized objects to immobilize the head, taping the head to a spinal board and immobilizing the head on the shoulders using hands and arms. The airway should be assessed and opened in the simplest way possible and this should be carried out without moving the cervical spine (see earlier).

## BREATHING

Breathing abnormalities are common following trauma. Causes include pneumothorax, hemothorax, rib fractures and gastric dilatation. Children with traumatic injuries should be given supplemental oxygen and any specific underlying disease treated as appropriate. A pneumothorax should be decompressed by needle thoracostomy (above). Gastric dilatation should be decompressed by a gastric tube. If a basal skull fracture is suspected the gastric tube should be passed orally rather than nasally to avoid inadvertent placement in the brain!

## CIRCULATION

Problems with circulation may be due to hypovolemia, tension pneumothorax or cardiac tamponade. Hypovolemia is the most common, particularly after intra-abdominal injuries. Small babies may become hypovolemic from an intracerebral bleed but this is unusual and other causes must be sought first. Some of the signs of hypovolemia are mimicked by trauma, in particular altered level of consciousness and poor peripheral pulses. A low blood pressure is a sign of great importance, indicating the need for urgent fluid replacement.

I.v. cannulae should be inserted into large veins, ideally avoiding fractured limbs. At the same time blood should be taken for laboratory analysis. If the child is stable and blood is not required urgently a simple 'group and save serum' is all that is required. Where the child is unstable blood will be required urgently. Ideally this blood should be fully grouped and cross-matched but occasionally O-negative blood will be needed. If sufficient blood is obtained the rest can be sent for full blood count, serum amylase and possibly urea and electrolytes. The value of each in managing the child will depend on the nature of the injury, underlying illness and local laboratory policies.

## DISABILITY

Most head injuries are minor with the incidence of intracranial bleed being much less in the pediatric population than in the adult population.<sup>42</sup> As part of the first assessment the complete coma score, e.g. the Glasgow Coma Scale, does not need to be assessed. It is sufficient to document whether the child is Awake, responding to Verbal stimuli, responding to Painful stimuli or Unresponsive (the AVPU scale). Pupillary reflexes may be documented but at this stage they will not alter management significantly. Indeed pupillary responses are often confusing. While the medical team are assessing airway, breathing, circulation and disability the nursing team should undress the child, apply a cardiac monitor and a pulse oximeter and prepare to assist with airway and i.v. access procedures. Surgical trays should be made available if required.

## SECONDARY SURVEY

Once the airway, breathing and circulation have been addressed a full secondary survey of the child should be carried out. Every part of the body will be examined both visually and by palpation. Judicious use of plain X-ray, ultrasound and computed tomography (CT) will aid the diagnostic process. Minor injuries that may have been missed on the first brief survey will be detected and will lead to further treatment and investigation. Injuries that are commonly detected during the secondary survey include bleeding from the ear and nose, small pneumothoraces, gastric dilatation and minor fractures to the peripheries.

## HEAD INJURY

Head injury is a significant cause of morbidity and mortality in the pediatric population.<sup>43</sup> The relatively large head changes the center of gravity and the head is one of the most commonly injured parts of the body in the pediatric population.

The causes of pediatric head injury include falls from a height, motor vehicle collisions and child abuse.

While most children who sustain significant head injury will lose consciousness it should be borne in mind that hypoxia, hypovolemia or both are significant causes of altered level of consciousness. Sharples et al<sup>44</sup> have shown that children transferred to a central neurosurgical unit with head injury were more likely to die as a result of associated hypoxia and/or hypovolemia due to respiratory or circulatory distress than death from the head injury. It must be questioned whether these children actually needed to be transferred at all as the head injury was often a relatively minor part of the problem. It is extremely important to exclude respiratory or circulatory problems before diagnosing intracranial problems as the cause of the altered level of consciousness.

The role of the emergency department in managing head injury is straightforward but it is important to grasp the concept of primary and secondary brain injury.

Primary brain injury occurs at the time of impact. Any damage done at this stage is usually irreversible. Secondary brain injury occurs early due to an extra insult, commonly hypoxia, hypovolemia and brain edema. Later infection, hydrocephalus and seizures may contribute substantially. The management of these later problems will fall to inpatient teams, but emergency staff members need to be aware of their role in identifying circumstances where and when they are likely to occur. There is a complex relationship between the primary injury and these other secondary factors. As a result of the initial injury there will be a degree of swelling secondary to a normal inflammatory response. Localized brain injury, which might occur if the child has been hit with a hard object such as a golf club or hammer, will result in a reasonably localized injury. Here the inflammation will be localized and will not cause generalized brain edema. At the other extreme is the small baby who is exposed to vigorous shaking (non-accidental injury). Here there will be diffuse brain injury with generalized inflammation throughout the brain. Postmortem examinations in this situation reveal multiple hemorrhages and diffuse brain edema that is often progressive and unstoppable. This malignant cerebral edema is almost impossible to treat and is usually the cause of significant morbidity and mortality associated with 'shaken baby syndrome'.<sup>45,46</sup> Most cases of head injury fall between these two extremes.

If the initial insult is associated with loss of consciousness then hypoxia will almost certainly follow as a result of an obstructed airway, usually from the tongue obstructing the oropharynx, or from vomitus entering the lungs. This will in turn cause cerebral anoxia with resultant cell damage and death and lead to a generalized inflammatory response with a variable degree of cerebral edema being present. The same situation will occur with other causes of hypoxia, e.g. pneumothorax, pulmonary contusion.

A decrease in perfusion pressure to the brain secondary to hemorrhage or other cause of hypovolemia will result in failure to deliver glucose and oxygen to the brain leading to an equivalent situation. Again as the inflammation increases the intracranial pressure also increases and unless there is adequate circulatory drive to perfuse the brain, a vicious circle ensues.

The primary role of the emergency department therefore is to ensure that the airway is open, that ventilation is maximized and that oxygen saturations are maintained between 95% and 100%, and to maintain circulation to enable cerebral perfusion to be normalized.

By the time the child gets to the emergency department a degree of intracranial swelling may already have taken place. In the early stages this will usually be due to an intracranial hematoma. Extradural, acute subdural or intracranial bleeds can all produce considerable pressure effects. It is important to recognize that children can sustain an extradural hematoma in the absence of fractures to the middle meningeal

region, in contrast to the adult population, and normal skull X-rays therefore can be misleading.<sup>47</sup> The role of the emergency department is to ensure the airway, breathing and circulation are maximized and that any other life-threatening injury is identified and controlled. Only then should the child be transferred to the scanning suite, when the formal diagnosis can be made. There will often be a dilemma between surgical hemostasis (e.g. from a ruptured liver or spleen) and management of significant intracranial hematoma. It is imperative in these situations to control the circulation and to ensure brain perfusion is maximized to reduce the effect of secondary brain injury from hypoxia and/or hypovolemia. This tension is not easy to resolve and takes considerable experience and seniority to ensure the optimum sequence of events occurs.

With CT there is often evidence of raised intracranial pressure and no evidence of intracranial bleed. In this situation the practitioner is dealing with cerebral edema and several mechanisms exist to try to reduce the pressure including: hyperventilation to maintain a PaCO<sub>2</sub> of about 4 kPa, use of mannitol or furosemide (frusemide) (or other loop diuretic) and sedative techniques such as barbiturate anesthesia. It should be noted that most of these measures only work on a normal brain and are of little benefit at best. Use of these agents should be discussed with the neurosurgeon.

The emergency department is responsible for identifying basal skull fractures by clinical examination. Physical signs that indicate a basal skull fracture include 'panda eyes' (raccoon eyes), blood or cerebrospinal fluid from the nose or ears or 'Battle's sign' (bruising over the mastoid process). Basal skull fractures are open fractures and there is a high risk that infection will supervene between 12 h and 24 h, or possibly later. The use of antibiotics for the management of basal skull fractures is controversial. There is no clear evidence that antibiotics will reduce the chance of meningitis but this should be discussed with the local neurosurgical unit.<sup>48</sup> Many children will have seizures subsequent to the head injury. This can result in hypoxia with the inherent risks discussed earlier. After supplying oxygen and assisting ventilation the fit should be stopped using diazepam 0.2 mg/kg. Assessment of the level of consciousness is now difficult and these children should undergo CT scanning. Phenytoin 15 mg/kg may be used to reduce subsequent seizures after discussion with the neurosurgical unit.

Once a child has had a secure airway established, oxygenation is maximized and circulation and perfusion restored to normal, the child should be transferred for definitive diagnosis to the CT suite under stringent transfer conditions. Transfer from the safety of the resuscitation room should not start until full transfer protocols have been instituted. Transfer from the emergency setting to the scanning suite is just as dangerous as traveling from one center to another.

## THORACOABDOMINAL INJURIES

Thoracoabdominal injury is relatively rare in the pediatric population compared with the adolescent and adult population. Most injuries are blunt although increase of firearms has meant that penetrating thoracoabdominal trauma is rising.<sup>25</sup> Many children with major thoracic injuries will die before reaching hospital although improvements in pre-hospital care may mean that an increasing number may survive. Injuries that fall into this category include traumatic dissection of the aorta and massive tension pneumothorax.

Traumatic dissection of the thoracic aorta is typically caused by rapid deceleration injury and most children will die in the pre-hospital phase. If they survive to reach hospital the diagnosis can be suspected by the presence of a widened mediastinum on a chest film associated with fractures of the upper ribs. It is best confirmed by either arteriography or CT. If suspected the child should be transferred to a thoracic surgical center.

Tension pneumothorax is treated by the insertion of a large-bore needle into the second intercostal space on the affected side. Signs of tension pneumothorax include signs of respiratory distress, distended neck veins and absent breath sounds on the affected side. Once the pneumothorax is drained using the needle a formal chest drain should

be inserted and connected to an underwater seal as soon as possible. Drainage of a pneumothorax on one side may reveal the presence of a lesion on the other side and this should be treated appropriately.

## MODERATE CHEST INJURY

The use of seat belts and seat restraints has led to an increase in chest wall bruising due to the seat belt physically restraining the child. Children who have seat belt abrasions to the chest and abdomen have been subjected to quite considerable deceleration forces. While the mostly likely thoracic injuries will be a fractured clavicle with or without a fractured sternum, it should be borne in mind that underlying myocardial contusion is possible. This is extremely difficult to detect clinically. The presence of slightly abnormal electrocardiograms (ECGs) and raised cardiac enzymes are unreliable. If there is any doubt the child should be admitted for a period of observation with continuous cardiac monitoring.

Fractured ribs are rare in the pediatric population. If seen in the infant or toddler group non-accidental injury should be suspected. Management is required for relief of pain. If there are more than three ribs fractured on one side the child should be admitted to a high-dependency care unit for intercostal blocks to be administered. Bilateral rib fractures may lead to a flail chest but this is rare in children.

## ABDOMINAL INJURY

Blunt trauma is the usual cause. Penetrating trauma increases in frequency as children get older. Blunt trauma can result in hemorrhage and loss of perfusion from rupture to solid organs such as spleen, kidney and liver; or peritonitis from injury to the bowel and pancreas. With each of these a strong index of suspicion is needed as early on the child can have minimal abdominal signs, but will subsequently develop significant problems. This is particularly so of pancreatitis and bowel perforation, where peritonitis can take between 6 h and 12 h to develop.

Intra-abdominal hemorrhage should be considered in any child who shows evidence of circulatory collapse following trauma. Clinical diagnosis is unreliable and imaging is almost certainly indicated, particularly if the child is stable. Ultrasound is a useful screening tool. In skilled hands even small amounts of free fluid can be detected. Most skilled ultrasonographers will be able to identify the site of bleeding if due to damage to solid organs, i.e. liver, spleen and kidney. If free fluid is present but no solid organ damage is identified then CT with contrast is indicated. Children who are unstable should have intra-abdominal bleeding suspected and treated according to the accompanying diagram (Fig. 36.3). Hepatic and splenic trauma will usually be treated conservatively provided the child remains stable.<sup>49</sup>

## SEAT BELT INJURY

A seat belt ideally involves three-point fixation with a lap belt and harness. If children are restrained using a lap belt alone and are involved in a high-speed collision there is a reasonable chance they will sustain a hyperflexion injury of the torso. This will usually result in intra-abdominal injury with a significant hepatic or splenic component. This will often be associated with a degree of spinal instability with fractures occurring in the L<sub>1</sub>, L<sub>2</sub> region of the lumbar spine.<sup>50</sup> Any child who has a significant lap belt injury to the midabdominal region should have spinal injury suspected and should have full spinal immobilization carried out until the spine has been fully cleared both radiologically and clinically (see SCIWORA as earlier).

## ORTHOPEDIC INJURY

*It should be stressed that orthopedic injuries are a long way down the order of treatment. Priority should be given to airway, breathing and circulation prior to doing anything with orthopedic injuries.*

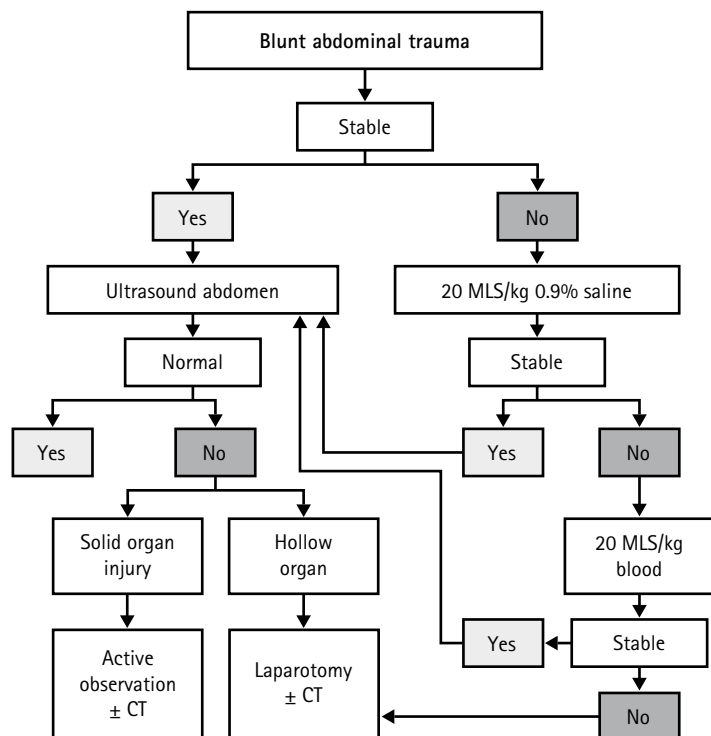

Fig. 36.3 Management of blunt abdominal trauma.

Orthopedic injury following trauma is common. Within the emergency department there are three aspects that should be considered:

1. recognition of the fracture;
2. identification of associated soft tissue injury that may cause compromise to the limb;
3. splintage and analgesia.

### RECOGNITION OF THE FRACTURE

If a bone is bent, it is broken! Of more concern is the occult undisplaced fracture. Such fractures can bleed into tight fascial compartments with subsequent compartment syndrome. Vascular compromise is particularly common with fractures of the elbow, where the brachial artery may be involved, and the tibia. If there is any concern about the presence of an occult fracture the area should be X-rayed to either confirm it or rule it out.

With all fractures the distal pulses should be palpated and distal neurological function should be checked. If the perfusion is adequate distal to the fracture site then all that is needed is for the limb to be splinted until life-threatening conditions such hypoxia or hypovolemia are corrected. Nerve injuries need to be noted and examined further when the child is stable.

### IDENTIFICATION OF ASSOCIATED SOFT TISSUE INJURY

Soft tissue injuries associated with fractures include:

1. tissue loss;
2. open wounds;
3. vascular damage;
4. nerve damage;
5. tendon damage.

Tissue loss and open wounds associated with fracture will lead to infection in the bone if not adequately treated and debrided. The emergency department is not the place to start this process but the wound should not be ignored. It is sufficient to assess the distal pulses and neurological function and as long as these are intact, dress the wound with a disinfectant dressing and leave further management to the orthopedic department. Broad-spectrum antibiotics effective against Gram positive, Gram negative and anaerobic organisms are important. Local policies

determine which antibiotics are given. Tetanus prophylaxis is also important if the patient is not fully immunized.

### ANALGESIA

Pain with a long bone fracture is severe and analgesia is greatly under-used. There is often a fear of masking intra-abdominal injury or of aggravating conscious level with head injury. Both of these are inadequate reasons to withhold analgesia in a child who is in considerable pain. Two methods of analgesia exist in this situation:

1. local and peripheral nerve block;
2. i.v. opiate.

### LOCAL AND PERIPHERAL NERVE BLOCK

The femur is most amenable to this management strategy. Successful block can be obtained by infiltrating a long-acting anesthetic such as levobupivacaine around the femoral nerve where it passes under the inguinal ligament lateral to the femoral artery. This will take 5–10 min to work (and can be preceded by a more fast-acting local anesthetic such as lidocaine or prilocaine). If epinephrine (adrenaline) is used great care must be taken not to inject epinephrine (adrenaline) into the femoral artery, which is adjacent to the nerve. Some authors advocate the use of sciatic nerve block for tibial fractures. To be effective however, this requires sophisticated equipment that is not always available within the emergency setting.

### INTRAVENOUS OPIATE

In trauma situations opiate analgesia should always be given intravenously. Recent reports on the efficacy of intranasal diamorphine should be treated cautiously. These reports compared intranasal diamorphine against intramuscular.<sup>51,52</sup> There is no place for the intramuscular route as absorption is unreliable. Whether i.v. opiate will be replaced by intranasal has yet to be established.

The weight of the child should be estimated by whatever means possible and the appropriate dose of opiate obtained. This should be further diluted to 10ml. This can then be titrated 1 ml at a time over a period of 10 min to maximal effect. As soon as the child becomes settled the

administration can be stopped and a further bolus given at intervals to maintain analgesia. Usually at this stage the pain drive will be sufficient to keep the child awake and to counteract any possible diminution of level of consciousness. If there is any concern subsequently about the ability to assess either level of consciousness or the abdomen then naloxone can be used to reverse the opiate. This is rarely necessary.

Once analgesia has been administered then the fractured limb should be splinted until the child can be brought to theater by the orthopedic surgeons. Splintage is an important consideration for analgesia in injured children. One of the major challenges for pediatric emergency departments is the absence of commercially available splints suitable for all the different shapes of children. Often these have to be fashioned on an ad hoc basis from plaster of Paris or some other newer synthetic casting material.

## BURN CARE

Burns are a common problem in children. Two broad issues need to be addressed:

1. the burn injury (by whatever cause);
2. complications such as smoke inhalation, hypothermia, toxic shock syndrome.

Although both issues can occur together, usually one or the other is the main problem on initial presentation to the emergency department. There are many etiologies for burn injury (Table 36.2). No matter what the cause, the approach to a burn injury is the same. The airway, breathing and circulation should be assessed and looked after as in all previous circumstances. Once these have been addressed it is important to identify the size of the burn. Management of the burn will depend on the following factors:

1. area involved;
2. depth of the burn;
3. site of the burn.

### AREA OF THE BURN

Small burns, i.e. less than 5% of total body surface area (TBSA), can be managed on an outpatient basis provided that the burn is superficial, does not involve a significant area and there are no complications present.

Treatment will consist of analgesia, usually oral, and dressings according to local policy. One method of dressing the burn is to use tulle gras impregnated with mupirocin, which is an effective anti-staphylococcal agent. Once the burn is greater than 5% TBSA analgesia requirements will usually necessitate admission and an i.v. opiate will be required. Whether the wounds are dressed or left open is dependent on local practice. Once the burn is greater than 10% TBSA then the child will need i.v. rehydration according to local formulae, e.g. Parkland formula.

### DEPTH OF THE BURN

Burns can be classified as superficial, partial thickness and full thickness. Superficial burns include those with erythema only or with small amounts of blistering. Partial-thickness burns are those that have a significant area of blistering, with either blisters intact or spontaneously

burst. Full-thickness burns present as white avascular areas that are insensitive to touch (it is unkind to touch burns in children and inspection is usually all that is required for diagnosis).

In reality a mixture of superficial, partial thickness and full thickness is usually present depending on the burning agent and the duration it has been in contact with the skin. In general all full-thickness burns should be referred to a plastic surgeon for immediate assessment and treatment. Partial-thickness burns may be suitable for outpatient care if they do not extend over a large surface area. Treatment is as discussed earlier.

### SITE OF THE BURN

Burns to the face, airway, mouth, pharynx, buttock and perineum, hands and feet and any circumferential burn to either the trunk or a limb need to be treated with a great deal of caution. Burns in any of these areas need to be referred to a burns specialist for inpatient treatment. Burns to the face and airway in particular, may require admission to an intensive care unit as the risk to the airway is quite considerable.

## COMPLICATIONS OF BURNS

In the emergency department it is important to identify those children with complications such as smoke inhalation, hypothermia or those with burns possibly from non-accidental injury.

### SMOKE INHALATION

Smoke inhalation is a complex entity with several mechanisms:

1. inhalation of toxic fumes such as carbon monoxide and/or cyanide;
2. local action of soot and other organic particles;
3. chemical burns from acids and other compounds.

Carbon monoxide poisoning and cyanide lead to asphyxia due to red cells being unable to release oxygen. It is the leading cause of death following house fires. Children who are suspected of having carbon monoxide poisoning should be resuscitated with 100% oxygen. If cyanide poisoning is suspected then treatment with standard cyanide kits is suggested either with dicobalt edetate if the child is comatose or hydroxycobalamin if the child is comatose but still perfusing.

Bronchial lavage may be considered if particulate matter or acids are considered to be present in the airway.

The net result of the contamination is a fulminant inflammatory process leading to significant pulmonary edema. This can be of insidious onset and consequently all children who are suspected of having had smoke inhalation should be admitted for a period of observation until such time as they are proved normal.

### TOXIC SHOCK

Toxic shock is a rare but significant complication of burn injury (and occasionally other minor wounds including those following minor surgery). Typically caused by staphylococcal toxins, streptococci have also been implicated. Usually the wound/burn will be colonized rather than overtly infected by the bacteria. Symptoms include fever  $> 38.5^{\circ}\text{C}$ , erythematous rash, vomiting, diarrhea and malaise. If a child presents within 2–3 days of sustaining a burn/wound with any or all of these signs or symptoms toxic shock should be suspected.

Treatment consists of identifying the cause (wound swab, blood for blood culture and serology), urgent resuscitation with fluids and antibiotics (which should reflect local streptococcal and staphylococcal antibiotic sensitivities) and local wound care as appropriate. Affected children should be admitted to a critical care area for further care.

## MANAGEMENT OF THE UNSTABLE CHILD WITH UNDERLYING PATHOLOGY

After securing the airway, breathing and circulation, the real challenge is to identify the actual disease process and the etiological factors that have led to the presentation so that the most appropriate therapy can be given.

Table 36.2 Causes of burn injury

1. Wet heat	Scald
2. Dry heat	Flame
	Hot surface
3. Radiation	Ultraviolet (sunburn)
	Iatrogenic (as radiation treatment in oncology)
4. Chemical	Acid
	Alkali
	Corrosive
5. Electrical	

The standard approach of taking a history and then doing a physical examination is often inappropriate. The history available at this stage can be scrappy and imprecise. Most information will be gained from a detailed physical examination. This is best done in a systematic fashion, excluding groups of illnesses in turn. Patterns of illness include:

1. infection and life-threatening infection;
2. seizure disorder and coma;
3. metabolic abnormalities;
4. cardiac lesions;
5. respiratory disorders;
6. surgical pathology;
7. poisoning.

## INFECTION

Life-threatening infection is relatively rare in the western world where vaccination and immunization are widespread. Diseases such as diphtheria and epiglottitis have been almost eradicated with effective vaccination but in areas where vaccination is less good or has waned these diseases continue to form important causes of mortality. Meningococemia continues to be one of the most important life-threatening infections to appear acutely to the emergency department.

When dealing with infection three broad age groups have to be considered:

1. 0–3 months;
2. 3 months–3 years;
3. 3 years and over.

### Children aged 0–3 months

Neonates and young infants have many of the problems related to infection. The symptoms with which these children present are many and varied.<sup>53,54</sup> They include going off feeds, failure to thrive, jitteriness and irritability. While many of these children will have an infection, other causes have to be considered. These include congenital anomalies such as congenital heart disease or inborn errors of metabolism or surgical causes such as intussusception and obstructed hernia.

Physical signs such as neck stiffness and bulging fontanelles are unreliable in this age group as are blood parameters such as white cell count and preponderance of neutrophils to lymphocytes. Clinical suspicion therefore is the mainstay of diagnosis and if there is any doubt children should have blood cultures taken and antibiotic treatment started. These children are usually admitted until such time as the diagnosis is reached.

### Children aged 3 months–3 years

The children at the lower end of this spectrum will still be prone to neonatal illness. Viral illness is more common than bacterial illness in this age group but underlying bacterial illness or bacteremia should still be considered. However, it is still important to recognize the child who is toxic, and who is 'not right'.<sup>55,56</sup> Physical signs are more precise, with these children often being pyrexial, tachycardiac and tachypneic. Signs such as neck stiffness are more reliable in the diagnosis of meningitis. Signs of chest infection, osteomyelitis and septic arthritis may be easier to detect.

### Children aged 3 years and over

Significant bacterial disease is relatively rare in this age group but includes chest infection, septicemia, urinary tract infection and orthopedic infection. Meningitis and meningococcal septicemia are still relatively rare. Abdominal conditions are easier to diagnose in these children because these children are better able to communicate symptoms.

### Meningococcal disease

Infection with *Neisseria meningitidis* is one of the most significant reasons for a child to be critically ill. Often starting as a vague nonspecific illness at any age this infection can kill within hours. The florid purpuric rash is often not present initially, more often developing from a subtle finding in

the early stages. Limb pains are common. (In the community, treatment should consist of intramuscular benzyl penicillin and urgent transfer to hospital with supplemental oxygen by mask. In the emergency department i.v. access and fluid replacement will be added. Fluid volumes of 60 ml/kg may be needed (in 10–20 ml/kg bolus) to restore perfusion. A cephalosporin (e.g. ceftriaxone, cefuroxime or cefotaxime) will be added to penicillin to control infection. Prompt transfer to the intensive care unit should be arranged when inotropic agents may be added to the management. It is helpful to complete an assessment of the Glasgow Meningococcal Prognostic score as soon as sufficient clinical data is available.

### Management of life-threatening infection

These children should be resuscitated and blood taken for full blood count, urea and electrolytes, blood glucose and culture. Capillary blood gas analysis may also help determine initial status of the child and monitor early response to resuscitation. Chest X-ray, urine culture and lumbar puncture may also be indicated. Care should be taken not to perform lumbar puncture on children who are unconscious as this may produce herniation of the brain through the tentorium with resultant brain death.

I.v. antibiotics should be administered according to local sensitivity patterns and protocols. Children should be admitted to a high dependency or intensive care unit where inotropic support may be needed.

### SEIZURE DISORDER

The list of underlying pathologies for patients presenting with seizure disorders is vast. Most will either be due to idiopathic epilepsy, a febrile seizure disorder or secondary to metabolic defects such as hypoglycemia or electrolyte disorder. Trauma should also be considered. Treatment should be aimed at stopping the seizure and at the same time trying to identify underlying treatable causes such as hypoglycemia and electrolyte imbalance. If fever is present this should be reduced as rapidly as possible.

### Management of seizure disorder in the emergency situation

First-line treatment is i.v. diazepam, 0.2 mg/kg to a maximum 0.6 mg/kg intravenously. Lorazepam 0.1 mg/kg is also acceptable. If i.v. access is not readily available then rectal diazepam (2.5–10 mg depending on age) or intranasal midazolam (0.2 mg/kg) are acceptable treatments. This should be followed (if the seizure is not stopped) by a slow i.v. administration of phenytoin 10–15 mg/kg under ECG control. At this stage if the child is still fitting then consideration must be given to reducing intracranial pressure, paralysis and ventilation in order to control the seizure with additional anticonvulsants. Such management will need an intensive care/high dependency unit.

Blood sugar should always be tested by strip testing. If the blood sugar is low this may reveal an underlying metabolic disorder. Further blood should be taken along with urine to help diagnose metabolic anomalies if present and the child given 10% glucose 3–5 ml/kg.

### COMA

Comatose children are particularly at risk of obstructing their airway so great care must be given to maintaining this. Once the airway is secured the underlying causes such as poisoning, epilepsy, head injury or other trauma, hypoglycemia or intracranial infection should be investigated. Treatable causes should be identified and treated appropriately and the child transferred to a high-dependency area as soon as possible. This may involve transfer via CT scanning if intracranial lesion is suspected. If trauma is suspected, particularly non-accidental injury, the child should be treated as with any other trauma victim and resuscitated aggressively prior to transfer.

### METABOLIC ABNORMALITIES

Diabetic abnormalities, either hypo- or hyperglycemia, are the commonest. Small babies may present critically ill as a result of an inborn error

of metabolism. While these are relatively rare they should be suspected in any child who presents close to the neonatal period, particularly if there is an intercurrent infection suspected. A strong clue to this might be the presence of hypoglycemia. Diabetic emergencies should be treated as detailed under the diabetic section (Ch. 15).

## CARDIAC LESIONS

Children with cardiac lesions present in one of two ways:

1. in heart failure;
2. in cardiac arrest.

Heart failure is often due to progression of cardiac abnormalities. Underlying disease processes such as renal failure with hyperkalemia may have to be considered. Previously well children may have developed myocarditis. Supraventricular tachycardia is the commonest underlying cardiac dysrhythmia to cause heart failure, particularly in the younger age groups. The treatment of heart failure should be aimed towards maximizing oxygenation and reducing the fluid load. Any underlying dysrhythmia should be treated appropriately according to local guidelines. The child should be transferred to a high dependency area as soon as possible where future treatment can be monitored and inotropic support given if necessary.

The management of cardiac arrest is described earlier (p. 1586). The underlying causes may include hypertrophic cardiomyopathy or dysrhythmia.

## RESPIRATORY DISORDERS

Common respiratory disorders to present include asthma, bronchiolitis, croup and foreign body in the airway. Recognition of respiratory distress/failure has been considered earlier. All children with respiratory disease should have oxygen delivery maximized and treatment directed to the underlying cause.

If it is suspected that a foreign body is wedged in the airway, the Heimlich maneuver or chest thrust maneuver may be necessary depending on the level of consciousness of the child.

## SURGICAL CAUSES

Surgical causes of collapse are often forgotten in the emergency department, particularly in those in the younger age group. Intussusception and obstructed herniae commonly cause symptoms such as vomiting. This vomiting is not typical of that of gastroenteritis; it may only consist of one or two vomits. After that the child becomes unduly collapsed. Intussusception in particular can present with a child who is deathly pale but without much else in the way of physical signs. The classic signs of redcurrant jelly stool and a palpable mass are often absent.<sup>56</sup>

Pyloric stenosis may present with a dehydrated alkalotic child if the vomiting has been profuse.

If a pubertal girl presents in a collapsed state, two diagnoses should be considered – drug overdose (either intentional or accidental) and ectopic pregnancy. These may be related, i.e. the pregnancy is the reason for the overdose. In both situations resuscitation is vital. Pregnancy may be the result of child sexual abuse and this should be treated, if suspected, along local guidelines.

## POISONING (see Ch. 6)

Poisoning in children is commonest between the second and third year of life. Children who are poisoned usually present with minimal signs or symptoms. The role of the emergency department is to identify the child who is at risk of either airway or circulatory collapse and to deal with these problems accordingly. All doctors working in emergency departments should have a good working knowledge of pharmacology of medications that are both prescribed and bought over the counter. The knowledge of the potential side-effects will help in determining which children can be discharged and those that need to be admitted for further care.

The role of gastric decontamination in this age group is difficult. The current trend is to move away from gastric lavage, which is a particularly unpleasant process. The role of syrup of ipecacuanha has also been challenged. There is evidence to suggest that it will only be effective (if at all) if administered within 1 h of the ingestion. The current vogue is for decontamination using charcoal. Most children will actually drink charcoal despite it looking unpleasant and this probably is the method of choice for all children who actually require gastric decontamination.

Specific antidotes are available for only a few poisons. Staff working within the emergency department should be familiar with these and their usage.

## CONCLUSION

The pediatric emergency medical system has many facets, all of which need to be coordinated to provide for the streamlined care of sick or injured children. The aim should be prevention if at all possible. If prevention is not possible then facilities must exist for the efficient care of all children within a seamless emergency medical structure capable of providing all aspects of emergency care and rehabilitation back to the community.

## PEDIATRIC INTENSIVE CARE

### INTRODUCTION

Intensive care is distinguished from high-dependency or ward care by the level of observation and the level of intervention required by the patients. Close observation is assured by:

- The numbers of staff: at least one nurse per patient and at least one doctor awake and working on the unit at all times;
- The skill level of staff: only experienced pediatric intensive care nurses are allowed to work at the bedside and the resident medical staff members have to have advanced resuscitation and airway skills. There are high levels of supervision from senior staff. Higher levels of intervention take the form of:
  - Continuous physiological monitoring: this will often involve additional circulatory access such as arterial and central venous lines but may also include a variety of other techniques, for example more invasive hemodynamic monitoring, indwelling oximetric catheters, intracranial pressure monitoring;
  - Intensive care dependent techniques of organ–system support: the term ‘intensive care dependent’ meaning that it would be inappropriate to contemplate undertaking such support for a critically ill child without the level of monitoring and supervision available on the pediatric intensive care unit. Examples include mechanical ventilation, inotropic or mechanical circulatory support and renal replacement therapies such as hemofiltration.

Pediatric intensive care units cater for critically ill children from birth to 16 years of age but the age distribution is heavily skewed towards the lower age range. The median age of admissions is frequently less than 1 year and the mean is usually around 3 years. The units are predominantly geared towards emergency admissions since typically only about 30% of admissions are booked in advance in association with elective surgery or other procedures. The case mix bears comparison with the predominant causes of death in pediatrics, which themselves change with age. Infections and congenital abnormalities along with their attendant surgery figure prominently in young patients, whereas malignancy and trauma are commoner in older patients. Of admissions, 40% occur in the context of congenital heart disease whether they are new presentations, elective admissions after surgery or emergency admissions for other causes such as respiratory infection complicating pulmonary edema. Otherwise primary respiratory problems account for about 20% of admissions with strong seasonal and geographical variations. Major trauma also displays seasonal variation (lower in winter and highest during summer holidays) but accounts for up to 15% of admissions overall. Neurological problems (other than trauma) make up less than 10%.

The contribution of other diagnostic categories is more varied, depending upon the allocation of neonatal surgical patients and other services. Survival rates amongst critically ill children are generally high (about 92% of admissions) compared to the intensive care of other age groups. The length of intensive care stay is another skewed distribution (most are of very short duration, median circa 24 h) but the mean varies from 2 to 4 d depending principally on the quality of local 'step down' (high-dependency) facilities. This average length of stay is comparatively short compared to neonatal and adult intensive care.

Many intensive care admissions are critical emergencies and decisions to admit the patient under these circumstances are not difficult or often disputed. However, the apparently abrupt decline in a patient's condition is frequently the manifest decompensation of a process or processes that have been proceeding for some time and hence could, at least in theory, have been identified in advance. The final common pathway of cellular hypoxia/ischemia and organ dysfunction that leads to death in children is initiated by circulatory or respiratory failure and ends in asystole. The potential benefits of intensive care are therefore best realized by pre-emptive intervention to avert probable further deterioration.

Hence it is important to learn to recognize the sick child. Firstly, recognize ominous diagnoses for which the likely course of the disease is known (e.g. purpura fulminans in meningococcal septicemia). Alternatively, try to realize the severity of illness from basic clinical signs. Work on a system-by-system basis taking respiration and circulation first. The two key questions are:

1. How much work is being done? Which then indicates a second question: how sustainable is this level of physiological effort? and
2. How effective is it? (since ineffective effort will need to be supplemented sooner rather than later).

For example the work of breathing can be assessed by the respiratory rate, tidal volume and the apparent ease or otherwise of chest expansion. Look for the use of accessory muscles and the strain involved. Breathing may be difficult due to poor compliance or airway obstruction (listen for inspiratory stridor or expiratory wheeze) and there may be subcostal, intercostal, costal or sternal recession, tracheal tug or head bobbing, etc. Assess the effectiveness of breathing by the adequacy of chest expansion, the amount of oxygen required to avoid desaturation, conscious level, heart rate, presence of sweating and adequacy of peripheral perfusion as well as measurements of oxygen saturation and formal blood gases. Remember that cyanosis is a preterminal sign in respiratory failure and that premature infants respond to stress (including hypoxia) with bradycardia rather than the tachycardia otherwise expected first.

Once compensatory mechanisms have been exceeded, a precipitate and rapid deterioration occurs. Hence it is also very important to use recent *trends* in physiological observations as an indication of the patient's current condition and likely progress. Early intervention is far more likely to be successful and the use of thresholds for action usually causes delay even if they are based upon age-appropriate norms and reference ranges.

In the acute presentation of critical illness, the ultimate cause (i.e. the diagnosis) may not be apparent. Hence a treatment plan may have to be devised that addresses all the possibilities until further information becomes available. The sequence of priorities is to Resuscitate, then Diagnose and Treat, i.e. *Resuscitation comes first*. If immediate resuscitation is not necessary, still concentrate on physiology/pathophysiology (in terms of work and effectiveness) to decide how and when to instigate specific organ system support and monitoring. Then proceed with investigations that may lead to more specific treatment. The ultimate diagnosis may be made over a broad timeframe and the patient may sometimes have left intensive care before the whole clinical picture is apparent.

## POST-RESUSCITATION STABILIZATION AND TRANSFER

The initial resuscitation of acutely ill children is often described as being followed by a period of 'postresuscitation stabilization'. This may be prolonged and it may be found necessary to defer some aspects of

care depending upon the resuscitation priorities. For example in severe trauma the resuscitation can involve emergency surgery after which the patient is moved to the intensive care unit. At this point reassess the patient and complete a secondary survey. The resuscitation may have also created problems that need to be identified and dealt with. Studies suggest that medically significant complications due to cardiopulmonary resuscitation are rare in children (< 3%). Those complications that have been reported include retroperitoneal hemorrhage, pneumothorax, pulmonary hemorrhage, epicardial hematoma, and gastric perforation.

Once resuscitation is complete or nearing completion, prepare the patient for longer term intensive care by revision/augmentation of airway and vascular access. For example oral intubation may need changing to nasal and if necessary replace intraosseous access with a central venous line and peripheral i.v. cannulae. An arterial line may be required. Good intensive care is about doing simple things well. Hence procedures such as the style of intubation, the manner of endotracheal tube fixation and the method of securing drips should all be controlled by unit protocol unless otherwise contraindicated. For example routine, non-essential revision of the intubation is unwise if the airway was precarious initially or if intubation was difficult to achieve. But in all other circumstances, especially if the patient is to be transferred, the most stable and familiar techniques should be employed.

Oxygenation is the highest priority but adequate minute volume must be provided to clear carbon dioxide. Assess both by serial measurements of arterial blood gases. Acidosis may have metabolic consequences such as hyperkalemia (a compartment shift) or pharmacological effects such as failure to respond to catecholamines. It may aggravate symptoms of poisoning with drugs that are weak acids. Correct any respiratory acidosis by increasing minute volume particularly if the  $[H^+] > 63 \text{ nmol/L}$  ( $\text{pH} < 7.2$ ). Treat the cause of any metabolic acidosis in preference to giving bicarbonate, since without treatment of the cause the acidosis will recur. I.v. bicarbonate may be indicated to compensate for recognized bicarbonate losses (e.g. ileostomy fluid) or to recruit a pharmacodynamic response (e.g. if there is a poor response to inotrope therapy due to acidosis) but otherwise runs the risk of increasing the work of breathing (through  $\text{CO}_2$  production) and aggravating intracellular acidosis ( $\text{CO}_{2(aq)}$  and  $H^+$  ions diffuse into cells more rapidly than bicarbonate).

A normal blood pressure is not a sufficient assessment of the cardiovascular system. Determine the adequacy of the circulation by assessing end organ (cellular) function using markers like urine output, mental state, degree of metabolic acidosis or serum lactate levels. Remember that resuscitation may have compensated for the presenting problem rather than resolved it. Furthermore a variety of other problems are common after acute resuscitation. Look for dilutional anemia, which can arise as a consequence of large intravascular volume boluses having been given during resuscitation. Give red cell transfusion priority if oxygen delivery is critical or compromised (one possible cause of metabolic acidosis). Also establish an appropriate ongoing i.v. fluid and electrolyte regime at this point that includes maintenance requirements, metered replacement of any deficit and comprehensive replacement of ongoing losses. If inotropic or chronotropic support is required then use titratable infusions of short-acting agents in preference over longer acting agents whose effects may persist when the current hemodynamic state changes. Measure the blood glucose level since hypoglycemia is common and not detectable by clinical observation in the obtunded, sedated or otherwise critically ill child. The risk of hypoglycemia is increased in smaller and younger patients as a consequence of low glycogen reserves and a high basal metabolic rate. The dose of glucose in acute hypoglycemia is 0.5 g/kg. This dose must be followed by repeated assessment of the blood glucose level to check that a therapeutic effect has been achieved and that the resulting level is maintained. The normal maintenance requirement for babies is 6 mg/kg/min.

For all but the most straightforward of resuscitation scenarios the patient then requires further management on an intensive care unit. For all but the simplest cases this should be a specialist pediatric intensive care unit particularly if it is difficult to anticipate what the length of intensive

care unit stay will be or if it is likely to be more than 24 h. Transfers within hospital or between hospitals usually occur after stabilization and are conducted without undue haste by a retrieval team from the pediatric intensive care unit. The use of a skilled and trained transfer team substantially reduces critical incidents and morbidity. The need for such transfer is entirely predictable and so detailed protocols should be prepared in advance including specified indications and provision for more urgent movement. Training in intensive care transport must be practical and is best provided by supervised episodes accompanying a skilled team. Trainees must become familiar with the modes of transport used and must attain higher levels of proficiency in equipment maintenance and repair than are necessary for clinical staff within a hospital environment. This is because technical backup is not available during transfers.

## RESPIRATORY SYSTEM

### INDICATIONS FOR MECHANICAL VENTILATION

One of the commonest reasons for arranging intensive care admission is a decision to start mechanical ventilation. Infants and children have less respiratory reserve than adults, which leads to a relatively high incidence of respiratory failure during severe illness. Respiratory support may be indicated:

- to secure the upper airway;
- to reduce the work of spontaneous breathing;
- to supplement gas exchange in respiratory disease;
- to achieve desirable hemodynamic effects;
- as an incidental requirement during sedation or anesthesia;
- due to neurological disease with or without respiratory complications.

If the patient has adequate airway protection reflexes it may be possible to provide mechanical support with minimal sedation and without intubation.<sup>57</sup> Select such patients carefully on their own merits. Successful nose mask or face mask ventilation requires a degree of patient cooperation and a pressure controlled device with the capacity to deliver high flows to compensate for any leak. Negative pressure devices, whether tank or cuirass, have the disadvantage of obstructing access to the patient. So-called 'non-invasive' ventilation should only be provided in an environment where anesthetic and airway skills are readily available.

### TECHNIQUE OF INTUBATION

The purpose of recognizing sick children is to enable appropriate early intervention. Hence intubation is usually performed as part of the induction of anesthesia. There are two basic approaches to the administration of an anesthetic: i.v. (usually a rapid sequence induction) and inhalation. Anesthetic skills, equipment and assistants are required for both. Rapid sequence induction is the preferred approach for most situations especially when regurgitation and aspiration of stomach contents are potential problems. It is contraindicated when the airway is compromised or when intubation may be difficult, in which case inhaled anesthetics are used.

Use a straight-bladed laryngoscope to view the larynx in infants because its position is high (at the level of the C4 vertebra) and anterior compared to the adult. The large, soft, sigma-shaped epiglottis can be kept under the blade if it obscures the laryngeal inlet. In older children, use a curved blade and lift away from you (as opposed to rotating) for a better view of the vocal cords. Once beyond puberty the larynx has assumed its adult position.

Use noncuffed tubes in prepubertal children because the larynx has a gradually tapering shape narrowest in the subglottic region (behind the cricoid cartilage). The tube should be small enough to permit a small leak of air under pressure, giving reassurance that excessive pressure is not being exerted on the subglottic tracheal mucosa where damage would otherwise lead to scarring and subsequent stenosis. After puberty the vocal cords are the narrowest part of the airway so use cuffed tubes in more mature children. The ideal position of an endotracheal tube tip is at the level of the sternoclavicular junction on the chest X-ray. In infants

the trachea bifurcates at the level of T2. The tip of the tube will move significantly when the neck is flexed (moves down) or extended (moves up).

Always attempt to preoxygenate the patient and make sure that you are proficient in airway intervention techniques because any interruption in ventilation in babies and infants very quickly leads to hypoxemia. Their high metabolic rate means faster consumption of oxygen and greater carbon dioxide production. Furthermore normal ventilator settings must include the routine use of positive end expiratory pressure because atelectasis occurs early and at a higher volume relative to the functional residual capacity of older children and adults.

### CHOICE OF VENTILATOR

Ventilators differ in relation to their power source, cycling characteristics, method of generating gas flow and the provision of gas supply for spontaneous breaths. The 'cycling' label is attached to the parameter (pressure, time, volume or flow) that determines when inspiration stops and expiration starts.

The choice of cycling method will affect the behavior of the ventilator as the patient's condition changes (Table 36.3).

The method by which gas flow is generated affects the choice of 'control' mode (e.g. pressure control and volume control) and hence the pattern of pressure and flow over time during inspiration. The terms 'support' or 'assist' are applied to modes where the breath is initiated by the patient then detected and supported by the ventilator. 'Mandatory' or 'control' breaths are initiated by the ventilator and may be blended with 'support' (e.g. synchronized intermittent mandatory ventilation with pressure support).

For neonates there is a historical preference for using continuous flow, pressure-regulated, time-cycled ventilators. They are less susceptible to the fluctuations in tidal volume that are generated by the disparity between tidal volume and total gas volume in the ventilator circuit. They also do not generate large pressure fluctuations when the patient is uncoordinated with the ventilator and can function in the presence of a modest leak around the endotracheal tube. However, when compliance changes (e.g. as muscle relaxants wear off, or disease severity worsens) large changes in delivered tidal volume occur. Despite being intrinsically sensitive in the detection of circuit disruption, older models may not be capable of detecting absent tidal volume (endotracheal tube blockage). They must therefore be used in combination with an apnea monitor.

For older patients there is a historical preference for volume-controlled ventilation. Nevertheless improved technology is making it easier and sometimes more appropriate to ventilate smaller patients with such devices. However, even with newer models, when compliance changes or airway obstruction develops, airway pressure escalates and the effective tidal volume is reduced as gas is compressed in the ventilator tubing.

### VENTILATOR SETTINGS

Oxygenation is critical. Since oxygen is poorly soluble in water, the important factors in oxygen uptake across the lung are:

- the amount of blood flow (e.g. the cardiac output);
- the hemoglobin concentration;

Table 36.3 Ventilator cycling

	Low compliance/high airways resistance	High compliance/low airways resistance
Volume cycled	$V_T$ becomes a smaller % of cycled volume PIP increases	i.t. becomes short PIP falls
Pressure cycled	i.t. and $V_T$ both fall	i.t. becomes very long $V_T$ increases
Flow cycled	i.t. and $V_T$ both fall	i.t. and $V_T$ both rise
Time cycled	No effect	No effect

i.t., inspiratory time; PIP, peak inspiratory pressure;  $V_T$ , tidal volume.

- the effective surface area of the lung (after the effects of shunt, deadspace and ventilation–perfusion matching);
- the diffusion gradient for oxygen.

All of the above can be manipulated independently but the ventilator is only used for the last two. To increase the diffusion gradient for oxygen, increase the inspired oxygen concentration. The effective surface area of the lung can be increased (within limits) by increases in tidal volume and mean airway pressure. Some components of shunt may be relatively fixed and not respond to changes in ventilation. It is important not to overventilate under these circumstances. Deadspace is proportionately more significant at low tidal volumes. Ventilation–perfusion matching changes with posture and positioning of the patient as well as other changes in ventilation technique.

Carbon dioxide diffuses easily across respiratory membranes and comes in and out of solution easily. Hence the rate-limiting step in removal across the lung is the speed with which equilibrated (alveolar) gas is replaced with fresh gas, i.e. the alveolar minute ventilation. Use tidal volume and respiratory rate to influence the minute volume and create responses in arterial carbon dioxide level. At low tidal volumes deadspace is more significant and reduces the effectiveness of each tidal volume in clearing carbon dioxide. There are therefore limits to how much a reduction in tidal volume can be compensated by increasing respiratory rate.

Wherever possible, choose ventilator settings that can be considered therapeutic, such as the use of higher levels of positive end expiratory pressure in pulmonary edema to reduce alveolar water content or in bronchomalacia to maintain patency of the conductance airways. Lung volume and  $[H^+]$  (via carbon dioxide partial pressure;  $PCO_2$ ) can also be used to manipulate pulmonary vascular resistance. The amount of work required to breathe is increased when compliance is poor or when airway resistance is high. Try to adapt ventilator settings to match the disease state and avoid complications such as gas trapping (dynamic hyperinflation), for example allow a long expiratory time if the patient has bronchospasm.

## CONSEQUENCES OF VENTILATION

Endotracheal intubation and mechanical ventilation are not natural processes and are associated with hazards that can be minimized by appropriate attention to detail. Choose the correct size and length endotracheal tube. Take care to ensure that the inhaled gases are humidified to 100% relative humidity at body temperature. Avoid high pressures and tidal volumes. Any ventilator settings that induce overinflation are likely to induce or aggravate lung injury although the specific settings involved will differ between restrictive and obstructive diseases. Peak pressure is far more dangerous than end expiratory pressure and many of the problems previously associated with peak pressure are as much to do with the associated high end inflation lung volume and tidal volume as anything else. Previously injured lungs are more susceptible to ventilator-induced lung injury and if the disease is not homogenous it may be the less severely diseased segments that receive the greater insult.

## NEWER VENTILATION STRATEGIES

In recent times the concept of minimizing the stress of mechanical ventilation has become pivotal in the ventilation of patients with respiratory disease. The appeal of novel approaches to ventilation is often based upon their potential (even if unproven) abilities in this respect. The simplest approaches include improved coordination between the ventilator and the patient. More complex approaches are aimed at providing increasing degrees of ‘lung rest’. The conventional and best validated method of providing lung rest is extracorporeal membrane oxygenation (ECMO), which is a modified form of cardiopulmonary bypass. ECMO can be used to achieve total lung rest (gas exchange during prolonged apnea) and the circuit can be configured to provide pulmonary (venovenous cannulation) or cardiopulmonary support (venoarterial cannulation).

Examples of ventilation strategies with proposed benefits in terms of reducing ventilator-associated lung injury include:

- Permissive hypercarbia: where (pressure-limited) minute ventilation is minimized in the hope of reducing lung stress. To perform this technique, once hypoxia is overcome, allow arterial carbon dioxide levels to rise to limits dictated by the associated rise in hydrogen ion concentration (e.g.  $\leq 63$  nmol/L correlating with  $pH \geq 7.2$ ). Over time, metabolic compensation allows higher and higher carbon dioxide levels to be tolerated.<sup>57–60</sup>
- High-frequency oscillation: these devices use the continuous distending pressure (mean airway pressure) to recruit and maintain lung volume. Gas exchange is achieved by a high-frequency vibration (6–12 Hz). Minimal tidal volumes (less than deadspace) result from the amplitude of the vibration, which itself is highly attenuated within the respiratory tract, hence minimizing shearing forces.<sup>58</sup> Use the amplitude ( $\Delta P$ ) preferentially to control the partial pressure of carbon dioxide in arterial blood ( $PaCO_2$ ). The fall in tidal volume as frequency increases attenuates carbon dioxide removal, which is otherwise highly efficient.
- Inhaled nitric oxide<sup>61–63</sup>: in responsive patients, ventilation perfusion mismatch can be reduced by NO, which causes vasodilatation in ventilated areas. Some cases of pulmonary hypertension may also respond.
- Liquid ventilation (usually in the form of perfluorocarbon-assisted gas exchange)<sup>64</sup>: this technique involves first gradually replacing the functional residual capacity of the lung by slow instillation of perfluorocarbon during conventional ventilation. This causes bulk distention of the alveoli and considerable recruitment of lung volume. Subsequent tidal ventilation with 100% oxygen is more effective as the low surface tension at the perfluorocarbon:gas interface improves compliance.
- Intratracheal pressure release ventilation<sup>63,65</sup>: where expiratory flows are augmented increasing respiratory efficiency at lower tidal volumes and lower mean pressures.

## WEANING VENTILATION

Improving respiratory function is reflected in the behavior of the patient and the ventilator. In the latter case the effects depend upon the mode of ventilation employed at the time. Improved compliance or airways resistance during volume-controlled ventilation causes airway pressures to fall. With pressure-controlled ventilation under the same circumstances, tidal volumes increase and the partial pressure of oxygen in arterial blood ( $PaO_2$ ) may rise as the  $PaCO_2$  falls. Effective tidal volume can be usefully expressed in relation to deadspace using end tidal carbon dioxide measurements. In flow-cycled ventilator modes such as pressure support, the inspiratory time decreases as compliance improves. Close observation of the patient and regular blood gas measurement allows you to respond to these changes.

Start to deliberately wean patients from mechanical ventilation when the pathology or indication for ventilation is resolving or finished. The speed of successful weaning is dictated by the adequacy of the response and the skill lies in getting the best performance out of the partially dependent patient. The patient must be able to take over ventilation without excess energy expenditure, and there must be adequate respiratory muscle strength, hemodynamic stability and a good nutritional state. Only extubate electively when the patient:

- is hemodynamically and metabolically stable;
- is making effective efforts to breathe;
- is sufficiently awake and alert;
- has protective airway reflexes.

Prior to extubation, always ensure that there is adequate provision of equipment, medication and staff to deal with complications such as laryngospasm, which might require urgent reintubation.

## CARDIOVASCULAR SYSTEM

Another common reason to arrange intensive care admission is the need to perform invasive monitoring of the circulation using arterial or central venous lines. This need arises:

- as a wise precaution in case of potential instability, e.g. after major surgery or other trauma;
- in the treatment of shock such as during large volume fluid losses/replacement;
- when blood pressure is excessively high or low;
- when vasoactive drugs are being administered by infusion.

### RECOGNITION OF SHOCK

Do not rely on blood pressure in the first instance or alone to assess the circulation. Shock is defined as inadequate perfusion of tissues (in particular oxygenation) and its severity is assessed in terms of end-organ function. When flow measurements are available, the global delivery of oxygen to the tissues can be calculated as the product of the oxygen content of arterial blood and the cardiac output; but not all of this oxygen is available to the tissues. Factors that influence the distribution of blood also apply and may be particularly affected by disease. The two most sensitive and clinically useful organs in the assessment of the circulation are the brain and the kidney. Altered conscious level is an important sign of shock and up to the point of acute renal failure urine output is a good marker of renal perfusion. The patient with severe cardiovascular dysfunction (shock) generally has peripheral pulses that are difficult to feel, poor capillary refill, cool extremities, decreased urine output and altered sensorium. A *low blood pressure* is a preterminal *sign* since blood pressure can be maintained by intense vasoconstriction even in the presence of a markedly reduced circulating volume. The fall in blood pressure thus represents decompensation and indicates that the patient is out of control.

It is important to monitor fluid losses and replacement accurately. In the short term this can be approximated by the fluid balance but remember to extend the comparison over days. Weigh the patient regularly and match your impressions with clinical and laboratory observations.

### RECOGNITION OF HEART FAILURE

Heart failure is distinguishable from shock. It is a more chronic condition in which the heart fails to respond adequately to its preload and hence fails to obey its normal Starling relation. There may be diastolic or systolic dysfunction or both and the problem may apply to specific ventricles or regions of myocardium. Fluid retention results from 'back pressure' as well as humoral responses to a reduced cardiac output. Although true heart failure can occur in children, most patients with signs that would represent heart 'failure' in an adult are in fact displaying the manifestations of a left-to-right shunt. These patients may have positively athletic cardiac function.

### RECOGNITION OF CONGENITAL HEART DISEASE

Suspect congenital heart disease especially and most importantly in neonates with shock or cyanosis but also in patients with:

- murmurs;
- pulmonary edema;
- rhythm disturbances;
- abnormally severe symptoms from respiratory disease;
- failure to thrive.

Right-to-left shunts cause cyanosis and rarely cause murmurs because they are relatively low volume shunts occurring at low pressure. Left-to-right shunts cause pulmonary and ventricular volume overload. The loudness of the murmur is to some extent inversely proportional to the size of the shunt. Sustained high pulmonary blood flow causes pulmonary hypertension. Ventricular outflow tract obstruction (pressure overload) tends to cause ventricular hypertrophy. Ventricular hypertrophy is associated with decreased ventricular compliance (diastolic dysfunction).

Congenital heart disease can produce many combinations of defects, which also evolve according to the loading forces they create.

It is essential to recognize duct-dependent lesions. These present early in the neonatal period. Duct-dependent pulmonary flow presents with cyanosis and duct-dependent systemic flow with heart failure and/or shock in the first week of life. Both require an infusion of prostaglandin (typically 20 ng/kg/min) and urgent evaluation by a pediatric cardiologist.

### TREATMENT OF SHOCK

The first line in cardiovascular resuscitation and support is an intravascular volume bolus of 20 ml/kg. Such preload augmentation should increase stroke volume and therefore blood pressure even if heart failure is suspected as well as shock. The most common cause of an inadequate response to this treatment is that the magnitude of the problem has been underestimated and inadequate fluid volumes have been used, hence the protocol for repeating the boluses of i.v. fluid at least twice if there is an inadequate response. However, do not give excessive amounts of intravascular volume if heart failure is present. In rapid large volume resuscitations the central venous pressure is a useful guide to how the volume is being handled by the circulation. Palpating the liver edge can also help; hepatic engorgement suggests right ventricular volume overload.

Both myocardial contractility (and hence stroke volume) and heart rate are increased by catecholamines. The first-line inotropic support started after the second or third fluid bolus is usually adrenaline (0.05–0.5 mcg/kg/min) or dopamine (2–10 mcg/kg/min). Cardiac output can also be influenced by manipulation of afterload (end systolic ventricular wall tension) for example by agents that affect the systemic vascular resistance. The term 'systemic vascular resistance' refers to a global approximation of the resistance of the circulation to blood flow. It is calculated after measuring cardiac output by dividing the pressure drop across the circulation by the measured blood flow. Reduction of afterload may improve cardiac output in conditions where there is a left-to-right shunt. Increases in afterload (e.g. using alpha adrenergic agents) are an important component of support in shock states such as septic shock when characterized by a low systemic vascular resistance.

The intrinsic response of the cardiovascular system both to disease and resuscitation depends upon the age of the patient and the nature and stage of palliation of any congenital heart disease as well as any intercurrent disease. The fetal circulation is characterized by the fetal connections, a high pulmonary vascular resistance and a low systemic vascular resistance. The neonatal (transitional) circulation is characterized by the potential persistence of all the fetal connections other than the umbilical vessels, reactive pulmonary vasculature and limited inotropic and chronotropic reserve; that is to say reduced capacity to increase contractility in response to catecholamines and a poor return in terms of cardiac output for increases in heart rate (despite a rate-dependent cardiac output in bradycardia). The neonatal heart also displays muted (e.g. to potassium) or accentuated (e.g. to calcium) responses to various electrolytes and drugs compared to later life. In infancy and childhood the myocardium adapts progressively to its new loading conditions and develops an increased reserve to beta adrenergic stimulation.

In refractory shock, i.e. failure to respond to intravascular volume loading, it is crucially important to get accurate monitoring of the circulation. Then consider the following possible explanations:

- Overestimation of the filling pressures: both central venous and pulmonary capillary wedge pressures are heavily influenced by thoracic pressure and hence positive pressure ventilation. Use the end expiratory values in your evaluation.
- Systolic cardiac dysfunction: depression of the contractile state of the myocardium can occur with a range of common disorders, for example sepsis, acidosis, hypoglycemia, hypoxia or hypocalcemia. In addition, drugs (especially antiarrhythmics) can also decrease the contractile state. A hydrogen ion concentration greater than 63 (pH < 7.2) can decrease the effectiveness of catecholamines and may need to be corrected.

- Diastolic dysfunction: when the compliance of the myocardium is poor as can occur alongside depression of systolic function or more independently as a result of congenital heart disease, the end diastolic volume does not increase normally in response to fluid challenge, whilst the end diastolic pressure increases markedly. Poor myocardial compliance is aggravated by catecholamines.
- Extrinsic cardiac compression: tamponade can restrict atrial and therefore ventricular filling resulting in a low end diastolic volume and low cardiac output despite high measured filling pressures. Echocardiography rapidly detects pericardial fluid and in extremis, given a compatible history, a pericardial tap may be indicated as part of resuscitative efforts.

The problem may be specific to one ventricle, particularly in congenital heart disease. It is often wise to request the opinion of a pediatric cardiologist in patients with refractory shock. Left ventricular preload is commonly inferred from left atrial pressure after cardiac surgery or pulmonary capillary wedge pressure under other circumstances. Swan-Ganz catheters are available, which are small enough to use in patients as young as 18 months.

## THERAPEUTIC EFFECTS OF VENTILATION IN CIRCULATORY FAILURE

Patients in significant shock should be intubated and ventilated. Since this will probably involve the induction of anesthesia, take care to pick the right moment. There is no substitute for experience in these sorts of judgments. Anesthetic agents have cardiovascular side-effects and the best approach is usually to optimize resuscitation before anesthetic induction. In contrast when patients are deteriorating rapidly and are likely to continue to do so, early ventilatory support is a priority. Patients in shock require less anesthetic to suppress the central nervous system but they take longer to respond to i.v. injections of anesthetic agents because of the reduction in effective blood flow.

Positive pressure ventilation can have a variety of hemodynamic effects, most of which are therapeutic for patients with normal anatomy but who have cardiovascular instability. The right ventricular preload is reduced by the rise in intrathoracic pressure. Left ventricular preload may be decreased as a consequence or increased as pulmonary venous blood is encouraged to leave the lung. The dominant effect can often be inferred from the systemic arterial pressure trace looking for effects reminiscent of a Valsalva maneuver or the opposite during inspiration. Left ventricular afterload is reduced by the effects of raised intrathoracic pressure on the ventricle and by encouraging diastolic arterial flow out of the thorax. The effects on right ventricular afterload depend upon the pervading pulmonary vascular resistance. Further cardiovascular benefits in terms of the treatment of shock are achieved by the decreased work of breathing and decreased oxygen consumption associated with sedation and paralysis. Reduction in alveolar water content can also improve lung compliance and oxygenation.

There are a wide variety of situations in pediatric intensive care where cardiopulmonary interactions dictate management, for example patients with high pulmonary vascular resistance and right to left ductal shunts, patients with univentricular physiology or patients with cavopulmonary connections and hence passive pulmonary blood flow as a result of cardiac surgery. Patients with low or critical pulmonary blood flow may have extraordinarily compliant lungs and experience symptomatic reductions in cardiac output during positive pressure ventilation. Patients with high pulmonary blood flow have predictably noncompliant lungs.

## CENTRAL NERVOUS SYSTEM

### LEVEL OF CONSCIOUSNESS

Determine the patient's level of consciousness in a reproducible fashion. Describe the stimulus required to elicit a response and then describe the organization or sophistication of that response. At lower and lower levels of consciousness, greater stimuli (voice then pain) achieve less organized reactions. The commonest nomenclature used to describe this

relationship is the Glasgow coma score, which breaks the responses into three groups: 'eyes' (4-point scale), 'vocalization' (5-point scale) and 'motor' responses (6-point scale). There are a variety of adaptations for preverbal or intubated patients. The AVPU classification distinguishes patients who are Alert, respond to Voice, respond only to Pain or who are Unresponsive. Painful stimuli administered peripherally can elicit spinal reflexes and mislead the unwary as to the sophistication/localization of the response. Avoid this by causing pain in a cranial nerve distribution, e.g. by pressure under the supraorbital ridge and documenting the response particularly of any limb movement. Patients who respond only to deep pain (Glasgow coma score  $\leq 8$ ) or who are unresponsive (Glasgow coma score 3) are unlikely to have adequate airway protection reflexes and are likely to require intubation.

### LEVEL OF AWARENESS

Sedation (hypnotic) agents obtund the patient, i.e. induce mental blunting often with amnesia. They are used to induce stupor so that symptoms and treatments are better tolerated. Sedation is usually provided by continuous or intermittent doses of benzodiazepines. Although these agents dull the responses they do not induce normal sleep and are not analgesics.

### PAIN CONTROL

Analgesia is a high priority in intensive care and the need to provide adequate analgesia is arguably increased by the use of sedative or anesthetic agents. Conscious children naturally use distraction and play as coping mechanisms for dealing with pain and distress. They can be encouraged in their efforts by diversion therapy. Stress and anxiety amplify children's apparent distress. Anything that can minimize such stress such as the presence of a parent, a full stomach, or a degree of sedation is to be encouraged. Assessment of pain control may be difficult; first because of the patient's age and communication skills and secondly because of appropriate sedation, which impedes the response even to age-appropriate pain assessment tools. It is best to anticipate and assume that pain is present and to treat it accordingly with a morphine infusion.

### TRAUMATIC BRAIN INJURY

In severe diffuse brain injury, particularly that caused by trauma, cerebral edema worsens over the first 24–48 h and is accompanied by a loss of the capacity to autoregulate cerebral blood flow. It therefore becomes highly important to keep parameters that influence cerebral blood flow as stable as possible. These include the cerebral perfusion pressure, the PaCO<sub>2</sub>, the PaO<sub>2</sub>, regional metabolic demand and autonomic activity.

'Neuroprotective' intensive care should be instigated after significant brain injury (e.g. Glasgow coma score  $< 12$ ). The intention is to minimize secondary brain injury but as yet there are no therapeutic approaches outside those aimed at adequate perfusion and oxygenation of the brain. The strategy includes:

- elective sedation;
- mechanical ventilation with strict attention to adequate oxygenation and avoiding hypercarbia (keep PaCO<sub>2</sub> within the normal range);
- cranial CT scan in the early *postresuscitation* phase of management to determine the need for neurosurgery and the subsequent management of raised intracranial pressure;
- nursing with the head midline and with a 30-degree upwards head tilt and avoid stresses that increase intracranial pressure;
- circulatory support to maintain the cerebral perfusion pressure.

Maintenance of the cerebral perfusion pressure requires intracranial pressure monitoring. This enables the detection of raised intracranial pressure as well as allowing the determination of the adequacy of cerebrovascular autoregulation. Intraventricular drains are preferred for this purpose firstly because they are more reliable than the alternatives. The second advantage of an intraventricular drain is that it enables venting of cerebrospinal fluid to control recalcitrant peaks of intracranial pressure from other causes such as cerebral edema. The treatment

of raised intracranial pressure depends upon the cause. Neurosurgery may be required for space-occupying lesions such as hematomata. Hydrocephalus can be treated via the intraventricular drain. However, the first-line treatments for cerebral edema are medical maneuvers designed to reduce the cerebral water content (fluid restriction or infusion of hypertonic saline or mannitol). If raised intracranial pressure is problematic or unresponsive then barbiturates (thiopental) should be used for sedation since these agents uncouple the relationship between cerebral blood flow and the metabolic consumption of oxygen. The use of barbiturates may necessitate increased use of pressors to maintain the cerebral perfusion pressure. The ultimate management for raised intracranial pressure that cannot be lowered by medical means is craniectomy (removal of bone flaps to allow cerebral expansion at lower pressure).

Anticonvulsants should be given in traumatic brain injury particularly if any component of contusion or hemorrhage is seen in the brain substance on CT scan. Breakthrough seizures may only be detected by hemodynamic or pupillary signs and should be confirmed/monitored by electroencephalogram (EEG) or alternative electrophysiological monitoring and treated aggressively. The natural tendency to become pyrexial should be counteracted by therapeutic cooling to normothermia in order to prevent increases in cerebral metabolic oxygen demand. The possible merits of cooling to varying degrees of hypothermia are currently under investigation.

The duration of neuroprotective intensive care is usually judged by the behavior of the intracranial pressure over time. A minimum period of 24 h after injury is wise since cerebral swelling increases over this period. Imaging techniques such as CT and magnetic resonance imaging (MRI) are insensitive when detecting raised intracranial pressure. After 10 d any opportunity to prevent secondary brain injury has probably passed and patients should be woken and weaned from support.

## METABOLIC COMA

Many components of neuroprotective intensive care are routinely transferred from traumatic brain injury where their justification is far from complete, to other forms of encephalopathy where there is even less evidence of their utility. Whilst loss of cerebrovascular autoregulation may occur in both conditions, in metabolic coma the insult is cytotoxic rather than vasogenic and cerebral edema is frequently more persistent. Metabolic and infective causes of coma may also be preceded by delirium, which is not a feature of traumatic brain injury.

## SEIZURES

The diagnosis of 'status epilepticus' is made on the basis of the duration of continuous or consecutive seizures (30 min or longer). The protocol for resuscitation of patients in status epilepticus culminates in barbiturate coma after a further 30 min of progressive treatment with lesser measures. This is usually achieved by i.v. induction and maintenance of anesthesia with thiopental and followed by transfer to the pediatric intensive care unit. Subsequent treatment on the intensive care unit depends upon the cause and prior duration of the seizures. Make rigorous attempts to detect potentially treatable causes such as hypoxia, fever, hypoglycemia, hypocalcemia, infection (do not perform a lumbar puncture in the acute phase after protracted seizures), poisoning, trauma, raised intracranial pressure and kernicterus.

Seizures that lasted for less than 2 h before admission are unlikely to be complicated by secondary cerebral edema and it is worth allowing sedation to wear off so that the patient can wake up and be extubated. The longer the history the greater the risk of complications such as cerebral edema, hyperthermia and rhabdomyolysis. Don't forget to perform fundoscopy to detect papilledema and to watch patients carefully for signs of hypertension or bradycardia (since the third component of Cushing's triad – hypoventilation – is masked by anesthesia and mechanical ventilation). A cranial CT may be warranted and if cerebral edema is present give mannitol and consider intracranial pressure monitoring.

Seizures that recur or persist on the intensive care unit can be highly problematic and the mortality and morbidity are appreciable. Persistent seizures imply an unresolved cause so comprehensive investigation is necessary. In recalcitrant cases it can be worthwhile monitoring the EEG during the acute phase of a new treatment to ensure that a sustained period of burst suppression has elapsed before trying to wean the dose of anticonvulsant. Trials of pyridoxine in infants with resistant seizures should also be monitored by EEG. If no diagnosis or specific treatment is forthcoming a variety of drug regimens can be tried to reach a state of seizure control without excessive obtundation. It is not appropriate to sedate patients to the point of anesthesia and nurse them on an intensive care unit when their seizures are due to an incurable or degenerative condition.

## FLUIDS AND RENAL REPLACEMENT THERAPY

Fluid and electrolyte balance are covered elsewhere in the text. In general terms the tendency to fluid retention and edema in critical illness make fluid regimes on intensive care highly restrictive once intravascular volume is assured. There is also a low threshold for the use of diuretic and renal replacement therapies on the pediatric intensive care unit.

There are two approaches to conventional renal replacement therapy: peritoneal dialysis and extracorporeal circulation. In childhood the peritoneum has a greater surface area proportional to body mass, making peritoneal dialysis more effective than it would be in older patients. Short-term renal replacement therapy can also be provided by hemofiltration. The favored venovenous approach to hemofiltration minimizes the hemodynamic consequences of this approach. A variety of techniques are available. Water removal can be achieved by ultrafiltration without replacement fluid. Solute clearance is enhanced by higher ultrafiltration rates in which the solutes are removed by bulk flow. The high ultrafiltration rates are achievable when providing replacement fluid. It is this approach that is termed 'hemofiltration'. Hemodiafiltration is an attempt to increase solute removal by additional diffusion but this can be achieved with high volume hemofiltration (e.g. with prefilter administration of replacement fluid) or dialysis. The removal of larger molecules (e.g. protein bound moieties) from the circulation can be achieved by plasmapheresis.

These modalities are used in many more situations than just renal failure.<sup>66-68</sup> Renal replacement techniques are occasionally used electively, e.g. to allow large volume transfusions of clotting factors prior to liver transplantation in fulminant hepatic failure. They are also used therapeutically in inflammatory conditions such as the systemic inflammatory response syndrome (e.g. after cardiopulmonary bypass or in severe sepsis) and Guillain-Barré syndrome. Plasmapheresis and plasmapheresis have also been tried in a variety of 'desperate diseases' such as lupus nephritis and polymyositis, though with no evidence of benefit. The liver replacement device Molecular Adsorbents Recirculating System (MARS<sup>®</sup>) represents an alternative to plasmapheresis in the attempt to clear protein bound toxins. It uses adsorbent membranes and recycles the albumin it uses but its clearance profile has not been shown to be greater than plasmapheresis. Pediatric patients require smaller quantities of albumin replacement during plasmapheresis than adults because smaller exchange volumes are used.

## HOST DEFENCE

Infections are a major cause of mortality in young children and immunosuppressed individuals such as transplant recipients and those receiving cytotoxic chemotherapy. The invasive treatments and monitoring techniques used in intensive care increase the chances of nosocomial infection as do debilitating illnesses themselves. However, liberal antibiotic policies are a major stimulus for the generation and selection of multiresistant organisms. Normal intensive care procedures do not require antibiotic prophylaxis. Reserve antibiotic treatment for patients who have had procedures that do require prophylaxis, e.g. abdominal surgery, those with proven infection or those for whom the consequences

of delay in treatment pending culture results are unconscionable. Use acute phase reactants and other tests (which predict positive cultures with varying degrees of success) to aid in decisions to withhold antibiotic treatment as well as decisions to commence.

## A COMBINED ORGAN SYSTEM APPROACH TO CRITICAL ILLNESS

To conclude this section there follows a logical approach, consistent with the points covered earlier, to a disease with multiple organ system problems, in this case fulminant hepatic failure.

### FULMINANT HEPATIC FAILURE

The typical history of patients with fulminant hepatic failure is one of nausea and malaise, followed by jaundice and coagulopathy (unresponsive to vitamin K). The most rapidly progressive cases develop hypoglycemia, metabolic acidosis and hyperammonemia in association with coma before jaundice is detected. There is no definitive treatment available and management depends upon supportive care, with liver transplantation in selected cases. Currently most patients receive *N*-acetyl cysteine in the acute phase. The mortality without transplantation is 50–80% but rises to more than 90% when there is severe encephalopathy or coagulopathy. Early transfer to a specialist center with a transplant program is therefore advisable. In many patients the cause is never identified despite extensive investigation and if hepatic failure is severe enough, the diagnosis is largely academic unless it is likely to recur in a transplanted liver or contraindicate treatment by transplantation. The intensive care priorities follow the ABCD (airway, breathing, circulation, disability) approach.

Comatose patients (grade IV encephalopathy) will require intubation for airway protection and ventilation. Avoid nasotracheal intubation because of the coagulopathy. Cardiac output, blood pressure and hemoglobin concentration must all be sustained in order to preserve cerebral oxygen delivery. Ventilate with a modestly increased fractional inspired concentration of oxygen ( $\text{FiO}_2$ ), even if the patient does not have pulmonary complications. Hemodynamic instability is common, often a low systemic vascular resistance and variable cardiac output. Use invasive cardiovascular monitoring (at least central venous pressure and arterial lines) and anticipate a need to use inotropic agents with alpha agonist activity (e.g. noradrenaline). Remain vigilant to detect hypovolemia due to occult/acute hemorrhage.

Identify treatable causes of coma such as hypoglycemia or subclinical status epilepticus. Hypoglycemia specifically should be anticipated, appropriately supplemented with i.v. dextrose (without compromising the fluid restriction) and closely monitored. A computed tomography (CT) scan can be useful to exclude cerebral hemorrhage as the cause of acute neurological deterioration. Cerebral edema is present in 75% of patients with grade IV encephalopathy. Assume that cerebrovascular autoregulation is impaired. It may be possible to measure intracranial pressure but intraventricular catheters and intraparenchymal

bolts both require aggressive correction of coagulopathy first and even then the risk of bleeding may not be returned to normal. Furthermore such a strategy would mask an important marker of liver function (the prothrombin time). Nevertheless ventilate to a low normal  $\text{PaCO}_2$  and assume that cerebral blood flow will bear a linear relationship with cerebral perfusion pressure. Use pressor support to a level that implies that the cerebral perfusion pressure is likely to be adequate and avoid potential rises in intracranial pressure by a policy of minimal handling, nursing with head midline and a 30-degree head up position. Elective paralysis prevents coughing and straining but makes it difficult to identify status epilepticus without EEG monitoring. Minimize cerebral oxygen demand principally by recognizing and controlling seizures, and avoiding hyperthermia. Barbiturate coma may be preferred and is induced by thiopental infusion in doses sufficient to cause a burst suppression EEG.

Plasmafiltration may temporarily improve encephalopathy. Efficacy has not been proved and it has not been shown to alter outcome. In larger patients MARS will probably use less albumin but has not been formally compared to plasmafiltration. Attempts to alter gut pH and flora to reduce the number of urea splitting organisms present are also theoretically justifiable.

Impose a therapeutic fluid restriction (e.g. 50% of normal) even to the point of hypernatremia as high as 150 mmol/L. This may require the use of high concentration dextrose solutions to provide adequate carbohydrate. Mannitol is not likely to have a dramatic effect on cerebral edema since the insult is cytotoxic and therefore ongoing. Concurrent renal failure aggravates fluid overload and complicates both the management of cerebral edema and the correction of coagulopathy. Avoid mannitol if there is oliguric renal failure. Treatable causes of prerenal failure such as hypovolemia or hypotension due to hemodynamic instability should be corrected but the practitioner should have a low threshold for hemofiltration, particularly if there is a metabolic acidosis.

Since the prothrombin time is the best prognostic liver function test, only correct coagulopathy with fresh frozen plasma ( $\pm$  cryoprecipitate) if there is a therapeutic indication such as bleeding, the need to establish intracranial pressure monitoring or imminent surgery. Supplement the platelet count if it falls below 50 when the patient is also coagulopathic.

Treat metabolic complications as they arise. Seek the cause of metabolic acidosis rather than treating blindly with bicarbonate. Increased lactate production due to impaired oxygen delivery/extraction and impaired metabolism can impair the response to inotropes and recurs inexorably if the cause cannot be treated. Recurrent acidosis can be treated without causing hypernatremia by moderate volume hemofiltration using a bicarbonate buffered replacement fluid.

Secondary sepsis is likely as a consequence of invasive treatment, gut translocation of organisms and impaired cellular and humoral immunity. Maintain a high index of suspicion for infection if the patient's clinical condition fluctuates. This approach should be extended to starting blind therapy with broad-spectrum antimicrobial and antifungal agents when dramatic changes in clinical condition occur.

## INTRODUCTION

Pediatric surgery encompasses a wider range of surgery than any other surgical specialty. It is confined to an age group rather than an organ system. In the older child, adult surgeons may deal with some commoner problems.

Congenital problems presenting in the neonatal period or later, together with other conditions peculiar to childhood, should be treated in a specialist center by trained pediatric surgeons backed by pediatric anesthetists, pediatric radiologists, pediatric pathologists and experienced nursing staff specifically trained in the care of children. In a general hospital the child should be nursed on a children's ward and if there is no pediatric surgeon, care should be provided by the surgeon who is treating the child *together* with a pediatrician.

In the case of the neonate, a particular surgical challenge is encountered not only in the requirement for a meticulous surgical technique but also in careful pre- and postoperative management. The reward is the prospect of a full three score years and ten survival compared with the commonly sought 5-year survival in many aspects of adult surgery.

The presence of an anomaly requiring surgery is often detected antenatally by ultrasound, enabling discussion with the parents, obstetrician, pediatric surgeon and neonatologist. The parents can thus be prepared and reassured, where possible, that although an abnormality has been detected it can be treated. They can visit the surgical neonatal unit, meet the staff and, where appropriate, the timing of delivery may be planned to facilitate optimal transfer of the baby to the awaiting surgical unit or direct to the operating theater. Pregnancy is a time of potential parental stress and unless great care is taken in explaining the possible consequences of an antenatally diagnosed anomaly their anxiety will be increased.

The most significant development in pediatric surgery in the last decade has been the adoption of minimally invasive surgical techniques – mainly laparoscopy and thoracoscopy. The majority of major operations in children can be accomplished through 'key-hole surgery', which results in less postoperative pain, less analgesia, less ileus, earlier postoperative feeding, fewer wound infections and reduced hospital stay.

## NEONATAL SURGERY

### RESPIRATORY PROBLEMS

Whilst respiratory distress in the newborn is primarily the domain of the neonatologist some causes may be surgical and early referral to a pediatric surgeon may be of lifesaving importance.

### CAUSES OF RESPIRATORY DISTRESS IN THE NEWBORN

1. Upper airway:
  - a. choanal atresia;
  - b. nasal encephalocele;
  - c. tumors of the nasopharynx;
  - d. Pierre Robin syndrome;
  - e. macroglossia;
  - f. hemangio/lymphangiomas of oral cavity;
  - g. laryngotracheoesophageal cleft;
  - h. laryngeal web;
  - i. laryngeal stenosis;
  - j. hemangioma of larynx;
  - k. laryngomalacia;

- l. tracheomalacia;
  - m. tracheal stenosis;
  - n. cystic hygroma;
  - o. cervical teratoma;
2. Intrathoracic:
    - a. congenital lobar emphysema;
    - b. cystic adenomatoid lung malformation;
    - c. bronchogenic and lung cysts;
    - d. enterogenous cysts;
    - e. pneumothorax;
    - f. sequestration of lung;
    - g. vascular ring;
    - h. congenital heart disease;
    - i. Diaphragmatic hernia;
    - j. eventration of the diaphragm;
    - k. esophageal atresia and tracheoesophageal fistula.

*Choanal atresia* is obstruction of the posterior nares by a bony or occasionally membranous septum. If bilateral it is a neonatal emergency, as babies are obligate nasal breathers. An oral airway will overcome this problem until the obstruction is relieved.

An oral airway is also of benefit in *Pierre Robin syndrome*, where there is a hypoplastic mandible and central cleft palate, the tongue falling posteriorly to occlude both the oropharynx and the nasopharynx. An airway can be maintained in position for several weeks, the baby being fed nasogastrically or via a gastrostomy. A tracheostomy may be easier to manage and is maintained until the mandible grows. It also facilitates repair of the cleft palate, which is associated in the majority of cases.

A *laryngeal web*, if complete, leads to death in utero. If partial, the symptoms may merit emergency tracheostomy. *Laryngomalacia* leads to inspiratory stridor, which usually resolves in the first 2.5 years of life. *Tracheomalacia* is commonly associated with esophageal atresia. It has been postulated that the hypertrophied upper pouch, containing swallowed liquor, compresses the developing trachea, preventing the normal growth of tracheal rings. The problem increases postoperatively, sometimes making it impossible to extubate these babies. The diagnosis may be confirmed radiologically by lateral screening of the neck, observing the anteroposterior narrowing of the trachea with inspiration. Aortopexy, suturing the aorta to the back of the sternum, thus pulling the pretracheal fascia and hence the anterior tracheal wall forward, is sometimes of benefit. Prolonged intubation may allow time for the tracheal rings to become more supportive but may itself lead to subglottic stenosis. Tracheostomy is required in some cases.

*Congenital lobar emphysema* leads to overexpansion of a lung lobe with compromise of ventilation. Half the cases present within days of birth, the remainder in the first few months of life. The most common cause is bronchomalacia of the associated bronchus although some cases may be caused by external compression. The baby may present with feeding difficulties due to dyspnea. The diagnosis is made radiologically and the most commonly affected lobes are the left upper lobe or the right middle lobe. Treatment is lobectomy in severe cases but in many conservative management is appropriate.

*Cystic adenomatoid lung* and *congenital lung cysts* can present in much the same way as lobar emphysema. Their expansion produces respiratory distress. Congenital cysts tend to be unilocular and solitary. *Cystic adenomatoid malformation* is due to excessive overgrowth of bronchioles with multiple cysts lined by cuboidal and ciliated pseudostratified columnar epithelium. The left lower lobe is commonly affected and the appearance may antenatally or even postnatally be mistaken for a diaphragmatic hernia. Treatment is resection of the affected lobe, which can now be safely performed thoracoscopically.

*Pulmonary sequestration* is a mass of lung tissue not communicating with the bronchial tree and which receives its blood supply from an anomalous systemic vessel. It may be within the substance of the lung (intralobar sequestration) or completely separate (extralobar). Areas of sequestration are thought to arise from an extra bronchopulmonary bud of the foregut. They most commonly occur in the left lower lobe and the blood supply comes direct from the aorta, above or below the

diaphragm. The anomalous blood supply may be identified by ultrasound techniques, avoiding the need for angiography. The condition usually presents with respiratory infections, more commonly after the neonatal period. The treatment is resection.<sup>1</sup>

## Diaphragmatic hernia

Diaphragmatic hernia may be congenital or acquired, the latter usually being traumatic in origin. Congenital diaphragmatic hernia arises due to an abnormality in the formation of the diaphragm between the fourth and tenth weeks of fetal life.

The commonest herniation is the Bochdalek type, a posterolateral defect, possibly a failure of closure of the pleuroperitoneal canal. It has been postulated that the primary anomaly is in the developing lungs that fail to induce diaphragmatic closure and this may explain hypoplasia in the contralateral lung. A hernia through the foramen of Morgagni is less common in neonates. This defect is retrosternal, to the right or left of the midline. The third site for herniation is the esophageal hiatus – the so-called hiatus hernia.

The true incidence of congenital diaphragmatic hernia is difficult to ascertain as so many die at birth; others present as live births and others after the neonatal period. This lesion represents 8% of major fatal congenital anomalies noted in a British perinatal mortality survey (present in one in 2200 of all births). In Edinburgh the incidence is one in 7000 live births, other series report 1:4000–1:10 000.

Some cases are now detected antenatally by ultrasound but the majority present with respiratory distress – cyanosis, dyspnea and tachypnea – either immediately after birth or within a few hours. Occasionally, particularly on the right side, the presentation may be later, the defect being present at birth but actual herniation of abdominal content occurring as a postnatal event. The later the onset of symptoms, the better the prognosis. Examination reveals a scaphoid abdomen, bowel sounds on auscultation of the affected side of the chest and a shift of the apex beat to the right in the case of a left-sided hernia. The right side is less common, perhaps due to plugging by the liver, but if a defect is present here it tends to be large with herniation of the liver as well as bowel.

Once air has been swallowed after birth a chest X-ray confirms the diagnosis, showing gas-filled loops of bowel on the affected side of the chest with displacement of the mediastinum to the opposite side (Fig. 37.1).

Fig. 37.1 Diaphragmatic hernia (left-sided Bochdalek defect).

### Treatment

A nasogastric tube is passed to reduce the gaseous distention of the bowel with air. In the past the surgical repair of the hernia was a true emergency, it being felt that the sooner the hernia was reduced the more easily the lungs could expand. Babies were operated on virtually regardless of condition and the survival rates were poor. It has been shown that respiratory mechanics, far from improving, frequently deteriorate as a result of repair of the hernia. The role of urgent surgery has thus been re-evaluated. It has always been known that the babies with the least hypoplastic lungs fared better. These also tend to be the cases that present after hours rather than immediately at birth. Now an initial, non-surgical approach to diaphragmatic hernia has been adopted in most centers with the aim of improving pulmonary function and reducing pulmonary vascular resistance.<sup>2,3</sup> After diagnosis the baby is intubated and hyperventilated to reduce the PaCO<sub>2</sub> to < 4.7 kPa (< 35 mmHg) and paralyzed. Metabolic acidosis is corrected with bicarbonate therapy. A chest X-ray is taken to verify the endotracheal tube position and exclude a pneumothorax. A preductal arterial line (radial) is sited for blood gas and pressure monitoring. The ventilatory index (mean airway pressure × respiratory rate) is calculated and this should be < 1000 with a PaCO<sub>2</sub> < 5.3 (< 40 mmHg) prior to surgery. If the index is higher, high-frequency oscillatory ventilation is instituted. Tolazoline may be administered to reduce pulmonary vascular resistance and prevent shunting through the ductus arteriosus. In some centers extracorporeal membrane oxygenation (ECMO) is used for prolonged support with variable results. Whatever the method of stabilization preoperatively, it must be carried out in a surgical unit as it is the pediatric surgeon who must be in a position to determine the timing of surgery.

### Operative treatment

An abdominal approach is usually preferred with a transverse upper abdominal incision on the side of the hernia. The bowel and other organs are reduced and the defect in the diaphragm examined. If the defect is large a patch of prosthetic material may be used. Repairing a defect under tension merely reduces lung compliance. An underwater seal drain is positioned prior to completion of the repair. If the baby's condition is very stable the repair may be accomplished thoracoscopically.

Postoperatively, support is maintained until the baby can be weaned from the ventilator. A few patients who require little or no ventilatory support preoperatively may be extubated immediately. Of the remainder the mortality rate still remains around 50%, although it is hoped that the change in preoperative management will improve the outlook.

### Eventration of the diaphragm

This is due to a deficiency in the muscle of the diaphragm. The thin layer becomes attenuated and bulges up into the thorax. Extensive eventrations are similar to diaphragmatic hernia presenting in the neonatal period. Smaller eventrations present later and require localized plication.

### Esophageal atresia

Atresia is absence or closure of a normal body orifice or passage (Greek *a* = negative, *tresis* = hole). A fistula is an abnormal communication between two epithelial surfaces.

Esophageal atresia is a congenital defect of unknown etiology, the great majority of cases being associated with a tracheoesophageal fistula. The incidence is approximately 1 per 3000 live births. Many babies with esophageal atresia are premature and of low birth weight. The lower the birth weight, the greater the mortality. More than half the babies presenting with esophageal atresia have associated congenital abnormalities, commonly associated with vertebral, anorectal, cardiac, tracheoesophageal, renal and limb anomalies (VACTERL). This was formerly known as the VATER complex. The anatomical varieties of esophageal atresia and related disorders are illustrated in Figure 37.2.

### Clinical features

Maternal hydramnios is so common that all babies born to a mother with hydramnios should have a tube passed to assess the patency of the esophagus. In cases with esophageal atresia the tube will be arrested about 10 cm from the lips. If the diagnosis is not made in this manner then the baby will be noted to froth at the mouth, choke, cough or become dyspneic and cyanosed. These symptoms will be exacerbated by attempts to feed the baby. The patency of the esophagus should then be tested by a firm tube of at least 10 or 12 FG, which should be passed orally. Acid secretions aspirated from the tube may have refluxed through the fistula so radiological confirmation of the position of the tube is necessary if suspicion is high.

A Replogle tube is a double lumen plastic catheter that can be passed via the nose into the upper esophageal pouch, enabling continuous suction to be applied without causing damage to the mucosa. Suction is applied to the end of the catheter, air passing along the finer of the two lumina as secretions are aspirated. If the latter are particularly thick, careful irrigation may be carried out via the finer lumen tube.

A plain chest X-ray with gentle pressure on the Replogle tube enables the distal extent of the pouch to be ascertained. The presence of air in the stomach and bowel confirms the presence of a distal tracheoesophageal fistula (TEF) (Fig. 37.3). In the case of atresia without a fistula there

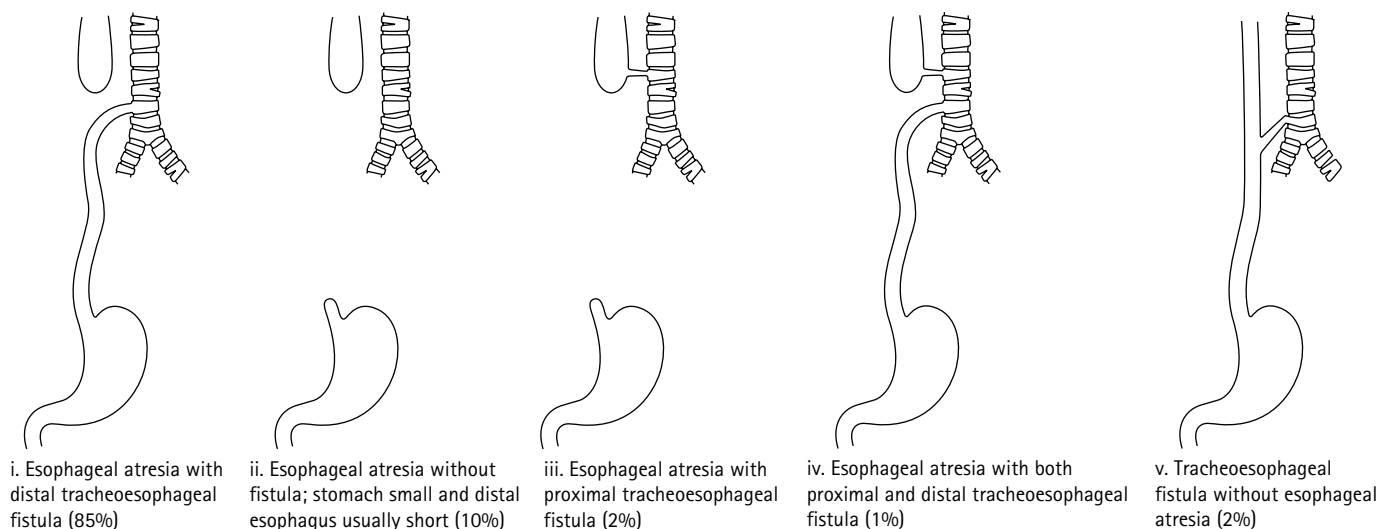

Fig. 37.2 Esophageal atresia and tracheoesophageal fistula.

Fig. 37.3 Esophageal atresia with distal tracheoesophageal fistula.

Fig. 37.4 Esophageal atresia without TEF.

is absence of air in the stomach (Fig. 37.4). Occasionally there may be associated duodenal atresia, but providing there is a TEF, then the gas pattern should clarify this (Fig. 37.5).

Some surgeons like to use 1–2 ml of contrast to define the upper pouch but there is great danger of spillage into the tracheobronchial tree and the procedure is unnecessary. Preoperatively, apart from adequate aspiration of the upper pouch, opinions differ as to the best position in which to nurse the baby. Some advocate the Trendelenburg (head down) position to prevent aspiration of secretions but this may lead to reflux of gastric content via the fistula into the lungs (especially the right upper lobe). Others, to prevent this, advise a head up position. A horizontal and semiprone position reduces the incidence of right upper lobe collapse and seems satisfactory.

### Treatment

In the commonest type of anomaly (with a distal TEF), surgery does not have to be performed immediately in the middle of the night but can be safely left until the following day. If pneumonitis is present, it is

Fig. 37.5 Esophageal atresia with duodenal atresia.

justifiable to delay treatment for 24 h or more to allow chest physiotherapy and appropriate antibiotics to be administered. A right posterolateral thoracotomy is made and, via an extrapleural approach, the fistula is divided and repaired and an end-to-end anastomosis between the proximal and distal esophagus is made in a single layer. A fine transanastomotic silastic tube is passed nasogastrically prior to completion of the anastomosis so that early nasogastric feeding can be instituted. In some centers the operation can be safely performed thoracoscopically.

On the fifth postoperative day a contrast swallow is performed to confirm patency of the anastomosis and exclude leakage at this site. If leakage is present it can usually be safely managed conservatively. Anastomotic stricture, if it occurs, is treated by esophagoscopy and bougienage or balloon dilation under X-ray control. Most children, following a successful repair, have a persistent brassy cough or 'seal bark' that may last for a few years. This is probably due to a degree of tracheomalacia.

Dysphagia due to abnormal motility in the esophagus both above and below the anastomosis may be due to vagal nerve damage or, more probably, an intrinsic abnormality associated with the lesion. This, like the seal bark, usually resolves by the age of 2 years.

Cases of esophageal atresia without a fistula are best managed initially by gastrostomy and aspiration of the upper pouch via a Replogle tube. In my experience, delayed primary anastomosis can be achieved after 3 months of regular stretching of the upper pouch by the nursing staff using a Nelaton catheter at feed times. Once there is radiological evidence of a gap of less than 3 cm, as visualized with a metal bougie in the lower pouch (passed per gastrostomy) and a radiopaque tube in the upper pouch, surgery can be carried out thoracoscopically or via thoracotomy. Postoperatively, the infants are electively paralyzed and ventilated for up to 7 d to relieve the tension on the anastomosis, a technique also of value in tight anastomosis in the common type of atresia with a distal fistula.<sup>4</sup> Others favor construction of a cervical esophagostomy followed by gastric transposition, jejunal or colonic interposition to bridge the gap between the upper pouch and the stomach.

### H-type tracheoesophageal fistula

These occasionally present in the first few weeks of life with coughing or cyanosis on feeding. More commonly they present much later with recurrent chest infections, a history of coughing on feeds, and sometimes abdominal distention. Because the fistula runs obliquely upwards from esophagus to trachea, the flow of esophageal content into the trachea is limited and intermittent. The diagnosis is made at a contrast swallow under screening. Treatment is surgical division of the fistula, usually via a cervical approach.

### DUODENAL OBSTRUCTION

Duodenal obstruction may be intrinsic (atresia, membrane, stenosis or anular pancreas) or extrinsic (Ladd's bands with or without volvulus of the midgut).

#### Intrinsic duodenal obstruction (Fig. 37.6)

The etiology of duodenal atresias and other intrinsic duodenal obstructions differs from that of intrinsic obstructions in the remainder of the small intestine. It appears to be a failure of luminal development due to an early insult and there are often associated abnormalities. Down syndrome is present in 30% of cases. In 10% there is esophageal atresia, and a further 10% have anorectal anomalies. Cardiac and renal anomalies may also be associated. Cardiac abnormalities are particularly common in those with Down syndrome.

Atresia or stenosis usually affects the second or occasionally the third part of the duodenum.

Complete obstructions present with vomiting within 24 h after birth. The vomitus may or may not be bile stained, depending on whether the obstruction is proximal or distal to the ampulla of Vater. In those with bile-stained vomitus the meconium, if passed, may also be normally bile stained as there may be openings of the bile duct proximal and distal to the obstruction via Wirsung's and Santorini's ducts.

In maternity units where passage of a nasogastric tube is a routine soon after birth, aspiration of more than 20 ml of fluid may be indicative of a duodenal or small bowel obstruction.

Abdominal distention, if any, is confined to the upper abdomen due to obstruction of the stomach and duodenum.

The diagnosis is confirmed by a plain erect X-ray that demonstrates the characteristic 'double bubble' appearance of air–fluid levels in the stomach and duodenum (Fig. 37.7). The double bubble may also be detected antenatally, ultrasound detecting fluid distention of the stomach and duodenum.<sup>5</sup> An incomplete obstruction, stenosis, or membrane with a small hole in it may allow air to pass through to the rest of the bowel, thus masking the double bubble (Fig. 37.8), but a contrast study confirms the presence of obstruction (Fig. 37.9). Sometimes the diagnosis may be delayed several months or even a year or two if sufficient food can pass through.

#### Treatment

If there is any delay in diagnosis of a duodenal obstruction then any resulting metabolic disturbance must be corrected preoperatively. At laparotomy a duodenoduodenostomy is the procedure of choice (Fig. 37.10), or for a stenosis or membrane a duodenoplasty may be performed,

Fig. 37.6 Duodenal anomalies.

Fig. 37.7 'Double bubble' in duodenal atresia.

Fig. 37.8 Plain film of baby soon after birth.

opening the duodenum lengthways across the obstruction and closing it transversely. Resection of a diaphragm must be undertaken cautiously to avoid damage to the ampulla of Vater.

An anular pancreas (Fig. 37.10a) is caused by the failure of the normal migration of the ventral bud to join the dorsal one. It is rarely a true ring around the duodenum but more commonly associated with an intrinsic obstruction within the duodenum (membrane or stenosis). A duodenoduodenostomy is performed with no attempt to divide the pancreas for fear of fistula formation.

Fig. 37.9 Upper gastrointestinal contrast study on same baby as Figure 37.8.

Fig. 37.10 (a) Anular pancreas with intrinsic duodenal membrane. (b) Duodenoduodenostomy with gastrostomy and transanastomotic silastic feeding tube.

### Extrinsic duodenal obstruction

Ladd's bands may obstruct the duodenum, occasionally alone but more commonly in association with a midgut volvulus (volvulus neonatorum). Such a volvulus may present in the neonatal period or at any age and arises due to an incomplete, or malrotation of the bowel. By the sixth week of intrauterine life the gut tube elongates to a greater extent than can be accommodated in the developing abdominal cavity and thus herniation through the umbilical ring occurs. During the next month the bowel undergoes an anticlockwise rotation returning to the abdominal cavity by the tenth week. By the time the stomach has rotated to the left, the duodenal C-loop has formed and the small bowel, followed by the large bowel, returns to the abdomen. The cecum and ascending colon pass to the right of the abdomen, the latter becoming retroperitoneal. The small bowel mesentery is then fixed between the duodenojejunal flexure and the ileocecal region. Failure of the cecum and ascending colon to reach their normal position results in a short base to the midgut mesentery and peritoneal bands passing from the cecum (in the midline or to the left side) to the right posterior abdominal wall. These bands (Ladd's bands) obstruct the duodenum. In addition, the short base to the mesentery allows a midgut volvulus to arise, the bowel rotating in a clockwise direction, and resulting in duodenal obstruction. A plain X-ray will show a double bubble and usually a small amount of gas in the bowel more distally. Contrast studies may confirm the diagnosis. An upper gastrointestinal study may show a duodenal obstruction and a typical coiled spring sign. An enema may show an anomalous position of the cecum.

Once any electrolyte or acid-base disturbance is corrected, laparotomy must be performed without delay to avoid ischemia of the midgut.

### SMALL BOWEL OBSTRUCTION

This may arise due to an abnormality directly associated with the bowel itself (intrinsic), pressure from without (extrinsic), or obstruction within the lumen (intraluminal).

#### Intrinsic anomalies

These are mainly atresias, membranes, stenoses and duplications of the bowel. Atresias may arise anywhere along the length of the bowel, being most common in the distal ileum and rarely seen in the colon. Their likely cause is an interruption of the mesenteric vessels in utero. These vary from membranous obstruction in continuity, those with or without an associated gap in the mesentery and multiple atresias, to the so-called apple-peel type deformity with extensive loss of mesentery and bowel, the distal small bowel receiving its blood supply from the middle colic vessels through a precarious continuity between marginal arcades (Fig. 37.11).

The bowel proximal to the obstruction is distended and hypertrophied and distally the bowel is collapsed, often with a microcolon (unused) although babies with obstructions of this kind may pass meconium of normal appearance. The latter is dependent on the timing of the vascular accident in utero.

The diagnosis is confirmed by plain X-ray, which will show a number of distended loops of small bowel with air-fluid levels in an erect view (Fig. 37.12). The level of obstruction can be estimated by the number of distended loops. There will be absence of air distal to a complete obstruction.

Contrast studies have a limited role in the diagnosis of such obstructions unless to exclude intraluminal or functional conditions.

#### Treatment

Preoperative treatment involves passage of a nasogastric tube and correction of electrolyte imbalance by appropriate administration of i.v. fluids. If the diagnosis is established early there is little or no requirement for i.v. resuscitation.

Operative treatment involves laparotomy, resection or tapering of grossly dilated bowel proximal to the atresia (to prevent problems of postoperative peristaltic inertia) and then anastomosis between the dilated proximal bowel and the collapsed distal bowel.

#### Duplications

Duplications of the alimentary tract can occur at any level from mouth to anus. A length of bowel may be duplicated, the two segments sharing a common blood supply and muscular wall yet having separate mucosal

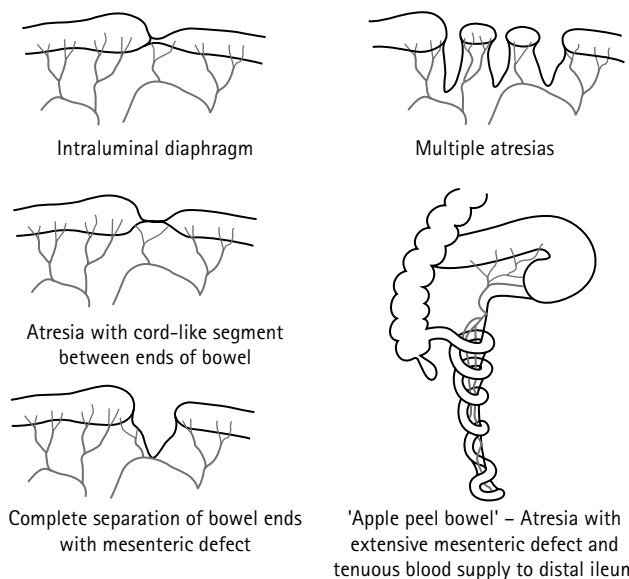

Fig. 37.11 Small bowel atresias.

Fig. 37.12 Jejunal atresia.

linings. They may or may not communicate, and it is the noncommunicating type that tends to form a short cystic segment which, by accumulation of secretions within it, leads to intestinal obstruction. Such duplications may be palpable as a cystic intra-abdominal mass that together with the signs of intestinal obstruction lead to the diagnosis. Ultrasound and contrast studies may be of value.

**Treatment.** The treatment usually involves a localized bowel resection but if the duplication is extensive in length or at a site such as the ileocecal junction, the mucosa of the duplicated segment should be dissected out, thus avoiding extensive resection or loss of the ileocecal valve.

### Extrinsic anomalies

Extrinsic anomalies leading to intestinal obstruction include hernias (inguinal or internal), localized volvulus, bands, vitellointestinal remnants and mesenteric cysts.

An incarcerated inguinal hernia is the commonest cause of intestinal obstruction at any age. The inguinal region must thus be carefully examined when any patient, neonate or older, presents with intestinal obstruction. Internal hernias are rare and can only be identified at laparotomy.

Localized volvulus may arise in relation to bands, duplication cysts and vitellointestinal remnants. Treatment at laparotomy varies according to the causative factor and the condition of the affected bowel. Mesenteric cysts may lead to local volvulus or may present as a palpable cystic mass. They are treated by resection.

### Intraluminal anomalies

Intraluminal causes of intestinal obstruction include meconium ileus, milk curd obstruction and meconium plug syndrome.

Around 10–15% of patients with cystic fibrosis present in the neonatal period with obstruction of the distal ileum (meconium ileus). The distal few centimeters of ileum contain pale grey 'rabbit pellets' of inspissated meconium proximal to which is a segment containing hard green-black meconium and, more proximally still, distended loops containing tarry fluid meconium and air. Distal to the obstruction is a microcolon

and usually no meconium is passed, presenting signs being abdominal distention and bile-stained vomiting within a few days of birth.

Plain abdominal films show gross abdominal distention with few fluid levels and often a ground glass appearance (of air bubbles in the viscid meconium) in the right iliac fossa. Sometimes there are signs of calcification from perforation and leakage of meconium antenatally.

Volvulus of the hypertrophied distended bowel may also lead to atresia, or perforation may occur after birth.

The presence of meconium ileus has no relationship to the subsequent 'severity' of the cystic fibrosis.

### Conservative management

Treatment can be either conservative or operative. Conservative management involves the administration of a Gastrografin enema under fluoroscopic control. Gastrografin with 0.1% Tween 80, a detergent, added as a wetting agent has a high osmolarity of 1900 mOsm/L and acts by drawing fluid into the bowel, thus freeing the inspissated meconium in the distal ileum. It is essential, therefore, that the baby is adequately hydrated and an i.v. infusion must be in progress. If necessary the procedure may be repeated after 24 h. If there is calcification the procedure is best avoided for fear of reperforation.

### Surgical management

For cases in which there are complications such as perforation or signs of meconium peritonitis (calcification) or after failed Gastrografin enema, operative treatment is required. Laparotomy is performed via an upper transverse abdominal incision. Intestinal resection is necessary for bowel that is grossly dilated or of doubtful viability. A Bishop Koop ileostomy may be performed. This is a Roux-en-Y anastomosis between the end of the proximal limb of ileum and the side of the distal limb, bringing the end of the latter out of the abdomen as an end ileostomy in the right iliac fossa. This acts as a safety valve through which the distal ileum can be irrigated. In the case of continued obstruction the stoma will function. Once it is relieved, bowel contents pass the natural way.

Milk plug or mild curd obstruction also occurs in the distal ileum and may be due to the administration of inappropriately concentrated artificial milk feeds, or possibly a transient low bile acid excretion. The management is similar to that described earlier.

### MECONIUM PLUG SYNDROME/SMALL LEFT COLON SYNDROME

Meconium plug syndrome must not be confused with meconium ileus. It is sometimes described as small left colon syndrome. The distal colon or rectum is plugged by sticky grey-white mucus distally with sticky meconium above it. The presentation is usually at about 2 d with a history of failure to pass meconium. There is evidence of low intestinal obstruction with generalized abdominal distention, frequently with a history of bile-stained vomiting and X-ray showing gaseous distention. There are multiple fluid levels present in the majority of cases.

The diagnosis is made by contrast enema. Initially barium is used to exclude Hirschsprung disease, but then changed to water-soluble contrast when the appearance of a meconium plug is seen in a narrowed left colon. The colon is usually narrow up to the splenic flexure, where it becomes dilated (Fig. 37.13). It has been postulated that there is a discrepancy in the activity of the parasympathetic supply from the vagus nerve (supplying the bowel to two thirds of the way across the transverse colon to the splenic flexure) and the sacral parasympathetics that supply the remainder. Whatever the etiology, the enema invariably proves to be therapeutic with satisfactory evacuation of meconium. The abdomen in most cases decompresses over 24 h and feeds can then be introduced. If bowel evacuation is not normal then Hirschsprung disease must be excluded.

### HIRSCHSPRUNG DISEASE<sup>6</sup>

Hirschsprung, a Danish pediatrician, described two patients who died at 7 and 11 months from constipation associated with gross abdominal

Fig. 37.13 Small left colon syndrome.

distention and a highly dilated hypertrophied colon full of feces. There is absence of ganglion cells in the myenteric plexuses (both Auerbach's and Meissner's) of the most distal bowel and extending proximally for a variable distance. Aganglionosis involving only the rectum or rectosigmoid is often termed 'short segment' Hirschsprung disease and affects males five times more commonly than females. 'Long segment' Hirschsprung disease, extending above the sigmoid, has an equal sex incidence and a greater likelihood of siblings being affected. In short segment disease there is a 1 in 20 risk that brothers will be affected and a 1 in 100 risk for sisters. In long segment disease the risk to all siblings is 1 in 10.

In a few cases there is total colonic aganglionosis with disease extending into the small bowel and in extremely rare cases involving the whole alimentary canal. At least 70% of cases are short segment, 25% long segment and about 5% total colonic.

Hirschsprung disease differs from many other alimentary tract abnormalities in that the birth weight is usually within the normal range. It is uncommon in premature and low birth weight babies. Associated congenital anomalies are uncommon apart from Down syndrome, which affects 1 in 20. The cause of the disease is unknown. It has been postulated that it is due to a failure of migration of ganglion cells from the neural crest, which normally proceeds in a craniocaudal direction having entered the upper end of the alimentary tract.<sup>7</sup> Differentiation of ganglion cells occurs in the wall of the gut between the seventh and eighth week of intrauterine life and proceeds in a craniocaudal direction.

### Clinical features

Usually the symptoms of Hirschsprung disease are manifest within the first few days of life. This is certainly the case in all long segment or total colonic cases but some short segment cases and especially 'ultrashort' segment cases may present later, even into old age.

Failure to pass meconium within the first 24 h, abdominal distention, bile-stained vomiting and reluctance to feed are the main symptoms. Diarrhea may be the presenting feature of Hirschsprung enterocolitis, a devastating complication of the condition that has a high mortality. The etiology of Hirschsprung enterocolitis is unknown but apart from

diarrhea it is associated with gross abdominal distention and circulatory collapse. A rectal examination results in the explosive passage of flatus and loose stool, deflating the abdomen.

### Diagnosis

A plain abdominal X-ray shows distended small and large bowel, sometimes with multiple fluid levels on an erect film. A barium enema is best carried out without a previous rectal examination as then the narrow aganglionic bowel with dilation proximally is demonstrated. A delayed film at 24 h, again avoiding an invasive rectal examination, shows retained barium and often a clear indication of the level of disease with a cone-shaped transition zone between normal bowel above and the narrowed aganglionic distal segment.

Definitive diagnosis is by rectal biopsy. A suction biopsy is adequate to confirm the absence of ganglion cells in the submucosal plexus, specimens being taken at 1 and 3 cm above the dentate line. Histochemical staining will demonstrate excessive acetyl cholinesterase activity in abnormal nerve trunks and absence of ganglion cells.

### Treatment

Once the diagnosis is made, bowel washouts may be sufficient to maintain bowel decompression prior to a laparoscopically assisted 'pull through' procedure. Others prefer a defunctioning stoma, proximal to the diseased bowel. A definitive procedure is then carried out when the infant is 3–12 months of age, depending on the surgeon's preference. It usually consists of excision of the aganglionic bowel and a pull through procedure.

If enterocolitis supervenes (and it can even happen after a definitive procedure, especially if an aganglionic segment remains), then rapid replacement of lost fluid by a suitable electrolyte solution, often preceded by plasma, is required. This should be combined with saline bowel washouts using a two tube technique, one to run saline in, preferably above the aganglionic segment, the other at a slightly lower level to allow evacuation. Broad-spectrum antibiotics are usually administered prophylactically although infection has not been shown to be the precipitating factor. Enterocolitis is the most lethal complication of Hirschsprung disease.

## UROLOGICAL PROBLEMS IN THE NEONATE

### Posterior urethral valves

The commonest obstructive uropathy in male children is valvular obstruction of the posterior urethra. Occasionally the diagnosis is made on antenatal ultrasound. A large proportion of cases present in the first 2 weeks of life, the majority in the first 6 months and the remainder, whilst usually becoming apparent in the first few years, may present as late as early adult life.

The neonate may present with retention of urine or dribbling and a palpably distended bladder with or without infection or uremia. Later presentation is usually with incontinence or infection.

The valves are classically folds of mucosa attached just below the verumontanum and attempts to void lead to apposition of the valves. The obstruction leads to dilation of the posterior urethra, the bladder, the ureter and renal pelvis.

As micturition commences in the fetus in the first trimester, the back pressure on the kidneys may lead antenatally to severe damage – renal dysplasia. Occasionally the bladder hypertrophy is such that reflux no longer occurs but the ureters remain dilated and tortuous.

### Diagnosis

A micturating cystourethrogram (MCU) is diagnostic in this anomaly, demonstrating the gross dilation of the posterior urethra and usually the refluxing dilated ureters and bilateral hydronephrosis.

### Treatment

Disruption of the valves is required. This may be effected by pulling the inflated balloon of a Fogarty catheter across the valves or by

delicately disrupting them with a Whitaker hook. A resectoscope can be used transurethrally and the valves either fulgurated or, to avoid a deep destruction of tissue, cut with a cold knife. If renal function is particularly poor, temporary drainage via bilateral cutaneous ureterostomies (preferably ring ureterostomies) may be required.

### Prune belly syndrome (triad syndrome)

This consists of deficiency of the anterior abdominal wall muscles, cryptorchidism and urinary tract deformities. The abdominal muscular deficiency is mainly in the lower abdomen, the whole abdominal wall taking on the wrinkled appearance of a prune (Fig. 37.14). The ribs may be flared outwards at the lower costal margin and respiratory infections are common.

Surgery is best avoided unless there is significant renal impairment. In severe cases ring ureterostomies may be required, followed at a later date by tapering and reimplantation of the ureters, trimming of the bladder, orchidopexies and excision and repair of the lower anterior abdominal wall. Some cases have a functional urethral obstruction, which may require urethrotomy. Other cases show urethral stricture or even a diverticulum at the site of the prostatic utricle.

### Urachal anomalies

The urachus in the embryo connects the bladder to the allantois. It is normally obliterated to form the median umbilical ligament. It may, however, persist as a patent urachus in the neonate, requiring repair. Occasionally the two extremities of the urachus close, leaving a cyst in the middle that becomes filled with secretions and may present as a mass or more commonly, when it becomes infected, as an abscess.

### Bladder exstrophy (ectopia vesicae)

This is part of a range of lower abdominal wall defects, ranging from epispadias, through exstrophy of the bladder, to the even more catastrophic vesicointestinal fissure or cloacal exstrophy.

In bladder exstrophy there is a lower abdominal wall anomaly in which there is wide separation of the pubic bones, the bladder surface

Fig. 37.14 Prune belly syndrome.

Fig. 37.15 Ectopic vesicae.

being flat and exposed with the two ureteric orifices clearly visible (Fig. 37.15). In the male there is complete epispadias with a strip of urethral mucosa on the dorsum of a short broadened, flattened penis. In the female there is also an epispadiac urethra with a bifid clitoris and separation of the labia anteriorly at the level of the vaginal orifice.

The bladder is best repaired soon after birth. If necessary, bilateral iliac osteotomies enable the pubic bones to be better approximated thus facilitating the repair. Careful construction of the bladder neck is vital to achieve subsequent continence, and in the male later repair of the severe epispadiac deformity is required. If the bladder repair is unsuccessful it may be necessary to carry out a urinary diversion procedure.

### EXOMPHALOS AND GASTROSCHISIS

These are two distinct conditions of different etiology. Although formerly exomphalos was believed to be more common, gastroschisis is now seen more frequently. Antenatal diagnosis of both conditions by ultrasound examination is now almost routine. Gastroschisis also gives rise to an elevated maternal serum alpha-fetoprotein and distinction from other anomalies such as neural tube defects is by ultrasonography. Gastroschisis is not an indication for termination of pregnancy whilst exomphalos major, with its high incidence (30–40%) of associated anomalies, may be.

#### Exomphalos

Exomphalos (omphalocele) is a herniation of intra-abdominal contents through the umbilical ring into the umbilical cord. Defects less than 4 cm in diameter are classified as *exomphalos minor* (Fig. 37.16). There are rarely associated abnormalities in this group.

*Exomphalos major* (Fig. 37.17), on the other hand, commonly has coexisting abnormalities and a defect greater than 4 cm in diameter, presumably arising through failure of development of the anterior abdominal wall prior to herniation of the midgut loop. In a large defect, not only the intestines (small and large) herniate but also the liver, spleen, stomach, bladder and even ovaries and fallopian tubes in the female. Incomplete or malrotation of the bowel is common and the associated abnormalities often include cardiac defects; 20% of cases are anencephalic. In the *Beckwith–Wiedemann* syndrome there is exomphalos, macroglossia and gigantism. The baby is large for his gestational age with an exomphalos, a big tongue and large solid viscera. There is also a facial nevus flammeus in the center of the forehead and odd indentations in the ear lobe (Fig. 37.18). There may also be pancreatic hyperplasia leading to severe neonatal hypoglycemia.

Fig. 37.16 Exomphalos minor.

Fig. 37.17 Exomphalos major.

Fig. 37.18 Earlobe indentations in Beckwith–Wiedemann syndrome.

An *omphalocele* is usually covered by a sac composed of the fused layers of amniotic membrane and peritoneum. The sac may rupture ante-, intra- or postpartum.

### Treatment

In a large omphalocele, conservative management may be appropriate in the neonatal period. Silver sulfadiazine dressings\* or simple alcohol solution should be applied daily until an eschar forms. Epithelialization of the sac from the periphery results over the ensuing weeks. It may take 3–4 months before the infant can be discharged home, returning for later surgical repair of the ventral hernia. Other methods of treatment include mobilization of skin around the defect and skin coverage or coverage with prosthetic material and later repair of the ventral hernia. If the defect is small enough, with stretching of the anterior abdominal wall, primary repair may be possible as in gastroschisis (see later). In cases with an apparently simple herniation through a small defect into the umbilical cord it is tempting to twist the cord to reduce the contained bowel into the abdominal cavity, then simply ligate the cord. Such a temptation must be strongly resisted as all too frequently there is a Meckel's diverticulum or another cause of adherence of the bowel to the sac and serious damage may result. Formal surgical repair is always indicated.

### Gastroschisis

Gastroschisis is a complete defect through all layers of the anterior abdominal wall extending up to about 3 cm in length and usually lying to the right of a normally attached umbilical cord (Fig. 37.19). It is almost as though a short transverse incision had been made with a scalpel antenatally. The etiology is unknown. Almost all the small and large bowel are eviscerated through the small defect – in most instances from stomach to rectum inclusive. Other organs are rarely apparent. The eviscerated bowel is markedly thickened, apparently foreshortened, matted together and often covered with a confluent gelatinous layer like 'gut in aspic'.

If possible, delivery should be in a perinatal center close to the regional pediatric surgical center. The decision whether to deliver the baby with exomphalos or gastroschisis by Cesarean section or vaginally is an obstetric one. The results of treatment of the baby are not significantly improved by cesarean delivery.

Fig. 37.19 Gastroschisis.

At delivery it is essential that the baby is placed in a plastic bag extending to above the level of the defect and leaving the head and, if necessary, the upper limbs exposed. The bowel must not be allowed to become contaminated, the baby being transferred in a transport incubator directly to the pediatric surgical operating table and the baby extracted from the bag aseptically, by the surgeon, once anesthesia is induced. The passage of a nasogastric tube prior to transfer reduces bowel distention and resulting ischemia if the anterior abdominal wall defect is very small. Transport in a polyethylene bag helps reduce hypothermia, which would otherwise result from heat loss by evaporation. These babies rapidly drop their temperature from 37°C to 35°C when exposed for even a few minutes to site an i.v. infusion. The application of warm saline soaked swabs is not a good idea as they rapidly cool, increasing the heat loss.

### Treatment

Recently bedside reduction with or without a preformed silo have changed the immediate management of gastroschisis.<sup>9,10</sup> Providing the temperature has been adequately maintained and no significant fluid loss has occurred, direct transfer to the surgical neonatal unit and direct reduction or application of a preformed silo achieve the best results. If the bowel is particularly matted then surgical reduction in theater may be required. Leaving the cord intact and not enlarging the defect with either technique gives the best cosmetic result. The defect is usually so small that the umbilicus is not eccentric in position.

Postoperatively, no ventilatory support is required for ward reductions. A prolonged ileus however necessitates i.v. nutrition for days or in some cases even weeks. The prognosis in gastroschisis cases treated in this manner is excellent.

### SACROCOCCYGEAL TERATOMA

The sacrococcygeal teratoma is the commonest teratoma presenting in the neonatal period. They tend to be large and protrude from the space between the anus and the coccyx (Fig. 37.20). The lesion is usually

Fig. 37.20 Sacrococcygeal teratoma.

covered in skin but the most protuberant part may be necrotic due to vascular compromise. The tumor may also extend up into the pelvis and a large retrorectal component is palpable in all cases. In a presacral teratoma there is no protrusion behind the anus and the presentation may be later in the first year of life.

The tumor may be both solid and cystic in nature. A very large tumor may give rise to dystocia and if diagnosed antenatally is best delivered by Cesarean section.

Treatment is excision within the first few days of life. A double 'chevron' incision is made with the baby in a prone position and with careful excision and reconstruction of the pelvic floor which, despite its gross stretching, recovers normal function (Fig. 37.21). Excision of the coccyx is an essential component of the operation as failing to do so may predispose to the development of a yolk sac tumor.

There is usually an elevated alpha-fetoprotein level in the baby at birth and this should decline appropriately following excision. Even benign tumors should be followed up into adulthood as recurrence of benign or malignant elements may occur.

### ANORECTAL ANOMALIES

Congenital anomalies of the anus and rectum are reported to occur in 1 in 1800 to 1 in 10 000 live births. In Edinburgh the incidence is 1 in 3100. There is a wide spectrum of anomalies and many attempts have been made to classify them. Recently a new international diagnostic classification system, operative groupings and a method of postoperative assessment of continence was developed by a large contingent of participants experienced in the management of anorectal malformations<sup>11</sup>.

An anatomical approach simplifies matters (Table 37.1).<sup>12</sup> The lesions are grouped according to whether the end of the rectum is above levator ani, *high* (supralelevator), or below, *low* (translevator). There is also an *intermediate*, partially translevator group. The essential component of the levator ani in these malformations is the puborectalis sling, which is the key to fecal continence.

Fig. 37.21 Postoperative appearance of Figure 37.20.

Table 37.1 Classification of anorectal malformations (Stephens 1984<sup>12</sup>)

Female	Male
<i>High</i>	<i>High</i>
Anorectal agenesis: With rectovaginal fistula Without fistula	Anorectal agenesis: With recto-prostatic-urethral fistula Without fistula
<i>Intermediate</i>	<i>Intermediate</i>
Rectovestibular fistula Rectovaginal fistula Anal agenesis without fistula	Rectobulbar urethral fistula Anal agenesis without fistula
<i>Low</i>	<i>Low</i>
Anovestibular fistula Anocutaneous fistula Anal stenosis Cloacal malformations Rare malformations	Anocutaneous fistula Anal stenosis Rare malformations

Fig. 37.22 Low anorectal anomaly.

In the male a high lesion commonly communicates with the urethra whereas in the female, with the genital tract intervening, the fistula is to the vagina. A low lesion may open onto the skin of the perineum, or in the male, track forwards along the median raphe of the scrotum (Fig. 37.22), or in the female, towards the vestibule. In addition, a severe cloacal anomaly may arise in girls with urethra, vagina and rectum opening into a common channel. Anal stenosis may arise in either sex and presents with the passage of toothpaste-like motions.

### Treatment

Anal stenosis is treated by graduated anal dilation with Hegar's dilators. A low lesion with a long subcutaneous tract should have the latter opened and anoplasty performed. An anovestibular fistula can also be managed by a cutback procedure. This may result in rather close proximity of anal and vaginal openings (shotgun perineum) but the perineum develops as the child grows, separating the orifices. To avoid this appearance some prefer to transpose the anal opening to a more normal site.

High and intermediate lesions, and low lesions where the diagnosis is not at first obvious, require a defunctioning colostomy in the neonatal period. A sigmoid colostomy will enable subsequent adequate wash-outs of the distal loop, a procedure that is especially important in lesions communicating with the urinary tract. Prophylactic antibiotics are also required in such cases.

Once the colostomy is established, formal contrast studies via the distal loop (distal loopogram) define the level of the lesion accurately. Definitive repair is then deferred for a few weeks or months depending on the preference of the surgeon. The procedure of choice is the posterior sagittal anorectoplasty described by de Vries and Pena,<sup>13</sup> requiring meticulous technique and a thorough understanding of the anatomy. Some now perform a laparoscopically assisted pull through.

### NEONATAL NECROTIZING ENTEROCOLITIS (NEC)

This condition is described in detail in Chapter 12. Presenting as it does with abdominal distention and bile-stained vomiting, it is occasionally considered that the baby has intestinal obstruction but the presence of blood in the stool and pneumatosis intestinalis, often with portal venous gas, are pathognomonic of NEC. The management is conservative, wherever possible with nasogastric decompression, i.v. feeding and broad-spectrum antibiotics. The criteria for surgical management include pneumoperitoneum, persistent and increasing abdominal tenderness and continued clinical deterioration despite appropriate medical management. Operative management includes resection of necrotic bowel and stoma formation. Occasionally localized drainage under local anesthesia is of value in extremely ill babies, with appropriate intervention at a later date. Conservatively managed survivors often develop intestinal strictures requiring later resection. Asymptomatic strictures identified on contrast studies are best kept under review, reserving surgery for symptomatic cases.

### BILIARY ATRESIA

Biliary atresia is a condition in which the extrahepatic bile ducts are grossly nonpatent. The condition is characterized by obstructive jaundice. There has traditionally been a division into 'correctable' biliary atresia, where only the distal ducts are occluded, and 'noncorrectable', in which the proximal ducts are occluded.

Presentation is with jaundice persisting beyond the first 2 weeks of life. Appropriate tests are carried out to exclude causes of hepatocellular disease (hepatitis A, hepatitis B, toxoplasmosis, rubella, cytomegalovirus, herpes, syphilis, listeriosis, galactosemia, fructosemia, alpha 1-antitrypsin deficiency, etc.) It is vital not to waste too much time awaiting the results of all tests as delay in treatment of biliary atresia will adversely affect the progress. Suspected cases must therefore be referred early to a center capable of undertaking the necessary investigation and surgery. Ultrasound will rarely show a gallbladder and may show increased hepatic parenchymal echoes in biliary atresia. An isotope liver scan using a <sup>99m</sup>Tc iminodiacetic acid (IDA) radiopharmaceutical will demonstrate good hepatic uptake but no excretion into the bowel at 24 h. In hepatocellular jaundice there is a decrease in hepatocyte clearance.

Some surgeons prefer to do a percutaneous liver biopsy, which may be strongly indicative of biliary atresia, but others proceed directly to operative cholangiography if there is a positive IDA scan. This is carried out through a small transverse right upper abdominal incision. The gallbladder is often small and fibrotic, making a cholangiogram impossible. Occasionally patency of the cystic duct and common bile duct may be identified and, rarely, biliary hypoplasia.

### Treatment

The procedure of choice for extrahepatic biliary atresia is Kasai's hepatic portoenterostomy. This was first described in Japanese in 1959 and only in 1968 in English.<sup>14</sup>

Kasai reports satisfactory bile drainage in 80% of cases. In other series this ranges from 35 to 75% (personal small series 75%). Many will develop portal hypertension and cholangitis (various modifications of Kasai's procedure are carried out to reduce this complication). Liver transplantation is of great value in cases that fail to achieve or maintain bile drainage following the Kasai procedure.

## SURGERY OF THE INFANT AND CHILD

### HEAD AND NECK, FACE AND MOUTH

#### Embryological abnormalities

##### *Branchial arch–abnormalities*

Sinuses, fistulae, cysts and cartilaginous elements may be apparent at birth or may be noted in infancy or later in childhood. These anomalies arise from the first and second pharyngeal arches and clefts. First cleft remnants are rare and include a tract from the external auditory canal to the upper lateral neck. They may present with recurrent abscesses in the neck, and treatment involves excision of the whole tract, usually a sinus, being blind ending at the external auditory canal. Abnormal development of the first arch results in cleft lip and palate, abnormal shape of the pinna, and deafness due to malformation of the malleus and incus.

Second branchial remnants are more common. In theory sinuses should be more common than fistulae but the reverse is true and cysts are the least common, often presenting in adult life. Fistulae have a skin opening over the anterior border of the lower third of the sternomastoid. This may be noted to discharge clear mucus. The tract passes upwards between the internal and external carotid arteries to open in the tonsillar fossa.

The length of this tract often necessitates two incisions to facilitate its removal, one being at the skin opening and the other parallel to it, at a higher level, to follow the tract through the carotid bifurcation.

Branchial cysts manifest themselves as they slowly enlarge with secretions, appearing in late childhood or young adulthood. They tend to lie deep to the anterior border of the upper third of the sternocleidomastoid muscle. They may become infected. The treatment is excision.

Cartilaginous branchial remnants may appear along the anterior border of sternocleidomastoid. They do not usually have an associated tract and are excised purely for cosmetic reasons.

##### *Thyroglossal cysts*

These are more common than branchial remnants. The thyroid develops as a diverticulum from the floor of the pharynx, leaving it attached to the foramen cecum (at the junction of the anterior two thirds, and posterior one third of the tongue) by a stalk, the thyroglossal duct, which is normally completely reabsorbed. The tract of a persistent thyroglossal duct should developmentally be ventral to the hyoid bone but differential growth results in part of the duct reaching its deep surface. A thyroglossal cyst arises typically in the midline of the neck anteriorly, or occasionally just to one or other side of the midline. By virtue of its attachment to the thyroglossal duct the cyst moves on swallowing or protrusion of the tongue (Fig. 37.23a–c). The cyst is usually at the level of or just below the hyoid bone but can be anywhere along the line of the duct. Surgery is best performed when the lesion is diagnosed, as infection may arise and lead to difficulty in complete excision. The operation involves not only removal of the cyst but the body of the hyoid and the tract must be followed up to the level of the foramen cecum. Failure to do this is likely to lead to recurrence.

##### *Dermoid cysts*

These usually occur at sites of embryological fusion. These may be in the midline. A dermoid cyst in the neck may be mistaken for a thyroglossal cyst although it will not move on swallowing or protrusion of the tongue. A common site is the external angular dermoid cyst in the eyebrow area at the outer angle of the eye. Occasionally there may be a dumbbell extension intracranially. They occur if ectodermal cells become buried beneath the skin surface during development. An inclusion dermoid cyst may similarly arise secondary to trauma.

##### *Cystic hygroma*

Commonly arising in the neck, these fluid-filled lesions of lymphatic origin may be found elsewhere, including the axilla and groin or, rarely, on the trunk. They are either present at birth, sometimes being diagnosed on antenatal ultrasonography, or may appear within the first 2 years or sometimes later. Usually arising in the posterior triangle of the neck,

they may sometimes be very large indeed, extending into the floor of the mouth and tongue, where complete excision may prove difficult, leading to disfigurement and occasionally the need for a tracheostomy. Infection leads to difficulty with subsequent surgery, which is thus best performed soon after diagnosis. Aspiration of the cysts and injection of a streptococcal derivative 'OK432' (Picibanil) is a treatment that is proving to be an effective alternative to surgery.<sup>15</sup>

##### *Salivary gland enlargement*

This may arise secondary to a calculus in a duct (the submandibular duct in particular). Parotid duct calculi are rare but recurrent swelling of the gland may be due to sialectasis, seen on a sialogram as dilated duct radicles. The treatment is to advise the sucking of acid drop sweets to promote salivary flow and at the same time massaging the gland from back to front. If infection supervenes then antibiotics must be administered.

##### *Ranula (Latin rana = frog)*

This is a sublingual cyst that may be small or may fill the floor of the mouth. It may be related to a salivary or mucus gland. It is thin walled and contains clear viscid fluid. Care is required not to damage the submandibular duct during its excision and marsupialization is often safer.

##### *Tongue tie*

A short lingual frenum leads to maternal anxiety regarding future problems with speech. Speech therapists confirm that there will be no speech problem and others that the anterior third of the tongue will grow and a normal appearance will result. Tongue tie may lead to difficulty with breast-feeding. Division of the tongue tie in a baby prior to appearance of dentition is a simple procedure for a surgeon in the outpatient clinic. In the older child, general anesthesia is required. Tongue tie may occasionally present beyond the first 2 years and the current author personally believes in division, as all children deserve to be able to stick their tongue out – if only to lick an ice cream!

##### *Cervical lymphadenopathy*

Cervical lymph nodes are readily palpable in most children. Lymphoma is rare, but persistent painless enlargement of a cervical node is best diagnosed by excision biopsy although it is reasonable to administer an antibiotic in doubtful cases and re-examine the child in 2 weeks. Cat scratch disease, *Toxoplasma* and both tuberculosis and atypical mycobacterial infections may occur and usually affect jugulodigastric and submandibular nodes.

In mycobacterial infections, nodes may feel fixed to deeper tissues and to skin and may caseate and discharge. Sinus formation may result from abscess rupture or incomplete excision. Antituberculous chemotherapy is necessary once the diagnosis has become established.

Acute suppurative cervical lymphadenitis usually results from an upper respiratory tract infection. Early administration of antibiotics may lead to resolution without abscess formation but if an abscess does form it should be allowed to point before drainage. Kaolin poultices seem old fashioned but are still of value in this process.

##### *Sternomastoid tumor*

This is the commonest cause of torticollis in childhood (other causes include hemivertebrae, acute fasciitis, cervical adenitis and ocular muscle imbalance). The cause of this lesion is unknown. It is more common in babies born by breech presentation and was considered to be a result of trauma to the muscle during delivery. It seems likely, however, that it arises in utero, resulting in breech presentation. Within the muscle there is an area of endomyosial fibrosis with atrophied muscle fibers surrounded by collagen and fibroblasts. The infant presents usually at 2–3 weeks of age with a hard swelling within the substance of sternocleidomastoid. The shortening of the muscle makes the infant look upwards and to the opposite side. It is important to commence physiotherapy as soon as the diagnosis is made. The parents are taught how to stretch the muscle by rotating the head towards the side of the tumor. These stretching exercises should be carried out twice daily and must continue

Fig. 37.23 (a) Thyroglossal cyst; (b) and (c) show elevation on tongue protrusion.

for at least the first year, diminishing in frequency thereafter. Failure to treat adequately leads to shortening of deeper cervical structures and craniofacial asymmetry. Surgical division of the muscle and deeper strictures is necessary in cases that fail to respond or are missed in the neonatal period.

### Thyroid swellings

(see Chapter 15).

### PYLORIC STENOSIS

Though often called congenital, hypertrophic pyloric stenosis only very rarely has its onset of symptoms at birth and has never been described in a stillbirth. Vomiting normally commences around 2–3 weeks of age, becoming more frequent and projectile. The vomitus is of gastric content (milk) and is never bile stained. It may become brownish or visibly bloodstained due either to an accompanying gastritis or to rupture of capillaries in the gastric mucosa from frequent vomiting. The baby fails to thrive, becomes constipated and dehydrated, developing a hypochloremic alkalosis from the loss of gastric acid.

Examination reveals a hungry, worried looking baby and if recently fed, visible gastric peristalsis, and a wave traveling from the left hypochondrium towards the right may be apparent (Fig. 37.24). The diagnosis is confirmed during a test feed. For this the surgeon and the nurse or mother sit facing in opposite directions, the surgeon to the left of the nurse (Fig. 37.25). The baby is fed with the bottle in the right hand or at the left breast of the nursing mother. The surgeon palpates the tumor with the left hand. It is felt as an olive-shaped mass that lies just to the right of the midline, in the right hypochondrium. Contraction of the tumor is noted with variation in palpability, thus confirming that it is not confused with a Riedel's lobe of liver, or similar anomaly. If difficulty is encountered in palpating the tumor, the passage of a nasogastric tube to wash out the stomach may facilitate the procedure (it may be that the filled gastric antrum has previously obscured the pylorus). This seemingly ritual routine not only enhances the chance of palpating the tumor but avoids the calamity of the baby vomiting over the examiner's trousers!

Most surgeons will only operate if they can palpate the tumor but if difficulty is encountered in palpation, ultrasound examination is now the diagnostic investigation of choice.

Fig. 37.24 Pyloric stenosis: visible peristalsis.

### Treatment

First the hypochloremic alkalosis together with any associated hypokalemia is corrected by administering 5% dextrose in 0.45% saline with added potassium chloride if required. Although the use of 0.45% saline takes twice as long to correct the deficit as normal saline would, it is safer to administer. Preoperative gastric lavage is also performed and the nasogastric tube left in situ.

Once the electrolyte and acid–base deficit is corrected, surgery is performed under general anesthesia. The universally accepted operation of choice is the pyloromyotomy attributed to Ramstedt.<sup>16</sup> Actually the first recorded use of this procedure was by Sir Harold Stiles<sup>17</sup> in the Royal Hospital for Sick Children, Edinburgh on 3 February 1910, a year prior to Ramstedt's operation performed on 28 July 1911 and published in 1912. Unfortunately Stiles' patient died on the fourth postoperative day, either from gastroenteritis or delayed chloroform poisoning!

The pylorus can be delivered through a right transverse upper abdominal or a periumbilical incision, and an incision is made from the pyloroduodenal junction well onto the antrum of the stomach. The incision extends down into the muscle, which is then spread bluntly, all muscle fibers being ruptured, allowing the intact mucosa to bulge. The pylorus is returned to the abdomen and the wound closed.

Fig. 37.25 Pyloric stenosis: test feed.

A laparoscopic approach is preferred in centers where the surgeons have the appropriate skills and is already proving to have better results with less postoperative gastric paresis.

Oral feeding can be commenced within 4 h. Some choose a graduated feeding regime of dextrose, half strength, then full strength milk introduced over 24–48 h. Others advise a more rapid return to normal feeds. Certainly breast-fed infants come to no harm from being returned to the breast initially for a short time, gradually increasing to normal feeding time.

Vomiting in the first 24 h postoperatively is not unusual and is presumably related to preoperative gastritis. If persistent it usually settles after gastric lavage. Most babies will be fit for discharge within 24–72 h after surgery.

### GASTROESOPHAGEAL REFLUX

This is due to incompetence at the cardia and is another cause of vomiting that may commence as early as the neonatal period. The condition may or may not be associated with a hiatus hernia. The infant vomits effortlessly at any time, and usually appears unconcerned about the problem. The vomiting need not be related to feed times. The vomitus may be coffee ground or streaked with bright red blood if there is associated peptic esophagitis. The diagnosis is confirmed by barium studies and pH studies together with endoscopy, if indicated. Most cases respond to conservative management of thickening the feeds, sitting the baby up at all times (although there is dispute about this) and the administration of an antacid such as Gaviscon. In more severe cases an  $H_2$  antagonist or a proton pump inhibitor is used. If, however, the infant fails to thrive, has persistent peptic esophagitis, recurrent aspiration pneumonitis or a proven large 'sliding' hiatus hernia, then a surgical antireflux procedure is required. If an esophageal stricture has already developed it will usually resolve after surgery but in some cases bougienage or balloon dilation is required. Various antireflux operations have been devised, the most popular being the Nissen fundoplication. The esophagus and the gastric fundus is mobilized, the right crus of the diaphragm tightened

and wrapped around the abdominal esophagus. This operation is now best performed laparoscopically,<sup>18</sup> reducing postoperative discomfort and length of hospital stay.

Children with severe neurological handicap are especially prone to gastroesophageal reflux and hiatus hernia. Usually their parents or carers welcome the surgical treatment of these children, as their well-being is so obviously improved. Presumably they suffer a great deal of discomfort related to esophagitis and their frustration is increased by their inability to complain. The results of surgery in such cases is invariably rewarding.

### INTUSSUSCEPTION

Intussusception is the invagination of part of the intestine into itself. An intussusception arising in the ileum may pass all the way round the large bowel to appear at the anus. The lead point is known as the *intussusceptum*, the sheath as the *intussusciptiens* and between these are the entering and returning layers of the bowel. Naturally, the mesentery with its vessels is drawn between the entering and returning layers, leading to engorgement of the vessels and diapedesis of red cells into the lumen of the bowel. Mucus is produced by the engorgement of the mucosal cells and, mixed with the red cells, creates the classic redcurrant jelly stool. Eventually a strangulating obstruction occurs and gangrene of the intussusceptum may result.

In infants the lead point is presumed to be an enlarged Peyer's patch, the lymphoid tissue presumably responding to a viral stimulant. This becomes the apex of the intussusception, which then proceeds for a variable distance into the colon. The peak incidence is in infants 3–9 months of age. The timing has been attributed to a change in the bowel flora associated with weaning. In older children the lead point may be an invaginated Meckel's diverticulum, a polyp, an enteric cyst, or hemorrhage into the bowel wall in Henoch-Schönlein purpura or leukemia. It is more common in boys than in girls, some reporting a ratio as high as 5:1, but in Edinburgh the ratio is only 1.2:1. Some report seasonal variation, possibly related to infectious agents.

The presentation is with a painful cry, drawing up the knees and going pale, presumably in relation to colic (88% in our series). The colicky pain is intermittent and occurs with increasing frequency as the condition progresses, rather like labor pains. Vomiting is a common symptom (86%) and the passage of redcurrant jelly stools is frequent (56%).

On examination, between attacks of colic, an abdominal mass is usually palpable. This is typically sausage shaped and commonly palpable in the ascending or transverse colon. A small percentage of intussusceptions present at the anus.

### Investigation

Plain abdominal X-ray will often show a filling defect corresponding to the intussusception and will demonstrate any obstruction by the presence of fluid levels within the bowel. Ultrasound can identify a 'target sign' corresponding to the layers of the intussusception. Occasionally a contrast enema may be used diagnostically in frankly obstructed cases.

### Treatment

First an i.v. infusion is set up. Some collapsed infants require blood or plasma for primary resuscitation, others only require isotonic fluids. A nasogastric tube may be passed, especially if vomiting has been a marked symptom at presentation. Preparation is as for a surgical reduction; the operating room is arranged in case it is required but in most cases non-operative reduction is first attempted. The only contraindications to non-operative management are a seriously ill child with a prolonged history, marked intestinal obstruction or evidence of peritonitis (rare).

Hydrostatic reduction has been intermittently popular since first advocated by Hirschsprung in 1876. A barium enema under X-ray screening is used as a therapeutic technique and is frequently successful. Recently air has been used for reduction rather than barium. (The

method has for centuries found favor in China, where fire bellows have traditionally been used.) Air is an excellent contrast medium and scientific control of the pressure is by attaching the rectal Foley catheter to a sphygmomanometer, increasing the pressure to 100 mmHg if necessary. This method appears to have a greater success rate than barium and in the rare occurrence of perforation, proves safer.

Surgical reduction is required for those in whom non-operative reduction fails. The intussusception is reduced manually by stripping it back from the point the apex has reached. Pulling on the entering layer of bowel can lead to serosal splitting or rupture of the bowel. Once the intussusception is reduced appendectomy is usually performed. This may help to prevent recurrence by adherence of the cecum in the right iliac fossa. If reduction proves impossible then a limited bowel resection may be required.

Recurrence rates of 2–4% have been recorded and seem unrelated to the method of reduction.

## APPENDICITIS

This is the most common condition for which emergency abdominal surgery is required in childhood. Its symptomatology and management are similar to those in adults although in the very young child there may be difficulty in making the appropriate diagnosis. Appendicitis is still a condition with significant morbidity and mortality. In a recent series, reporting on the last 5 years of the 1970s, there were four deaths related to appendicitis in children in Scotland. Delay in diagnosis can thus convert an eminently treatable condition into a lethal one.

Classically the condition presents with pain, vomiting and fever. The pain commences periumbilically, the distended appendix causing dull and poorly localized midgut pain via visceral nerve fibers to the tenth thoracic nerve root. The pathology of appendicitis is of spreading inflammation from the mucosa through the wall to the serosa. Serosal inflammation leads to peritoneal inflammation and the pain is accurately localized to the right iliac fossa – classically at McBurney's point (two thirds along a line from the umbilicus to the anterior superior iliac spine). Atypical presentation leads to difficulty in diagnosis, especially in the very young. Neonatal appendicitis is exceedingly rare and the mortality rate is high. In the preschool child the diagnosis is also difficult and a high perforation rate is encountered. The preschool child may present with anorexia, listlessness, fever, vomiting and diarrhea.

Care must be taken in the examination of the child with suspected appendicitis. The tongue may be coated and there is a classic 'fedor oris', a sweet smell on the breath perhaps partly related to ketones. The child is reluctant to climb onto the examination couch. The chest is examined to exclude a right lower lobe pneumonia, which may easily lead to a mistaken diagnosis of appendicitis. Examination of the abdomen must be very gentle, starting in the left lower quadrant and gradually working round each quadrant to finish in the right iliac fossa. Clumsy technique can lose a child's confidence and lead to voluntary guarding. Tenderness at McBurney's point remains the cardinal sign of appendicitis.

Involuntary guarding and rigidity are reliable signs of peritonitis or peritonitis. There is no excuse in endeavoring to elicit rebound tenderness as, if present, the child's confidence is immediately lost, the pain being so severe, thus precluding subsequent examination. Likewise, rectal examination should be reserved for cases with negative or equivocal abdominal findings, where it may be the only means of diagnosis of a pelvic appendicitis. It may otherwise confirm a diagnosis of constipation or, in females, gynecological disease. It must be remembered that the appendix can adopt a variety of intra-abdominal positions circumferentially around the attachment to the cecum. A retrocecal appendix may have few abdominal signs initially, although psoas spasm may be apparent.

There are no investigations that can prove the presence of appendicitis. The white cell count need not be raised and an X-ray, whilst occasionally showing a fecolith, is generally unhelpful. Ultrasound is now of value in recognizing a thickened appendix with surrounding edema.

The differential diagnosis includes intestinal diseases such as gastroenteritis, Crohn disease and other causes of terminal ileitis such as

*Yersinia* infection, Meckel's diverticulitis and leukemic typhlitis, mesenteric adenitis and deep iliac adenitis. In addition, gynecological problems such as salpingitis and ovarian cysts must be considered. Urinary tract infection may also be confused with appendicitis, the situation being further complicated by the possible occurrence of pyuria when an inflamed appendix is adjacent to the bladder. Finally, medical disorders such as right basal pneumonia, diabetes mellitus, Henoch–Schönlein purpura and sickle cell disease have all been misdiagnosed as appendicitis. In fact almost all causes of acute abdominal pain in childhood must be considered but appendicitis is the commonest surgical emergency.

## Treatment

If necessary, preliminary resuscitation of the patient by administration of i.v. fluids should be considered. Once the patient has been adequately hydrated then appendectomy is carried out through a skin crease incision an inch or more below McBurney's point to leave a neat scar well below the 'bikini line' or preferably a laparoscopic approach is used. At induction of anesthesia a single dose of broad-spectrum antibiotics such as an aminoglycoside and metronidazole, to cover bowel flora including *Escherichia coli* and *Bacteroides fragilis*, is administered to endeavor to prevent postoperative complications such as wound infections and intra-abdominal abscesses, especially pelvic and subphrenic. If an appendix mass is palpated some prefer conservative management with bed rest, i.v. fluids and antibiotics with an interval appendectomy at 3 months. Others proceed to appendectomy appropriately covered by antibiotic therapy.

## PRIMARY PERITONITIS

This has a similar presentation to appendicitis but without a history of central pain moving to the right iliac fossa. The abdominal signs are those of peritonitis especially in the lower abdomen. At operation diffuse peritonitis is found with peritoneal exudate, yet no obvious focus of infection. The commonest causative organisms are pneumococci and streptococci. The source of infection has been thought to be the genital tract, the condition being commoner in girls, but the occasional occurrence in boys leads one to suspect blood-borne spread. There may be a preceding or coexisting upper respiratory tract infection. The management is appropriate antibiotic therapy (usually penicillin).

## MECKEL'S DIVERTICULUM

Meckel's diverticulum arises from the vitellointestinal duct, which leads from the primitive gut to the yolk sac. Persistence of the proximal end of the duct occurs in 2% of the population (the 2 ft from the ileocecal valve, 2 in long story is erroneous: it may be a variable length and variable distance from the ileocecal valve).

The vitellointestinal duct can lead to a number of anomalies if it persists (Fig. 37.26). The duct itself may remain patent to the umbilicus and thus present as a fistula in neonates. Partial obliteration may give rise to cyst formation or a persistent fibrous cord from the umbilicus to the ileum may act as an axis for localized volvulus or lead to bowel obstruction.

A Meckel's diverticulum may become inflamed, lead to hemorrhage or invaginate into the ileum and cause intussusception. Meckel's diverticulitis has an identical presentation to acute appendicitis and must always be considered if a normal appendix is identified at surgery.

Bleeding in relation to a Meckel's diverticulum arises because the lining often contains heterotopic gastric mucosa (35–49%). This leads to peptic ulceration of the adjacent normal ileal mucosa (Fig. 37.27). Bleeding usually occurs in preschool children, especially toddlers. It may be intermittent passage of a small amount of altered blood in the stool, although massive hemorrhage with the passage of maroon or even bright red blood is more common. After adequate resuscitation, with blood replacement, a Meckel's scan should be performed. This is a <sup>99m</sup>Tc pertechnetate isotope scan that has an affinity for parietal cells. The stomach is visualized on the scan image, together with the bladder,

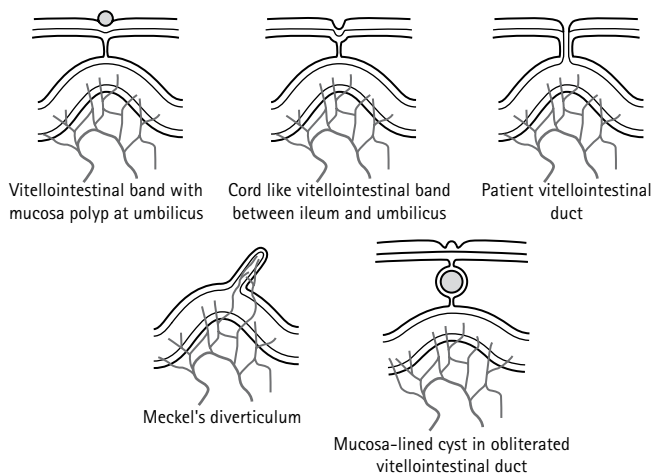

Fig. 37.26 Vitellointestinal remnants.

Fig. 37.27 Peptic ulcer at junction of gastric and ileal mucosa in Meckel's diverticulum.

as the isotope is excreted through the kidneys. A third 'blob' of isotope is likely to indicate ectopic gastric mucosa in a Meckel's diverticulum (or rarely in a duplicated segment of bowel). Priming the patient with cimetidine for a few days enhances the scan image. Laparoscopy can avoid the need for a scan and even in the absence of a Meckel's demonstrate the presence or absence of blood in the upper small bowel. An appropriate upper or lower gastrointestinal endoscopy can then be performed under the same anesthetic.

The treatment is in all cases Meckel's diverticulectomy, the diverticulum being found on the antimesenteric aspect of the ileum 40–100 cm proximal to the ileocecal valve.

**SUPERIOR MESENTERIC ARTERY SYNDROME**

This syndrome, a cause of acute and chronic abdominal pain in childhood, is due to obstruction of the third part of the duodenum by the superior mesenteric artery. It has variously been called 'Cast syndrome', 'Wilkie's syndrome', 'chronic duodenal ileus' and 'arteriomesenteric duodenal compression syndrome'. It may be congenital or acquired, the latter being due to rapid growth without associated weight gain, rapid weight loss or from hyperextension of the vertebral column in a plaster cast. The presentation may be acute or chronic with acute obstructive symptoms or intermittent abdominal pain and vomiting. Contrast studies, if performed between attacks, may show little but if performed in an acute episode will demonstrate obstruction of the third part of the duodenum. The superior mesenteric artery normally subtends an angle of 45 degrees with the aorta but under the conditions described earlier

the angle may decrease to 15 degrees, thus occluding the underlying duodenum.

Management is conservative or surgical, the former being alteration of diet, nursing prone and removing or windowing a plaster cast if present. Surgical management entails division of the ligament of Treitz and transposition of the small bowel to the right side in a position of nonrotation.<sup>19</sup>

**CHOLEDOCHAL CYST**

This is a cystic dilation of the choledochus (the common bile duct). The etiology is unknown but some believe it to be related to the reflux of pancreatic secretions into the common duct. The presentation may be in infancy with obstructive jaundice suggestive of biliary atresia, or in the older child with intermittent jaundice, abdominal pain and vomiting often associated with fever suggestive of ascending cholangitis. The diagnosis is by ultrasonography. Treatment consists of excision of the cyst and a Roux-en-Y choledochojejunostomy or hepaticojejunostomy. Failure to excise the entire cyst may result in carcinoma of the cyst wall in the long term.

**CHOLELITHIASIS**

Gallstones are uncommon in childhood but must be considered in children with hereditary spherocytosis. If metabolic stones develop then cholecystectomy is required, but in hemolytic disease the gallbladder is usually normal and simple cholecystotomy and removal of the stones is all that is required. This procedure should always be considered at the time of splenectomy in these children.

**INGUINAL HERNIA AND HYDROCELE**

These conditions have the same origin in childhood – the presence of a patent processus vaginalis. The only difference between them is the caliber of the processus (Fig. 37.28). If wide a hernia is produced, if narrow then peritoneal fluid may tract down to the tunica vaginalis. This explains the use of the term 'hydrocele' from the Greek *hydro* = water, *kele* = hernia. (A similar derivation applies to encephalocele, omphalocele, ureterocele, etc.) Frequently hydrocele is spelt, erroneously, 'coele', even in textbooks: it is not derived from coelom (Greek *koiloma* = hollow).

The processus vaginalis is an outpouching of peritoneum drawn down by the descent of the testis. The distal portion persists as the tunica

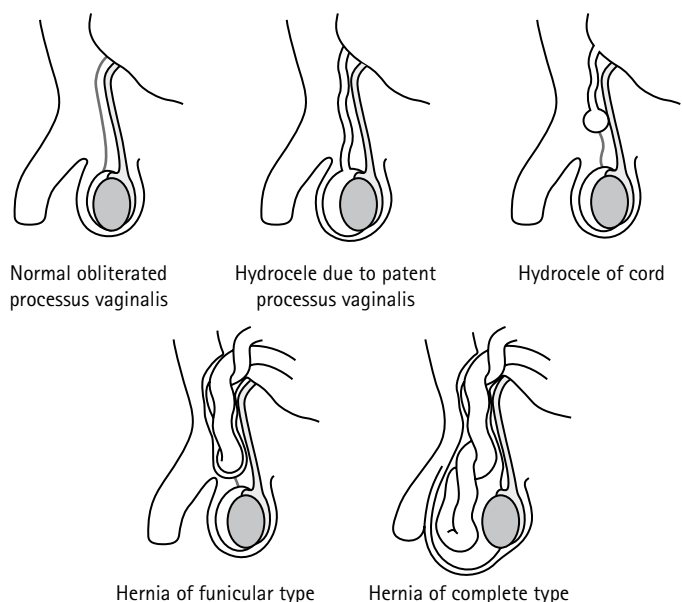

Fig. 37.28 Inguinal herniae and hydroceles.

vaginalis but the intervening communication with the peritoneal cavity is normally obliterated. Persistence of a widely patent processus along its whole length results in a hernia of the 'complete' type – a scrotal hernia. Obliteration of the distal portion results in a 'funicular' hernial sac. Similarly, a hydrocele of the cord can arise, the distal portion being obliterated and the proximal communication narrowed.

These conditions are more common on the right side than the left, presumably related to the later descent of the right testis. They may also arise in girls, although hernias are less common. Occasionally an ovary may prolapse into a hernia – at surgery it must be inspected to confirm that it is indeed an ovary and not a testis in testicular feminization syndrome (Fig. 37.29). Chromosomal analysis may be of value in excluding this condition in girls with bilateral hernias but the incidence is extremely low. The hydrocele equivalent in a female is a hydrocele of the canal of Nuck – a small diverticulum of peritoneum accompanying the round ligament of the uterus through the inguinal canal.

In general, hydroceles are only treated surgically if they persist beyond the age of 1 year, the majority resolving spontaneously prior to that. In toddlers there is often a history of a hydrocele increasing in size towards the end of the day – the fluid slowly returns to the peritoneum through the narrow processus when the child is recumbent at night. Surgery consists of ligation and division of the patent processus vaginalis through a small inguinal incision.

Inguinal hernias are treated with a similar operation. If the hernia is not obvious on examination, despite a typical history, tickling may increase the intra-abdominal pressure to demonstrate the hernia, but its presence can be confirmed by rolling the spermatic cord over the pubic bone with the index finger, thickening being apparent in the presence of a hernia.

If a scrotal swelling is present, a hydrocele can usually be distinguished from a hernia by the fact that the surgeon can get above it. Rarely does a hydrocele extend up into the inguinal canal. Transillumination may be misleading, as the thin bowel wall with intraluminal fluid in a young infant will also transilluminate. The surgery is a semi-urgent herniotomy. There is no requirement for herniorrhaphy (repair).

Incarceration of an inguinal hernia implies irreducibility, which will lead to strangulation of the bowel if left untreated. Gentle reduction is attempted. Force must not be applied and unless reduction is easy the child should be sedated with i.m. morphine and tipped head down; occasionally gallows traction is of benefit. If reduction is unsuccessful, immediate surgical reduction and herniotomy are necessary. If it is successfully reduced then herniotomy must be performed before the infant is discharged.

Confirmation of the previous incarceration may be made by observing an increase in testicular size on the affected side (a positive Robarts' sign). This results from venous obstruction of the pampiniform plexus, which can result in testicular infarction in cases where the hernia is not urgently reduced.

Fig. 37.29 External female genitalia and normal testis in testicular feminization syndrome.

## FEMORAL HERNIA

This is uncommon in children but, as in adults, is recognized by the swelling lying below the inguinal ligament and lateral to the pubic tubercle. Femoral herniorrhaphy is required.

## UMBILICAL HERNIA

By the time the umbilical cord has separated in the newborn the umbilical ring has usually closed but in a proportion of children a defect is left, resulting in an umbilical hernia. There is a higher incidence of this condition in blacks than in whites. Umbilical hernia occurs in Beckwith syndrome, Hurler syndrome, trisomy 18, and trisomy 13.

The vast majority of umbilical hernias will resolve spontaneously within the first 2 years of life. Incarceration and strangulation in umbilical hernias in childhood are so rare that they need not cause concern. Persistence of the hernia beyond the age of 2 years merits surgical repair, provided that care is taken to ensure that the incision lies within the umbilical folds.

A *paraumbilical hernia* usually lies in the linea alba immediately above the umbilical ring. This will not close spontaneously and surgical repair is required.

## EPIGASTRIC HERNIA

An epigastric hernia occurs through the linea alba, usually midway between the xiphisternum and the umbilicus. It presents as a pea-sized swelling occasionally associated with pain and results from herniation of extraperitoneal fat through the defect. It is best treated surgically although it can safely be left alone.

## SURGICAL ASPECTS OF THE GENITOURINARY TRACT

### ANOMALIES OF TESTICULAR DESCENT

It is best to consider the following distinct entities: the testis arrested in the normal line of descent (true undescended), ectopic testes and retractile testes. In addition, testes may be atrophic or absent (anorchia).

#### Testes arrested along the normal line of descent

The term *cryptorchidism* (Greek *cryptos* = hidden, *orchis* = testis) should be reserved for impalpable, usually abdominal, testes. There is a higher incidence of undescended testes in premature than in full-term babies. Two thirds of undescended testes in newborn infants will descend, usually by 6 weeks in term and 3 months in preterm babies. There is an increased incidence of cryptorchidism in anencephalics and other cerebral anomalies.

#### Ectopic testes

These have descended as far as the external inguinal ring and then become deviated into the superficial inguinal, perineal (Fig. 37.30), suprapubic or femoral ectopic sites. The commonest by far is the superficial inguinal pouch, above and lateral to the external inguinal ring.

#### Retractile testes

The cremasteric reflex in young children will draw the testes into the region of the superficial inguinal pouch very readily but they can be manipulated back down to the bottom of the scrotum. The testis would normally reside in the scrotum if such a child is in a warm bath or relaxed in bed.

#### Anorchia

Anorchia may be on one or both sides. If on one side alone there may be ipsilateral renal agenesis. If the baby is fully masculinized but both testes are absent it must be assumed that they have atrophied subsequent to torsion or infarction during development. Absence of testicular tissue

Fig. 37.30 Perineal ectopic testis.

and therefore lack of Müllerian inhibitory hormone during early gestation can lead to Müllerian development along female lines. The lack of androgenic stimulation (testosterone) from the testes leads to failure of Wolffian duct development.

### 'Ascending testis'

Some boys with recorded testicular descent at routine clinic checks in infancy may be found later at preschool or school medicals to have an undescended testis. This phenomenon of the 'ascending testis' was noted first by Atwell.<sup>20</sup> It has been suggested that this is caused by failure of elongation of the spermatic cord during differential body growth, so that the testis is drawn up by absorption of the processus vaginalis.

### Treatment

It has been shown that adverse morphological changes occur in undescended testes from the second year of life onwards with a statistically significant reduction of spermatogonia and tubular growth. Most surgeons therefore choose to perform orchidopexies between 2 and 3 years of age. An associated hernia is an indication for earlier surgery. There is no place now for delaying surgery until 9 or 10 years of age. Any testis that has not descended in the first year of life will not appear later.

The treatment of the true undescended testis and the ectopic testis is orchidopexy, the testis and cord being mobilized via an inguinal approach and usually fixed in the scrotum in a subdartos pouch. Intra-abdominal testes may best be treated laparoscopically in a staged Fowler-Stephens procedure where in the first stage the testicular vessels are divided and 3–6 months later the testis may be advanced to the scrotum supplied by the artery to the vas, which has had time to hypertrophy.

### Malignancy in the undescended testis

Testicular malignancy occurs in 0.0021% of adult males. Undescended testes occur in 0.28% of the population and 12% of cases of testicular malignancy are reported to occur in testes known to have been undescended. There is thus a 40 times greater incidence of malignancy in cryptorchid patients than in the general population. Orchidopexy probably does not eradicate the problem but at least the testis is placed in a position where early malignancy may be detected. In unilateral undescended testes there is also an increased risk of malignancy in the contralateral testis.

### Fertility

Only one third of those following bilateral orchidopexy and two thirds of those after unilateral orchidopexy appear to have a sperm count sufficient to be potentially fertile. It is hoped, however, that these figures will be improved by the change in policy over the past few years to operate on the majority of cases in the second year of life.

## THE ACUTE SCROTUM

This may result from torsion of the testis, torsion of a testicular appendage, epididymo-orchitis or idiopathic scrotal edema or, rarely, a testicular tumor.

### Torsion of the testis

Torsion of the testis most commonly occurs in the neonatal period or at puberty, with a few cases presenting in the intervening years. In the neonate the torsion occurs outside the tunica vaginalis. In the neonatal period there is a plane of mobility between the tunica vaginalis and the outer layer of the scrotum. Presentation is with a reddened hemiscrotum with a hard, swollen, often indurated testis. This is not infrequently noted 24 h after birth although the torsion may have occurred at delivery. On exploration, through a groin incision, the testis is often black and infarcted but usually it is 'given the benefit of the doubt', untwisted and replaced in the scrotum, although the majority will atrophy.

After the newborn period, torsion occurs secondary to an abnormally high investment of the tunica, the testis often being described as having bell-clapper fixation. Presentation is with pain, which is usually testicular in position but theoretically, as testicular innervation is from T10, it should be felt centrally in the abdomen. Examination reveals a swollen hemiscrotum often with edema and erythema, depending on the length of history. There is exquisite tenderness on palpation. The treatment is emergency surgery as delay will affect the viability of the testis.

Preoperative isotope scanning or Doppler probing to confirm the diagnosis merely wastes time. The scrotum is explored, the testis derotated and, providing surgery is carried out within 6 h, the testis is likely to become pink under warm towels. It is then fixed in the scrotum. As the anomalous tunical attachment is likely to be bilateral, orchidopexy is also performed on the other side.

### Torsion of testicular appendages

Embryological remnants are commonly attached to the testis. The hydatid of Morgagni is attached to the upper pole and is a Müllerian duct remnant. It varies in size from a pinhead to a pea or may be absent. Other remnants include the appendix epididymis (a Wolffian tubercle remnant), the paradidymis or organ of Giraldés (another mesonephric remnant) and the vas aberrans of Haller. The hydatid of Morgagni is the most common to undergo torsion, which leads to less acute pain than testicular torsion, the pain being usually at the upper pole of the testis where occasionally a bluish nodule is seen through the scrotal skin. An infarcted hydatid can give rise to considerable swelling and inflammation and doubtful cases are best explored (Fig. 37.31) to exclude testicular torsion. In any case, the necrotic hydatid is best excised as an emergency, giving instant pain relief. If treated conservatively the pain lingers on for up to 2 weeks.

### Epididymo-orchitis

This is rare in children unless there is an associated renal tract anomaly. If the latter has already been established then it is safe to treat with antibiotic therapy. If, however, the clinical picture cannot be distinguished from torsion of the testis, exploration is mandatory to establish the diagnosis.

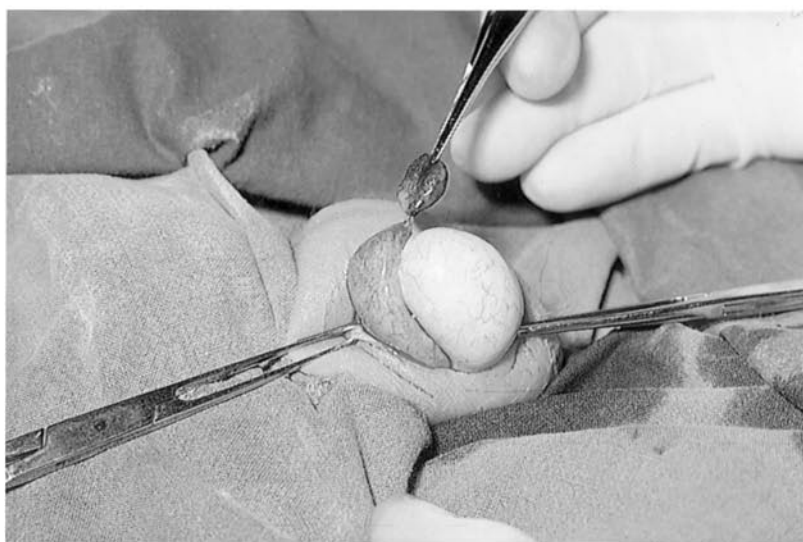

### Idiopathic scrotal edema

This is a fascinating entity presenting with erythema and edema of the scrotum suggestive of a possible underlying torsion. The erythema and edema spread beyond the scrotum however into the groin and perineum (Fig. 37.32). Usually the process is confined to one side of the scrotum and the adjacent groin and perineum.

The etiology is unknown. It may be an allergic phenomenon; it is occasionally associated with an eosinophilia and may respond to anti-histamine therapy. Some suggest it may be caused by an insect bite. The testis is nontender and the condition settles within a few days.

## CIRCUMCISION

Routine circumcision of the newborn as commonly practiced in the USA is to be condemned, the incidence of complications, including death, far outweighing the supposed advantage of avoiding such problems as carcinoma of the penis. The latter is virtually unknown in those who practice adequate hygiene. The fact that it is 'more hygienic' is often used as an excuse for circumcision but one does not chop off the ears to save washing them, or the feet because they may smell! It has been suggested that lack of carcinoma of the cervix in Jewish women is related to male circumcision but Aitken-Swan & Baird<sup>21</sup> showed no difference

in incidence in wives of circumcised and uncircumcised men. In 1975 a committee of the American Academy of Pediatrics stated: 'There is no absolute medical indication for the routine circumcision of the newborn. A program of good penile hygiene, simply retracting the foreskin to wash away accumulated smegma on a daily basis, would appear to offer all the advantages of circumcision without the attendant surgical risks or the increased risk of meatal stenosis'.<sup>22</sup>

Nonretractability of the prepuce, in childhood, should not be used as an excuse for 'lopping off an innocent and useful appendage'. Bokai<sup>23</sup> in 1869 was the first to draw attention to the physiological adherence

Fig. 37.32 Idiopathic scrotal edema.

Fig. 37.33 Fibrous phimosis (balanitis xerotica obliterans).

of the foreskin, there being fusion of the glans and the prepuce developmentally. Diebert,<sup>24</sup> in 1933, showed that separation of the prepuce in the human penis is due to keratinization of the subpreputial epithelium, a process not complete at birth but accomplished during early childhood. Phimosis (a muzzling, from Greek *phimos* = muzzle) is thus physiological at birth.

Apart from religious or tribal reasons there are few indications for circumcision. The only valid one is a fibrous phimosis (Fig. 37.33). This may be due to inappropriate attempts at retraction at an early age, causing splitting and scarring of the preputial meatus, or perhaps is related to recurrent infections. In its most severe form it presents as balanitis xerotica obliterans with scarring of the underlying glans and urethral meatus. Meatal strictures also arise after neonatal circumcision secondary to meatitis, which arises in the absence of the protective covering of the foreskin. Ballooning of the foreskin is often seen as an indication for circumcision but it will usually resolve in time. Recurrent balanitis or balanoposthitis is possibly related to partial separation of preputial adhesion and infection of inadequately draining secretions. This can readily be resolved by separation of the adhesions. Previously this was normally carried out under general anesthesia but with the advent of EMLA cream (eutectic mixture of local anesthetics) the separation can readily be carried out painlessly and simply in the outpatient clinic or GP surgery.<sup>25</sup> Daily retraction with application of petroleum jelly for a few days to prevent readherence followed subsequently by normal preputial hygiene is all that is required.

In examination of the foreskin in small boys it often appears tight on attempted retraction. The simple technique advocated in 1950 by Sir James Spence<sup>26</sup> should be adopted: 'Retract the prepuce and you will see a pinpoint opening, but draw it forward and you will see a channel wide enough for all the purposes for which the infant needs the organ at that early age. What looks like a pinpoint opening at 7 months will become a wide channel of communication at 17 years.'

## Operation

Circumcision is thus performed either for religious or tribal reasons, for fibrous phimosis or, perhaps most frequently, for remuneration! Hypospadias is a contraindication for neonatal circumcision, as is a buried penis. Neonatal circumcision is practiced, often without anesthesia using a Plastibell or a Gomco clamp. In the former, a plastic ring is placed under the foreskin and a string tied round the foreskin in a groove in the plastic device. Redundant skin together with the device separates off within a few days, leaving a very neat cosmetic result. A Gomco clamp has a similar action but rather than the string, a cutting device removes the prepuce and compresses the skin edges causing them to fuse and prevent hemorrhage. In older children a surgical cutting technique with absorbable sutures is used. In many cases of phimosis a foreskin preserving preputioplasty is sufficient.

## PARAPHIMOSIS

This occurs when a narrowed foreskin is retracted behind the corona glandis penis and cannot be returned. The constriction leads to engorgement of the glans and of a cuff of foreskin distal to the tight band but behind the corona (Fig. 37.34). Firm manual compression with gauze and EMLA cream will usually reduce the edema and facilitate return of the foreskin. If this fails, injection of hyaluronidase into the swollen ring of prepuce, under general anesthesia, followed by compression, allows reduction (Fig. 37.35). Occasionally the tight constricting band needs to be incised. Circumcision is frequently advocated following paraphimosis but, surprisingly, the foreskin is usually easily retractable a fortnight after the event and recurrence is exceptional.

## HYPOSPADIAS (Greek *hypo* = below, *spadon* = rent)

This is one of the commonest congenital anomalies, occurring in 1 in 400 live male births. The meatus lies in an abnormal position on the ventral aspect of the penile shaft or even scrotally or perineally. The

Fig. 37.34 Paraphimosis.

Fig. 37.35 Reduced paraphimosis.

foreskin tends to be deficient in its ventral aspect and thus is described as 'hooded'. Thirdly, there is chordee, a ventral flexion of the penis, the incidence and degree of which increases as the meatus is more proximally placed. The meatus itself may be narrowed leading to potential problems of back pressure. In the majority of cases the meatus is coronal in position; rarely it is glandular. Of the remainder, most are on the penile shaft but a few lie more proximally still in the scrotum or perineum. It is often thought that hypospadias is frequently associated with upper renal tract anomalies but in fact the incidence of these is much the same as in the general population, except perhaps in the most severe types of the deformity. In those penoscrotal and perineal types there may be associated undescended testes and the possibility of an intersex state must be investigated.

There are over 200 operations described in the literature for the correction of hypospadias. This gives some indication of the complication rate, each newly described repair aiming to be an improvement in this regard. The age for surgery is mainly the surgeon's preference. It has always been agreed that, where possible, correction should be complete by the time the boy starts school so that he may stand and pee like his peers! The more distally placed the meatus the easier it is to achieve a successful result. The essential components to the repair of the more severe varieties are release of the chordee and urethral reconstruction. The chordee is related to tight fibrous bands distal to the meatus and thought possibly to relate to atrophy of that portion of the corpus spongiosum. It is, however, possible to have chordee without hypospadias so the etiology is uncertain. Fistula formation is unfortunately common

following hypospadias repair and a few unfortunate cases require multiple interventions to achieve successful closure. The aim of all modern repairs is to create a terminal meatus on a well-formed glans and a penile shaft that is straight on erection together with a good cosmetic result (a good 'body image').

## EPISPADIAS

In its most extreme form this is associated with bladder exstrophy. Otherwise it may be balanic, penile or penopubic. It may also occur in girls. In epispadias the urethra is deficient dorsally. The penis is flattened with a splayed glans and shortened, the crura being attached to often separated pubic bones. The prepuce is deficient dorsally with a ventral hood prepuce and there is dorsal chordee. Occasionally the problem is not obvious, the foreskin being complete and phimotic and the penis buried, but once the prepuce is retractable the condition is revealed. In the female the clitoris is duplicated on either side of the wide open urethra, defective dorsally (Fig. 37.36). The treatment is likewise dependent on sex and severity and the degree of continence and the success rate is variable.

## URINARY TRACT INFECTION – SURGICAL ASPECTS

Medical management of urinary tract infections in neonates and in older children is discussed in Chapter 18.

The commonest cause of infection is *vesicoureteric reflux*. There remains much controversy over the role of surgery in vesicoureteric reflux.<sup>27</sup> Reflux in the presence of infection leads to pyelonephritis, the extension of the intrarenal reflux, if present, leading to scarring. If the child can be kept free of infection, the reflux may improve or resolve. Severe reflux should be treated surgically. This entails a transvesical operation to lengthen the submucosal tunnel of the ureter. It has a high rate of success but in a few cases leads to stenosis. More recently, a new technique involving the endoscopic injection of Teflon submucosally<sup>28</sup> beneath the ureteric orifice has been devised (STING – subureteric Teflon injection). This has proved very successful but long-term results have yet to be evaluated. Other substances such as Bioplastique, collagen or 'Deflux' may be used as concern has been raised that Teflon may migrate to the brain or elsewhere, although the original authors refute this concept. Deflux, a polysaccharide gel of a dextranomer and hyaluronic acid, is now the most widely used substance for this purpose.<sup>29</sup>

*Stenosis* of the lower end of the ureter requires reimplantation, the stenotic segment being excised.

*Duplex ureters* may be an incidental finding without causing problems in the majority of cases. If detected in investigation of a urinary tract infection, there is usually an associated anomaly. The ureter from the upper pole tends to enter the bladder at a lower level. Thus the lower pole ureter has a shorter intramural course and a tendency to reflux. The upper pole ureter has a tendency to stenosis, an association with a ureterocele and a possible tendency to open below the bladder neck, leading to incontinence. It may even open ectopically into the vagina.

If there is reflux of both ureters, reimplantation of both, in their common sheath, is usually the treatment of choice. Occasionally they join at a higher level leading to yo-yo reflux between the two and a predisposition to infection. This is treated either by heminephroureterectomy if one moiety is shown to have poor function on isotope studies, or else anastomosis at the level of the pelvis may be advocated.

A *ureterocele* may arise in relation to the upper pole ureter. It represents herniation of the intramural portion of the ureter into the bladder. Its meatus may be stenosed, may open below the bladder neck or may even on occasion allow reflux. The ureterocele may obstruct the lower ureter or even lead to bladder outlet obstruction by prolapsing across the internal urethral meatus. The ureterocele may be incised endoscopically to relieve an acute problem, especially of value in the infant, or may be excised with ureteric reimplantation,

Fig. 37.36 Female epispiadias.

if appropriate. If an isotope scan shows minimal function in the affected moiety then partial nephroureterectomy may be the treatment of choice.

*Hydronephrosis* may be due to obstruction at the pelviureteric junction (PUJ) or, if the ureter is also dilated, to vesicoureteric obstruction or vesicoureteric reflux. Obstruction at the PUJ may be due to congenital narrowing, high insertion of the ureter, or aberrant renal vessels. The presentation is usually with investigation of a urinary tract infection. It may be diagnosed antenatally or in the older child may present with a Dietl's crisis, acute obstruction at the PUJ secondary to kinking after an abnormal fluid load. This may not present until the first beer-drinking spree in a young adult! In the neonate, antenatally diagnosed hydronephrosis may be a stable condition that can be monitored with serial ultrasound examinations and isotope studies as some infants will acquire normal drainage across the PUJ as they grow. At any age an isotope study will indicate whether the kidney has already suffered major damage. If its contribution to total renal function is less than 10% then nephrectomy is the treatment of choice. If there is doubt in an acute presentation, a percutaneous nephrostomy tube may be inserted under ultrasound guidance and further isotope studies, after draining for 1–2 weeks, may show improvement. If there is reasonable function but a definite PUJ obstruction then the treatment of choice is a pyeloplasty. This involves excision of the redundant extra renal pelvis and pelviureteric junction with reanastomosis of the proximal ureter to the dependent portion of the repaired pelvis.

## CONGENITAL VASCULAR MALFORMATIONS

### Hemangiomas

These are malformations of developing blood vessels. They commonly appear in the skin but may develop in any organ.

### Strawberry nevus

These usually appear at about a week of age and may rapidly enlarge in the first few months of life. They then stop growing and usually resolve spontaneously by intravascular thrombosis. This process is normally complete by 5–7 years of age, leaving only a minor blemish or none at all. Unless they are causing a problem such as occlusion of the eyelids, which can lead to permanent visual impairment, surgery is best avoided. The parents must be reassured that even the most unsightly

facial lesions will resolve within a year or two of the child starting school. A few involute so rapidly that they become ulcerated. This is most common in lesions subject to trauma as on the perineum or back. Scarring will result from ulceration.

### Stork mark

This is a superficial capillary hemangioma that may be seen on the forehead, bridge of the nose and upper eyelids. The lesion is often v-shaped, pointing down to the nose and there is a corresponding mark on the nape of the neck. These marks presumably arise from the stork suspending the baby by the head in its beak! Again the parents can be reassured that the frontal lesion will resolve spontaneously although the nuchal one will commonly persist throughout life, usually hidden by the hair.

### Port wine stain (nevus flammeus)

Unlike a strawberry nevus this is present at birth and may be very disfiguring, as it becomes darker and increasingly nodular with age. In recent years laser treatment with a pulsed tuneable dye laser has considerably improved the appearance of these lesions in childhood.<sup>30</sup>

*Sturge–Weber syndrome* is a severe form of port wine stain on the scalp and face, in the distribution of one of the branches of the trigeminal nerve, associated with an underlying vascular anomaly of the arachnoid covering the cerebral hemisphere. This leads to epilepsy, hemiplegia and mental retardation.

### Cavernous hemangioma

These may occur alone or in association with a capillary lesion in the overlying skin. They increase in size after birth but usually in proportion to the growth of the infant. Most resolve spontaneously but some persist, requiring excision, if appropriate, or injection with sclerosants. Care must be taken in the latter option not to lead to ulceration of the skin. Very large lesions may lead to high output cardiac failure due to arteriovenous shunting. Embolization under radiological control may be required although some lesions regress on oral corticosteroid therapy.

### Kasabach–Merritt syndrome

In the neonate, large or multiple hemangiomas are occasionally associated with a generalized bleeding disorder caused by the trapping of platelets within them, which produces a profound thrombocyto-

penia. A course of prednisone, 2–4 mg/kg per 24 h can effect dramatic improvement, or, if this fails, embolization of the hemangioma can be considered.

### Lymphangioma

These are similar to hemangiomas but involve lymphatics. They may also occur anywhere in the body but in particular they may present as a *cystic hygroma* most commonly arising in the cervical region (see earlier under 'Head and neck').

Mixed *hamartomatous* lesions may contain hemangiomatous and lymphangiomatous elements.

### CLEFT LIP AND PALATE

The main etiological factor in these anomalies is genetic. In about one third of patients there is a family history. The incidence is about 1 in 700 births. The ratio of cleft lip (with or without cleft palate) to cleft palate alone is about 2:1.

The lip, alveolus and the portion of the hard palate anterior to the incisive foramen are derived from the maxillary and medial nasal processes. These fuse by the sixth week. The remainder of the palate forms from the palatine shelves. These grow from the maxillary swellings and fuse from anterior to posterior in the ninth to twelfth weeks. At the same time the nasal septum grows down to meet the palate.

Clefts result from failure of these lines of fusion. They vary in severity from a notch in the margin of the lip to a complete cleft in the maxilla. They may be unilateral or bilateral. Figure 37.37 illustrates the major types of cleft lip and palate.

Treatment is aimed at both a good cosmetic result with normal growth as well as a functional closure to facilitate swallowing and speech. The repair of the lip and alveolus is usually performed at around 3 months of age and the palatal defect between 6 and 15 months to give the best chance of normal speech. A multidisciplinary approach is required including a plastic surgeon, orthodontist, speech therapist, ENT surgeon, audiologist, etc.

### BURNS

Thermal injury is a common childhood accident in all countries. Predisposing factors include primitive, poor or overcrowded housing, families under stress, flammable clothing, ignorance and lack of insight in parents.

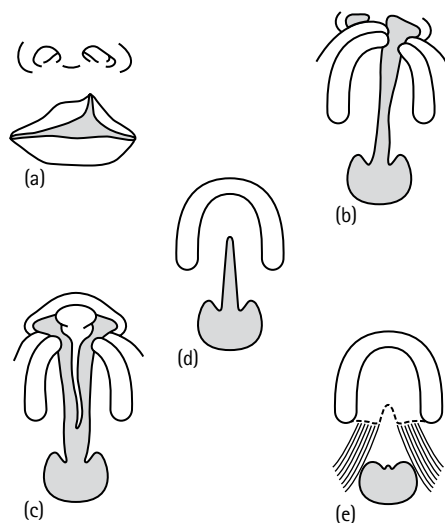

Fig. 37.37 (a) Incomplete unilateral cleft lip. (b) Complete unilateral cleft lip and palate. (c) Complete bilateral cleft lip and palate. (d) Isolated cleft of soft palate. (e) Submucous cleft palate.

The toddler, exploring his world on hands and knees or with unsteady gait, is a ready victim and boys are burned more often than girls. Scalding with hot liquids is by far the commonest cause of injury in this age group. Flame burns are less common than they were, but house fires still claim victims with the added risk of smoke inhalation injury. Other causes include contact with hot objects, chemicals, friction and electric current.

### Severity of injury

This depends on three main factors:

1. **Extent.** Heat damages the underlying capillaries, causing them to leak protein-rich fluid. The resulting loss from the circulation reaches a critical level when the extent of the burn exceeds about 10% of the body surface area, and the child will require i.v. resuscitation. Extent is measured by using a chart (Fig. 37.38) or by taking the area of the hand as about 1%. Erythema should be discounted when making this measurement.
2. **Depth.** Healing depends on whether epithelial elements survive in the dermis. Partial-thickness burns will heal by outgrowth of epithelial cells from hair follicles and sweat glands; they can be subdivided into superficial, which heal in less than 3 weeks and do not cause scars, and deep dermal, which take longer to heal and cause hypertrophic scars. Deep or full-thickness burns can heal only from the margins. The depth of tissue destruction is determined by the temperature of the agent, the duration of its contact, the skin thickness and the victim's age.
3. **Site.** Burns of the face and hands are particularly serious, and those of the perineum cause problems in management. While the skin is the site of injury in most instances, the epithelial linings of the respiratory and upper alimentary tracts may be damaged separately or together with a skin burn.

### Pathophysiology

#### Local

The fluid loss from the circulation is at its maximum immediately after the burn and decreases over the following 48 h. A deep burn destroys significant numbers of red cells. The insulating and protective functions of skin are lost, and body heat, water and electrolytes pass from the body in much increased amounts. Nitrogen losses also rise.

Fig. 37.38 Chart for calculating percentage area burned in childhood. A = 1/2 of head; B = 1/2 of one thigh; C = 1/2 of one leg. The percentages of these areas vary with age.

### General

There is a massive rise in the secretion of stress hormones.<sup>31</sup> Urinary water and sodium excretion fall and potassium and nitrogen losses increase. The larger the burn, the more profound the reaction tends to be. The catabolic phase lasts until the burn is healed.

### Treatment

#### First aid

After separating the child from the source of the injury, clothing should be removed and the burn cooled by immersion in lukewarm water or by use of a wet cloth (the risk of hypothermia must be remembered). The burn can then be covered with a clean cloth or clingfilm until definitive local treatment is possible.

#### Pain

A partial-thickness burn is very painful, while deeply burned skin is anesthetic. Potent analgesia by the i.m. or i.v. route is essential. Throughout treatment, attention must be focused on the avoidance of pain during practical procedures; analgesic or anesthetic drugs should be selected and used with precision.

#### Shock

Where the area burned exceeds 10% of the body surface, an i.v. infusion will be required. The restoration and maintenance of an effective circulation can be achieved with plasma, purified protein solution, dextran or balanced salt solutions. The quantities to be given vary with the weight of the child and the extent of the burn. The rate of administration is rapid initially and usually lasts for 36–48 h. Close patient observation, hourly urinary output measurement by an indwelling urethral catheter and serial hemoglobin and hematocrit estimations provide adequate control data. A central venous pressure line can be helpful in the severe case, but it has been indicted as a major source of infection if maintained for days in the burned patient.

### System management

#### Respiratory system

Where a child has been rescued from a burning building or where clothing has burned over the face, airway problems can be anticipated. Arterial blood gases should be monitored and intubation and assisted ventilation may be necessary. Bronchopneumonia is a frequent later complication of large burns.

#### Central nervous system

Toddlers with even minor scalds are liable to convulse in the first 2 d with serious or even fatal outcome. The cause is thought to lie with early fluid shifts and the lag that occurs within the brain and its meninges. Papilledema is not always present. Diazepam and mannitol (1 g/kg i.v. over 20 min) gain quick control of fits and brain swelling, and phenytoin sodium and dexamethasone prolong the effect. Focal neurological deficits may occur at any time, probably as a result of septic emboli.

#### Urinary system

In the first 2 d after injury increased levels of antidiuretic hormone limit urinary output. Infusion should be used circumspectly and a serum sodium level of not less than 130 mmol/L should be maintained.

In deep burns, thermal damage to red blood cells causes hemoglobinuria, which may lead to tubular necrosis and renal failure. If rapid restoration of circulating fluid volume does not clear the urine, a solute diuretic such as 20% mannitol should be given without delay. A catheter may be required to monitor urine output or avoid contamination of the burn. It should be removed as soon as possible.

#### Cardiovascular system

Electrical current injury may cause cardiac damage and an ECG examination is advisable after such an injury. General anesthesia is best avoided until the tracing has returned to normal.

Tachycardia persists throughout recovery from a large burn and is largely a product of a high metabolic rate to offset the high evaporative heat losses. Heat regulation is disturbed and the child must be kept warm to avoid hypothermia.

#### Hemopoietic system

Loss of red cells, destroyed by a deep burn, must be replaced by early transfusion. Further losses take place during surgery and erythropoiesis remains depressed until a large burn has healed. The red cell mass must be maintained by transfusion if the body is to achieve quick healing.

#### Alimentary system

Gastric stasis is common in the early hours after a large burn but oral intake should be started as soon as possible. Ranitidine has reduced the incidence of hemorrhagic gastritis and Curling's ulcer is now rarely seen.

Accurate naked weights, obtained twice weekly from admission, guide the clinician through the early weight gain of fluid retention, diuresis, the catabolic phase, and the anabolic phase that comes more quickly and strongly in the child.

#### Nutrition

Daily fluid intake must take account of increased losses through the burn wound. A high calorie intake is needed to balance heat loss and minimize lean tissue breakdown. A protein intake at the upper end of the normal range is adequate. Iron and vitamins C and B complex are supplemented to combat anemia and aid wound healing. The seriously burned child cannot take food in solid form and it is kinder and more effective to give most of this as a fortified liquid feed. A fine-bore nasogastric feeding tube for this purpose should be passed in all children with burns over 15%. The planned intake should be achieved stepwise over the first 1–2 weeks. Early forcing of high food intake may predispose to a post-stress diabetes that may be resistant to insulin. Neglect of food intake will result in a profound weight loss, hypoproteinemia, and failure of the burn to heal.

#### Musculoskeletal system

While immobilization may be unavoidable for practical reasons, its use will increase muscle wasting and delay the recovery of an effective musculature. Regular active exercises should be performed wherever possible. Joint positioning and joint movement require constant attention if severe, and possibly permanent, joint contracture is to be avoided.

#### Local care

Infection is the major complication of all but the smallest burn. It can destroy surviving epithelium and penetrate a deep burn, with a risk of invasive infection. The commonest organism is *Staphylococcus aureus* but the beta-hemolytic streptococcus is feared for its destructive capabilities and *Pseudomonas aeruginosa* can be dangerous on extensive burns. Constant monitoring, scrupulous hygiene and prevention of overcrowding are essential to control infection. Large burns should be isolated. Where appropriate, early excision and grafting can lead to healing before infection can occur. Local antibacterial agents are valuable but systemic antibiotics must be used with care as they can easily lead to superinfection with resistant organisms or fungi.

A superficial burn will, if protected from infection and trauma, heal in less than 3 weeks and is usually dressed with a well-padded gauze and cotton wool dressing with a Vaseline gauze inner layer. Deeper burns need skin grafting, unless very small.

#### Toxic shock syndrome

This can follow even very minor burns in the child<sup>32</sup> and can have a mortality rate of 11%.<sup>33</sup> It is therefore essential to recognize and treat it on suspicion. Signs are of an unwell, irritable child, 3 d or longer after a burn, with pyrexia and three or more of the following: rash, hypotension,

diarrhea or vomiting, inflamed mucous membranes, *Staphylococcus aureus* on wound swabs and occlusive dressings.

Treatment is with i.v. fluids, gammaglobulins (0.4 g/kg) or fresh blood or fresh frozen plasma (10 ml/kg over 4 h), exposure of the burn, topical antibacterial agent and i.v. antibiotics.

### Scarring

A superficial burn should leave little physical trace; the healed skin will be dry and should be creamed several times a day. With deeper injuries, scarring is unavoidable. The hypertrophic scar reaction is most intense in childhood. On the face, it disfigures and distorts features. On the flexures, it limits joint movement. Unrelieved scar contraction impedes growth of that part and deforms the growing skeleton. Spontaneous resolution of the hypertrophic scar is slow, variable and incomplete. Its full development may be cut short and its regression accelerated by elastic compression, intralesional injection of steroid hormones, or application of silicone gel. Secondary surgical procedures are often required to replace the worst scars, their timing and

scope being dictated by the physical, psychological and educational needs of the child.

### Psychological support

A close rapport between child, nurse, parents and doctor is fundamental in such a taxing hospital stay, which can extend over months. The child deserves explanation, occupation, and freedom from recurring pain. The parents, whose guilt feelings should be appreciated, should be incorporated into the therapeutic effort. The help of an interested and experienced psychiatrist may be invaluable.

### Prognosis

Intensive early therapy can resuscitate a child with the gravest of surface burns. However, long-term survival is rare where 70% or more of the skin is destroyed. A child who survives a burn with significant scarring faces the prospect of physical and psychological problems that will probably become worse during adolescence. Continued longterm support is needed for patient and family for many years.

## INTRODUCTION

Relief from pain and suffering is a basic human right no matter what age, level of cognitive development or ability to communicate. Although children's pain is still often under-recognized around the world, in recent years there have been enormous advances in our understanding of pain in childhood.<sup>1</sup> Today, in the twenty-first century, it seems incredible to think that less than 20 years ago there was considerable debate about whether newborn infants were capable of feeling pain, and whether the benefits of potent analgesics outweighed their risks in young children. Since that time the study of the developmental neurobiology of pain has left little doubt that even the youngest and most premature infant is capable of pain perception, and we have learned to safely manage pain at all ages.<sup>1,2</sup>

Pain is a subjective experience, not necessarily proportional to any underlying physiological damage and is powerfully influenced by psychological, social and cultural factors. A common definition is that adopted by the IASP (International Association for the Study of Pain), the largest multidisciplinary international professional organization concerned with pain research and practice:

'Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage. Note: The inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment.'

Children may experience pain for many reasons, and because of its complex nature a rigid system of classification is not possible. For clinical purposes it can be helpful to consider painful experiences as acute, chronic and recurrent. Acute pain, lasting days or weeks is often clearly related to causes such as trauma or common illnesses, like accidents, ear and throat infections, appendicitis and sickle cell disease. Medical interventions are also an important cause of acute pain including immunization, diagnostic procedures and postopera-

tive pain. Chronic pain, lasting months or years may also be associated with obvious underlying disease such as chronic rheumatological disorders, orthopedic problems in cerebral palsy and progressive malignant disease. However a large group of children with chronic pain, which may be constant but is often recurrent, have much less obvious tissue damage or have pain persisting far beyond the expected normal of period recovery from injury. These pains may occur in a wide range of sites, may be associated with other diffuse symptoms including sympathetically mediated changes and are frequently associated with prominent and sometimes extreme behavioral changes.

Physiologically, pain can also be classified as either 'nociceptive' or 'neuropathic' according to the underlying neural mechanism. Nociceptive pain is that which results from a normal, intact, nervous system. It is usually self-limiting, resolving as the underlying injury resolves, and it will respond to the 'classical' analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids. In contrast, neuropathic pain is due to damage or malfunction of the nervous system, it is particularly characterized by spontaneous pain, unpleasant abnormal painful sensations or dysesthesias and sometimes associated sensory deficits. Neuropathic pain may persist despite treatment for considerable periods, sometimes the underlying injury is not obvious, and crucially it does not respond well to classical analgesics and may require alternative treatment strategies. Both nociceptive and neuropathic pain may co-exist in the same patient, and accurate diagnosis will assist in the selection of appropriate therapy.

## ASSESSMENT

A thorough assessment of pain forms the foundation for its prevention and management. There is substantial literature on pain assessment in children, and the subject has been extensively reviewed.<sup>3-7</sup> Children's age, developmental level and also the type of pain they are experiencing will

influence the approach to assessment, and in all situations a broad picture acknowledging the complex nature of pain and the multiple factors which influence it needs to be constructed. The majority of available pain assessment tools are designed to measure pain intensity in developmentally normal individuals, mostly in acute settings. Recently tools have also been developed for use in children with severe neurological disability.<sup>8,9</sup> Questionnaires designed to measure functional impairment due to chronic pain are also available; see later sections of this chapter for more detail.<sup>10,11</sup>

### SELF-ASSESSMENT

Since pain is a subjective experience the ideal or 'gold standard' approach is one of self-reporting with as much information as possible about the pain coming directly from the child. A detailed history is especially important when the pain is chronic or the cause unknown and aims to discover the sites of the pain, its nature, frequency, severity, precipitating and relieving factors and other associated symptoms. Additional wider aspects to consider include the effect of the pain on the child and family's daily life, their coping skills and the meaning of the pain for them and within their culture. A variety of formal self-report tools to measure pain intensity have now been developed and validated; the majority of these have been designed to help children quantify acute pain usually on a numerical scale, typically in the range 0–10, where 0 equals no pain and 10 the worst pain imaginable. They can also be valuable in the wider assessment of long-term pain and also to monitor the effectiveness of treatment. The type of self-report scale used will depend on age, developmental level and setting. No scale can be universally recommended and each has its advantages and limitations.<sup>12</sup> However there are many children in whom self-reporting cannot be used, and in whom one or more proxy measures such as behaviors or physiological parameters have to be used.

### ADOLESCENTS AND SCHOOL-AGE CHILDREN

Older children are usually able to use classical visual analogue scale (VAS), and numerical rating scales (Fig. 38.1). More user-friendly scales such as those using drawings of faces depicting different degrees of

pain are suitable for this age group and can also be used for pre-school children down to the age of about 4 years.<sup>13,14</sup>

### TODDLERS AND YOUNG CHILDREN

Toddlers and young children can provide simple information about their pain and its site but may not have the abstract concepts or verbal ability to describe its nature or intensity.<sup>3–5</sup> Young children tend to choose the extreme ends of the scales, and the type of face and the way it is depicted may also influence their ratings.<sup>15,16</sup> Another example is the poker chip tool, which uses small plastic blocks to represent 'pieces of hurt' with options of picking up between 1 and 4 to indicate pain severity.<sup>17</sup>

### BEHAVIORAL AND MULTIDIMENSIONAL ASSESSMENT

Infants, preverbal children and children with severe developmental delay are unable to report their own pain. Assessment depends on observation of the child and knowing them well. Health care workers consistently underestimate children's pain compared with children's own self-reports and although parents' ratings are closer to the children's own they still tend to underestimate the pain.<sup>18</sup>

In infants indicators for pain that have been studied include facial expression, cry, motor movements and changes in behavioral state and patterns.<sup>5</sup> Preterm infants' responses appear to be less vigorous than those of full-term infants and their expression of pain cues are more subtle. Evaluation of pain through facial expression is best established and typical characteristics that express pain include eyes tightly closed, furrowed brows, broadened nasal root and deepened nasolabial furrow with a squared mouth and taut tongue.<sup>19</sup> A variety of tools to measure pain in neonates and infants are available; some 'multidimensional scales' combine behaviors and physiological parameters.<sup>5</sup> A number of behavioral scales have also been developed for preverbal children that may also be used in older children unable or unwilling to self-report. Two have been used extensively for postoperative pain are FLACC (Fig. 38.1), and CHEOPS, which use observation of verbal and facial

FLACC	Behavioral pain assessment		
	Scoring		
Categories	0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging or being talked to, distractible	Difficult to console or comfort

Each of the five categories: (F) Face; (L) Legs; (A) Activity; (C) Cry; (C) Consolability; is scored from 0–2 which results in a total score between 0 and 10

Fig. 38.1 Behavioral and self-report pain scales (Adapted from <sup>13,21</sup>).

expressions of pain, behaviors, changes in muscle tone, and movement.<sup>20,21</sup> In intensive care settings the multi-dimensional COMFORT score has become popular.<sup>22</sup>

Assessment of pain in children with severe developmental delay poses a complex problem that has only recently been addressed by researchers. One approach is to document 'normal' and 'pain-related' behaviors in individual children over a period of time in order to estimate pain intensity associated with painful events such as surgery.<sup>9</sup>

## PHYSIOLOGICAL RESPONSES

Physiological responses to pain are activated by the autonomic nervous system and include tachycardia, sweating, increasing secretion of catecholamines and adrenocorticoid hormones. These have not proved to be clinically reliable or useful as they are part of a global response to stress and not specific to pain; also, measurement of hormonal changes is invasive and slow.

## CLINICAL MANAGEMENT OF PAIN

Both nonpharmacological and drug treatments of pain have a place in clinical pain management, the balance depending on the mechanism, source and circumstances of pain.

## NONPHARMACOLOGICAL APPROACHES

### Psychological

The unpleasant nature of pain and the many factors influencing it mean that all pain and pain management is immersed in a psychological context that needs to be taken into account.

Some approaches are very simple. Parents offer children the support children value most at times of stress, but they are still sometimes mistakenly excluded from their child's presence and care. Clinical staff need to be aware of the distress and anxiety that pain causes children, particularly in the Accident and Emergency unit, postoperatively and on the wards. Simple and honest explanations of disease processes and thorough preparation for procedures and surgery can help reassure children and families, enhance feelings of control and so reduce anxiety.<sup>23</sup>

A variety of more formal techniques have also been used effectively and well validated in a wide range of clinical situations, including the use of relaxation, cognitive approaches including distraction, imagery and thought blocking, and hypnosis.<sup>24-28</sup> Children are often very willing and co-operative subjects and enjoy the novelty of these techniques and the sense of control they engender. Such techniques are very effective for procedural pain management, and they are also used in a variety of chronic pain conditions to improve pain coping skills, with particular success in children with headache.<sup>29</sup>

### Physiotherapy

Physiotherapy has a range of useful techniques that can contribute to pain management and are particularly important for children with chronic pain. These aim to restore optimal physical function by promoting strength and mobility, as well as to decrease pain. They include the use of active and passive exercise, often combined with goal setting and close monitoring. A number of other physical pain reduction techniques are frequently used concurrently such as desensitization of cutaneous hypersensitivity, local heat and cooling, hydrotherapy, ultrasound and TENS (transcutaneous electrical nerve stimulation).<sup>30,31</sup>

## PHARMACOLOGICAL APPROACHES

### Selection of analgesics: multi-modal analgesia

A relatively small range of analgesics is used in children. Selection of the most appropriate depends upon the cause and severity of the pain, the age and general condition of the patient, the setting and the facilities for supervision, monitoring and treatment of any side-effects. The underlying neural mechanisms responsible for the clinical characteris-

tics of both acute and chronic pain, and the influence of development on pain processing are becoming better understood. Increased pain sensitivity and tenderness (hyperalgesia and allodynia) at and near the site of injury are known to be the result of multiple changes within the CNS involving many neural and chemical mediators. The individual components of these 'pain pathways' can be targeted by combining different analgesics in order to compound their effects, thereby increasing efficacy.<sup>32</sup> A combination of analgesic drugs and techniques, with complementary modes of action, maximizes the therapeutic advantage of each whilst keeping the doses and side effects to a minimum. This is the rationale underpinning the 'pain ladder' concept, in which new and more potent drugs are added as pain increases (Fig. 38.2). Whenever possible, analgesic pharmacotherapy is also combined with suitable nonpharmacological techniques in order to further reduce the pain response.

## Mild analgesics

### Paracetamol

Paracetamol is one of the most widely used drugs in children; it is available in oral, i.v. and rectal preparations. It is regarded as a safe and effective analgesic for mild and moderately severe pain; it can be used at all ages, including the neonate. Traditionally, paracetamol is thought to act centrally. Analgesia is attributed to inhibition of cyclo-oxygenase and thereby prostaglandin production in the CNS; other mechanisms have also been proposed including antagonism of serotonin (5HT) and possibly N-methyl D-aspartate (NMDA) receptors.<sup>33,34</sup>

Although several systematic reviews have demonstrated the analgesic efficacy of paracetamol for mild pain in the adult, few studies have been performed in children.<sup>35-40</sup> The analgesic efficacy of paracetamol is probably low; the correct dosage is important and for moderate or severe pain is probably best combined with other agents, typically opioids and nonsteroidal anti-inflammatory drugs (NSAIDs). Paracetamol does not reduce the pain response to heel lance or to circumcision in neonates although it does appear to have a small effect on late post-circumcision pain.<sup>41,42</sup>

Paracetamol is conjugated to glucuronide, sulphate or cysteine and excreted. In normal circumstances less than 10% is metabolized to a potentially hepatotoxic metabolite, N acetyl P amino benzoquinone imine (NAPQI). NAPQI is neutralized by combination with hepatic glutathione or with N acetyl cysteine and excreted harmlessly unless this pathway is saturated due to overdose or conjugates are in reduced supply. The p450 isoenzyme responsible for metabolism of paracetamol is developmentally regulated, with lower activity in the neonate, and this may confer some protection. However reduced clearance in neonates may lead to accumulation of the drug and its metabolites and so a reduced daily dose is usually recommended. Paracetamol hepatotoxicity is a well recognized dose-dependent complication associated with acute ingestion of more than 150 mg/kg. Long-term paracetamol treatment can also lead to toxicity at lower doses and it has been suggested that the maximum recommended dose should not be given for more than

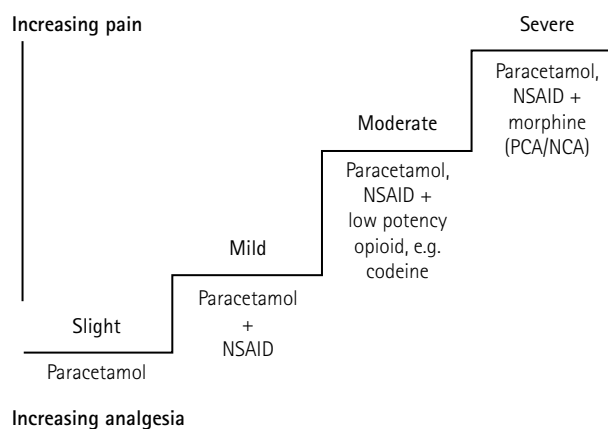

Fig. 38.2 Analgesic ladder. NCA, nurse-controlled analgesia. PCA, patient-controlled analgesia.

5d.<sup>43</sup> Risk factors for toxicity include: chronic ingestion, especially in the malnourished due to reduced hepatic glutathione stores; pre-existing liver impairment (single doses are reasonably safe); hepatic enzyme induction and miscalculation or misinterpretation of commercial package labeling leading to accidental overdose.

The recommended total daily oral dose is 30 mg/kg in pre-term neonates 28–32 weeks' postmenstrual age, 60 mg/kg up to 3 months and 90 mg/kg in infants and older children.<sup>44</sup> This is usually given in divided doses 3 or 4 times daily. Absorption after oral paracetamol is excellent, rectal bio-availability is lower and more variable at 25–98% of the administered dose. In order to achieve therapeutic plasma levels a higher initial rectal dose is recommended (of the order of 30–40 mg/kg) followed by regular doses as above but not exceeding recommended maximum daily doses. The introduction of i.v. paracetamol has been a considerable advance, currently the recommended dose is 60 mg/kg/d for children weighing 10–50 kg and 4 g/d for those > 50 kg.<sup>44</sup>

### Propacetamol

Propacetamol is an intravenously injectable pro-drug which is hydrolyzed to paracetamol 2:1 (1 g propacetamol yields 0.5 g paracetamol). It is useful when other preparations/routes of administration for paracetamol are not available; it is important that this preparation is not confused with i.v. paracetamol. The pharmacokinetics of propacetamol have been studied in neonates and children, and it has been used for postoperative pain.<sup>45–47</sup> Transient but mild platelet dysfunction after propacetamol has been described; contact dermatitis in health care workers may also occur.

### Nonsteroidal anti-inflammatory drugs

This group of drugs is thought to exert their effects mainly peripherally by cyclo-oxygenase inhibition (cf paracetamol); they also inhibit the release of inflammatory mediators from neutrophils and macrophages. Cyclo-oxygenase helps to catalyze the conversion of arachidonic acid to prostaglandins, which modulate many auto-regulatory physiological processes including sensitization of normally high threshold nociceptors at sites of inflammation. The NSAIDs ibuprofen, diclofenac and ketorolac are used widely for pain due to injury, surgery and many acute and chronic disease processes. These three drugs are used interchangeably in clinical practice, but their effect and side-effect profiles may differ at an individual patient level. [Table 38.1](#) shows doses and routes; ibuprofen is available 'over the counter' in the UK, diclofenac is presented in a convenient rectal formulation, and ketorolac is available parenterally. Piroxicam, a long-acting NSAID which can be given once daily, is useful in long-term treatment and if compliance with multiple-dosing is a problem ([Table 38.1](#)).

### Side-effects and toxicity

**Asthma:** caution is advised in the use of NSAIDs in the presence of wheezing as they are known to be cross-reactive with aspirin-induced asthma. The risks may have been overemphasized in children and

short-term ibuprofen treatment appears to pose very little risk.<sup>48</sup> Aspirin is not used in children apart from special circumstances such as Kawasaki syndrome (see Ch. 19, p. 649) because of the risk of Reye's syndrome. Aspirin-induced asthma is very rare in the young and one study in children with asthma found no deterioration in respiratory function after diclofenac administration.<sup>49</sup>

**Renal:** kidney function is regulated by prostaglandins and two mechanisms of NSAID nephrotoxicity have been described. Functional renal failure can occur in a dose-dependent fashion, disappearing on withdrawal of the drug. Pre-existing poor function and dehydration may be contributing factors. Dose-independent interstitial nephritis with or without nephritic syndrome is rare; treatment is conservative or with corticosteroids.<sup>50,51</sup>

**Coagulopathy:** Platelet function is altered by NSAIDs due to their reversible inhibition of thromboxane A2 and platelet endoperoxides. Gastrointestinal blood loss can occur particularly associated with peptic ulceration. Increased intraoperative and postoperative blood loss, which is not usually clinically significant, has also been described. Simultaneous prescription of H<sub>2</sub>-receptor antagonists can help reduce the risk of gastrointestinal problems.<sup>52,53</sup>

**Infants and neonates:** NSAIDs are rarely given to those under the age of 3 months and are not usually used for pain indications in neonates due to fears of possible interference with cerebral blood flow autoregulation and risk to immature renal function.

**Gastrointestinal:** the normal protective function of the gastric mucosa is reduced by NSAIDs and this can lead to peptic ulceration. It is not usually a problem in short-term use; some newer drugs may be beneficial (see later).

### NSAIDs and cyclo-oxygenase

Cyclo-oxygenase exists in two isoforms: COX-1 and COX-2. COX-1 is found in virtually all cell types; COX-2 is expressed in some organs, notably the brain and lung, but is specifically induced in inflammation in conjunction with a rapid rise in prostaglandin levels. The traditional NSAIDs are nonselective for these isoforms but individual drugs may differ slightly in their ability to depress activity. Selective COX-2 inhibitors have reputedly fewer gastrointestinal side-effects in comparison with nonselective NSAIDs and may therefore widen the indications for NSAIDs. However the exact consequences of this selectivity is not yet fully understood; for example their use in the adult has been found to be associated with increased risk of adverse cardiovascular events and the incidence of renal complications may be similar to nonselective inhibitors. The use of COX-2 selective NSAIDs has not been adequately studied in children so at present there is little evidence upon which to evaluate their use.

### Opioids and related drugs

Opioids exert their effects by acting at opioid receptors primarily in the spinal cord and brain. Despite the fact that morphine is one of the oldest and most widely used analgesics, opioid pharmacology is still not fully understood and many important questions remain unanswered. Opioids are the most powerful analgesics available with high efficacy for many types of acute and chronic pain, with the notable exception of neuropathic pain. Important considerations when prescribing opioids include their unpleasant and potentially dangerous side-effects and the development of tolerance, which can be troublesome. Neonates in particular appear clinically to be more susceptible to the depressant effects of opioids; the causes of this are probably multifactorial but have not been fully explained (see later).

The doses and possible routes of administration of the commonly used opioids for children are shown in [Table 38.2](#). Morphine has a fairly direct relationship between dose, efficacy and side effects. The same is not true for all other opioids; partial agonist drugs such as buprenorphine have a ceiling effect and others such as codeine and pethidine have unacceptable side-effect profiles at high doses, which limit their use.

**Table 38.1** Nonsteroidal analgesics

Drug	Routes of administration	Doses	Notes
Ibuprofen (above 5 kg)	Oral	30 mg/kg/d (3–4 divided doses)	Max. 2.4 g/d
Diclofenac	Oral or rectal	3 mg/kg/d (3 divided doses)	Max. 150 mg/d
Ketorolac	Oral i.v.	0.5–1 mg/kg (4 times daily) 0.5 mg/kg (4 times daily)	Dosage restrictions apply in some countries. Max. 40 mg/d
Piroxicam	Oral	0.3–0.5 mg/kg/d	Maximum dose 20 mg in children > 6 years

Table 38.2 Opioids

Drug	Routes of administration	Doses	
Codeine	Oral	1 mg/kg (4 times daily)	
	Rectal	1–1.5 mg/kg (4 times daily)	
Oxycodone/hydrocodone	Oral	0.2 mg/kg (4 times daily)	
Morphine	Oral	0.2–0.4 mg/kg (4 times daily)	Long-acting oral preparations available
	Intravenous	0.05 mg/kg	
	Subcutaneous	0.05 mg/kg	
Fentanyl	Epidural	0.02–0.05 mg/kg	
	OTFC (oral transmucosal)	1–10 µg/kg	See relevant product
	Transdermal	1–3 µg/kg	See relevant product
	Intravenous	0.5–1.5 µg/kg/h 1 µg/kg/h	Loading dose (if required) Incremental dose
Pethidine	Epidural		Infusion
	Oral	2 mg/kg (4 times daily)	Incremental/loading dose
	Intravenous	0.5–1 mg/kg	Incremental/loading dose
	Subcutaneous	0.5–1 mg/kg	
Methadone	Oral	0.2 mg/kg (3 times daily)	Useful long acting opioid
	Intravenous	0.1–0.2 mg/kg	

### Morphine

Morphine is the prototype, high potency opioid and enormous experience in its use often makes it the drug of choice for severe pain. The pharmacokinetics and clinical use of morphine in children have been studied extensively.<sup>54,55</sup> The pharmacokinetics and efficacy of morphine are developmentally regulated, although outside the neonatal period, which is characterized by high variability, efficacy is largely predictable and dose related.<sup>56</sup>

Morphine is well absorbed orally; formulations of morphine include a suspension and a slow-release compound (MST). Parenteral morphine

is usually given intravenously either by intermittent dosing, continuous infusion or in a patient-controlled analgesia (PCA) or nurse-controlled analgesia (NCA) regimen see Table 38.3. Subcutaneous infusion of morphine is also used, particularly in palliative care and when i.v. access is difficult or precious. Preservative-free (as a precaution against chemical toxicity) morphine is also effective in the epidural space, usually combined with local anesthetic.

Nausea and vomiting, sedation, and respiratory depression are the most frequently seen acute adverse effects of morphine; itching also

Table 38.3 Protocols for i.v. morphine administration

<b>1. Morphine infusion</b>	
Preparation:	Morphine sulphate 1 mg/kg in 50 ml solution
Concentration:	20 µg/kg/ml
Initial dose:	2.5–5.0 ml (50–100 µg/kg)
Infusion:	0.5–1.5 ml/h (10–30 µg/kg/h)
<b>2. PCA</b>	
Preparation:	Morphine sulphate 1 mg/kg in 50 ml solution
Concentration:	20 µg/kg/ml
Initial dose:	2.5–5.0 ml (50–100 µg/kg)
Programming	Background infusion: 0–0.2 ml/h (0–4 µg/kg/h)
	PCA dose 0.5–1.0 ml (10–20 µg/kg/h)
	Lockout interval: 5 min
<b>3. NCA</b>	
Preparation:	Morphine sulphate 1 mg/kg in 50 ml solution
Concentration:	20 µg/kg/ml
Initial dose:	2.5–5.0 ml (50–100 µg/kg)
Programming	Background infusion: 0.5–1.0 ml/h (10–20 µg/kg/h)
	NCA dose 0.5–1.0 ml (10–20 µg/kg/h)
	Lockout interval: 20 min
<b>4. Subcutaneous morphine</b>	
Preparation:	Morphine sulphate 1 mg/kg in 20 ml solution
Concentration:	50 µg/kg/ml
Initial dose:	Infusion: 1–2.0 ml (50–100 µg/kg)
Programming	0.2–0.4 ml/h (10–20 µg/kg/h)

Source: Pain control service, Great Ormond Street Hospital for Children.

occurs, especially after epidural morphine. Depression of gastrointestinal motility and constipation are a problem with prolonged use. In clinical practice, non-life-threatening side-effects can be treated by reducing the dosage of morphine, often in palliative care by waiting for tolerance to the side-effect to develop – drowsiness almost always wears off in a few days, or with appropriate therapy, e.g. anti-emetics, antipruritics and laxatives. In an emergency, adverse effects of morphine can be reversed with the opioid antagonist, naloxone 4–10 mcg/kg.

### **Fentanyl**

Fentanyl is a synthetic, high potency (100 × morphine) lipid soluble opioid. Its main use is during general anesthesia, where its efficacy, rapid onset and short initial half-life are an advantage. Fentanyl is usually given intravenously; it is also a popular choice for ventilated neonates and infants on ICUs (see later). Postoperatively fentanyl is commonly infused into the epidural space as its high lipid solubility may limit rostral spread and reduce the incidence of some complications, notably respiratory depression, retention of urine, and itching, in comparison with morphine. Fentanyl is available as oral (transmucosal) and transdermal (fentanyl patch) preparations which can be used for procedural pain and pain in chronic conditions and palliative care.

Fentanyl is very potent with a fast onset after i.v. administration. Opioid related side-effects of sedation, respiratory depression and itching are to be expected. High doses, > 5 mcg/kg, have also been associated with chest wall rigidity and are usually only given when respiration is controlled.<sup>57,58</sup>

### **Codeine**

Codeine is a low potency opioid used for mild to moderate pain including some postoperative pain and cancer pain. It is often combined with other analgesics for best effect, particularly paracetamol and NSAIDs (Fig. 38.2). Codeine is a morphine prodrug; the response to codeine is more variable than that to morphine and this may be due to genetic (and possibly developmental) differences in metabolizing capacity.<sup>59</sup> Of individuals from some populations, 10% or more will not benefit from codeine analgesia; despite this they may experience some adverse effects as codeine can produce these without metabolism to morphine.<sup>60</sup> Codeine should not be administered intravenously as it causes hypotension.

### **Oxycodone and hydrocodone**

Oxycodone and hydrocodone are semi-synthetic opioids suitable for moderate to severe pain, especially in combination with paracetamol or NSAIDs. Oxycodone is active by oral, buccal, sublingual and i.v. routes.<sup>61</sup> Sustained-release formulations have also been used in children.<sup>62</sup>

### **Tramadol**

Tramadol is a synthetic moderate potency analgesic which has a novel dual mode of action by a combination of inhibition of serotonin and norepinephrine reuptake and  $\mu$ -opioid receptor agonism by its active metabolite o-desmethyltramadol. Metabolism of tramadol is by the same cytochrome P450 enzyme subgroup responsible for codeine metabolism, and therefore may be subject to the same drawbacks (see earlier). Tramadol has been used for early postoperative analgesia in children with good effect. It has also been used in the caudal epidural space, where it appears to have a slow onset (about 1 h) and moderate potency.

### **Pethidine**

Pethidine is a synthetic opioid which has few advantages over morphine. Pethidine is metabolized to norpethidine, which is neurotoxic, causing tremor, twitching, agitation and even convulsions. Norpethidine is probably also the cause of abnormal neurobehavioral tests in the neonate following maternal pethidine for labor pain. High and repeated dosage and renal impairment are risk factors, but convulsions have been reported with low doses in the therapeutic range. The traditional use of pethidine in acute sickle cell pain has declined subsequent to reports of convulsions in children.

Pethidine was originally considered to induce less nausea and vomiting and to be less depressant to the respiratory center of the fetus and

neonate than morphine. If it is administered in equi-analgesic dosage these differences are not apparent, although it remains popular in some centers.

Pethidine has also been recommended for use in pancreatitis as it was thought to be less likely to precipitate spasm of the sphincter of Oddi than morphine or other opioids. Evidence from adult literature does not support this hypothesis as all opioids including pethidine appear to elevate intrabiliary pressures; the question has not been examined in children.<sup>63</sup>

## **Novel systemic analgesics**

### **Clonidine**

Clonidine is an alpha-2 adrenoceptor agonist with multiple effects including analgesia, sedation, anti-hypertension, anti-sialogogue, and others. Clonidine has a direct effect on spinal pre- and postsynaptic adrenoceptors in the dorsal horn; it also has many supraspinal effects which may also contribute to analgesia. The pharmacology, use and advantages of clonidine and other alpha-2 adrenoceptor agonists appear to be particularly useful in managing postoperative pain although moderate dose-independent reductions in blood pressure have been found at doses within the therapeutic range 0.625–2.5 mg/kg. The efficacy of clonidine in the neonate is not established; severe respiratory depression after a single dose of 2  $\mu$ g/kg caudal clonidine has been reported.

### **Ketamine**

Ketamine is an antagonist at the glutamate NMDA receptor. The receptor is important in the generation of hyperalgesia and ketamine may therefore be helpful in controlling nociceptive and neuropathic pain. High doses of 1–2 mg/kg have been used for many years as a general anesthetic. At 'low dose', < 1 mg/kg, ketamine has been found to be an effective analgesic both systemically and epidurally. The use of low-dose ketamine for postoperative pain in adults is fairly commonplace, although its efficacy has not been clearly ascertained.<sup>64</sup> There are many reports of its use in children, including analgesia-sedation in the pediatric ICU, and for procedural pain and postoperative pain. Ketamine in high doses induces neurobehavioral and cognitive depression sometimes accompanied by psychotomimetic effects characterized by bizarre dreams or hallucinations. Ketamine has been shown to have toxic effects to the infant mouse brain, and this observation together with the potential for abuse is has lead to a reappraisal of its use in humans.<sup>65</sup>

## **Local anesthesia**

Local anesthesia has a particularly important role in pediatric pain management as it is often extremely effective and avoids many of the complications of systemic analgesics.

### **Bupivacaine and levobupivacaine**

The amide-type local anesthetic bupivacaine and its isomer levobupivacaine are popular because of their long duration of action. Bupivacaine has been used widely for most types of local anesthetic procedure in children: following trauma, wound infiltration after surgery, peripheral nerve blocks and epidural analgesia. It is almost universally the drug of choice for epidural analgesia, where it can be infused for several days for postoperative pain, and sometimes longer for other indications. The pharmacokinetics of bupivacaine and levobupivacaine in children have been studied. Neurotoxicity and cardiotoxicity have been reported, with a slightly less risk with levobupivacaine. However the incidence of these adverse events appears to be low with both drugs if dosage recommendations are not exceeded.

Local anesthetic creams and gels are widely used for procedural pain and are discussed in the relevant sections.

## **MANAGEMENT OF ACUTE AND POSTOPERATIVE PAIN**

Pain after surgery is a largely predictable event and therefore analgesia should be planned in advance according to the expected pain and postoperative setting. Pediatric anesthetists have special training in

the use of systemic analgesics and local anesthetic techniques for surgery and they should also take some responsibility for postoperative pain management. Many of the principles and techniques used for postoperative pain may also be applied to other sources of acute or acute on chronic pain. Examples are post-traumatic injury, acute sickle cell crisis, mucositis (ulceration at a mucosal surface) and many others.

## ANALGESIA FOR MINOR AND AMBULATORY OR DAY-CARE SURGERY

Most routine surgery in children is relatively minor and very often undertaken on a day-case or day-stay basis. Analgesia for day surgery should be effective and not delay discharge from hospital. The objective is to maximize comfort and mobility with little sedation or other side-effects. Postoperative nausea and vomiting (PONV) is a particular problem. In practice, this means limiting or avoiding the use of sedatives and opioids whilst encouraging the use of local anesthetic techniques. Health care workers need education and training to ensure that all runs smoothly and patients are pain free at discharge. Further analgesia will usually need to be continued at home for several days managed by parents who will need information and support in order to be able to do this effectively. Postoperative pain should be mostly treatable with 'over-the-counter' analgesics, which are safe and easily obtainable by parents at home, otherwise the suitability of a procedure for day surgery must be questioned. Take home 'packs' containing analgesics and written information are often supplied to families at day-surgery centers.

### Local anesthetic techniques

Infiltration of the surgical wound can be used in many situations, especially for very superficial surgery, its utility being limited mainly by the need for large volumes of local anesthetic and dosage restrictions. Infiltration is effective for a number of common pediatric procedures including herniotomy, eye surgery, dental surgery and tonsillectomy. A range of peripheral nerve blocks are frequently used. The ilioinguinal and iliohypogastric nerves, which supply the sensory innervation to the groin area, are easy to locate and block. Surgical exploration of the inguinal region includes hernia repair, ligation of patent processus vaginalis and orchidopexy. Recognized complications include quadriceps weakness due to spread of local anesthetic to the femoral nerve. The distal third of the penis is supplied by the dorsal nerves, which are easily blocked by an injection of local anesthetic at the base of the penis. Analgesia is suitable for circumcision, minor hypospadias repair and surgery on the urethral meatus. Dorsal nerve block has also been particularly advocated for neonatal circumcision, which is performed in some countries without general anesthesia.

### Caudal block

There is an enormous literature extending back at least 30 years describing caudal epidural local anesthesia in children. Caudal block is effective for most operations below the level of the umbilicus; bupivacaine lasts 4–6 h by this route. Opioids, ketamine and clonidine have also been used either alone or in combination with local anesthetic, prolonging analgesia to 12 h or longer. The complications of caudal analgesia are rare but include temporary leg weakness, delayed micturition, vascular puncture, dural puncture, and inadvertent intravascular or intradural injection of local anesthetic. Epidural infection or neurological sequelae have not been reported after single caudal local anesthetic injections.

### Systemic analgesia

Potent analgesia is likely to be necessary in the early postoperative period, even after minor surgery. Institution of systemic analgesia after surgery should be planned to ensure a smooth and comfortable transition from the immediate postoperative and post-anesthesia recovery phase. Drugs, timing and routes of administration selected are important. Reactive, p.r.n. or 'as required' dosing schedules are not appropriate during the period of expected postoperative pain, and if used they are likely to lead to avoidable painful intervals while drugs are taking effect.<sup>66</sup>

## Postoperative nausea and vomiting

Nausea and vomiting is a common cause of morbidity after minor and day-care surgery; its causes are multifactorial, and it is associated with poor analgesia and not with preoperative anxiety. Risk factors for PONV include a previous history of PONV, general anesthesia, the use of opioids, early resumption of oral fluids and certain surgical procedures, notably tonsillectomy and strabismus surgery. 5HT antagonists (e.g. ondansetron) are popular for prophylaxis and first-line treatment, the synthetic corticosteroid dexamethasone, either alone or in combination has potent anti-emetic effects. Combination anti-emetic therapy is probably the most effective treatment (Table 38.4).<sup>67</sup>

## ANALGESIA AFTER MAJOR SURGERY

As the oral route is rarely available after major surgery for at least the first postoperative day, and often much longer after gastrointestinal operations, other options must be utilized. Local anesthetic techniques, performed under general anesthesia before or after surgery can reduce analgesic requirements in the early postoperative period.<sup>68,69</sup> After major operations further analgesia can be accomplished by infusion of local anesthetic through a catheter located at the site of the block, e.g. continuous epidural analgesia. More commonly pain after major surgery is managed with morphine or other opioids. Paracetamol, NSAIDs, codeine and morphine are all readily available in rectal formulations, which are popular. Rectal absorption for many drugs is known to be erratic and unpredictable, and a fatality following rectal morphine in a child has been reported. Nevertheless rectal administration of less potent drugs appears to be safe and is still widespread for paracetamol and NSAIDs.

### Parenteral opioid infusions

Morphine infusion has been used safely for postoperative analgesia in children for more than 20 years, the dose range in nonventilated children in general ward areas is around 10–30 mcg/kg/h. Either i.v. or s.c. routes can be used for morphine infusions, although the latter requires more concentrated solutions (Table 38.3). A wide range of morphine requirements after surgery in children has been observed and inadequate analgesia on the first postoperative day is more frequent at infusion rates < 20 mcg/kg/h.<sup>70</sup> Patient-controlled analgesia (PCA) is popular for children 5 years or older; there is a substantial literature describing its use and efficacy.<sup>71–73</sup> Nurse-controlled analgesia (NCA) is a modified continuous morphine infusion suitable for children who are unable to operate the PCA handset. Nursing staff can administer extra doses of morphine on the basis of pain assessments or before painful care or movement by operating the PCA handset. NCA increases flexibility, total morphine consumption and parent and nurse satisfaction with analgesia.<sup>74</sup> Protocols for morphine infusion, PCA and NCA are given in Table 38.3. Inadequate analgesia, nausea and vomiting, excessive sedation and respiratory depression can be troublesome problems in the postoperative period. Better pain assessment, appropriate dosing, multi-modal analgesia and

Table 38.4 Drug treatment of opioid side-effects

<b>1. Respiratory depression</b>		
Naloxone*	(Infant–12 years)	10 µg/kg i.v.
	(12–18 years)	1.5–3 µg/kg i.g.
<b>2. Nausea and vomiting</b>		
Cyclizine	1 mg/kg	Oral/i.v.
	3 times daily	(< 6 years max. 25 mg)
		(> 6 years max. 50 mg)
Ondansetron	0.1 mg/kg	Oral/i.v.
		(< 12 years max. 4 mg)
		(> 12 years max. 8 mg)
Dexamethasone	0.1 mg/kg	i.v.

Larger doses may be required for severe overdose. Lower doses should be used postoperatively with titration to obtain respiratory response while maintaining adequate analgesia.

clear protocols should minimize poor efficacy and side-effects. Naloxone should always be available when opioids are being infused.

## MANAGEMENT OF NEONATAL PAIN

Pain in the neonatal period requires special consideration because the immaturity of many body systems has profound and often unpredictable effects on both the response to pain and analgesics. Advances in perinatal care have meant that many younger and smaller patients undergo diagnostic and therapeutic procedures and present for surgery in early life. The management of these painful situations is hindered by our inability to accurately measure pain in this group and a lack of information on the precise effects of many analgesics during early postnatal development. Research in the fields of pain assessment and the developmental neurobiology and pharmacology of pain may soon influence practice, but for the present pharmacological neonatal pain management is largely based on the empirical and judicious use of, opioids (principally codeine, morphine, and fentanyl), paracetamol, and local anesthesia.

### OPIOIDS

Despite the fact that opioids are widely used in the neonatal period both for pain and sedation little is known of the thresholds for treatment or response in the term or preterm neonate.<sup>75</sup> The pharmacokinetics of morphine and other opioids have been investigated and clear relationships between age and volume of distribution and plasma clearance have been established.<sup>16</sup> Underlying medical condition is probably also important as the maturation in morphine clearance observed in infants in the first few months of life is delayed in those undergoing corrective cardiac surgery in comparison with age-matched controls after other surgical procedures.<sup>76</sup> The lack of sensitive pain measurement tools and failure to correlate plasma morphine levels with analgesia has led some authors to use the emergence of side-effects such as respiratory depression to quantify the response to morphine.<sup>77</sup> Although there is no clear dose-response relationship between plasma morphine and respiratory depression, a common threshold in neonates and infants of around 15–20 ng/ml has been suggested.<sup>77,78</sup> Based on this finding, the dose of morphine to reach this target level has been investigated and found to be 5–15 mcg/kg/h in the neonate, some 25–50% lower than in older children; suggested protocols are shown in Table 38.5.<sup>54,78</sup> Clearly, determination of the analgesic dose-response for opioids in the neonate still remains an important priority for further research.

### PARACETAMOL

Paracetamol is considered to be safe and effective in the neonatal period although, as with adults and older children, the plasma level associated with analgesia is not known.

The majority of pharmacokinetic studies have assumed plasma levels associated with the antipyretic effect of paracetamol to be therapeutic,

and therefore a guide to dosing schedules. The pharmacokinetics of paracetamol have been shown to be age dependent; neonates have a higher volume of distribution (174%) and lower clearance (62%) in comparison with older children.<sup>79</sup> Paracetamol is metabolized in the liver, where it is conjugated to glucuronide, a small amount being oxidized by cytochrome P450 to a potentially hepatotoxic product (see earlier) which is conjugated to glutathione. Both these pathways are immature in the neonate and show high variability; enhanced sulfation of paracetamol has been demonstrated, which may compensate for reduced glucuronidation.<sup>80</sup> The current recommended oral dose of paracetamol in the term neonate is 60 mg/kg/d, with 30–45 mg/kg/d suggested for pre-term infants; there are variations between different countries regarding this. The route of administration is important as bioavailability is very variable; in term neonates 20 mg/kg rectal paracetamol 6 hourly (80 mg/kg/d) does not reliably achieve therapeutic plasma levels and an initial dose of 30 mg/kg is recommended.<sup>81</sup> In pre-term neonates 20 mg/kg is effective but prolonged elimination results in accumulation if the dosing interval is less than 8 h.<sup>81</sup> I.v. paracetamol has not yet been adequately investigated in the neonate but reports of its use are starting to appear.<sup>82</sup> Propacetamol, the paracetamol pro-drug has been used in the neonate; at less than 10 d old, 30 mg/kg/d of paracetamol (60 mg/kg/d of propacetamol) maintained plasma levels between 4 and 10 mg/L, whereas after 10 d double this dose was required.<sup>45</sup>

### LOCAL ANESTHESIA IN THE NEONATE

Local anesthesia is popular in the neonate as it avoids many of the problems associated with systemic drugs. Topical local anesthesia, infiltration and nerve blocks including epidural anesthesia can be used in the newborn. Neonates may be more susceptible to toxic effects of local anesthetics so lower doses are generally recommended. Local anesthetics are extensively protein bound, the free (unbound) fraction is considered to be pharmacologically active and therefore also important for toxicity. The protein A-acid glycoprotein (AAG) and albumin are the most important plasma proteins involved and AAG levels are lower in neonates. Prilocaine is a constituent of the topical formulation eutectic mixture of local anesthetics (EMLA) and its use in the neonate has been a cause for concern. A metabolite of prilocaine, orthotoluidine is produced, which leads to the development of methemoglobin, (oxidized hemoglobin), which has a reduced oxygen carrying capacity. Methemoglobin is reduced to hemoglobin by the enzyme methemoglobin reductase, which is developmentally regulated. Neonates are also particularly susceptible because fetal hemoglobin is more easily oxidized than adult hemoglobin. Studies have shown that EMLA can be used safely in neonates provided the dose is limited proportionally.<sup>83,84</sup> In a systematic review of analgesia for neonatal circumcision, local anesthetic techniques were found to be the most effective and were recommended for this procedure.<sup>85</sup>

### SUCROSE AND NONPHARMACOLOGICAL PAIN MANAGEMENT

Sweet tasting solutions such as glucose and sucrose have been found to reduce pain responses to brief procedures in the neonate.<sup>86–88</sup> Sucrose has become popular, and there are commercially available preparations for clinical use. The analgesic effect of sucrose is thought to be related to the release of endogenous endorphins, however administration of naloxone did not decrease the analgesic effect in one trial.<sup>89</sup> Non-nutritive sucking using a pacifier, breast-feeding, and tactile stimulation have all been found to reduce pain associated responses in neonates.<sup>90–93</sup>

### MANAGEMENT OF PAIN IN THE ICU

In the intensive care unit (ICU) sources of pain include the underlying condition, the presence of endotracheal and other tubes, drains and catheters and also the many procedures which such patients frequently undergo. See section on neonatal pain for details of techniques.

Table 38.5 Suggested morphine infusion protocols in the neonate\*

Neonatal morphine infusion		
Preparation:	Morphine sulphate 1.0 mg/kg in 50 ml solution	
Concentration:	20 µg/kg/ml	
Initial dose:	0.5–5.0 ml (10–100 µg/kg)	
Infusion:	0.1–0.7 ml/h (2–14 µg/kg/h)	
Neonatal NCA		
Preparation:	Morphine sulphate	1 mg/kg in 50 ml solution.
Concentration:	20 µg/kg/ml	
Initial dose:	0.5–5.0 ml (10–100 µg/kg)	
Programming	Background infusion:	0.0–0.5 ml/h (0–10 µg/kg/h)
NCA dose	0.5–1.0 ml (10–20 µg/kg/h)	
Lockout interval:	20 min	

\* With full cardiorespiratory monitoring in intensive care areas, higher doses may be appropriate when respiration is supported.

## OPIOID INFUSIONS, TOLERANCE AND WITHDRAWAL

Opioid infusions provide background analgesia, sedation, improve comfort and facilitate synchronization of respiration with artificial ventilation in neonates and older children.<sup>94,95</sup> Morphine is the drug of choice, although fentanyl is a useful alternative, particularly if pulmonary hypertension is a concern.<sup>96</sup>

A characteristic feature of opioid infusions for more than a few days is progressive tolerance to both the analgesic and sedative effects and it is not uncommon for patients to receive doses far in excess of what is normally considered therapeutic. Intermittent administration is less likely to cause tolerance than continuous infusion but this can be impractical. Use of a background infusion with intermittent doses when necessary, e.g. for routine care, blood sampling, endotracheal suction and other procedures may reduce the likelihood of tolerance. This is very similar in concept to NCA (see earlier). Multi-modal analgesia may also be helpful and the use of agents such as clonidine and low-dose ketamine may reduce tolerance.

Abrupt withdrawal of opioids after 5 or more days of continuous use is very likely to result in the appearance of symptoms and signs of withdrawal. Gradual reduction of infusion rates by 10–20% per day should not delay tracheal extubation of the airway or discharge from ICU and will usually prevent unpleasant and distressing symptoms and potentially dangerous cerebral excitatory phenomena including convulsions. If necessary oral preparations can be used and weaning from high doses continued in low dependency areas, even at home. Clonidine and benzodiazepines ameliorate the withdrawal syndrome associated with opioids. High-dose infusions of benzodiazepines, such as midazolam, may result in benzodiazepine withdrawal, which can be avoided by substituting a long-acting benzodiazepine such as lorazepam with subsequent gradual withdrawal.

## CHRONIC PAIN

There is no precise definition of when a pain becomes chronic as it is strongly influenced by patient perception. In acute pain the prevailing mood tends toward anxiety, whereas in chronic pain withdrawal from daily life and even depression can predominate. Hope remains strong in acute pain whereas despair can dominate the chronic situation. In acute pain the person is able to focus on the pain itself but with chronic pain it becomes all pervasive.<sup>97</sup>

Effective management depends on recognizing the need to tackle both the underlying cause for the pain and its wider manifestations. Pain may be constant, such as in progressive cancer or related to exacerbations, such as in rheumatoid and connective tissue disorders. In other disorders a combination of background chronic pain interspersed with acute episodes including from procedures such as in sickle cell disease, osteogenesis imperfecta and epidermolysis bullosa. Specific treatment aimed at reversing or relieving the underlying illness is the most effective approach accompanied by short- or long-term analgesia. Analgesics are chosen according to the severity of the pain and whether it appears to be primarily related to tissue damage to inflammatory or neuropathic elements. Psychological assessment may identify a role for cognitive and behavioral pain management skills.

## SICKLE CELL DISEASE

The dual aspects of acute and chronic pain are vividly represented by sickle cell disease, where the severe pain of sickle cell crises exemplifies acute pain whereas the recurrent nature of the crises, their unpredictable nature and the lifelong and incurable nature of the disease results in aspects characteristic of chronic intractable pain.<sup>98</sup> Management of pain for these children and young people has a poor record, with inappropriate fears of addiction and misunderstanding of cultural aspects of the illness, resulting in analgesics being under used. Current approaches recognize the need to give patients more credence and con-

trol, by enabling a more rapid response at the start of a crisis including i.v. opioids by PCA and using nonpharmacological approaches.

## CHRONIC PAIN SYNDROMES

A significant number of children present with symptoms of pain but where a physical cause is not evident, where the pain seems disproportionate to the tissue damage or where pain persists after previous damage appears to have healed.

### Complex regional pain syndrome

One common picture, often occurring with limb pains is that of increasing disability and associated sympathetically mediated features such as edema, decreased temperature and pallor or cyanotic coloring of the affected part, hyper-esthesia of the skin, muscle wasting and eventually osteoporosis and atrophy. This has been called reflex sympathetic dystrophy (RSD) in the past but is now considered part of the spectrum of chronic regional pain syndrome (CRPS). Although sympathetic nervous system involvement is not invariable fatigue, widely disseminated pains and other features such as malaise, disability, school absence and family disruption are common. Significant analgesic use is usual and reported as rarely effective in relieving the pain. Sometimes these children are labeled as malingering or disbelieved, resulting in anger and frustration. CRPS is more common in girls, and in contrast to adult presentations, the lower limb is usually involved.<sup>99</sup> A confident diagnosis of CRPS depends on careful exclusion of an observable underlying pathology and effective intervention begins with acknowledging the reality of the pain and symptoms, of the impact on the child and family and a recognition of the complex and ill-understood nature of the problem. The causes are not clearly understood and appear to involve features of neuropathic pain, with a persistent and inappropriate upregulation of pain perception, in the wider context of a bio-behavioral response to the pain. Early diagnosis of CRPS is thought to improve prognosis, immobilization of the affected limb is strongly contraindicated and a regimen of desensitization treatment with active and passive movement should be introduced as soon as possible.<sup>100</sup> The most successful management is multidisciplinary.<sup>99,100</sup> As well as medical and nursing input it involves physiotherapy, psychological and pharmaceutical assessment followed by the development of a comprehensive treatment program, with the involvement of the child and family. Interventions should be outpatient based, but in severe situations intensive inpatient programs may be needed.<sup>31</sup> Care includes the gradual withdrawal of inappropriate analgesics, and cautious use of medications effective in neuropathic pain such as the sodium channel blockers gabapentin and the tricyclic antidepressants; there is little evidence to support the use of sympathetic blocks for CRPS.<sup>99</sup> Learning coping skills, cognitive-behavioral therapy, graded exercise, goal setting and regular support and monitoring are the mainstays of treatment. The course may be one of improvement and relapses.

## PALLIATIVE CARE

Pediatric palliative care is a holistic approach to the care of children with life-limiting and life-threatening illness, where symptom management is addressed alongside the provision of practical, psychological, social and spiritual support for the whole family. It should be provided from the time of diagnosis of a life-limiting or life-threatening condition and should continue through life, death and bereavement. It is not confined to the terminal phase of an illness and can co-exist alongside life-prolonging and life-saving treatments.

### WHO NEEDS PALLIATIVE CARE?

Many of the relevant illnesses are specific to children, are very rare and have a protracted course. Some are familial and may affect several children in the same family, with genetic implications for the parents and healthy siblings.

Children who may benefit from a palliative care referral can be considered in four broad groups:<sup>101</sup>

1. life-threatening conditions where curative treatment may be possible but may fail. Palliative care is needed in times of prognostic uncertainty or when cure becomes impossible. Cancer is an example;
2. conditions where there are long periods of intensive treatment aimed at prolonging life, but where life expectancy is significantly reduced. Cystic fibrosis and acquired immune deficiency syndrome (AIDS) fit this pattern;
3. progressive conditions where treatment is entirely palliative and may extend over many years. Neurodegenerative diseases and many inborn errors of metabolism are examples;

4. irreversible but nonprogressive conditions causing severe disability, such as severe cerebral palsy.

#### PROVIDING SERVICES FOR THE FAMILY

The overall needs for children and their families have been summarized in the Association for Children with life-threatening or terminal conditions and their families (ACT) Charter (Fig. 38.3).<sup>102</sup> These must be considered when planning and delivering palliative care services.

An increasing recognition of the need for pediatric palliative care services has resulted in an increase in the number of children's hospices and community teams and medical and nursing specialists providing these services.

- Every child shall be treated with dignity and respect and shall be afforded privacy whatever the child's physical or intellectual ability.
- Parents shall be acknowledged as the primary carers and involved as partners in all care and decisions involving their child.
- Every child shall be given the opportunity to participate in decisions affecting his or her care, according to age and understanding.
- An honest and open approach shall be the basis of all communication.
- Information shall be provided for the parent, the child, the siblings and other relatives, appropriate to age and understanding.
- The family home shall remain the center of caring whenever possible. Care away from home shall be provided in a child-centered environment by staff trained in the care of children.
- Every child shall have access to a 24-hour multidisciplinary children's palliative care team for flexible support in the home, and be in the care of a local pediatrician.
- Every child and family shall receive emotional, psychological and spiritual support to meet their needs. This shall begin at diagnosis and continue throughout the child's lifetime, death and in bereavement.
- Every family shall be entitled to a named keyworker who will enable the family to build up and maintain access to an appropriate network of support.
- Every family shall be given the opportunity of a consultation with a pediatric specialist who has particular knowledge of the child's condition.
- Every family shall have access to flexible short-term breaks (respite care) both in their own home and away from home, with appropriate children's nursing and medical support.
- Every child shall have access to education and other appropriate childhood activities.
- The needs of adolescents and young people shall be addressed and planned for well in advance.
- Every family shall have timely access to practical support, including clinical equipment, financial grants, suitable housing and domestic help.

Fig. 38.3 ACT Charter.<sup>102</sup>

## LOCATION OF CARE

It is important that families are given choices as to where their child receives care. Many will prefer to care for their child at home,<sup>103</sup> whereas others will prefer hospital or hospice care. Families must be brought to a realistic expectation with regard to the needs of their child as their health deteriorates and the support that is available, particularly if they choose to be at home. They will also need access to advice and support 24 hours a day from professionals with palliative care expertise, or supported by professionals with this specialist knowledge. There should be sufficient flexibility to enable the family to move between home and/or hospice, as they choose, without care being compromised.

## SYMPTOM MANAGEMENT

As parents frequently worry that their child will experience symptoms that will be difficult to control it is important to provide them with detailed and honest information about the management of their child's current and anticipated symptoms. Both they and their child need to take an active part in planning a practical and acceptable regimen of care, in order to instill a level of competence and confidence in controlling pain and discomfort and in understanding their child's management.

As death approaches parents will need and value further information, including knowledge of the possible modes of death and the physical signs that suggest death is imminent. Knowing what to expect and having a clear plan of action as the situation changes can enable families to cope better.

Almost all families can be reassured that death will be peaceful, but if there are concerns about the possibility of sudden distressing symptoms (such as convulsions, acute agitation, or bleeding) these should be discussed openly. Emergency drugs (e.g. anticonvulsants, analgesics and sedatives) should be accessible in suitable doses via appropriate routes.

## PATTERN OF SYMPTOMS

Although many unpleasant and distressing symptoms are common to a number of different illnesses, their underlying cause (and therefore the approach to symptom management) may be different. For rare conditions anticipation of possible symptoms will require input from specialist pediatricians and nursing staff.

Children with malignant disease often have a relatively short final illness, lasting weeks or months, with pain from tumor progression as a predominant feature whereas in nonmalignant conditions onset may be more insidious with less prominence of pain and greater likelihood of muscle spasms, gastroesophageal reflux, seizures and respiratory distress.

## ASSESSMENT OF SYMPTOMS

Thorough assessment of any symptom is essential before developing a plan of management. As much information as possible should be elicited, and this can be particularly challenging in nonverbal children and those with severe developmental impairment.<sup>104</sup> A range of tools are available to assess pain in children of different ages and developmental levels, but similar tools are not yet sufficiently developed to aid the assessment of other symptoms. Parents and carers should also be asked to contribute their observations to the assessment, as they will notice subtle changes that may not be apparent to health care professionals. Psychological and social factors affecting the child and family are often significant and should be considered as part of an assessment.

## ROUTES OF DRUG ADMINISTRATION

The preferences of the child and family need to be taken into account. Taking a lot of medication can be difficult and complex regimens should be avoided. It is important to find the most acceptable route for the child and to be flexible to changing situations, such as a deteriorating swallow or an increasing reluctance to comply with medication regimens. Key issues in deciding routes of administration include:

- The oral route is often preferable and the child should be allowed to choose between liquids capsules and whole or crushed tablets.
- Long-acting preparations are more convenient and less intrusive.
- As the condition deteriorates the treatment plan often has to be simplified, routes of administration altered and priority given to those drugs that contribute most to the child's comfort.
- Some children prefer rectal medication to needles when the oral route is not possible and rectal preparations can also be helpful in the final hours when the child's level of consciousness has deteriorated.
- If parenteral drugs are needed they are usually given by continuous s.c. infusion, not as boluses. An i.v. line can be used if it is already in place. The transdermal route should also be considered.
- Intramuscular drugs are painful and should be avoided.

## NON-DRUG MANAGEMENT

Adopting a holistic approach that addresses the psychological, social and spiritual concerns of the child and family is likely to achieve better symptom management than medication alone. Explaining the reason for the symptom agreeing a logical step-wise approach and reassuring the child and family that the situation is not going to be allowed to go 'out of control' are the foundations of successful management. Other measures that can be used alongside or in place of drug therapy include careful positioning of the child, maintaining a calm environment, distraction, imagery and relaxation techniques, play, art and music therapy.

## PAIN

Pain management will include treating the underlying cause of the pain, where possible. For example, bony metastases may be treated with radiotherapy and painful muscle spasms with muscle relaxants rather than analgesics. Where treatment of the underlying cause is not possible, or does not relieve pain sufficiently, analgesics should be used alongside psychological and practical approaches. The WHO ladder of analgesia has been widely adopted, although recent evidence has shed some doubt on the routine use of codeine as up to 10% of the population may be poor metabolizers of the drug to morphine (the active metabolite). Poor efficacy is also a feature in infants because of immature enzyme systems.<sup>105</sup>

### Opioid-sensitive pain

#### **Strong opioids**

These are used extensively in managing pain in pediatric palliative care. When prescribing strong opioids for children, the following points should be considered:

- long-acting morphine preparations are effective and convenient;
- short-acting preparations will be needed for breakthrough pain;
- where oral administration is difficult or impossible the use of transdermal patches (e.g. fentanyl) has proved invaluable;<sup>106</sup>
- sudden onset of severe pain may require break-through analgesia with a faster onset of action than oral morphine. Fentanyl lozenges, buccal or intranasal morphine may be appropriate in these situations.<sup>107,108</sup>
- studies of the pharmacokinetics of oral opioids and their metabolites suggest that in young children metabolism is more rapid than in adults and they may require relatively higher doses;
- neonates and children under 6 months old usually require a lower starting dose of opioids because of their reduced metabolism and increased sensitivity.<sup>109</sup>

#### **Side-effects of opioids**

Many doctors lack experience of using strong opioids in children, which can lead to unnecessary caution, underdosing and inadequate pain control. Respiratory depression with strong opioids is not usually a problem in children with severe pain and in general the side-effects from opioids tend

to be less marked than in adults. Nausea and vomiting are rare and routine anti-emetics are often not needed. Constipation is the most common side-effect of opiates and regular laxatives should always be prescribed.

Parents and children should be warned that they may become drowsy during the first few days of starting opioids but reassured that this will resolve. Itching usually responsive to antihistamines may also be a problem within the first few days. If either somnolence or pruritus remain troublesome, switching to an alternative preparation, such as fentanyl or hydromorphone is usually effective.<sup>110</sup>

### Parental concerns about opioids

Parents may express concern that opioids will precipitate death, or worry that if they are started 'too early' they will lose efficacy as the illness and symptoms progress. Others find the transition to opioids difficult from a psychological and emotional perspective and that by agreeing to use opioids they are acknowledging that their child is going to die imminently.

Parental concerns require sensitive discussion and support. Parents must be assured that:

- their child will receive appropriate analgesia in the lowest dose needed to relieve pain;
- opioids do not precipitate death when used appropriately;
- there is no upper or ceiling dose for effective pain relief.

### Musculoskeletal pain

Nonsteroidal anti-inflammatory drugs (NSAIDs) are often helpful for musculoskeletal pain, although caution is needed in the presence of bone marrow infiltration because of the increased risk of bleeding. Bisphosphonates should also be considered, particularly in children with long-term conditions associated with immobility, such as osteogenesis imperfecta.<sup>111</sup> Oral chemotherapy may be helpful in reducing tumor-related musculoskeletal pain.

### Headaches in malignant disease

Headaches from central nervous system leukemia respond well to intrathecal methotrexate whereas those associated with raised intracranial pressure, are best managed with gradually increasing analgesics. Although steroids may seem helpful initially, the symptoms will inevitably recur as the tumor increases in size, necessitating increased doses of steroids with associated side-effects that almost always outweigh the benefits.<sup>112</sup>

### Neuropathic pain

Neuropathic pain can often be helped by antiepileptic and antidepressant drugs. Ketamine can also be helpful, either orally or by continuous infusion.<sup>113,114</sup> For severe pain unresponsive to these drugs, intrathecal, epidural anesthesia and nerve blocks should be considered.

### Muscle spasm and dystonia

These can be particularly problematic in children with neurological conditions and untreated can cause considerable pain and discomfort. An assessment of seating should be a priority as simple changes can have significant benefits. Muscle relaxants such as diazepam, baclofen and dantrolene may also be required.<sup>115</sup>

### Gastro-esophageal reflux

A significant proportion of children with neurological impairment and/or disorders affecting muscle tone experience pain associated with gastro-esophageal reflux. Management should include a combination of approaches, such as attention to the feeding regimen, posture during and after feeds, as well as medical approaches including drugs to reduce acid production and to increase gastric emptying. Surgical management should also be considered for some children<sup>116</sup> (see Chapter 19: gastro- and hepatology chapter section GOR pp 605)

### Nausea and vomiting

Nausea and vomiting can be a significant symptom in children with raised intracranial pressure and in a variety of other diseases causing metabolic disturbance or impaired gastrointestinal function. Anti-emetics

that work well in one situation (e.g. ondansetron in cancer patients undergoing chemotherapy) may be far less useful in other situations (e.g. cancer patients not having chemotherapy), so must be selected according to their site of action and the presumed cause of symptoms. This is summarized in Table 38.6.

### Seizures

Children with neurodegenerative diseases often develop seizures as part of their ongoing disease with increasing problems in seizure control as the disease progresses. Other children may only develop seizures towards or during the terminal phase of their illness. Sudden acute onset of seizures can be treated with rectal diazepam or buccal midazolam.<sup>117</sup> Repeated severe or continuous seizures in a terminally ill child can be treated at home with a continuous subcutaneous infusion of midazolam and/or phenobarbitone.

### Agitation and anxiety

Agitation and anxiety may reflect a child's need to talk about his or her fears and distress. Open communication should be encouraged throughout the child's illness, so that anxiety and fears can be addressed while the child is still able to communicate easily. If additional drugs are needed, benzodiazepines, haloperidol and levomepromazine can provide relief, especially in the final stages of life.

### Respiratory symptoms

Dyspnea, cough, and excess secretions can all cause distress to children and anxiety for their parents. If the underlying cause of the symptom can be relieved, even temporarily, this may be appropriate. Palliative radiotherapy, for example, can bring good symptomatic relief to some children with primary or secondary thoracic tumors.

### Breathlessness

Where treatment of the underlying cause is unlikely to be beneficial, symptom relief can be addressed by combining drugs with practical and supportive approaches. Fear is often an important element in dyspnea and reassurance and management of anxiety may help to relieve symptoms. Simple practical measures include finding the optimum body position, using a fan, and relaxation exercises. Opioids can help to relieve the sensation of breathlessness and small doses of sedatives, such as diazepam or midazolam, can relieve the associated anxiety.

Increasing hypoxemia may result in headaches, nausea, daytime drowsiness, and poor-quality sleep. Intermittent oxygen may help relieve these symptoms and can be given relatively easily at home.

### Secretions

Excess secretions may occur during the terminal phase and are often a problem for children with chronic neurodegenerative diseases as they become less able to cough and swallow. Oral glycopyrronium bromide, or hyoscine hydrobromide (given transdermally or subcutaneously) can often help to reduce the secretions. For children in the terminal stage of an illness, altering the child's position to allow secretions to

Table 38.6 Medical management of nausea and vomiting

Cause of vomiting	Recommended drugs
Drug induced and metabolic	Haloperidol Levomepromazine Ondansetron
Poor gastric outflow	Metoclopramide Domperidone
Gastric outflow obstruction	Octreotide Hyoscine butylbromide
Raised intracranial pressure	Cyclizine Hyoscine Dexamethasone (in short courses of 3–5 d)

drain orally may provide temporary relief. Suction equipment may be helpful in some situations, but can stimulate increased production of secretions and also increase the burden of nursing care for the parents.

## ANEMIA AND BLEEDING

The treatment of anemia by blood transfusion in the late stages of a child's life should only be used in the relief of symptoms.

Florid bleeding (e.g. severe hemoptysis or hematemesis) is extremely frightening for a child and their carers and when this occurs death is usually very rapid. If this is a serious risk both an analgesic and a sedative, such as morphine and midazolam should be readily available. In an emergency, parents can give these drugs by the buccal route and should repeat the dose every 15 min until the child is calm. Medication should be continued by continuous s.c. or i.v. infusion.

Many children with malignant diseases have widespread bone marrow infiltration and low platelets. Petechiae and minor gum bleeding are common although significant bleeding is unusual. Minor gum and nose bleeding can be managed by direct application of tranexamic acid to the bleeding point. Platelet transfusions should only be used to manage bleeding that is severe or that interferes with the child's quality of life.

## IMPAIRED APPETITE AND POOR FEEDING

For many children, disease progression is associated with impaired appetite, which parents often find extremely distressing. For children, constant attempts by parents to encourage them to eat are similarly distressing.

Reasons for reduced feeding should be explored and reversible causes treated where possible. Assisted feeding, via a nasogastric tube or gastrostomy, may be necessary for children with slowly progressive disease, especially where this is associated with a declining ability to swallow but not a reduced appetite. For children with a poor appetite and rapidly progressive disease, nasogastric or gastrostomy feeding is usually inappropriate and can cause increased nausea and vomiting.

Where a child has a poor appetite or cannot tolerate amounts of food that parents consider acceptable, parents should be encouraged to relax nutritional goals and to provide only small amounts of food that the child enjoys, throughout the day. It is important to explain to parents that a reduced appetite is part of the disease progression and encouraging the child to eat more than they can manage may make them feel more unwell.

## PSYCHOSOCIAL AND SPIRITUAL SUPPORT

All children and young people facing death or with a reduced life expectancy deserve help in maintaining as much normal life as possible, ensuring good access to play, education and social experiences and assistance in focusing on and achieving appropriate goals. A number of themes facing the sick child and family have been identified and these occur at diagnosis and then recur at different critical points throughout the course of the illness. Awareness and attention to these difficulties and common themes can provide valuable support for families:

- the need to be given appropriate information;
- the importance of enabling children and families to identify and express their emotions and spiritual needs;
- recognition that emotional and spiritual needs and ways of coping vary between different members of the family and at different times during the illness;
- awareness of the difficulty for families of living with uncertainty;
- acknowledging the benefits of and enabling open and honest communication both within families and between families and professionals;
- the value of empowering families and enabling them to retain choices and a sense of control.

For the parents and siblings of children with nonmalignant diseases, the prolonged time course and enormous nursing demands will increase the stress and practical difficulties. Throughout the course of a child's illness and death family members are likely to experience a huge range of feelings, such as sadness, despair, depression, hopelessness, anger, guilt, resentment of the sick child and isolation. Siblings often feel a sense of exclusion and neglect, although those who are very involved in caring for the sibling may also express positive experiences.<sup>118,119</sup>

Talking openly with families and with the sick child, however difficult, is usually helpful in reducing the child's level of anxiety and improving the family's later adjustment.<sup>120</sup> Most children are already aware, through their own interpretation of verbal and nonverbal cues, of much more about their illness and situation than most adults expect. Listening to their cues, exploring their fears and worries, responding honestly but gradually and using a range of nonverbal approaches (play, stories, art) are all skills that can help and which members of the multidisciplinary palliative care team can bring to the family and child.<sup>121</sup> Factors which need to be taken into account when talking with children include the child's age and developmental level, their likely understanding of their illness and of death, the child and family's past experiences and the family's normal communication pattern and culture.<sup>122,123</sup>

## THE BEREAVED FAMILY

It is essential that the emotional support provided throughout the child's life is continued through the family's bereavement. The grief suffered after the loss of a child has been described as the most painful, enduring and difficult to survive and is associated with a high risk of pathological grief. Parents lose not only the child they have loved, but their hopes for the future and their confidence in themselves as parents. It puts an additional stress on their own relationship and alters the whole family structure. The brothers and sisters who are grieving may continue to feel isolated and neglected as their parents can spare little time or emotion for them. Ideally the professionals who know the family well and have been involved throughout the sick child's life should continue to be available through their bereavement. Grief is likely to continue over many years, and its depth and persistence is often underestimated. Parents value continuing contact with professionals who have known their child and the opportunity to talk about the child and their grief when others in the community expect them to 'have come to terms with it'.<sup>124</sup> This support, initially more frequent and gradually decreasing, helps facilitate the normal tasks of mourning. Most families will not need formal counseling but it is important to be able to recognize when there are signs of abnormal grief that may require referral for specialist help.

Helping to care for a child with a life-threatening illness, and for the family of such a child, is rarely easy. It presents many challenges both in terms of the professional tasks that may be required and to our own emotional resources. Though the task may seem daunting, families greatly value professionals who stay alongside them throughout their journey, providing practical help and support in an almost intolerable situation. Parents will have a lasting memory of their child's death and as professionals we have the opportunity to ensure this memory is as good as it can be.

## CONCLUSION

Knowledge and skills in pain management and palliative care have been increasing in recent years. It will be essential to continue to these developments, to challenge misinformation and to work towards enhancing pain management and reducing suffering for children, throughout the world. Although little evidence-based information is available to date it is likely that employing the basic principles of pain and relief and control and good communication with children and families will ensure optimal management.

## REFERENCE RANGES FOR BIOCHEMICAL LABORATORY TESTS

### INTRODUCTION

It is important to note that there are no internationally accepted worldwide reference ranges available for laboratory data. It should also be noted that it is difficult for individual laboratories to collect their own data on 'normal' subjects for ethical and logistical reasons. This problem is highlighted particularly with neonatal and pediatric reference ranges and hence many of the data available today still originate from historical studies. There are many variables which affect particular biochemical parameters and must be considered before specific data from an individual patient can be reliably used. These variables are summarized below as a prompt when considering reference data. The values detailed in this chapter are therefore a **guide only** to interpreting laboratory data for neonates, infants and children and must never be considered as absolute. They apply to the specific laboratory methods used by the individual laboratories and centers from which the assembled data has been sourced and will not necessarily apply to methods used in other laboratories.

In addition to reference ranges, many laboratories have defined 'action limits' for a number of analytes, e.g. sodium, potassium, glucose, calcium and C-reactive protein (CRP). Action limits are usually concentrations which could indicate medical emergencies and therefore need acting on promptly; values are usually agreed between laboratories and medical staff in individual units. The laboratory will usually have in place a telephoning protocol to the clinician in charge of that patient. Action limits should be differentiated from reference ranges.

### Methodology

Measurement of an analyte using different technologies may significantly affect the result and hence reference ranges. This is because different methods use different characteristics of a compound to quantify the amount: this may be a chemical reaction with another molecule to produce a product which can be measured, an immunological feature or parameters based on fluorescence, light absorption or electrical activity. For example, sodium can be measured using the principle of light absorption by flame photometry or electrical activity by ion selective electrodes (ISEs). Values derived from ISEs are lower than those from flame photometry. Interference from other molecules is another factor which may be a problem for some methods used – such an

example is interference by ketones in creatinine measurement. Bilirubin measurement may be interfered with by hemoglobin in some methods and therefore capillary blood samples, in which there is a greater risk of hemolysis compared to venous samples, require special attention when choosing a suitable method. Due attention must be given when a patient is referred from one hospital or clinic to another if laboratories use different analytical methods. In such circumstances apparent differences in the value of analytes may be due to the different methodologies and not to physiological changes.

### Neonatal reference ranges

Providing reference range data for the neonatal period is even more difficult than for other age ranges in view of the number of physiological processes that the newborn undergoes. The birth process and subsequent rapid growth and maturation result in significant changes during the first four weeks of life for many analytes such as cortisol, TSH and thyroxine, which are all elevated immediately after birth in order to provide the newborn with the hormonal stimulation it requires to adapt to life outside the womb. Biochemical changes are also seen with different feeding regimens. Two notable examples include higher values of urea in bottle fed compared with breast fed infants, and significant differences in some amino acid levels associated with the use of formula milks.

### Patient variables

Reference range data can also differ between gender, gestation, age and ethnicity. There can be marked differences in values for certain analytes, obvious examples between male and female being hormones, and differences across age range are highlighted by alkaline phosphatase. It must therefore be remembered that the cohorts of patients used to derive the reference ranges detailed in this chapter may not directly relate to the population from which the individual patient under consideration has been drawn. Where significant differences occur this has been annotated in the tables with specific text.

### Specimen type

The specimen type used in the collection of the reference range data is stated in the tables where appropriate. The use of different types (plasma vs. serum) or anticoagulants (lithium heparin vs. EDTA) can greatly affect the results obtained by certain methodologies and this must be taken into account. For some analytes, such as glucose, triglycerides

and amino acids, fasting is of particular importance. These features are noted in the tables where relevant.

### Measurement and units

In this chapter, reference values are generally given in SI units and, where considered appropriate, a conversion factor has been given to convert from weight units. This is the number by which weight units need to be multiplied in order to convert weight units into SI (Système International d'Unités) units.

The SI unit of quantity is the mole (the molecular weight of a substance expressed in grams) and the unit of volume is the liter, therefore the SI unit used in these tables is moles/Liter or mol/L. Smaller multiples of this SI unit are generally used to convert the figure into a whole number or to reduce decimal points:

Millimole/L (mmol/L)  $\times 10^{-3}$

Micromole/L ( $\mu\text{mol/L}$ )  $\times 10^{-6}$

Nanomole/L (nmol/L)  $\times 10^{-9}$

Picomole/L (pmol/L)  $\times 10^{-12}$

For enzyme measurements, where the weight and therefore molarity is often unknown, activity is measured rather than the absolute quantity of the enzyme. The International Union of Biochemistry recommended in 1964 that enzymes should be expressed in international units (IU). In this scheme 1 IU is the amount of enzyme that will catalyze the transformation of 1 micromole of substrate per minute. In addition to IU of measurement, units/liter or U/L is now in common use.

### Data interpretation

The correct interpretation of laboratory results from an individual patient can only be carried out with adequate liaison with the local laboratory which should be able to provide the appropriate reference ranges taking into consideration the patient variables, methodology and sample type used.

The ranges provided in this chapter are based on literature sources, our own studies, unpublished data from specialist groups, and in some cases a combination of sources.<sup>1-36</sup>

Key: y = year  
m = month  
d = day

## LABORATORY REFERENCE VALUES

Table A.1 Blood and plasma reference ranges (common 20 analytes)

Analyte	Age	Reference range	Weight unit (where applicable)	Conversion factor	Comments	
Alanine aminotransferase (ALT)	Neonate	0–40 U/L			Gross hemolysis will cause false elevation	
	Infants	10–80 U/L				
	Children	10–40 U/L				
Alkaline phosphatase (ALP)	Preterm	Up to 1500 U/L			Alkaline phosphatase activity changes markedly through life and reference ranges are highly method dependent. These ranges should be used as a guide only and you should refer to your local laboratory for their reference ranges	
	Neonate	Up to 700 U/L				
	Infants	250–1000 U/L				
	2–5 y	250–850 U/L				
	6–7 y	250–1000 U/L				
	8–9 y	250–750 U/L				
		<i>Male</i>		<i>Female</i>		
	10–11 y	250–730 U/L		250–950 U/L		
	12–13 y	275–875 U/L		200–730 U/L		
	14–15 y	170–970 U/L		170–460 U/L		
16–18 y	125–720 U/L		75–270 U/L			
Ammonia	Neonate	< 100 $\mu\text{mol/L}$	$\mu\text{g}/100\text{ ml}$	0.54	Venous samples are preferred. Capillary concentrations are generally higher. Venous ranges are shown	
	Infants/children	< 40 $\mu\text{mol/L}$				
	Preterm or sick neonate	< 150 $\mu\text{mol/L}$				
Aspartate aminotransferase (AST)	Neonate	< 120 U/L			Gross hemolysis will cause false elevation	
	Infants	< 80 U/L				
	Children	15–50 U/L				
Bilirubin, total	Neonate 2–6 d	Up to 217 $\mu\text{mol/L}$	mg/100 ml	17.1		
	Neonate 6–10 d	Up to 230 $\mu\text{mol/L}$				
	> 1 m	1.7–26 $\mu\text{mol/L}$				
Bilirubin, unconjugated	0–10 d	10–180 $\mu\text{mol/L}$			Conjugated and unconjugated values are method dependent; older methods may measure direct and indirect bilirubin which is different	
	11d–20 y	3–17 $\mu\text{mol/L}$				

Analyte	Age	Reference range	Weight unit (where applicable)	Conversion factor	Comments
Calcium	0–5 d 5 d – 1 y 2–5 y > 5 y	1.95–2.75 mmol/L 2.15–2.75 mmol/L 2.15–2.65 mmol/L 2.20–2.60 mmol/L	mg/100 ml	0.25	Interpretation of calcium concentration should take into account the albumin concentration as hypoalbuminemia reduces the total calcium concentration. An equation for 'adjusted calcium', which takes into account the albumin concentration, should be available from your local hospital
Chloride		95–106 mmol/L	mEq/L	1	
Cholesterol	Birth 1 w 1–3 y 4–6 y 7–9 y  10–11 y 12–13 y 14–15 y	0.5–3.2 mmol/L 1.7–4.2 mmol/L 1.2–4.7 mmol/L 2.8–4.8 mmol/L 2.9–5.3 mmol/L  <i>Male</i> 3.3–6.0 mmol/L 3.3–6.0 mmol/L 2.8–5.8 mmol/L	mg/100 ml	0.026	Cholesterol rises rapidly after birth and levels are higher when fed on human rather than cows' milk
		<i>Female</i> 3.3–6.3 mmol/L 3.3–5.6 mmol/L 3.4–5.6 mmol/L			
Cortisol	At 9 am At midnight	180–550 nmol/L < 130 nmol/L	µg/100 ml	27.6	Stress raises cortisol levels. Cortisol levels are lower in neonates but reach near adult levels by 2 m of age. Hydrocortisone and prednisolone cross react with many assays, but dexamethasone generally does not
Creatine kinase (CK)	Newborn  Infant  4–6 y 7–9 y 10–11 y 12–13 y 14–15 y 16–19 y	160–1230 U/L  60–305 U/L  <i>Male</i> 75–230 U/L 60–365 U/L 55–215 U/L 60–330 U/L 60–335 U/L 55–370 U/L			Activity increases after exercise or muscle trauma
		<i>Female</i> 75–230 U/L 60–365 U/L 80–230 U/L 50–295 U/L 50–240 U/L 45–230 U/L			
Creatinine	Neonate > 1 m and up to 2 y Up to 5 y 5 y and over	20–100 µmol/L 20–60 µmol/L  20–70 µmol/L 20–80 µmol/L	mg/100 ml	88.4	Levels rise gradually with age, are dependent on muscle mass and are very method dependent. Values shown are based on a Jaffe method and should be used as a guide only. Contact your local laboratory for its method-related reference ranges
Glucose	Neonate 12–24 h 25–48 h 4–7 d Over 7 d	2.4–5.4 mmol/L 2.9–5.2 mmol/L 3.2–5.9 mmol/L 3.9–6.0 mmol/L	mg/100 ml	0.055	Symptomatic hypoglycemia is usually associated with concentrations < 2.5 mmol/L. It is recommended that fasting glucose results > 6.0 mmol/L should be further investigated by WHO criteria. Ranges shown are for a fasting sample
γ-Glutamyl-transferase (γGT)	Newborns Infants Children	< 200 U/L < 120 U/L < 35 U/L			
Magnesium	Neonate > 1 m	0.48–1.05 mmol/L 0.6–0.95 mmol/L	mg/100 ml	0.411	
Osmolality		275–295 mmol/kg	mosmol/kg	1	
Phosphate	Neonate 1–3 y 4–6 y 7–11 y 12–13 y 14–15 y 16–19 y	1.55–2.65 mmol/L 1.25–2.10 mmol/L 1.3–1.75 mmol/L 1.20–1.80 mmol/L 1.05–1.75 mmol/L 0.95–1.75 mmol/L 0.90–1.50 mmol/L	mg/100 ml	0.323	Hemolysis and capillary samples give elevated results

(Continued)

Table A.1 Blood and plasma reference ranges (common 20 analytes)—Cont'd

Analyte	Age	Reference range	Weight unit (where applicable)	Conversion factor	Comments				
Potassium	Neonate	3.2–5.5 mmol/L	mEq/L	1	Hemolysis and delayed separation can give falsely elevated results. Ranges shown are for venous samples				
	1 w – 1 m	3.4–6.0 mmol/L							
	1–6 m	3.5–5.6 mmol/L							
	6 m – 1 y	3.5–5.1 mmol/L							
	> 1 y	3.3–4.6 mmol/L							
Total protein	Neonate	54–70 g/L	g/100 ml	10.0					
	1–3 y	60–70 g/L							
	> 3 y	60–80 g/L							
Triglyceride	1–3 y	0.33–1.48 mmol/L	mg/100 ml	0.011	Ranges shown are for a fasting sample				
	4–6 y	0.38–1.38 mmol/L							
	7–9 y	0.34–1.53 mmol/L							
	10–11 y	<i>Male</i> 0.28–1.63 mmol/L <i>Female</i> 0.46–1.66 mmol/L							
	12–13 y	0.28–1.72 mmol/L 0.44–1.54 mmol/L							
	14–15 y	0.40–1.95 mmol/L 0.43–1.60 mmol/L							
	Sodium	Neonate				132–145 mmol/L	mEq/L	1	Pseudohyponatremia can occur due to gross lipemia or hypoproteinemia when indirect ISE and flame photometry methods are used
	> 1 m	135–145 mmol/L							
Standard bicarbonate	Newborns	18–25 mmol/L	mEq/L	1					
	> 1 m	21–25 mmol/L							
Urea		2.5–6.6 mmol/L	mg/100 ml	0.357	Values in neonates and breast-fed infants may be lower				

Table A.2 Blood and plasma reference ranges

Analyte	Age	Reference ranges	Comments
Albumin	Newborn 1 y 4 y and older	25–50 g/L 35–50 g/L 37–50 g/L	Albumin concentrations in the preterm infant are <i>normally</i> lower than in the term infant and are not indicative of protein deficiency
Adrenocorticotrophic hormone (ACTH)		< 46 ng/L	There is diurnal variation with levels being higher in the morning. Samples should be taken at 10am with a serum cortisol
Aldosterone	Infants 1–4 y 5–9 y 10–15 y	165–2930 pmol/L 70–950 pmol/L 30–620 pmol/L 70–580 pmol/L	Patients should be on a normal salt diet and recumbent before blood collection
Amino acids		( $\mu\text{mol/L}$ )	Many laboratories perform qualitative amino acid investigations looking for an abnormal pattern before undertaking quantitative investigation
Taurine		20–120	These are approximate ranges for children and are only a guide; values for the neonate and infant will differ
Aspartic acid		1.0–20	Reference values will vary with age and feeding/fasting states – consult your specialized laboratory
Threonine		40–200	
Serine		70–200	
Asparagine		15–85	
Glutamic acid		15–80	
Glutamine		330–810	
Proline		40–330	
Glycine		110–340	
Alanine		120–600	
Citrulline		10–50	
Valine		130–350	
Cystine		25–70	
Methionine		5.0–40	
Isoleucine		30–100	
Leucine		50–200	
Tyrosine		30–100	
Phenylalanine		25–100	
Ornithine		20–135	
Lysine		70–270	
Histidine		45–120	
Arginine		10–110	
Amylase	Neonates > 1 m	< 50 U/L 30–100 U/L	
Androstenedione	Neonates Prepubertal Post puberty: male Post puberty: female	1.3–16.5 nmol/L 2.0–4.2 nmol/L 2.8–10.5 nmol/L 1.7–12.9 nmol/L	
$\alpha$ 1-antitrypsin		1.8–4.0 g/L	$\alpha$ 1-antitrypsin is an acute phase protein
Base excess		$\pm$ 2.5–2.5 mmol/L	
Bicarbonate or total CO <sub>2</sub>	Neonates > 1 m	18–23 mmol/L 20–26 mmol/L	
PCO <sub>2</sub>		4.7–6.0 kPa	
Carboxyhemoglobin		Up to 1.5% of total Hb	
Carotenes		0.9–3.7 $\mu\text{mol/L}$	
Catecholamines (plasma)			
Noradrenaline		591–2364 pmol/L 1773–5320 pmol/L	Supine Standing
Adrenaline		< 382 pmol/L < 546 pmol/L	Supine Standing
Dopamine		< 196 pmol/L	Supine and standing
Ceruloplasmin	< 4 m 4 m – 1 y 1–10 y 10–13 y > 13 y	0.09–0.27 g/L 0.14–0.41 g/L 0.24–0.47 g/L 0.18–0.27 g/L 0.24–0.71 g/L	

(Continued)

Table A.2 Blood and plasma reference ranges—Cont'd

Analyte	Age	Reference ranges	Comments
Copper	0–5 d	1.4–7.2 µmol/L	
	5 d – 6 m	4.0–11.0 µmol/L	
	> 6 m	11.0–22 µmol/L	
Dehydroepiandrosterone sulfate (DHAS)		<i>Male</i>	<i>Female</i>
	1–3 y	0.2–0.6 µmol/L	0.2–2.1 µmol/L
	4–6 y	0.1–5.1 µmol/L	0.2–1.0 µmol/L
	7–8 y	0.3–2.6 µmol/L	0.4–1.9 µmol/L
	9–10 y	0.4–2.0 µmol/L	0.4–4.3 µmol/L
	11 y	0.5–4.1 µmol/L	0.4–2.7 µmol/L
	12 y	0.5–9.4 µmol/L	0.8–4.8 µmol/L
	13 y	0.6–6.6 µmol/L	0.6–4.5 µmol/L
	14 y	0.5–7.8 µmol/L	0.8–8.2 µmol/L
	15 y	1.6–8.4 µmol/L	1.1–7.8 µmol/L
16 y	1.3–9.7 µmol/L	1.6–9.6 µmol/L	
Estradiol			Estradiol levels in children should only be interpreted on an individual patient basis. Reference ranges are therefore not quoted. Refer to your local laboratory for interpretation and guidance
α1-fetoprotein	> 8 m	< 10 KIU/L	Falls with time and should be less than 10 KIU/L by 8 m. Since a single AFP result is difficult to interpret, it is advisable to repeat the test in 2–3 weeks to look for an appropriate fall in concentration
Follicle-stimulating hormone (FSH)		<i>Male</i>	<i>Female</i>
	0–15 d	< 1 IU/L	0.2–3.0 IU/L
	15 d – 6 y	0.2–3.0 IU/L	0.2–6.0 IU/L
	7–10 y	0.2–4.0 IU/L	
	10–14 y	0.5–7.0 IU/L	
	Follicular Mid-cycle Luteal		2–24.0 IU/L 0.6–11.0 IU/L 0.6–9.0 IU/L
Free fatty acids		100–300 µmol/L	If FFA > 1000 FFA:3HB < 2 Fasting sample
3-hydroxy butyrate		0–300 µmol/L	Fasting sample
Galactose-1-phosphate		Not detected in normal children Treated galactosemics < 150 µmol/L Untreated > 1000 µmol/L	
Growth hormone (GH)	Insulin stress test GTT	> 17 mIU/L < 1.0 mIU/L	Random GH is of little value. Provocative tests should be used
HBA1c		4.7–7.9% of total Hb	
Haptoglobins		0.3–2.0 g/L	
17 hydroxyprogesterone	Infants (unstressed)	< 13 nmol/L	There is a rapid fall from very high levels of 17-OHP (maternal source) in the first 24–48 h of life making interpretation difficult. Premature and sick infants also have 2–3 fold higher levels of 17-OHP compared with values quoted for full term well infants. Concentrations in neonates with untreated CAH are usually > 60 nmol/L
	Infants (stressed)	< 40 nmol/L	
25 OH Vitamin D		12.5–75 nmol/L	
1,25-dihydroxy vitamin D		48–120 pmol/L	

Analyte	Age	Reference ranges	Comments		
<b>Immunoglobulins</b>					
IgG	Neonates	6.5–14.5 g/L			
	1–3 m	2.0–6.5 g/L			
	4–6 m	1.5–8.0 g/L			
	1 y	3.0–12.0 g/L			
	3 y and older	5.0–15.0 g/L			
IgA	Neonates	0–0.1 g/L			
	1–3 m	0.05–0.4 g/L			
	4–6 m	0.1–0.6 g/L			
	1 y	0.2–0.8 g/L			
	3 y and older	0.3–3.0 g/L			
IgM	Neonates	0–0.3 g/L			
	1–3 m	0.1–1.0 g/L			
	4–6 m	0.1–1.0 g/L			
	1 y	0.4–2.0 g/L			
	3 y and older	0.4–2.0 g/L			
Insulin			Insulin cannot be interpreted without a paired glucose and c-peptide result. Please refer to your local laboratory for guidance		
Iron	0–4 w	10–30.0 µmol/L			
	4 w–5 y	5–25.0 µmol/L			
	6–9 y		7–25.0 µmol/L		
			<i>Male</i>	<i>Female</i>	
	10–14 y	5–24.0 µmol/L	8–26.0 µmol/L		
	15–19 y	6–29.0 µmol/L	5–33.0 µmol/L	The value of plasma iron is of little value in the investigation of iron deficiency as there is much within-individual variation. In addition, many conditions such as infection, trauma and chronic inflammation are associated with low plasma iron concentration but normal total body iron stores	
Iron-binding capacity		<i>Male</i>	<i>Female</i>		
	1–5 y	48–79 µmol/L	48–79 µmol/L		
	6–9 y	43–91 µmol/L	43–91 µmol/L		
	10–14 y	54–91 µmol/L	57–103 µmol/L		
	14–19 y	52–102 µmol/L	52–101 µmol/L		
Lactate (plasma)	Neonates	Up to 3.0 mmol/L		Plasma lactate measurements are usually carried out as part of a timed profile and need to be interpreted with respect to glucose and other metabolites. CSF lactate: plasma lactate ratio should be calculated if a respiratory chain defect is suspected	
	> 1 m	1.0–1.8 mmol/L			
Lactate dehydrogenase	0–5 d	730–1650 U/L			
	1–3 y	400–720 U/L			
	4–6 y	375–700 U/L			
	7–9 y	335–590 U/L			
		<i>Male</i>	<i>Female</i>		
	10–11 y	345–550 U/L	305–605 U/L		
	12–13 y	375–590 U/L	305–505 U/L		
	14–15 y	290–570 U/L	315–460 U/L		
	16–19 y	275–525 U/L	275–525 U/L		
	Lead		<0.5 µmol/L		
Luteinizing hormone (LH)		<i>Male</i>	<i>Female</i>		
	0–15 d	<1 I/U	<1 I/U		
	15 d–10 y	0.7–2.2 I/U	0.7–2.2 I/U		
	10–13 y	0.3–5.0 I/U			
	13–60 y		0.5–8.0 I/U		
		Follicular		1–11.0 I/U	
		Mid-cycle		15–96 I/U	
Luteal		1–11.0 I/U			
Oxygen saturation	Umbilical artery	0.32%			
	Umbilical vein	26–73%			
	Children	86–101%			
	Newborns	30–80%			
	Older children	60–85%

	14–15 y	140–465 µmol/L	180–345 µmol/L
	16–19 y	235–510 µmol/L	180–350 µmol/L
Vitamin A	1–6 y	0.7–1.5 µmol/L	
	7–12 y	0.9–1.7 µmol/L	
	13–19 y	0.9–2.5 µmol/L	
Vitamin E	Newborn infants	5–14 µmol/L	
	2 y and older	12–28 µmol/L	
Zinc	Children	11.0–24.0 µmol/L	

Table A.3 Normal constituents of urine

Analyte	Age	Reference ranges	Comments
Amino acids			Urine amino acid concentrations vary widely with age, with high concentrations in the neonatal period and early infancy. Concentrations fall particularly over the first 6 months as the renal tubules mature Many laboratories perform qualitative amino acid investigations looking for an abnormal pattern before undertaking quantitative investigation
$\delta$ -aminolevulinic acid		<5.2 $\mu$ mol/mmol Creat	
Calcium	<7 m 7–18 m 19 m – 6 y >6 y	<2.4 mmol/mmol Creat <1.7 mmol/mmol Creat <1.2 mmol/mmol Creat <0.7 mmol/mmol Creat	These values refer to a random, spot urine taken when the overnight urine has been voided
Catecholamines		<i>Noradrenaline</i> <i>Dopamine</i> <i>HMMA</i>	These values refer to a random, spot urine
	0–6 m	0.32 mmol/mol Creat 2.2 mmol/mmol Creat 19 mmol/mmol Creat	
	6 m – 1 y	0.3 mmol/mol Creat 2 mmol/mmol Creat 16 mmol/mmol Creat	
	12–18 m	0.25 mmol/mmol Creat 1.8 mmol/mmol Creat 14 mmol/mmol Creat	
	18 m – 2 y	0.2 mmol/mmol Creat 1.6 mmol/mmol Creat 12 mmol/mmol Creat	
	2–3 y	0.17 mmol/mmol Creat 1.4 mmol/mmol Creat 11 mmol/mmol Creat	
	3–4 y	0.14 mmol/mmol Creat 1.25 mmol/mmol Creat 9 mmol/mmol Creat	
	4–5 y	0.125 mmol/mmol Creat 1.05 mmol/mmol Creat 8 mmol/mmol Creat	
	5–6 y	0.11 mmol/mmol Creat 0.9 mmol/mmol Creat 7 mmol/mmol Creat	
	6–8 y	0.09 mmol/mmol Creat 0.75 mmol/mmol Creat 6.5 mmol/mmol Creat	
	8–10 y	0.085 mmol/mmol Creat 0.65 mmol/mmol Creat 6 mmol/mmol Creat	
	10–12 y	0.08 mmol/mmol Creat 0.55 mmol/mmol Creat 5 mmol/mmol Creat	
	12–14 y	0.075 mmol/mmol Creat 0.5 mmol/mmol Creat 4.5 mmol/mmol Creat	
	14–16 y	0.07 mmol/mmol Creat 0.5 mmol/mmol Creat 4.5 mmol/mmol Creat	
	>16 y	0.07 mmol/mmol Creat 0.5 mmol/mmol Creat 4.5 mmol/mmol Creat	
Copper		<50 $\mu$ g/24 h	Random urines are not useful as results are not interpretable in most cases
Homovanillic acid (HVA)	0–6 m 6 m – 1 y 12–18 m 18 m – 2 y 2–3 y 3–4 y 4–5 y 5–6 y 6–8 y 8–10 y 10–12 y 12–14 y 14–16 y >16 y	25 mmol/mol Creat 25 mmol/mmol Creat 22 mmol/mmol Creat 19 mmol/mmol Creat 16 mmol/mmol Creat 13 mmol/mmol Creat 12 mmol/mmol Creat 11 mmol/mmol Creat 9 mmol/mmol Creat 8 mmol/mmol Creat 7 mmol/mmol Creat 6 mmol/mmol Creat 6 mmol/mmol Creat 4.5 mmol/mmol Creat	

(Continued)

Table A.3 Normal constituents of urine—Cont'd

Analyte	Age	Reference ranges		Comments
5-hydroxyindole acetic acid (5HIAA)		< 50 µmol/24 h		
Lead		< 10 µg/24 h		
Magnesium	1–6 m	0.006–0.105 mmol/kg/24 h	Breast fed	
		0.006–0.132 mmol/kg/24 h	Formula fed	
	1–15 y	0.051–0.181 mmol/kg/24 h		
Magnesium/creatinine ratio	2–15 y	< 1.05 mmol/mmol Creat		These values refer to a random, spot urine taken when the overnight urine has been voided
Osmolality	Newborns delivery urine	79–118 mmol/kg		
	Maximum in neonatal period	600 mmol/kg		
pH	Newborns	5.0 or higher		
	Older children	5.3–7.2		
Phosphate	% Tubular reabsorption of phosphate (TRP)	> 80%		Values may be much different in the neonate
Porphobilinogen		0–10.7 µmol/L		
Potassium	Neonate	< 5 mmol/kg/d		These values refer to a 24 h urine collection and are dependent on potassium intake and gestational age
	Child	25–125 mmol/24 h		
Sodium		0.08–0.16 mmol/kg/24 h		These values refer to a 24 h urine collection
Aldosterone		6–60 nmol/24 h		In children, excretion rates would increase during childhood from < 1 mg/24 h in the first year
17-hydroxycorticosteroids	Adult	<i>Male</i> 4.0–14 mg/24 h	<i>Female</i> 2.0–12 mg/24 h	
	Children			
17-ketosteroids	Adult	<i>Male</i> 8–20 mg/24 h	<i>Female</i> 6–12 mg/24 h	Serum DHAS is a much better measurement
	0–1 y	0–1.0 mg/24 h	0–1.0 mg/24 h	
	1–5 y	1.0–2.0 mg/24 h	1.0–2.0 mg/24 h	
	6–10 y	1–4.4 mg/24 h	1.4–3.9 mg/24 h	
	11–12 y	1.3–8.5 mg/24 h	3.8–9.5 mg/24 h	
	13–16 y	3.4–9.8 mg/24 h	4.5–17.1 mg/24 h	
Pregnanediol	> 10 y		<i>Female</i> < 50 µg/24 h	Not a useful marker in pediatrics, measure serum progesterone
	12 y		20–600 mg/24 h	
Pregnanetriol	> 10 y		<i>Female</i> < 50 µg/24 h	17-hydroxyprogesterone has superseded this assay
	12 y		20–100 mg/24 h	
Vanillylmandelic acid (VMA)	0–1 y	0–18 mg/g Creat		
	2–4 y	0–11.0 mg/g Creat		
	5–9 y	0–8.3 mg/g Creat		
	10–19 y	0–8.2 mg/g Creat		
Total porphyrin		20–320 nmol/L		

Table A.4 Normal cerebrospinal fluid (CSF) values

Analyte	Age	Reference ranges	
WBC	Neonate Child	0–15/mm <sup>3</sup> 0–5/mm <sup>3</sup>

All factors except fibrinogen are expressed as unit/ml, where pooled plasma contains 1.0 unit/ml. All data are expressed as the mean, followed by the upper and lower boundary encompassing 95% of the population. Between 20 and 50 samples were assayed for each value for each age group. Some measurements were skewed due to a disproportionate number of high values. The lower limit, which excludes the lower 2.5% of the population, is given.

APTT, activated partial thromboplastin time; HMWK, high molecular weight kininogen; INR, international normalized ratio; PK, prekallikrein; PT, prothrombin time; VIII, factor VIII procoagulant; vWF, von Willebrand factor. \*Values that are significantly different from adults. From Chalmers & Gibson.<sup>38</sup>

## NUTRIENTS AND FORMULA FEEDS

### Introduction

#### Normal infants and children

**Infant (0–12 months).** Term infants with normal gastrointestinal function are fed either human breast milk or normal infant formula during the first year of life. Normal infant formula is defined as 'a food intended for nutritional use by infants in good health for the first year of life, and satisfying, by itself the nutritional requirements of such infants'. It is based on whey- or casein-dominant protein, lactose ± maltodextrin and amylose, vegetable oil and milk fat. Whey-dominant milks are the closest in composition to breast milk. Although some infant formulas contain novel nutrients such as long chain fatty acids (docosahexaenoic acid and arachidonic acid), nucleotides and prebiotics, the composition of all normal and soya infant formulas has to meet the UK's *The Infant Formula and Follow-on Formula Regulations 1995*,<sup>39</sup> which enact the European Community Regulations 91/321/EC.<sup>40</sup> The energy content by law must not be less than 60 kcal (250 kJ) and not more than 70 kcal (295 kJ) per 100 ml.

**Infant (over 6 months of age).** 'Follow-on formulas' are feeds designed for infants over the age of 6 months and 'constitute the principal liquid element in a progressively diversified diet'.<sup>40</sup> They are based on modified cows' milk. They contain less protein, calcium and phosphorus than cows' milk, but more than standard infant formula, and are fortified with other nutrients.

**Children over 1 year:** Growing up milk is fortified formula designed for children over 1 year. It is based on cows' milk.

#### Special infant formulas

It is essential that any infant or child who is intolerant of breast milk or normal infant formula, or whose condition requires nutrient specific adaptation, is prescribed a nutritional complete replacement formula in adequate volume. The composition of special infant formula has to meet the Commission Directive (1999/21/EC) on Dietary Foods for Special Medical Purposes.<sup>41</sup>

**Soya formula.** Soya infant formula is based on soya-protein isolate supplemented with L-methionine, taurine and carnitine. These formulas support normal growth, protein status and mineralization. Although they are suitable for cows' milk protein and lactose intolerance, the Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment (COT) has expressed concern about the use of soya infant formula in infancy.<sup>42</sup> Soya infant formula contains 18–41 mg/L of phytoestrogens. This is several times higher than the quantity in human breast milk. Although the COT report concluded that there is no direct evidence that soya infant formula affects the health of infants, particularly fertility, it is believed that soya infant formula may be a potential risk to the infant. Therefore it is not recommended that soya-based infant formula is used as the first choice formula for infants with cows' milk sensitivity or lactose intolerance, but it is widely used for infants with galactosemia because of the residual lactose content of low lactose formula and protein hydrolysate formula which are both derived from cows' milk.

**Protein hydrolysate formula.** Based on casein, whey, meat and soya, these formulas are suitable for infants with disaccharide and/or whole protein intolerance. Protein hydrolysates are the result of heat treatment and/or enzymatic cleavage, which is used in order to produce peptides of minor antigenic activity, with a molecular weight of less than 1200 daltons. Some of the formulas contain a significant proportion of their fat source in the form of medium chain triglyceride (MCT) oil.

**Low lactose formula.** This type of formula is based on whole cows' milk protein. Although suitable for lactose intolerance they contain residual lactose in very small quantities. They are unsuitable for infants with cows' milk protein intolerance.

**Elemental (amino acid based formula).** There is only one elemental nutritionally complete formula available for infants in the UK. There is evidence to demonstrate that the feed tolerance and growth of infants taking this formula is satisfactory.

**Other specialist formula.** A number of specialized formulas are available for liver and renal indications. High medium chain fat based formulas for conditions such as chylothorax and long chain fatty acid disorders are available. Ketogenic, low calcium and protein free feeds are also available. These should always be used under dietetic supervision.

### Complete enteral feeds

The composition of all enteral feeds has to meet the Commission Directive (1999/21/EC) on Dietary Foods for Special Medical Purposes.<sup>41</sup>

**Infant (0–12 months).** An infant with faltering growth may be given a high energy and nutrient dense feed containing between 9 and 11% energy from protein. Concentrating or supplementing normal infant formula should not be attempted without the advice of a pediatric dietitian.

**Children 1–6 years (8–20 kg).** A number of nutritionally complete 0.75 kcal/ml, 1.0 kcal/ml and over 1.0 kcal/ml ( $\pm$  fiber) ready to use feeds designed for the 1–6-year age group are available. They are all based on caseinates, maltodextrin and vegetable oils  $\pm$  added medium chain triglyceride oil (MCT) and contain residual lactose only. These products were originally designed for 1–6-year-old (8–20 kg) children, but some products have had Advisory Committee on Borderline Substances (ACBS) extensions for children weighing up to 30 kg (approximately 10 years of age).

**Children 7–12 years.** Nutritionally complete 1.0 kcal/ml and 1.5 kcal/ml ( $\pm$  fiber) ready to use feeds designed for this age group are available. They are also based on caseinates, maltodextrin and vegetable oils and contain residual lactose only. Their formulation is in between pediatric and adult feeds.

**Children 13 years and over.** There are no standard enteral feeds designed for teenagers, so adult feeds are given. The intake of protein, electrolytes, vitamins and trace minerals should be carefully assessed and monitored.

### Other dietary supplements

A number of dietary supplements, either based on carbohydrates, fat and/or protein, which can be used to enhance the nutrient density of the diet or nutritionally complete supplements are available. The amount and timing of supplements is important so as not to impair appetite. Ideally supplements should be administered after meals or at bedtime. Many supplements are high in sugar or maltodextrin. Care should be taken to prevent prolonged contact with teeth.

### Products for phenylketonuria

There is a wide range of phenylalanine-free protein substitutes for PKU. They have a high osmolality so should be administered with extra water. Some are nutritionally incomplete and require vitamin and/or other nutrient supplementation. Protein substitutes should be taken at least 3 times daily equally distributed throughout the day.

### Notes

The Advisory Committee on Borderline Substances (ACBS) advises GPs on prescription of products that are not drugs or medical devices. The committee is an advisory nondepartmental public body (NDPB), non-statutory and UK-wide. The approved list consists of foodstuffs such as enteral feeds or foods formulated for people with medical conditions.

Nutramigen is ACBS listed for disaccharide and/or whole protein intolerance where additional medium chain triglycerides are not indicated. Nutramigen Stage 2 is ACBS listed for the same indications but for infants from 6 months onwards. Pepti-Junior and Pregestimil are ACBS listed for disaccharide and/or whole protein intolerance or where amino acids are indicated. Pepti may be prescribed for cows' milk protein intolerance with/without secondary lactose intolerance. Neocate and Neocate Advance is ACBS listed for disaccharide or dietary protein intolerance where an elemental formula is specifically indicated.

								Prepare with distilled water as tap water may contain calcium. Monitor vitamin D levels.

Galactomin 17 is ACBS listed for proven lactose intolerance in pre-school children, galactosemia, and galactokinase deficiency. SMA LF and Enfamil Lactofree are ACBS listed for proven lactose intolerance. Caprilon and MCT Pepdite are ACBS listed for disorders in which a high intake of MCT is beneficial. Monogen ACBS listed for long chain acyl-CoA dehydrogenase deficiency, carnitine palmitoyl transferase deficiency, primary and secondary lipoprotein lipase deficiency. Locasol is ACBS listed for hypercalcemia and other conditions which require extreme calcium restriction in the diet. Galactomin 19 is ACBS listed for glucose-galactose intolerance.

Infant enteral feeds ACBS listed for disease-related malnutrition, malabsorption and growth failure in infancy. Both feeds are suitable for enteral and oral feeds.

Post-discharge formula ACBS listed for catch-up growth in pre-term (i.e. less than 35 weeks at birth) and small for gestational age infants, up to 6 months corrected age.

Calcium mg/100 g	130	640	4.5	Not declared	Not declared
Phosphorus mg/100 g	20	Not declared	24	13	20
Reconstitution	Bottle feed: add 2–3 level scoops of Carobel for every 60–90 ml (2–3 fl oz) hand-warm infant formula. Shake well and leave to thicken for 3–4 minutes. Breast feeds: add 6–7 level scoops of Carobel to 60 ml (2 fl oz) hand-warm water to form a thick gel. Feed in small quantities by spoon before and during the breast feed	Recommended concentration 0.5–1%. Bottle feed: add Nestargel in the quantity of cold water required for the feed; gently bring to the boil, stir and simmer for 1 minute; cool and add the formula powder; mix until smooth. Breast feeds: give 1 tablespoon of thickened Nestargel water (1% concentration) pre-feeds	No specific instructions given for infants. 1–3% concentration suggested. <sup>45</sup>		
Comments	An instant thickener 1 scoop = 0.7 g Carobel	An effective thickener; produces a smooth and stable thickened liquid. 1 scoop = 1 g Nestargel	Effective thickeners. Unsuitable for infants under 1 year, unless failing to thrive		An effective thickener. Unsuitable for infants under 1 year, unless failing to thrive. Each tub contains a 5 g scoop
Presentation	Box: 135 g	Can: 125 g	Can: 225 g, Sachets: 9 g	Tub: 375 g	Tube: 300 g, 12 kg, 6 kg
ACBS listed	Yes, for thickening feeds in the treatment of vomiting	Yes, for thickening feeds in the treatment of vomiting	Yes, for thickening of foods in the treatment of dysphagia	Yes, for thickening of foods in the treatment of dysphagia	Yes, for thickening of foods in the treatment of dysphagia
Side-effects	A minority of infants may develop loose stools. If used in galactosemia, the red cell galactose 1-phosphate should be monitored	A minority of infants may develop loose stools. If used in galactosemia, the red cell galactose 1-phosphate should be monitored	–	–	–

Table A.14 Miscellaneous

Product	Manufacturer	Description	ACBS Prescribable
Cornflour/cornstarch	Various	Maize starch BP-maize starch powder	Hypoglycemia associated with glycogen storage disease
Fructose	Various	Fructose BP Laevulose powder. 500 g	Glucose-galactose intolerance
Glucose/dextrose	Various	Glucose BP Dextrose monohydrate powder	Glycogen storage disease. Sucrose–isomaltose intolerance
SHS Module Flavour System	SHS International	Blackcurrant, orange, pineapple, tomato, *grapefruit, *cherry vanilla, *lemon and lime. Contains maltodextrin ±lactose, modified starch, sugar according to flavor. Presentation: 100 g tubs or *5 g sachets	For flavoring unflavored amino acid/peptide based products
Vitaflo Flavour Pac	Vitaflo International	Blackcurrant, lemon, orange, raspberry, tropical fruit. On a carbohydrate base containing sugar and sweeteners. Presentation 30 × 4 g sachets	For flavouring unflavoured amino acid products

Infants	1.7 mg/d
Biotin	10–200 µg/d
Vitamin E	
Men	Above 4 mg/d
Women	Above 3 mg/d
Infants	0.4 mg/d polyunsaturated fatty acids
Vitamin K	
Adults	1 µg/kg/d
Infants	10 µg/d
<i>Minerals</i>	
Manganese	
Adults	Above 1.4 mg/dN (26 µmol/d)
Infants and children	Above 16 µg/kg/d (0.3 µmol/kg/d)
Molybdenum	
Adults	50–400 µg/d
Infants, children and adolescents	0.5–1.5 µg/kg/d
Chromium	
Adults	Above 25 µg (0.5 µmol/d)
Children and adolescents	0.1–1.0 µg (2–20 nmol/kg/d)
Fluoride	
Children over 6 years and adults	0.5 mg/kg/d (3 µmol/kg/d)
Children over 6 months	0.12 mg/kg/d (6 µmol/kg/d)
Infants under 6 months	0.22 mg/kg/d (12 µmol/kg/d)

Extracted from Dietary Reference Values for Food Energy and Nutrients for the United Kingdom.<sup>46</sup>

**Table A.20** Multiple values proposed for adults. (Amounts per day, unless given in other items. If that for women is different from that for men, it is in parentheses)

Nutrient	Average requirement	Population reference intake	Lowest threshold intake
Protein (g)	0.6/kg body wt	0.75/kg body wt	0.45/kg body wt
Vitamin A (µg)	500 (400)	700 (600)	300 (250)
Thiamin (µg)	72/MJ	100/MJ	50/MJ
Riboflavin (mg)	1.3 (1.1)	1.6 (1.3)	0.6
Niacin (mg niacin equivalents)	1.3/MJ	1.6/MJ	1.0/MJ
Vitamin B6 (µg)	13/g protein	15/g protein	–
Folate (µg)	140	200	85
Vitamin B <sub>12</sub> (µg)	1.0	1.4	0.6
Vitamin C (mg)	30	45	12
Vitamin E (mg α-tocopherol equivalents)		0.4/g PUFA	4 (3)/d regardless of PUFA intakes
n-6 PUFA (as percentage of dietary energy)	1	2	0.5
n-3 PUFA (as percentage of dietary energy)	0.2	0.5	0.1
Calcium (mg)	550	700	400
Phosphorus (mg)	400	550	300
Potassium (mg)	–	3100	1600
Iron (mg)	7 (10, 6 <sup>a</sup> )	9 (16 <sup>b</sup> , 8 <sup>b</sup> )	5 (7, 4 <sup>c</sup> )
Zinc (mg)	7.5 (5.5)	9.5 (7)	5 (4)
Copper (mg)	0.8	1.1	0.6
Selenium (µg)	40	55	20
Iodine (µg)	100	130	70
For the following, acceptable ranges of intake are given:			
Pantothenic acid (mg)	3–12		
Biotin (µg)	15–100		
Vitamin D (µg)	0–10		
Sodium (g)	0.575–3.5		
Magnesium (mg)	150–500		
Manganese (mg)	1–10		

PUFA, polyunsaturated fatty acids.

<sup>a</sup>Postmenopausal.

<sup>b</sup>PRI to cover 90% of women.

Reproduced from Nutrient and Energy Intakes for the European Community.<sup>47</sup>

**Table A.21** EU reference intakes

Age group	Protein (g/kg body weight/d)	n-6 PUFA (% of dietary energy)	n-3 PUFA (% of dietary energy)	Vitamin A (µg/d)	Thiamin (µg/MJ)	Riboflavin (mg/d)	Niacin (mg/MJ)	Vitamin B <sub>6</sub> (µg/g protein)	Folate (µg/d)	Vitamin B <sub>12</sub> (µg/d)	Vitamin C (mg/d)
6–11 months	1.6	4.5	0.5	350	100	0.4	1.6	15	50	0.5	20
1–3 yr	1.1	3	0.5	400	100	0.8	1.6	15	100	0.7	25

<i>Pregnancy</i>	700	550	3100	<sup>e</sup>	7	1.1	55	130
<i>Lactation</i>	1200	950	3100	10	12	1.4	70	160

PUFA, polyunsaturated fatty acids.

<sup>a</sup>To cover 95% of population.

<sup>b</sup>To cover 90% of population.

<sup>c</sup>Neural tube defects have been shown to be prevented in offspring by periconceptual ingestion of 400 µg folic acid per day in the form of supplements.

<sup>d</sup>Postmenopausal.

<sup>e</sup>Supplements necessary.

Reproduced from Nutrient and Energy Intakes for the European Community.<sup>47</sup>

Table A.22 Daily intakes of those nutrients for which the recommendations are given in relation to body weight, energy or protein intakes<sup>a</sup>

Age group	Protein (g)	n-6 PUFA (g)	n-3 PUFA (g)	Thiamin (mg)	Niacin (mg)	Vitamin B <sub>6</sub> (mg)
6–11 months	15	4	0.5	0.3	5	0.4
1–3 yr	15	4	0.7	0.5	9	0.7
4–6 yr	20	4	1	0.7	11	0.9
7–10 yr	29	4	1	0.8	13	1.1
<i>Males</i>						
11–14 yr	44	5	1	1.0	15	1.3
15–17 yr	55	6	1.5	1.2	18	1.5
18+ yr (PTI)	56	6	1.5	1.1	18	1.5
(AR)	45	3	0.6	0.8	15	1.3
<i>Females</i>						
11–14 yr	42	4	1	0.9	14	1.1
15–17 yr	46	5	1	0.9	14	1.1
18+ yr (PRI)	47	4.5	1	0.9	14	1.1
(AR)	37	2.5	0.5	0.6	11	1.0
<i>Pregnancy</i>	57	5 <sup>b</sup>	1	1.0 <sup>b</sup>	14	1.3 <sup>c</sup>
<i>Lactation</i>	63	5.5	1	1.1	16	1.4 <sup>c</sup>

PUFA, polyunsaturated fatty acids.

<sup>a</sup>Population reference intakes (PRI) except where indicated as average requirements (AR) (calculated as mean group intake × PRI or AR).

<sup>b</sup>From 10<sup>th</sup> week of pregnancy.

<sup>c</sup>On protein increments in pregnancy and lactation.

Reproduced from Nutrient and Energy Intakes for the European Community.<sup>47</sup>

Fig. A.1 Nomograms for body surface area. After Du Bois Et Du Bois 1916.<sup>43</sup>

Fig. A.2 Nomograms for body surface area. After Haycock et al 1978.<sup>44</sup>
