The incidence of congenital syphilis is rising commensurate with the rise in the use of crack cocaine. All babies suspected of having congenital syphilis should receive penicillin, and this is also the drug of choice for neonatal Lyme disease. Fungal meningitis and abscess formation is mainly a problem of the VLBW baby requiring intensive care, in whom the morbidity from this complication is high.

**DEVELOPMENTAL ABNORMALITIES**

See Chapter 22 for further information about these conditions.

**METABOLIC AND ENDOCRINE DISORDERS****Introduction**

Whilst adequate energy is essential to sustain adequate growth of the brain, nutrients also need to be in the appropriate concentrations and supported by the correct hormonal milieu. Inborn errors of metabolism can alter the relative concentrations of amino acids and many of these conditions present in the newborn period with neurological symptoms. High ammonia levels are toxic to the nervous system so that disorders of the urea cycle also present with severe derangement of neurological function. Lack of thyroid hormone causes failure of neurological maturation which rapidly results in permanent damage; the prevention of cretinism by early identification of such individuals with screening and replacement therapy has been a significant advance. Preterm babies have low thyroxine in early postnatal life and studies have suggested a correlation between low levels of thyroid hormones and adverse neurodevelopmental outcome although replacement therapy has not proved a success.

**Urea cycle defects**

Hyperammonemia may present with severe neurological disturbance in the newborn period. Recognition is important because many of the conditions are inherited and the babies often succumb without the correct diagnosis being made. There may be lethargy, vomiting and convulsions. Plasma ammonia concentrations above 200 mg/L are toxic and can result from liver failure, enzyme defects of the urea cycle or other disorders of amino acid metabolism such as propionic acidemia and lysine intolerance. Further investigation consists of enzyme assay using leukocytes or liver cells.

**Hyperbilirubinemia**

Unconjugated bilirubin is lipid soluble and hence able to cross the blood-brain barrier. The classic neurological syndrome of acute bilirubin encephalopathy, presenting with opisthotonic posturing and fits, is rare but has re-emerged in recent years. Babies who are most at risk are those who are near term and those discharged early. Acute bilirubin encephalopathy carries a high risk of permanent damage due to kernicterus, with athetoid cerebral palsy and deafness. Kernicterus can now be imaged with MRI, and there are characteristic changes in the globi pallidi.

**Hypoglycemia**

Prolonged low glucose levels damage the newborn nervous system which is unable to utilize alternative energy sources. There has been much debate regarding the degree and duration of hypoglycemia required to be responsible for permanent brain damage. That damage can result from a prolonged period of symptomatic hypoglycemia at term is not in doubt, however. The evidence that asymptomatic hypoglycemia can cause permanent sequelae is not convincing. In preterm babies, there has been a suggestion that persisting glucose levels below 2.6 mmol/L were associated with a reduction in Bayley motor and mental development scores at 18 months. However, much more evidence is needed before definite guidelines can be formulated regarding moderate or asymptomatic hypoglycemia.

**NEONATAL CEREBRAL INJURY**

Perinatal stress such as hypotension or trauma can result in cerebral injury, and intracranial and extracranial hemorrhage remain a problem although the incidence has declined considerably. There are a number of important potential causes of intracranial hemorrhage at term (including inherited or acquired coagulopathy), listed in [Table 12.92](#). The preterm brain is especially vulnerable to postnatal damage from hemorrhage because of the presence of residual germinal matrix tissue, the extent of which can be appreciated with MRI. Neonatal brain injury is best considered as a spectrum with the end result depending on the type and degree of insult, the gestational age of the baby and any underlying factors. The problem is an important one because there is a relationship with later handicap.

**Table 12.92** Causes of intracranial hemorrhage at term

Choroid plexus hemorrhage, often secondary to straight sinus thrombosis
Hemorrhage into residual germinal matrix tissue
Hemorrhagic cerebral venous infarction
Thalamic – venous thrombosis into the straight sinus
Parasagittal – venous thrombosis into the parasagittal sinus
Temporal lobe – venous thrombosis of the vein of Labbe, the transverse sinus, the sigmoid sinus
Hemorrhagic cerebral arterial infarction
‘Stroke’ of the middle cerebral or other arterial territory
Primary ‘lobar’ cerebral hemorrhage
Cause unknown
Bleeding diathesis; NAITP, inherited or acquired coagulopathy, vitamin K deficiency

NAITP, neonatal alloimmune thrombocytopenia.

### Subgaleal (subaponeurotic) hemorrhage

The space between the scalp and the subaponeurotic layer outside the skull is a potentially large one, and significant blood loss can occur at around the time of birth (Fig. 12.47). There is a very strong association between subgaleal hematoma and ventouse delivery. Babies can become shocked very quickly after birth as a result of the massive blood loss, and the mortality of the condition remains high, around 20% in many series. The diagnosis rests on a high index of suspicion, and the demonstration of a fluctuant boggy swelling in the scalp which crosses suture lines.

### Subarachnoid hemorrhage

A small amount of subarachnoid blood is quite common after normal delivery, and as ever with bleeding disorders in the neonatal period it is important to exclude vitamin K deficiency bleeding. The outcome is generally good, but the presence of subarachnoid blood can cause seizures.

### Subdural hemorrhage

The incidence of this complication has fallen with more careful obstetric practice, although a small subdural collection is surprisingly common even after a normal delivery. The hematoma is thought to result from tearing of the bridging veins. Tears of the dura can lead to posterior fossa collections resulting in brainstem compression and coning. Ultrasound is not good at detecting subdural hemorrhage, and suspicion of the diagnosis is an indication for an urgent CT scan; a neurosurgical opinion is important as drainage may be required.

### Thalamic hemorrhage

This type of intracranial bleeding may be primary or secondary to extension from germinal matrix bleeding; sinus thrombosis is thought to be an important contributory factor, and venous infarction is thought to be the origin of many types of intracranial hemorrhage at term (Table 12.92). Term babies with primary thalamic bleeding can present at about 10 days of age with eye signs (deviation and sunseting) and fits.

Fig. 12.47 MRI showing a massive subgaleal collection associated with hypoxic-ischemic damage. (From Cheong et al<sup>862</sup> with permission.)

### Periventricular hemorrhage (PVH)

The preterm brain contains the germinal matrix, which contains actively dividing neuroblasts and glioblasts. The blood supply is via a capillary bed supplied by Heubner's artery, which is a branch of the anterior cerebral artery. The region of the germinal matrix situated at the head of the caudate nucleus is prone to bleeding, and this is the most common form of intracranial hemorrhage in preterm babies, although the germinal matrix is extensive and bleeding can occur at any site. The incidence of intracranial hemorrhage diagnosed with ultrasound in VLBW babies has reduced from around 40% to 15–20% since the widespread introduction of antenatal steroids and postnatal surfactant.<sup>863,864</sup> Rates as low as 13% have been reported from some centers, although one Canadian study found a wide range of incidence.<sup>865</sup>

The term PVH is often used as a generic one, encompassing several different types of hemorrhage in preterm babies. The mildest form is germinal matrix or subependymal bleeding alone. This is often abbreviated to GMH or SEH and is equivalent to grade 1 PVH in the classification of Papile et al.<sup>866</sup> Bleeding into the ventricular system, or intraventricular hemorrhage (IVH) was classified by Levene & de Crespigny<sup>867</sup> in 1983 as grade 2 PVH, but was subdivided by Papile into grade 2 when the ventricle was not distended and grade 3 when it was. Bleeding into the parenchyma of the brain (ParH) was classified by Levene as grade 3 PVH and by Papile as grade 4. A parenchymal hemorrhagic lesion is illustrated with the ultrasound scan appearance in Figure 12.48. Few now believe that parenchymal hemorrhage represents direct extension of intraventricular bleeding, and it is now clear that all echodense lesions diagnosed with ultrasound are not hemorrhagic in nature. As a result the older classification systems are no longer appropriate.

Repeated ultrasound scanning of cohorts of VLBW babies has revealed that the incidence and degree of hemorrhage relate to the birth weight and gestational age. The complication develops in early postnatal life, with the majority of lesions present 24h after birth. There are several risk factors. These include:

- gestational age;
- birth weight;
- RDS;
- artificial ventilation;
- hypercarbia;
- pneumothorax.

Less conclusive evidence exists for variables such as the mode and place of delivery, use of beta-sympathomimetics during labor, presence of coagulopathy, acidosis, bicarbonate administration, low blood pressure, fluctuating cerebral blood flow velocity and the administration of vasodilators such as tolazoline. The main problem is in distinguishing antecedent from associate. The best unifying hypothesis is that GMH-IVH results from a disturbance of cerebral blood flow in babies who are poor at cerebral autoregulation, and in whom there is often a bleeding tendency.

### Periventricular leukomalacia

Periventricular leukomalacia (PVL) was first recognized by pathologists. The 'white spots' appear at the boundary zone of the cerebral circulation in the immature brain and it seems likely that a period of low cerebral blood flow is often exacerbated by flow-metabolism uncoupling. Small cysts can be diagnosed during life with ultrasound (Fig. 12.49), but many cases of PVL are 'ultrasound negative' and are only diagnosed later on because of disability or MRI. Cysts can be imaged in between 8 and 17% of babies less than 1500 g. Some series include parenchymal echodense lesions persisting for more than 2 weeks but not evolving into cysts, and report a higher incidence of 25%.<sup>868</sup> There can be some difficulty in distinguishing this type of 'flare' from the normal peritrigonal 'blush' described by Di Pietro et al,<sup>869</sup> which is normal. It is very important to describe the ultrasound appearances in detail; an echodense lesion in a 1-day-old preterm baby is not at all the same entity as the pathological identification of cystic change in the white matter. Paneth et al<sup>870</sup> found white matter damage at postmortem in preterm babies with cerebral echodensity during life, but in very few were the lesions typical of classic periventricular leukomalacia. In many babies the white matter damage, with liquefactive necrosis and perivascular hemorrhage, was not restricted to the periventricular

(a)

(b)

(c)

**Fig. 12.48** Periventricular hemorrhage, (a) at postmortem and (b) imaged with ultrasound in life, (c) with diagrammatic representation.

region. Cysts disappear after a few months and are replaced by a thinning of the myelin layer. MRI confirms reduction in myelin content of the brain in babies with PVL, and shows that white matter damage is far more common than is suspected with ultrasound imaging alone.<sup>871</sup> The significance of the MRI finding of diffuse excessive high signal intensity (DEHSI) in the white matter has yet to be defined; DEHSI is very common in ex-preterm babies on MRI scans made at term corrected age.

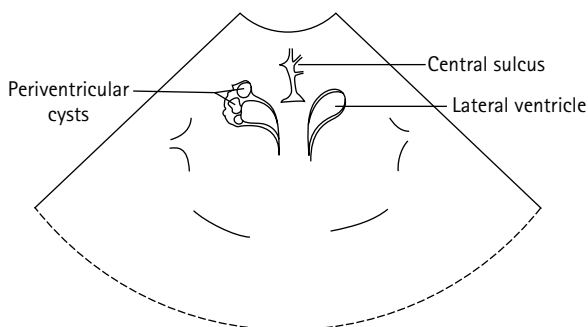

No agreement has yet been reached on the precise definition of the ultrasound appearances of a 'flare' but follow-up suggests that a persistent flare is predictive of outcome and hence represents genuine white matter injury. Early echodense lesions appear 24–48 h after an insult and are often followed in 2–4 weeks by appearance of cystic change. Studies are still emerging regarding the antecedents: antepartum hemorrhage, asphyxia, hypocarbia, and cytokine damage associated

(b)

(c)

**Fig. 12.49** Periventricular leukomalacia (a) at postmortem and (b) imaged with ultrasound in life, (c) with diagrammatic representation.

with chorioamnionitis and surgery (particularly for NEC) all appear to be important antecedent factors. The outlook for the survivors with bilateral occipital cystic PVL remains poor, although babies with small cysts confined to the frontal cortex can do well.

### Intracerebellar hemorrhage

Cerebellar bleeding can occur as an extension from intraventricular or subarachnoid bleeding or as an isolated clinically silent event in premature babies, and is increasingly recognized as a complication of prematurity.<sup>872</sup> It has been described in association with tight bands around the head. Management is usually conservative and a good outcome has been described at term although preterm babies fare less well.

### HYDROCEPHALUS AND VENTRICULOMEGALY

For more information on these conditions see Chapter 22. The following discussion is limited to preterm posthemorrhagic hydrocephalus and the outcome after an in utero diagnosis of ventriculomegaly.

## Etiology

Important causes to consider in the newborn period include:

1. cerebral malformations – Arnold–Chiari malformation, Dandy–Walker cysts, aqueduct stenosis, arachnoid cysts causing obstruction to CSF flow;
2. craniosynostosis, e.g. Apert syndrome;
3. obstruction by a mass – vein of Galen aneurysm, tumors;
4. posthemorrhagic hydrocephalus, particularly in preterm babies;
5. postmeningitic hydrocephalus;
6. X-linked congenital hydrocephalus.

## Posthemorrhagic hydrocephalus in preterm babies

This is the most frequent cause of acquired hydrocephalus arising in the neonatal period, and usually occurs secondary to periventricular hemorrhage. The natural history of ventricular dilation secondary to PVH is that at least half the cases will not progress to require shunting, an important consideration when assessing uncontrolled studies claiming effective ‘cures’.<sup>873</sup>

## Treatment

There is no place for compressive head wrapping, glycerol or isosorbide in the treatment of hydrocephalus in babies. The definitive treatment is surgical placement of a ventriculoperitoneal shunt and this will be required in most cases of congenital hydrocephalus. The difficult management decisions usually occur in preterm babies with posthemorrhagic dilation, as in some the ventriculomegaly will arrest, and some are too ill to undergo surgery. Suggestions that shunt placement could be avoided by early intervention with CSF drainage have not been borne out; trials of ‘washing out’ fibrinogen with CSF irrigation are under way. Acetazolamide and spironolactone were not of any benefit in a randomized controlled trial.<sup>874</sup> Management of this condition should therefore include a single diagnostic lumbar puncture in order to establish the intracranial pressure, whether the ventriculomegaly is of the communicating type and to exclude infection, and then a wait-and-see policy should be adopted with intervention planned if the head growth is more than twice the usual rate or the baby develops symptoms of raised intracranial pressure.

## Ventriculoperitoneal shunts

These can be inserted in babies as small as 1500 g. There is a high complication rate in such babies, 30% in some series, with frequent episodes of blockage. Many surgeons like to wait until the CSF protein is below 1.5 g/L before insertion, particularly in posthemorrhagic hydrocephalus when blood in the CSF makes it viscous. Ventriculoatrial shunting is no longer the method of choice, as the complications specific to this route were serious and included shunt nephritis, systemic sepsis and pulmonary hypertension.

## Prenatally diagnosed ventriculomegaly

Pediatricians are increasingly asked for help in counseling parents whose fetus has enlarged ventricles diagnosed on an antenatal ultrasound scan. Ventriculomegaly is the most commonly detected abnormality of the fetal brain, occurring in about 1–2 per 1000 of all fetuses. The usual basis of diagnosis is a lateral ventricular width, measured in a true transverse axial plane across the most posterior portion of choroid plexus in a fetus of more than 14 weeks, of more than 10 mm. A distinction is usually made between ‘borderline’ ventriculomegaly (10–12 mm), ‘mild’ ventriculomegaly (12–15 mm), and ‘severe’ ventriculomegaly (> 15 mm). Many of the fetuses will be found to have other abnormalities, and a specific search should be made for intrauterine infection, chromosomal abnormality and spina bifida. Even in the best hands some important associated cerebral malformations (notably agenesis of the corpus callosum) can be missed antenatally. The outlook for the group with ventriculomegaly and another abnormality in the CNS is generally poor, and many couples choose termination of pregnancy after counseling, particularly if the diagnosis is made early

enough. Of those diagnosed later, the differentiation between progressive and nonprogressive enlargement needs to be made. If the hydrocephalus is progressive and the pregnancy past 32 weeks’ gestation then early delivery and postnatal treatment may be considered. Fetuses with isolated borderline ventriculomegaly (10–12 mm) which does not progress have a good prognosis, about 90% being normal at follow-up although there is a risk of developmental delay.<sup>875,876</sup> Those with a persisting ventriculomegaly above 15 mm do badly.

## Prognosis

This depends on the underlying condition, and is worse for posthemorrhagic hydrocephalus than the congenital syndromes. Surgery has radically improved the outlook for some children with hydrocephalus, who can now expect to survive and attend normal school. Overall about 86% now survive and two thirds will have normal intelligence. For preterm babies the prognosis relates to the severity of the associated periventricular hemorrhage and the presence of fits in the neonatal period.

## RENAL DISEASE IN THE NEONATE

### DEVELOPMENT OF THE RENAL TRACT

The human embryo develops three sets of ‘kidneys’: the pronephros and the mesonephros which predominantly involute, and the metanephros which is the precursor of the functional kidney (Fig. 12.50). The metanephros can be identified from about 6 weeks post fertilization. It consists of the ureteric bud, which is a branch of the caudal mesonephric duct, and the metanephric mesenchyme, which is a concentration of intermediate mesoderm. The ureteric bud develops to form the collecting ducts, renal pelvis, ureter and bladder trigone. The metanephric mesenchyme forms the functional nephron.

The ureteric bud branches and a condensation of metanephric mesenchyme forms at the tip of each branch. Each condensation develops a

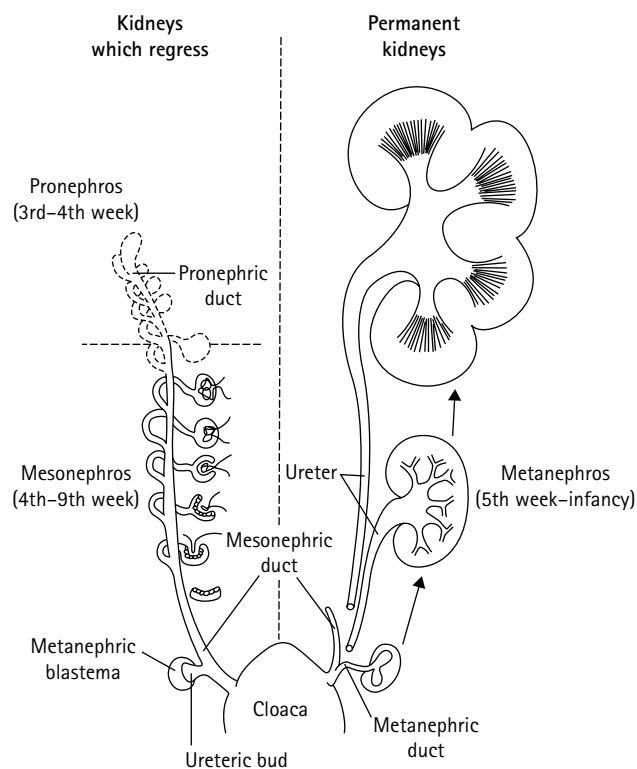

Fig. 12.50 Development of the three paired kidneys in utero. The pronephros and the mesonephros are shown on the left. On the right the development of the metanephros. (From Evan & Larsson 1992<sup>877</sup> with permission.)

lumen, which elongates to form a tubule and develops into primitive glomerular and proximal tubular epithelia (S-shaped body). Nephrogenesis continues with the distal end of the S-shaped body fusing with the neighboring ureteric bud to form a new layer of nephrons. Nephrogenesis continues up to 34–36 weeks' gestation after which no new nephrons are formed. Further expansion in nephron mass is achieved by increased tubular length and glomerular size.

## DEVELOPMENT OF RENAL FUNCTION

Fetal urine production begins between 6 and 10 weeks of gestational age and is initially an ultrafiltrate of plasma. The glomerular filtration rate (GFR) increases with gestational age and is higher in the fetus than in an age matched premature infant. Fetal homeostasis is maintained by the placenta. Postnatally GFR continues to increase until 2 years when it becomes equivalent to that of an adult when corrected for surface area (Table 12.93).<sup>878</sup> The relatively low neonatal GFR is both efficient and sufficient given the increased energy requirements that would be needed to deliver an increased GFR, the biochemical compatibility of breast milk and the effects of neonatal growth. However, the relatively low neonatal GFR must be considered when administering drugs that require renal excretion.

Fetal urine production rises from 4.5 ml/kg/h at 20 weeks to 6 ml/kg/h at 32 weeks and 8 ml/kg/h at 39 weeks and is the predominant contributor to amniotic fluid. The urinary excretion of sodium decreases progressively during fetal development from 120 mmol/L of amniotic fluid at 20 weeks to 50 mmol/L at term. It remains higher than that of an age matched neonate and increases sharply following birth. Infants born after 33 weeks' gestation are able to decrease their fractional excretion of sodium to less than 1% within 24 hours of delivery. Most premature infants lack this ability and continue to excrete an excessive amount of urinary sodium and are at risk of intravascular volume depletion and hyponatremia. The ability to conserve water is also impaired in the newborn because the osmotic threshold for ADH release is higher, the loops of Henle are shorter, the counter-current multiplier system is inefficient and there is a relative paucity of urea.

## ABNORMALITIES OF THE RENAL TRACT

Congenital anomalies of the urinary tract comprise up to 17% of antenatally diagnosed abnormalities<sup>879</sup> and are classified according to the anatomical area affected or the morphological appearance noted. The complexity of renal development and the interactions between mesenchyme and ureteric bud increase the propensity for abnormal development, as defects in one will often affect the associated development of the other. Advances in the understanding of the molecular and genetic mechanisms of abnormal urinary tract development have demonstrated gene defects associated with specific morphological abnormalities and the potential molecular pathogenesis of these defects. Classification of morphological abnormalities is therefore possible based upon either a descriptive or a molecular/genetic basis and will be discussed further in Chapter 18. Such abnormalities however have a major impact on the prevalence of end-stage renal failure in all age groups.

Renal agenesis is reported unilaterally in about 1 in 1400 infants, although precise figures are uncertain because many patients are

asymptomatic.<sup>880</sup> It may arise because of failure of the ureteric bud to develop, failure of the ureteric bud to contact the metanephric blastema, or failure of the bud and the metanephric blastema to interact and induce nephrogenesis. Bilateral renal agenesis is reported in 1 in 4000 births, with a male to female ratio of 2.5 to 1.<sup>880</sup> Bilateral renal agenesis is associated with oligohydramnios, Potter's sequence and fetal or perinatal death. Unilateral renal agenesis is generally asymptomatic, but abnormalities in the contralateral kidney have been reported<sup>881</sup> and it is often associated with abnormalities of other organs. The risk of recurrence can be determined in syndromic cases or if the mode of inheritance is known. The recurrence risk is 3% if there are no renal abnormalities in first degree relatives.<sup>882</sup> One study reported associated urogenital abnormalities in 9% and unilateral renal agenesis in 4.5% of first degree relatives of infants with bilateral renal agenesis.<sup>883</sup>

Misplacement of the ureteric bud on the mesonephric duct may lead to abnormal nephrogenesis and renal dysplasia. This is characterized histologically by the presence of primitive ducts and foci of metaplastic cartilage with or without cyst formation.<sup>884</sup> The association of reflux with renal dysplasia may occur as a result of the ureteric bud arising below the normal position. This then presents at the urogenital sinus earlier in gestation and migrates further laterally presenting a larger ureteric orifice which is consequently more prone to reflux.<sup>885</sup> As with renal agenesis, renal dysplasia may be found as a component of several differing syndromes with considerable clinical variation.

Multicystic dysplasia is characterized by the presence of multiple, noncommunicating and nonfunctioning renal cysts varying in size from a few millimeters to several centimeters. It is unilateral in 76% and bilateral in the remainder<sup>886</sup> with a reported incidence of 1 in 3–4000 and 1 in 10000 live births respectively.<sup>887</sup> It is the commonest cause of an abdominal mass in the newborn. Consistent evidence demonstrates that the perceived risk of hypertension or malignancy is unfounded<sup>888–890</sup> and that serial ultrasounds to ensure regression are all that is required.

Cystic disease of the kidneys may occur in isolation or in association with recognized syndromes. Isolated renal cystic disease in the absence of urinary tract obstruction may be identified antenatally as large hyperechoic kidneys on ultrasound. The presence of oligohydramnios is a poor prognostic sign and is frequently associated with neonatal death from pulmonary hypoplasia. Autosomal recessive polycystic kidney disease (ARPKD) is sometimes referred to as infantile polycystic kidney disease. This is a misnomer because the adult form (autosomal dominant, ADPKD) may also present in infancy. ARPKD is an uncommon disorder occurring in 1 in 40000 births,<sup>890</sup> the gene for which is mapped to chromosome 6.<sup>891</sup> It is characterized histologically by bilateral renal enlargement with numerous microscopic corticomedullary cysts. Associated liver changes including bile duct proliferation with portal fibrosis are invariably present. The prognosis of this condition is dependent on the severity of renal disease in the perinatal period with the most severely affected dying within the first year of life. ADPKD has a gene frequency of 1 in 1000<sup>892</sup> and has multiple gene loci, the commonest of which is on the short arm of chromosome 16.<sup>892</sup> The clinical course for ADPKD is generally more benign. However, cases that are detected antenatally have a similar prognosis to infants with antenatally detected ARPKD, with mortality approaching 50% in the first year of life.<sup>893</sup>

Failure of the kidney to ascend from the pelvis is the commonest form of renal ectopia. It has an incidence of 1 in 1200 in postmortem studies.<sup>894</sup> The ectopic kidney derives its blood supply from an anomalous source in the aorta or the pelvic vessels. Fusion of ectopic kidneys may occur in the midline, producing a discoid or 'pancake' kidney or following migration of the ectopic kidney to the contralateral side where fusion occurs with the normal kidney on that side. Fusion of kidneys also occurs to form a horseshoe kidney with an incidence of 1 in 400, where both kidneys are fused at the lower poles. Horseshoe kidneys are found at the level of the lumbar vertebrae as ascent is limited by the presence of the aortic bifurcation and the inferior mesenteric artery. As with ectopic kidneys, horseshoe kidneys are frequently asymptomatic but complications from a malrotated pelvis or ureter may result in

**Table 12.93** Increase in relative glomerular filtration rate in infancy. Values expressed as mean ( $\pm$  2 SD)

Age	ml/min	ml/kg	ml/min/1.73 m <sup>2</sup>
1 week	3.75 (2.5–5)	1.2 (0.8–1.6)	30 (20–40)
1 month	6 (4–8)	1.5 (1–2)	50 (30–70)
3 months	10.5 (7–14)	1.89 (1.2–2.4)	60 (40–80)
6 months	18.5 (12.5–25)	2.4 (1.6–3.2)	80 (60–100)
1 year	30 (20–40)	2 (2–4)	100 (75–125)
2 years	45 (30–60)	3.3 (2.2–4.4)	120 (90–150)

infection, ureteric obstruction or nephrolithiasis. Additionally there is an increased risk of neoplasia in horseshoe kidneys, most commonly Wilms' tumor.<sup>895</sup>

Abnormalities in ureteric development are the commonest abnormalities of the renal tract with duplex systems reported in up to 4% of the population.<sup>896</sup> This arises when two ureteric buds occur on one side and induce nephrogenesis in an upper and lower renal moiety, resulting in drainage through either a common or two separate ureters. The lower ureter migrates laterally, crossing the upper ureter, and is more prone to vesicoureteric reflux. The upper ureter is more prone to ectopic insertion and ureterocele development. These abnormalities are frequently asymptomatic.

Obstruction of the ureter due to stenosis at the pelviureteric junction or the vesicoureteric junction or due to external compression may result in hydronephrosis. Fetal ureteric obstruction may lead to renal dysplasia,<sup>897</sup> depending on the duration and the degree of ureteric obstruction. The investigation and postnatal management of these conditions will be discussed later. Bladder outflow obstruction is more common in males. It may be due to posterior urethral valves. Less commonly it is a feature of prune belly syndrome. This may be a consequence of transient fetal urethral obstruction and features include oligohydramnios, pulmonary hypoplasia, Potter's facies, a deficiency in the abdominal wall musculature, cryptorchidism, megacystis, megaureter and variable progression to renal failure. The role of fetal interventional surgery for bladder outflow obstruction is unclear. Benefits in pulmonary growth may occur following the insertion of a vesico-amniotic shunt in the presence of oligohydramnios, however the impact on postnatal renal function has been disappointing.<sup>898,899</sup>

## ASSESSMENT AND INVESTIGATION OF THE NEONATE WITH RENAL DISEASE

Careful history taking is important. An infant with autosomal dominant polycystic kidney disease may have asymptomatic parents but affected members of the extended family. Specific gene defects are recognized for many syndromic conditions, offering the possibility of pre-implantation or antenatal gene testing. In several conditions more than one gene defect exists, requiring linkage analysis to determine the presence of the condition in the fetus. A useful summary published by Rizk & Chapman outlines the genetic and clinical features of cystic and inherited conditions.<sup>900</sup>

Details of the pregnancy are also important. Oligohydramnios may indicate renal agenesis or dysplasia. Polyhydramnios occurs in association with fetal polyuric states such as nephrogenic diabetes insipidus or Bartter syndrome. The placenta may be enlarged (> 25% of birth weight) in autosomal recessive congenital nephrotic syndrome (Finnish type), which is also associated with an elevated maternal alpha-fetoprotein. The presence of a single umbilical artery may be associated with abnormalities of the renal tract. Thummula et al<sup>901</sup> performed a meta-analysis of 37 studies. Single umbilical artery was noted in 0.55% of live-born fetuses and was associated with a congenital abnormality rate of 27%, including abnormalities of the renal tract in 16%. More than half of the abnormalities were minor or self-limiting and isolated single umbilical artery in an asymptomatic infant was not considered to be an indication for detailed urological investigation.

The use of antenatal ultrasound to detect fetal anomalies is now routine in many areas and has created a previously unknown patient population. The finding of a renal abnormality on antenatal ultrasound should be treated with caution in all but the most severe cases as studies have shown that the majority of abnormalities detected are of hydronephrosis and are minor or self-limiting.<sup>902</sup> Parents should be reassured of this during the pregnancy. The identification and investigation of infants with antenatal hydronephrosis is not standardized and is determined by local protocols. Measurement thresholds for renal pelvis dilatation considered to be consistent with a degree of hydronephrosis increase with advancing gestation from > 6 mm at 20 weeks to > 8 mm at 20–30 weeks and > 10 mm at over 30 weeks.<sup>903–905</sup> These measurements should not be viewed in isolation. Infundibular or

**Table 12.94** Etiology of hydronephrosis detected antenatally<sup>913</sup>

Transient/physiological	63%
Pelviureteric junction obstruction	11%
Vesicoureteric reflux	9%
Megaureter	4%
Multicystic dysplastic kidney	2%
Ureterocele	2%
Posterior urethral valves	1%

calyceal dilatation is never a normal variant.<sup>906</sup> Ureteric dilatation, parenchymal thinning or abnormalities of the urinary bladder increase the likelihood of postnatal pathology. The definition of significant renal pelvic dilatation varies, with most studies accepting 10 mm as a threshold.<sup>907–911</sup> The etiology of hydronephrosis is consistent across studies<sup>912,913</sup> and is shown in **Table 12.94**. The current guidelines for the management of antenatally diagnosed renal pelvis dilatation adopted by the Scottish Paediatric Renal Group are shown in **Figure 12.51**. It is accepted that minor degrees of vesicoureteric reflux may be missed by the omission of a micturating cystourethrogram in some infants, however the clinical significance of this is felt to be minimal.

## PHYSICAL EXAMINATION

Renal disease in the neonatal period may present with nonspecific features such as poor feeding, weight loss, irritability, fever, jaundice or diarrhea. The possibility of associated renal abnormalities is increased in the presence of other congenital abnormalities or syndromes.

Inspection of the infant may reveal features consistent with oligohydramnios such as the classic Potter's facies or orthopedic anomalies, including talipes equinovarus. Urinary tract pathology should be anticipated when neural tube defects are identified. Examination of the external genitalia and visualization of the urinary stream are particularly important in the male infant as dribbling or a hesitant stream may be associated with posterior urethral valves. Approximately 30% of neonates void during or immediately after delivery, 92% within 24 h and 99% within 48 h. Failure to do so requires clinical assessment to exclude dehydration or bladder outlet obstruction. Ultrasonically confirmed bladder distention requires catheter drainage either per urethra or, in some units, suprapubically if there is a suspicion of a posterior urethral valve.

Most abdominal masses that are palpable in the newborn period are renal in origin.<sup>914</sup> Normal kidneys may be readily palpated with bi-manual examination. Ascites is rarely renal in origin. It may occur in association with generalized edema from fluid overload secondary to renal failure, or in association with hypoalbuminemia secondary to fetal hydrops or congenital nephrotic syndrome.

## INVESTIGATION – URINALYSIS

Frank hematuria is far less common than microscopic hematuria in the neonatal period. Possible etiologies are highlighted in **Table 12.95**. The association of an abdominal mass, hematuria and thrombocytopenia in a sick neonate raises the possibility of renal vein thrombosis. Doppler ultrasound should be used to ascertain the extent of the thrombosis of the renal vein and any extension into the inferior vena cava or into the contralateral renal vein. Renal vein thrombosis occurs in association with perinatal asphyxia and umbilical venous catheterization. The possibility of an inherited thrombophilia should be assessed by investigation of the child and the parents. Abnormalities have been reported in approximately 40% of cases.<sup>915,916</sup> There are no published data relating to the use of prophylactic anticoagulant therapy in this population. Bilateral renal vein thrombosis or extending caval thrombosis are cited as relative indications for the commencement of anticoagulant or less commonly thrombolytic therapy.<sup>915–917</sup> Intravenous unfractionated heparin, 20–25 u/h aiming for an activated partial prothrombin time of 1.5–2.5, has been used. Low molecular weight heparin at a dose

of 150 u/kg twice daily administered subcutaneously, aiming for an anti-factor Xa level of 0.5–0.9 IU/ml, has also been described. The outcome of renal vein thrombosis is generally good with a reported incidence of end-stage renal failure of less than 10%, and hypertension in up to 25%. However, significant degrees of renal damage are consistently reported<sup>915,916,918</sup> with recent evidence suggesting that a renal length over 6 cm is always associated with long term renal dysfunction.<sup>915</sup>

Hypercalcaemia may lead to nephrocalcinosis, which is reported in up to two thirds of very low birth weight neonates and is associated with tubular and glomerular dysfunction. Recent studies however suggest that in the majority of cases nephrocalcinosis resolves with no evidence of residual renal dysfunction.<sup>919</sup>

Proteinuria in the neonatal period is physiological<sup>920</sup> and is higher in the preterm than the term infant. Proteinuria exceeding 10 mg/m<sup>2</sup>/h after 5 days of age requires further investigation; possible etiologies are listed in Table 12.96.

## INVESTIGATION – BLOOD BIOCHEMISTRY

Following birth the plasma creatinine reflects the maternal creatinine and is elevated, particularly in preterm infants. Levels fall by the end of the first week. However, this fall may take several weeks in preterm infants due to tubular reabsorption of creatinine and a lower GFR. Urea concentration is affected by many variables including protein intake, hydration status and metabolic state and as such is unreliable in assessing renal function.

Urinary sodium excretion is greater in preterm infants as a consequence of relative aldosterone resistance and this can mean that sodium supplementation is necessary. Bicarbonate loss is also greater in preterm infants, causing them to exist in a more acidotic state. However the excretion of an acid load is not impaired, allowing the preterm infant to thrive.

## INVESTIGATION – IMAGING

Ultrasound examination of the fetal and neonatal urinary tract has been discussed earlier in relation to the investigation of antenatally observed hydronephrosis. The relatively low volume of urine produced by neonates in the first 48 h post partum may mask hydronephrosis persisting postnatally and for this reason delaying the initial postnatal ultrasound scan beyond this period has been advocated. This should not occur for cases of moderate to severe antenatally detected hydronephrosis (renal pelvis diameter > 15 mm) who require imaging within the first 48 h post partum. The use of nuclear scintigraphy in the assessment of the neonatal renal tract is well established with

dynamic isotopes such as  $^{99m}\text{Tc}$ -labeled diethylenetriaminepentaacetate (DTPA) and mercaptoacetyltriglycine (MAG-3) providing data on renal perfusion. As they are dynamic isotopes they also provide data on renal excretion, particularly in cases of suspected pelviureteric junction obstruction. However they are of limited benefit in assessing obstruction in the lower ureter at the vesicoureteric junction, which remains one of the few indications for the use of an intravenous pyelogram in the investigation of the neonatal renal tract other than prior to surgical intervention in cases of established obstruction. Assessment of differential renal function may be undertaken using these isotopes.  $^{99m}\text{Tc}$ -labeled diethylmercaptosuccinic acid (DMSA) is more sensitive and provides data on renal scarring. Because DMSA does not adhere well to immature tubular epithelium, unreliable results may be obtained in preterm infants, and in our institution DMSA imaging is not undertaken prior to 3 months of age.

Micturating cystourethrogram (MCUG) is mandatory for the assessment of infants with neonatal urosepsis with particular attention in males to the possibility of a posterior urethral valve. The role of the MCUG in the investigation of minimal antenatal hydronephrosis or in the investigation of a neonate in whom the sibling has reflux nephropathy is less clear. Recent evidence suggests that investigation in this cohort is seldom required and that ultrasound is a suitable alternative to MCUG.<sup>921</sup>

## CLINICAL CONDITIONS AFFECTING THE NEONATE

### Acute renal failure

Acute renal failure is a frequent occurrence in the neonatal intensive care setting, with up to a quarter of neonates presenting to intensive care showing evidence of renal failure.<sup>922</sup> The diagnosis of acute renal failure is dependent on repeated measurements of the plasma creatinine, as variations in gestation and maternal creatinine in combination with the normal postpartum diuresis make estimation of GFR from a single plasma creatinine measurement very difficult. A rise in plasma creatinine or indeed a failure to observe the physiological decline in creatinine post partum both indicate renal functional impairment. Preterm infants may have a transient period of oliguria ( $< 300 \text{ ml/m}^2/\text{d}$ ). The main cause of oliguria in the neonatal period is inadequate renal perfusion (pre-renal failure) as a consequence of hypotension, hypovolemia, hypoxia and acidosis. Early correction of impaired renal perfusion with volume expansion or pressor support may prevent progression to established renal failure. In the absence of pre-renal failure the most common cause is intrinsic renal disease. Ultrasound examination should be used to exclude congenital uropathy.

The general principles of management of acute renal failure are discussed in Chapter 18. There are some additional considerations in the management of neonatal acute renal failure. The relatively high surface area to weight ratio of the neonate results in increased insensible fluid losses. These are around  $0.5\text{--}1 \text{ ml/kg/h}$  in term infants, but due to higher transepithelial fluid losses they may be as high as  $3 \text{ ml/kg/h}$  in preterm infants.<sup>923</sup> Renal replacement therapy using peritoneal dialysis can be undertaken successfully in neonates with acute renal failure.<sup>924</sup> Improvements in vascular access and the use of pumped extracorporeal circuits have also made continuous renal replacement therapies a viable alternative, notwithstanding the attendant risks of vascular access and systemic anticoagulation. The outcome of non-oliguric renal failure is excellent<sup>925</sup> as it is almost exclusively a secondary event that responds to treatment of the initial cause.<sup>926</sup> However, oligo-anuric renal failure has a reported mortality of up to 78%.<sup>925</sup>

### Chronic renal failure

Chronic renal failure may develop in infants who fail to recover from acute renal failure and in infants with congenital renal abnormalities. Imaging of the renal tract will generally define the underlying etiology. In rare cases a renal biopsy may be required. The general principles of management of chronic renal failure are discussed in Chapter 18. In the

neonatal period particularly close attention to fluid balance and nutritional intake is required as many of these infants are polyuric, requiring over  $200 \text{ ml/kg/day}$ , and consequently require the input from specialist dietetic staff and frequent checks of body weight. Whilst chronic hemodialysis is feasible in smaller infants,<sup>927</sup> the renal replacement modality of choice is peritoneal dialysis. The impact on the family of having a baby with complex medical needs is profound and the services of the multidisciplinary team should be made available, including that of an appropriately trained psychologist.

### Hypertension

Hypertension is uncommon in the neonatal period and occurs most commonly in the intensive care setting.<sup>928</sup> As in older children, hypertension in the neonate is defined as a blood pressure greater than the 95th percentile for age, gender and weight.<sup>929</sup> Blood pressure measurement in sick neonates in intensive care is generally achieved by direct arterial measurement through the umbilical artery. Automated oscillometric blood pressure recording is also frequently used, although care must be taken in using the appropriate cuff size to avoid serious inaccuracies. The main causes of hypertension in the neonate are listed in Table 12.97. It is most commonly observed in sick infants where the etiology is multifactorial and the hypertension generally resolves with clinical improvement. Persisting hypertension is most commonly a consequence of renovascular or renal parenchymal disease. Determining the etiology of hypertension in the neonate can generally be achieved through a careful history and physical examination. Investigations other than renal tract imaging are rarely required. Treatment of the sick hypertensive neonate is best achieved using an intravenous agent, which allows immediate dose titration according to response. In neonates with blood pressure controlled with intravenous agents or those with mild hypertension, oral therapy should be commenced that is relevant to the etiology of the hypertension, e.g. in the presence of chronic lung disease and steroid usage, diuretic therapy would be the initial treatment of choice. The choice of antihypertensives is frequently dictated by local expertise and is reviewed in detail by Flynn.<sup>929</sup>

### Urinary tract infection

Urinary tract infection (UTI) in the neonatal period is more common in males and is significantly associated with abnormalities of the renal

tract.<sup>930,931</sup> The clinical features of a neonate with UTI are nonspecific and include vomiting, weight loss, poor feeding, fever, diarrhea and jaundice, and therefore a high index of suspicion is required. Treatment should be initiated without delay following specimen collection and should be administered intravenously in the first instance. The choice of antibiotic is likely to be determined by local preference with the majority of organisms responding to the standard neonatal sepsis protocol. Following treatment, prophylactic antibiotic therapy is advised at least until the completion of radiological investigation, the protocol for which is discussed further in Chapter 18.

## EYE PROBLEMS IN THE NEWBORN

A normal visual input is important for a child's development. This section will be concerned with the developing visual system, and the various problems which may befall it in the neonatal period.

### THE DEVELOPING VISUAL SYSTEM

#### Ocular growth

The ocular growth of the extremely preterm infant is particularly active, the retinal surface area doubling between 24 weeks' gestation and term. By term the infant's eye is at a relatively advanced stage of development: it increases only three times in volume to reach adult size, compared to the rest of the body which increases 20 times. In the first 2 years the surface area increases by a further 50%. Most of the postnatal growth of the eye takes place in its posterior segment, particularly in the peripheral regions of the retina. There is little growth in either the retina around the macula<sup>932</sup> or the anterior segment of the eye<sup>933</sup> so the line of sight is relatively unperturbed during development. The length of the globe does not reach its adult value of approximately 24 mm until the second decade.

#### Cornea

The normal cornea is hazy until about 27 weeks' gestation. Slight haze in preterm and term infants is not rare depending on the degree of immaturity. It clears rapidly. A cloudy cornea may be caused by infantile glaucoma (see below and Fig. 12.52), a corneal dystrophy, malformation of the anterior segment, and rarely, in congenital rubella, by keratitis.

#### Lens

Subtle lens opacities are quite common in preterm neonates. These are in the form of vacuoles and are best seen using the direct ophthalmoscope. They are transient, of no long term significance and their etiology is unknown. Congenital cataract is considered elsewhere (Ch. 31).

#### Vascular development

**Transient vascular systems.** In fetal life the eye has two transient vascular systems. The hyaloid vascular complex, which fills the vitreous cavity and extends forwards, also contributes to the second system, the tunica vasculosa lentis, a vascular structure which surrounds the lens. The hyaloid artery disappears by 28 weeks' gestational age while the tunica vasculosa lentis regresses between 28 and 34 weeks' gestational age. As the latter can readily be visualized by direct ophthalmoscopy the degree of regression can be used as a crude estimate of gestational age. Failure of regression can be an important sign of severe retinopathy of prematurity.

**Retinal vasculature.** The retina is avascular until the fourth month of gestation, relying entirely on the underlying choroidal circulation for its nutrients. From this time the mesenchymal precursors of the retinal vessels grow out from the optic disc and reach the periphery of the nasal retina around 32 weeks' gestational age, whilst in the temporal retina, which is the last area to be vascularized, this process is not complete until around term. The stimulus for vessel growth is tissue hypoxia mediated through retinal astrocytes and Muller cells, which secrete vascular endothelial growth factor (VEGF). VEGF is a vascular survival factor and, in synergy with IGF-1, is vital to the formation and maintenance of a normal mature retinal circulation.<sup>934</sup>

Fig. 12.52 Congenital glaucoma in the left eye. This eye is larger than its fellow, and the cornea is also slightly hazy (dulled corneal light reflex).

#### Visual pathway development

The retina has its full complement of cells by 24 weeks' gestational age, but retinal maturational changes continue, particularly in the fovea, for another 4 years or so. Myelination between the globe and the lateral geniculate nucleus starts at about 24 weeks' gestational age and is complete by 2 years. In the posterior visual pathway dendrite formation and synaptogenesis both lead to an increase in volume of the lateral geniculate nucleus and the visual cortex over the first 6 or so months of postnatal life, while myelination continues for at least a decade.

Ocular growth, the maturational changes within the eye, and the posterior sections of the visual system are all dovetailed so that they proceed at a predetermined and relatively unimpeded rate to reach a successful functional outcome. That this occurs relatively unimpeded is quite remarkable for the baby born before term, who is reared in an environment that is relatively hostile compared to the womb.<sup>935</sup>

### OPHTHALMIA NEONATORUM

Defined as conjunctivitis developing within the first 4 weeks after birth of life (Fig. 12.53), ophthalmia neonatorum is a notifiable condition as in the past it was one of the most important causes of childhood visual disability. Fortunately, in most countries, the situation has now changed, but even today permanent ocular damage can result and treatment must be appropriate and prompt. Although the clinical features of the various types of ophthalmia neonatorum are suggestive of a particular diagnosis they are not sufficiently characteristic to make a definitive diagnosis. A large number of organisms have been implicated and in order of frequency these are *Chlamydia trachomatis*, *Staphylococcus* sp., *Neisseria gonorrhoeae*, *Streptococcus* sp., *Haemophilus* sp., *E. coli*, and less frequently a number of other organisms including *Pseudomonas aeruginosa* and the herpes simplex virus.

Fig. 12.53 Ophthalmia neonatorum.

### **Chlamydia trachomatis**

This is the commonest cause of ophthalmia neonatorum (developing in 10–50% of those infants exposed) and although the clinical picture may be mild, subclinical infections are not unusual. About 70% babies with chlamydial infection are culture positive in the nasopharynx and pneumonia can develop.<sup>936</sup> The incubation period is usually 5–14 days with a peak incidence in the second week after birth. The condition can be unilateral or bilateral and may range from a mild erythematous response to a severe pseudomembranous conjunctivitis (streptococci are another cause of a pseudomembranous reaction). Only in the most severe infection is the discharge copious and purulent. Even mild disease can cause corneal scarring (pannus), but the risk of this complication is lessened by prompt treatment.<sup>936,937</sup>

### **Neisseria gonorrhoeae**

This infection is acquired during passage down the birth canal of the mother who has either untreated or partially treated gonorrhoea. Worldwide it is estimated that there were over 62 million new cases in 1999.<sup>938</sup> The incubation period is usually 2–5 days but conjunctivitis may present up to 3 weeks after delivery. Characteristically the gonococcus causes a marked inflammatory reaction with lid and conjunctival edema, and a copious purulent, greenish, sometimes blood-stained discharge held under pressure by the swollen eyelids. Disseminated infection can occur. This organism is particularly virulent as it alone can penetrate the intact cornea to cause blindness.

### **Herpes simplex virus**

When ophthalmia neonatorum is caused by this virus it is usually as part of a generalized infection. In addition to the conjunctivitis, corneal clouding and dendritic ulceration occur. In contrast to herpes simplex infections developing at other times of life, neonatal herpes has a propensity to affect both eyes, and to differentiate it from other causes of ophthalmia neonatorum there may be vesicular formation of the eyelid skin and corneal involvement.

### **Other organisms**

These do not individually give rise to distinctive clinical features, although in general a purulent discharge indicates bacterial origin or secondary involvement.

### **Diagnosis and treatment**

As the clinical features are at best suggestive but not pathognomonic, accurate diagnosis rests with laboratory tests. Culture media (blood and chocolate agar) should be inoculated immediately as *N. gonorrhoeae* cannot resist drying. Swabs from the conjunctivae must be taken before any topical or systemic antibiotic is administered. A further tissue specimen which must contain epithelial cells is applied directly to microscope slides and stained by Gram and Giemsa stains, looking in

the latter for the intracytoplasmic inclusions of *Chlamydia*, and multinucleated giant cells and intranuclear inclusions of herpes simplex. Direct enzyme immunoassay or immunofluorescent antibody assay of conjunctival discharge has high specificity and sensitivity for *Chlamydia*. Impression cytology of conjunctival cells is a rapid technique for diagnosing *Chlamydia*.<sup>936</sup>

In several countries, and many of the states in the USA, but not the UK, prophylaxis is routine and sometimes is mandatory, using 1% silver nitrate, 1% tetracycline ointment, or 0.5% erythromycin ointment. Neither silver nitrate nor erythromycin is protective against *Chlamydia*. Povidone–iodine 2.5% is more effective than all other prophylactic agents, is simple and cheap to prepare and yet, for reasons not readily apparent, is not used routinely.<sup>939,940</sup> Whichever preparation is used it is applied once to both eyes soon after birth. Silver nitrate is ineffective against established infection. Silver nitrate causes a chemical conjunctivitis which resolves after one or two days. All cases of ophthalmia neonatorum should be managed as though they are contagious and in many cases there will be infection by multiple organisms. Thus, gonococcal infection is frequently accompanied by chlamydial infection and infants need to be investigated appropriately; many will need to be treated for both conditions. It is also important to appreciate that both gonococcal and chlamydial infections may have a systemic component and treating the eye alone is not enough. Treatment must be started immediately, guided by clinical findings and the results of the histological stains. The first line of treatment for gonococcal infections is ceftriaxone administered by intramuscular or intravenous routes (25–50 mg/kg) as a single dose, although multiple doses may be preferred by some pediatricians.<sup>938</sup> Resistance to ceftriaxone has not been reported. For chlamydial infection oral erythromycin for 2 weeks remains the treatment of choice; as efficacy of treatment is 80%, a second course may be required.<sup>936,937</sup> For both gonococcal and chlamydial infections once systemic treatment has commenced topical antibiotics are not necessary, although it is important that the conjunctival discharge is washed away frequently by saline irrigation. In other words, treat the baby and the eye is naturally covered by this; the reverse is not true.

## **BIRTH TRAUMA**

### **Eyelids and orbit**

Ecchymosis of the eyelids is common but is of no long term consequence. Orbital hemorrhage causing proptosis occurs occasionally and is usually the consequence of a prolonged and difficult labor.

### **Ocular hemorrhages**

Hemorrhages into various ocular tissues are frequent with all types of delivery. Conjunctival hemorrhages resolve rapidly and without sequelae. It is not uncommon for the iris blood vessels to be markedly engorged following birth, and on occasion bleeding into the anterior chamber occurs causing a hyphema which also settles spontaneously.

The retina is the most frequent site of hemorrhage following birth. In decreasing frequency they may result from delivery by vacuum extraction, vaginal and forceps delivery, and least often following Cesarean section.<sup>941</sup> Frequently but not invariably bilateral, most retinal hemorrhages resolve spontaneously without trace over the ensuing days and weeks. If the hemorrhage is large and has a preretinal or vitreous extension this process may take up to 2–3 months, but even so it does not result in adverse sequelae. Neonatal retinal hemorrhages do not cause amblyopia. Sometimes it can be difficult to differentiate between retinal hemorrhages due to the birth process and a later acquired non-accidental injury. The distinction, which can be extremely difficult, rests on the history and whether the features of the hemorrhage are compatible with the history.

### **Cornea**

The cornea may be damaged by forceps injury. This is usually unilateral and causes a cloudy cornea. The first priority is to distinguish corneal cloudiness due to injury from infantile glaucoma (Fig. 12.54) which requires prompt treatment. Although in glaucoma the corneas

Fig. 12.54 Left cloudy cornea due to malformation of the anterior segment, the so-called anterior cleavage syndrome.

are characteristically enlarged, in the neonatal period this may be yet to develop and it is essential therefore to measure the intraocular pressure. Clouding following forceps trauma clears over a few weeks, but in the long term astigmatism, amblyopia and strabismus are likely sequelae.

### Cranial nerve palsies

Palsy of one of the ocular motor nerves is not rare and has in the past often been attributed to birth trauma – almost certainly incorrectly.

### RETINOPATHY OF PREMATURITY

Retinopathy of prematurity (ROP) is a potentially blinding disorder affecting infants born prematurely. Described first in the 1940s, there was an epidemic of retrolental fibroplasia (RLF), as it was then known. This was brought to an end in the early 1950s by the discovery that the high concentrations of oxygen being given at that time were important in its etiology. Concomitant with the increased survival of the extremely immature neonate over the past few decades, the incidence of ROP has again risen.

### Pathogenesis

ROP is a condition of the immature retinal vasculature and does not develop after the retina is fully vascularized. Retinopathy develops at the junction of the vascularized and yet to be vascularized retina. There are three theories of ROP pathogenesis. According to the first, classic theory,<sup>942,943</sup> the retinal vessels constrict and their endothelial cells are damaged due to raised (i.e. above normal for the fetus) PaO<sub>2</sub> levels. This leads to the production of angiogenic factors and subsequent vasoproliferation. The second theory<sup>944</sup> also postulates the production of angiogenic factors but proposes that this is not induced by vasoconstriction but by direct oxidative insult to the mesenchymal precursors (spindle cells), which then synthesize and secrete angiogenic factors generating the retinal vasoproliferative response.

Both theories invoke an oxidative insult, which might be due to a direct cytotoxic action of oxygen itself,<sup>942</sup> indirectly due to ischemia consequent upon the vasoconstriction,<sup>943</sup> or indirectly by oxygen-generated free radicals.<sup>944</sup> The most recent and third theory invokes growth factors and apoptosis.<sup>945,946</sup> The maintenance of the retinal vascular tree depends on a continuous supply of the survival factor VEGF acting in synergy with IGF-1.<sup>934</sup> Hyperoxia downregulates VEGF so halting retinovascular development and inducing endothelial apoptosis and excessive capillary regression. The resultant retinal ischemia generates an upregulation of VEGF, which in turn induces angiogenesis and the vasoproliferative response known as ROP.<sup>946</sup>

All theories concur that oxygen is implicated directly or indirectly in the initiation of ROP. However, once ROP has developed the retina is rendered ischemic and it is this ischemia which contributes to the vasoproliferative response of severe disease. Oxygen-dependent VEGF is implicated in all

stages of ROP development, and oxygen-independent IGF-1 permits VEGF to function maximally.<sup>934</sup> A trial to reduce the severity of the retinal ischemia associated with severe ROP by oxygen administration was unsuccessful.<sup>947</sup>

### Risk factors

Clinicians have tended to regard severe ROP as an inevitable, albeit unpredictable, occasional consequence of extreme prematurity. However, recent advances in our understanding allow us to challenge this complacency. By far the most powerful ROP risk factor is the degree of immaturity. However, many other risk factors have been implicated, of which the best known is supplemental oxygen administration. Interest in the role of oxygen in its pathogenesis has reawakened<sup>948</sup> with the finding that oxygen administration in the first few weeks of life is a risk factor for ROP incidence and severity. Fluctuations, even within the normal range, can increase the risk of severe ROP, and PaO<sub>2</sub> monitoring – being intermittent – may mask important variations.<sup>949</sup> These findings have major implications for neonatal care. Nevertheless, it has not been possible to define a concentration or duration of oxygen which is, or is not, associated with ROP. The current consensus is that hyperoxia is important in ROP initiation and the challenge for the future is to determine the safe lower oxygen limit so that severe ROP does not develop and there is no increase in neurodisability.<sup>948,950</sup> Hypoxia on the other hand may increase the severity of established ROP, which is known to be ischemic. Other possible risk factors include: ethnic origin, multiple birth, intrauterine growth retardation, blood transfusions, apneic episodes, hypercarbia, low pH, intraventricular hemorrhage and periventricular leukomalacia. A randomized controlled trial showed that early exposure to light is not a factor in ROP development.<sup>951,952</sup>

### Classification

The International Classification of Retinopathy of Prematurity was revised in 2005.<sup>953</sup> The major features of the revised classification are the introduction of the concept of a more virulent form of retinopathy [aggressive posterior ROP (AP-ROP)] and the description of an intermediate level of plus disease (preplus).

### Acute phase ROP (Fig. 12.55)

This is described by four parameters: severity by stage (1–5 and AP-ROP), location by zone (1–3), extent [clock hours of the retinal circumference (Fig. 12.56)], and the presence of ‘preplus’ or ‘plus’ disease (Fig. 12.57).

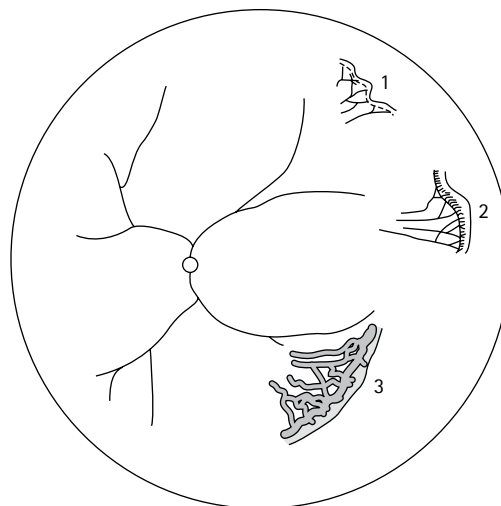

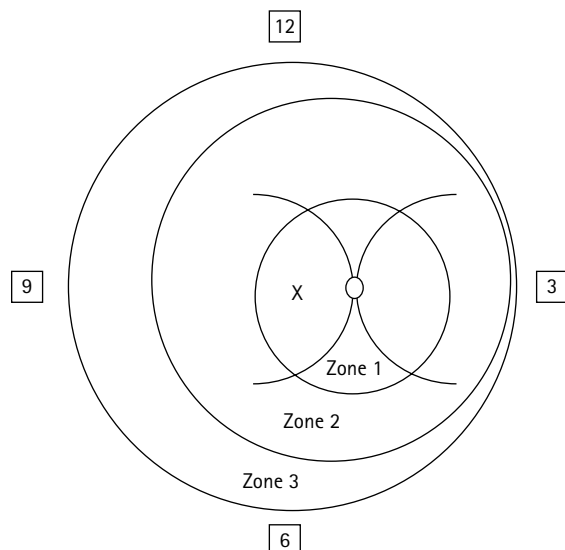

Fig. 12.55 Acute ROP: the first three stages of acute ROP presented for diagrammatic purposes on one retina. Each is shown as a short segment, but can extend over 360 degrees. Stage 1, demarcation line; stage 2, ridge; and stage 3, ridge with extraretinal fibrovascular proliferation. Note abnormal peripheral vascular arborization in all stages, but in stage 3 the vessels are engorged and the lesion is more posteriorly located. Note also that the retina is not fully vascularized.

**Fig. 12.56** Acute ROP: diagram of the retinal zones. Acute ROP develops at the advancing edge of the growing retinal blood vessels and ROP commencing in zone 1 has a marked propensity to become severe. Numbers on the periphery denote the hours of the clock which are used to describe extent.

**Fig. 12.57** Plus disease – retinal venous congestion and arteriolar tortuosity. Plus disease is the major indication that treatment is indicated.

#### Severity:

**Stage 1** – demarcation line, lying within the plane of the retina at the junction of the vascularized and avascular retina. The demarcation line is the accumulation of the mesenchymal precursors of the retinal vessels.

**Stage 2** – ridge; the demarcation line extends out of the plane of the retina (Fig. 12.58).

**Stage 3** – ridge with extraretinal fibrovascular proliferation. This is the stage of frank neovascularization, i.e. definitive new vessels are formed (Fig. 12.59).

**Stage 4** – subtotal retinal detachment.

**Stage 5** – total retinal detachment.

**Fig. 12.58** Stage 1 and 2 acute ROP. With a prominent ridge this is mostly stage 2, but to the left of the figure the ridge flattens to become stage 1.

**Fig. 12.59** Stage 3 ROP – ridge with fibrovascular proliferation. Hemorrhage disconnects a portion of the ROP lesion from the ridge.

**Aggressive posterior retinopathy of prematurity (AP-ROP).** Located in zone 1 or posterior zone 2, this form of ROP is uncommon, but untreated it rapidly progresses to stage 5. It is characterized by its posterior location, the prominence of plus disease and the deceptively featureless nature of the retinopathy.

**Location.** Retinal blood vessels grow centrifugally from the optic disc at the centre of zone 1 to zone 3. ROP in zone 1 is far more likely to become severe, and even if treated there is a far greater likelihood of a poor outcome than ROP in zone 3.<sup>954</sup>

**Extent.** The extent of ROP around the circumference is described in clock hours and this is one of the parameters used to indicate treatment.

**'Preplus' and 'plus' disease.** Important signs of ROP severity, in order of severity, include: congestion and tortuosity of the retinal vessel at the posterior pole, congestion of the iris vessels so that the pupil does not dilate readily with mydriatics (pupil rigidity), and vitreous haze. In practice, the critical signs are venous congestion and arteriolar tortuosity at the posterior pole as these signs drive treatment. Plus disease is defined as vascular abnormalities in at least two retinal quadrants close to the optic disc. Because plus cannot be sensibly quantified, the revised classification introduced the concept of preplus which describes rather loosely retinal vessels that are not normal but do not (yet) meet the criteria for plus.

#### Regressed ROP

Not all ROP undergoes complete resolution. Signs in the fundus which signify previous acute ROP are described according to their location, posterior or peripheral, and according to the structures involved, thus: *Vascular* – tortuosity, abnormal branching and arcades, and the straightening ('dragging') of the vessels around the disc (Fig. 12.60). *Retinal* – pigmentation, folding, stretching, detachment and vitreoretinal membranes.

#### Incidence

The incidence and severity of acute ROP rises with decreasing birth weight and gestational age. Quoted figures vary widely, probably due more to examination technique and frequency than neonatal factors. About 30–60% of babies weighing less than 1500 g develop some ROP. Severe disease is virtually confined to those infants < 1500 g birth weight and affects about 6% infants < 1250 g birth weight.<sup>955</sup>

#### Natural history

As the temporal retina is the last area to be vascularized, most acute ROP develops in that region, although in extremely immature babies it often starts in the nasal retina. The age at onset of acute ROP is governed by the postmenstrual age (PMA) of the baby rather than neonatal

Fig. 12.60 Signs of regressed ROP. Retinal fold extending from the 'dragged' optic disc. Peripheral pigmentation corresponds to the site of the acute lesion. (Reproduced with permission, Editor of the Practitioner.)

events. Thus contrary to expectation, ROP develops later postnatally in the smaller, very immature baby who is ill, compared to his larger, usually fitter more mature counterpart. Retinopathy of prematurity exceptionally requires treatment around 31 weeks' PMA, and never after complete retinal vascularization. The average age for treatment at 'threshold' is 37 weeks' PMA while that for 'prethreshold type 1' is 35 weeks' PMA (see below).<sup>956,957</sup>

### Treatment

Treatment is not required for mild ROP as this spontaneously resolves, while the outcome for stages 4 and 5 is so dismal that intervention cannot be justified. For many years, the indication for intervention was 'threshold' ROP, at which stage the untreated risk of blindness is 50%.<sup>958</sup> 'Threshold' is defined as stage 3 ROP in zone 1 and 2 which extends over 5 or more continuous, or 8 or more cumulative, clock hours of the retinal circumference in the presence of 'plus' disease. The subsequent Early Treatment for Retinopathy of Prematurity (ETROP) Randomized Trial<sup>957</sup> reported benefit of treatment at an earlier stage and resulted in a revision of the recommendations for treatment to 'prethreshold type 1', defined as:

1. zone 1, any stage of ROP with plus disease;
2. zone 1, stage 3 with or without plus disease; or
3. zone 2, stage 2 or 3 with plus disease.

Note that the revised treatment criteria include what was known as threshold but also include treating some eyes at an earlier stage known as prethreshold. Critically, the decision to treat has shifted from a complex assessment of the entire retina to the diagnosis of plus which is centered on the optic disc. Practically, the mean age for achieving the former is 37 weeks' and for the latter 35 weeks' PMA. It is important to emphasize that the time available for treatment once 'threshold' ROP has been reached is short, and ideally treatment should normally be undertaken within 48 h.

### Cryotherapy and laser

In 1988 the US-based Multicenter Trial of Cryotherapy for ROP demonstrated that cryotherapy reduced the unfavorable outcome of 'threshold' stage 3 ROP by about 50%<sup>958</sup> and this was maintained 10 years on.<sup>959</sup> However, 45% of children treated at threshold had a visual acuity of 6/60 or worse and this led to the early treatment (ETROP) study which reported a further improvement in outcome to treatment at prethreshold compared to conventional treatment (at threshold).<sup>957</sup>

Over the past decade, laser delivered through an indirect ophthalmoscope has largely supplanted cryotherapy as the treatment for severe ROP. Either cryotherapy or laser is applied to the peripheral retina anterior to the ridge (Fig. 12.61) over the full circumference of the globe. The

Fig. 12.61 Laser treatment for acute ROP. Laser has been applied to the avascular retina anterior to the ROP lesion.

procedure can be performed either under general anesthesia or sedation. While not all eyes respond to treatment, with early treatment at prethreshold both structural and functional outcomes are improved.<sup>960</sup>

### ROP screening

Screening is recommended for ROP that requires treatment.<sup>955,961,962</sup> UK guidelines specify that all babies of birth weight <1501 g and/or <32 weeks' gestational age are screened. Examinations for babies born before 27 weeks' gestational age should commence at 30–31 weeks' PMA, while for babies born at 27 weeks or over examinations should begin at 4–5 weeks postnatally. Examinations should be undertaken at least every 2 weeks (more frequently for babies with or at high risk of imminent severe disease) and continue until retinal vascularization is well into zone 3. As a rule the screening program should not cease before 37 weeks' PMA.<sup>957,961</sup>

### Treatment for end-stage disease

Not all ROP responds to treatment, and retinal detachment surgery and vitrectomy have been used for end-stage ROP. Vitrectomy is technically well within the scope of many surgeons but to date the visual results have been so poor that it is not recommended. Acute glaucoma sometimes develops in advanced disease. Removal of the lens may be helpful although this carries a risk of globe shrinkage.

### Differential diagnosis

For the preterm neonate this question hardly ever arises but there are a number of conditions that simulate ROP which may present in the full-term baby or in later life. These include autosomal dominant familial exudative vitreoretinopathy, Norrie disease, fetal ischemia (porencephaly, anencephaly), and Coats disease. The distinction may be impossible on ophthalmological criteria alone, and the family history and systemic aspects must be taken into account.

## OPHTHALMIC SEQUELAE OF PRETERM BIRTH

### Sequelae of ROP

Spontaneous and complete regression is the rule for mild ROP (stages 1 and 2) so that long term outcome is not significantly different from children born preterm who never developed ROP.<sup>963</sup> The single exception to this statement is strabismus, which is related to both ROP presence and stage. Severe ROP, even after treatment, generates sequelae which include refractive errors (myopia, astigmatism), strabismus, and visual acuity deficits ranging from the very mild to complete blindness. All stages 4 and 5 have a dismal visual outcome. The eye after severe ROP

is relatively unstable and a serious late complication of ROP is retinal detachment, which can develop at any age, even in adulthood.<sup>959</sup>

### Sequelae of prematurity

Visual development proceeds according to postmenstrual age rather than postnatal age and failure to appreciate this can result in unnecessary concern about visual functions in early infancy. Infants and children who were born prematurely, even after ROP has been accounted for, are more prone to suffer a range of visual pathway defects.<sup>963-968</sup> In reality the effects of ROP and neurological insults cannot be differentiated as the proportional effect of neurological damage suffered in the perinatal period compared to that due to prematurity per se is unknown. Neurological insults can vary in location and severity and not surprisingly result in a range of neuro-ophthalmic defects including reduced vision, eye movement disorders, refractive errors and optic atrophy. The causes of reduced vision depend on the nature of the insult, and the severity of the deficit can range from minimal to severe (cortical visual impairment).<sup>969,970</sup> Eye movement disorders include strabismus, gaze and saccadic palsies, and nystagmus. These are commonly associated with neurological insult; indeed the last three mentioned are almost certainly its direct consequence. The incidence of squint ranges from 11% to over 30%<sup>963,971</sup> and is particularly high in those with neurological damage such as cystic periventricular leukomalacia, especially if the lesion is posteriorly located. Myopia can be due to ROP;<sup>972</sup> but even in the absence of ROP the ex-preterm child and teenager is more likely to be myopic than his ex-full-term counterpart.<sup>963,973</sup>

### ROUTINE NEONATAL EYE EXAMINATION

Every baby should have an eye examination in the very early neonatal period before discharge from hospital or equivalent.<sup>974</sup> The following aspects need to be included and although the list looks formidable at first glance each examination need not take more than a minute or so. The neonatal eye examination while seemingly simple is not that easy to perform (puffy eyelids, etc.) and only 50% of congenital cataracts are diagnosed by 10 weeks of age, while 30% remain unidentified until after the first year.<sup>975</sup>

Look for conditions affecting both eyes, but be especially suspicious of asymmetry between the eyes.

### Signs of significant birth trauma

These have already been covered, and the word significant is included so that the pediatric resident performing this examination does not feel obliged to dilate pupils in order to look for retinal hemorrhage. Using the direct ophthalmoscope as torchlight, the anterior segment of the eye can be examined for corneal cloudiness, hyphema, etc.

### Ocular malformation

With the ophthalmoscope the following are examined:

- *Lids* – ptosis, hemangioma, dermoids.
- *Globe size*
  - microphthalmos
  - macrophthalmos, most important as this could be infantile glaucoma, but in the neonatal period the eyes may still be of normal size.
- *Conjunctiva* – injection or dermoid.
- *Cornea* – cloudiness, consider infantile glaucoma (Fig. 12.52). Opacities may be part of a malformation (Fig. 12.54).
- *Iris* – coloboma.

### Leukocoria (white pupil)

This is an important clinical sign which may signify a condition that is potentially lethal or may have severe consequences for vision. The red reflex is looked for by viewing the undilated pupil through a direct ophthalmoscope which is held at 33 cm from the eye. The absence of a red reflex must always be taken seriously and it requires *urgent* specialist referral. The red reflex can be difficult to visualize in the darkly pigmented baby, so take extra care under these circumstances.

Fig. 12.62 Leukocoria, a frequent presenting sign of retinoblastoma and cataract.

Causes of leukocoria (Fig. 12.62) include cataract, tumors (retinoblastoma), malformations (persistent hyperplastic primary vitreous, coloboma, retinal dysplasia as in Norrie disease and lissencephaly), myelinated nerve fibers, and inflammations (endophthalmitis). Conditions such as end-stage ROP, Coats disease and toxocariasis also can give a white pupil but always after the neonatal period.

### Ophthalmic family history

It is important to examine the eyes if there is a family history of a serious ophthalmic problem. In some conditions, for example dominantly inherited retinitis pigmentosa, the eyes at this time will be normal and it is not possible to determine whether or not the baby will be affected later. Certain fears can only be eliminated by a detailed examination and the diplomatic effect of this early examination is considerable and provides a good start to any subsequent involvement. A positive family history of infantile glaucoma and retinoblastoma even in the presence of a *normal* neonatal eye examination requires urgent referral and continued ophthalmological review.

## INFECTION AND IMMUNITY IN THE NEWBORN

### EPIDEMIOLOGY

Neonatal infections are estimated to cause 1.6 million deaths per year, accounting for 40% of all neonatal deaths in resource limited countries (reviewed in ref 976). The incidence of neonatal sepsis is uncertain, in part because definitions vary (bacteremia only,  $\pm$  focal sepsis,  $\pm$  clinical sepsis), as do definitions of its timing of onset [early onset (EO) sepsis is variably defined as < 48 hours, < 72 hours, < 5 days or < 7 days of age]. Postmortem examinations suggest that under-reporting is common.<sup>977</sup>

In resource limited countries, rates of bacteremia range from 1.7 to 33 and rates of clinical sepsis from 6.5 to 38 per 1000 live births. Such bacteremia rates are 3–20-fold higher than those of resource rich countries.<sup>976</sup> For example, Isaacs et al report an EO sepsis rate (< 48 hours of age) of 1.4/1000 live births from Australasian neonatal units,<sup>978</sup> Haque et al report rates of 1.6/1000 (< 72 hours of age) and 8.4/1000 (total) from a single UK unit<sup>979</sup> and Escobar et al report a rate of 1.2/1000 (total) for infants  $\geq$  2000 g from six US neonatal units.<sup>980</sup> Few population based UK data are available but a national (UK and Ireland) surveillance study in 2000–2001 identified 568 cases of group B streptococcal (GBS) sepsis in the first 3 months of life (total incidence 0.72/1000), of which 0.48/1000 were EO (< 7 days of age),<sup>981</sup> and another national study estimated the incidence of fungal sepsis in VLBW UK infants at 10/1000 live births.<sup>982</sup>

The incidence of sepsis is higher among babies of low birth weight. Blood culture-proven EO sepsis (< 72 hours of life) was 15/1000 in very low birth weight infants (< 1500 g) in the US National Institute of Child Health and Human Development (NICHD) Neonatal Research

Network with a late onset sepsis incidence of 210/1000.<sup>983,984</sup> The mortality is also higher in the VLBW population: 37% for EO and 18% for late onset sepsis.<sup>983,984</sup> The mortality from fungal sepsis in UK VLBW infants is 41%.<sup>982</sup>

One reason for uncertainty regarding the total burden of neonatal infection is that although sepsis may be diagnosed clinically, on the basis of clinical or laboratory markers, conventional blood or other sterile site cultures may be negative. Overall incidence estimates based only on culture positive infection may therefore underestimate the true burden of infection. Various factors may decrease the yield of blood cultures in the presence of true infection. This is particularly so in the case of pneumonia where bacteremia may be infrequent.<sup>985</sup> Antibiotics administered to mothers during labor may suppress the growth of bacteria in neonatal cultures and cultures may not be taken prior to the administration of antibiotics to the neonate. It is also possible that the volume of blood obtained from some neonates may be insufficient to grow the organism.<sup>986</sup> Using a definition of 'probable' GBS sepsis, for example, defined by positive surface swab cultures in the presence of clinical sepsis with no other explanation, several UK studies have suggested the incidence of GBS disease to be 1–3-fold higher than that defined by positive sterile site cultures alone.<sup>987–989</sup> Similarly, a US study estimated the incidence of culture proven infection to be 1.2/1000 live births and the additional incidence of clinical infection to be 2.2/1000.<sup>980</sup>

Neonatal infection is associated with significant morbidity. Approximately half of those with neonatal meningitis have long term neurodevelopmental problems at 5 year follow-up.<sup>990</sup> In a cohort of extremely low birth weight infants those who had neonatal infections were more likely to have cerebral palsy and a range of adverse neurodevelopmental sequelae. This was seen in those with sepsis alone, those with meningitis and, significantly, those with culture negative (clinical) sepsis as well.<sup>991</sup>

The most frequent organisms associated with neonatal infection are shown in Table 12.98.

Gram positive bacteria are the most frequent pathogens because of the increasing importance of coagulase negative staphylococci (CONS). They are particularly associated with low birth weight, use of intravascular catheters, late onset sepsis and nosocomial transmission. It can be difficult to differentiate contamination of blood cultures by CONS from true infection. CONS infection is associated with a low mortality.<sup>993</sup> Group B streptococcus, however, remains the most frequent cause of EO sepsis. Gram negative bacteria, especially those associated with multiple antibiotic resistance, are an important cause of infection and are increasingly associated with outbreaks in neonatal units. Fungal infections, most commonly *Candida albicans*, are an infrequent cause of neonatal sepsis and the incidence of invasive fungal infection in VLBW infants in the UK appears to be lower than that reported in studies from tertiary centers in North America and elsewhere. The mortality associated with fungal

infections is, however, considerable.<sup>982</sup> A UK-based analysis of neonatal deaths arising from maternal infection (defined as neonatal symptoms present in the first 48 hours of life) for the years 1981–1996 suggested that the top three identifiable bacteria were GBS (33%), *E. coli* (15%) and *Listeria monocytogenes* (6%).<sup>994</sup> A similar order of bacteria is responsible for neonatal meningitis in the UK with surprisingly little change between the 1980s and the 1990s.<sup>995,996</sup> Group B streptococcus remains the leading pathogen (39% of cases in 1985–7 and 48% in 1996–7), followed by *E. coli* (26% and 18%), other Gram negative rods (12% and 8%), *Streptococcus pneumoniae* (6% both periods) and *Listeria monocytogenes* (7% and 5%). The overall incidence of neonatal bacterial meningitis also has not changed: 0.22 cases/1000 live births (1985–7) versus 0.21 cases/1000 (1996–7). A Canadian review of 101 cases of neonatal meningitis (1979–1998) determined that 50% were due to GBS, 25% *E. coli*, 8% other Gram negative rods, 6% *Listeria monocytogenes*, and 3% nontypeable *Haemophilus influenzae*.<sup>997</sup> Other studies have noted an increase in meningitis due to *Enterobacter* sp. and *Serratia marcescens*; the majority of these Gram negative organisms were isolated from premature infants with late onset meningitis.<sup>998,999</sup> In resource limited countries, GBS meningitis appears to be much less frequent,<sup>1000</sup> although this is not universal.<sup>1001,1002</sup> Gram negative enteric organisms appear to account for the majority of early onset and *Streptococcus pneumoniae* for late onset meningitis in resource limited countries.<sup>1000</sup>

## PATHOGENESIS AND RISK FACTORS FOR NEONATAL INFECTION

Neonatal infection may be acquired in utero (congenital infection), during delivery (from the maternal genital or gastrointestinal tracts), while in the neonatal unit or from the home or community after discharge. The mother's race, age, socioeconomic status, and her susceptibility to certain pathogens (e.g. rubella, CMV) may increase the risk of transmission of microorganisms through the placenta to cause congenital infection. Maternal infection may be symptomatic or asymptomatic and signs of congenital infection in the baby may not appear for weeks, months or even years after birth. One of the main reasons for dividing neonatal bacterial infections into early onset and late onset is that this will often reflect the source of the infection. EO infections are usually caused by organisms which colonize the genital and gastrointestinal tracts of healthy women and transmission occurs just prior to or during delivery. Symptoms and signs will often manifest during the first week of life. Examples include group B streptococcus and *E. coli*. Prematurity, prolonged rupture of membranes (PROM), chorioamnionitis, maternal fever during labor and maternal urinary tract infection are all associated with an increased risk of early onset infection. In one US study an obstetric risk factor (preterm delivery, intrapartum fever or PROM > 18 h) was present in 49% of EO GBS and 79% of EO sepsis due to other bacteria<sup>1003</sup> and in a UK case control study, the odds ratios for EO GBS were 25.8 for PROM, 11 for rupture of membranes before labor onset, 10.4 for prematurity and 10 for intrapartum fever.<sup>1004</sup>

The source of late onset infection may also be the maternal genital tract, but more frequently infection will be derived from the environment or from other humans. Examples include the hands of health care workers (or parents and siblings), contaminated equipment, contaminated breast or formula milk feeds, blood transfusions or droplets from the upper respiratory tract of infected adults or children. The clear evidence that improvements in hand hygiene policies and rational antibiotic prescribing can reduce infant colonization and late onset infection rates demonstrates the importance of these particular environmental factors.<sup>1005,1006</sup>

The most important overall risk factor for neonatal bacterial infection, both early and late onset, is prematurity/low birth weight; such infants have a 3–10-fold greater risk of sepsis and/or meningitis than term infants. Yet the relationship between infection and preterm delivery is a complex one. There is increasing evidence that preterm delivery may itself reflect an excessive and inappropriate maternal

**Table 12.98** Organisms associated with early and late onset neonatal sepsis

	Organism
Early onset sepsis (0–6 days)	Group B streptococcus
	<i>Escherichia coli</i>
	Other Gram negative organisms, e.g. <i>Pseudomonas</i> sp., <i>Klebsiella</i> sp., <i>Haemophilus influenzae</i>
	<i>Listeria monocytogenes</i>
Late onset sepsis (7–90 days)	<i>Staphylococcus epidermidis</i> (and other coagulase negative staphylococci)
	<i>Escherichia coli</i>
	Other Gram negative organisms, e.g. <i>Serratia</i> sp., <i>Enterobacter</i> sp., <i>Citrobacter</i> sp.
	<i>Staphylococcus aureus</i> (including MRSA <sup>992</sup> )
	Group B streptococcus
	<i>Candida albicans</i> ( <i>Candida parapsilosis</i> )

response to infection or inflammation. For example, approximately 60% of mothers delivering extremely preterm (< 28 weeks' gestation) have histological evidence of chorioamnionitis.<sup>1007</sup>

## HOST DEFENSES

At birth the fetus passes from the sterile intrauterine environment through a birth canal that is colonized with potentially lethal bacteria to an extrauterine coexistence with microorganisms.

Host defense against invading microbial pathogens relies on the immune system (innate and adaptive), although the first barrier to infection is actually the mucosae (i.e. skin and mucous membranes). This barrier is frequently breached by medical procedures, e.g. cutting the umbilical cord, endotracheal intubation and breaking the skin to insert intravascular catheters, etc. It is an even more fragile barrier in preterm infants.

### Innate immune system

Once a bacterium enters the body the innate immune system is encountered. This consists of the complement system and the phagocytes and antigen presenting cells (macrophages, monocytes, dendritic cells, polymorphonuclear granulocytes). Additional protection may also be derived from the presence of maternal antibody (see below). A number of events occur in parallel. Bacteria are recognized nonspecifically via complement receptors that then interact with opsonizing serum components such as antibodies. At the same time, phagocytes sample pathogen-associated molecular patterns (PAMPs). PAMPs are evolutionarily conserved among microorganisms (including bacteria, fungi, protozoa and viruses) but absent from eukaryotic cells. Sensing of PAMPs occurs through pattern recognition receptors present on the cell surface or within the cell such as Toll-like receptors (TLR). TLRs carry individual specificity for a certain range of PAMPs; for example, TLR 4 is the receptor for the lipopolysaccharide of Gram negative bacteria. TLRs are pivotal in both recognition and then in transduction of recognition signals across the host cell membrane. Recognition signals then trigger expression of genes, the products of which include inflammatory cytokines (e.g. TNF-alpha, IL-6, IL-12) and co-stimulatory molecules which control innate immune responses [e.g. recruitment of further polymorphonuclear leukocytes (PMNs)] as well as the development of antigen-specific acquired immunity (for a comprehensive review of TLRs see ref 1008).

The complement system also has a major role in the defense against bacterial, viral and fungal infections. The classic pathway is activated mainly by antigen-antibody complexes or aggregated immunoglobulins. The alternative (properdin) pathway is activated by endotoxins or complex polysaccharides. There is no transfer of complement from mother to fetus. Although complement synthesis begins early in the first trimester, term infants have slightly diminished classic and significantly diminished alternative pathway levels. C3, C4 and C5 are the most important functional components of the system and are approximately 50% of adult levels in term infants. Much lower levels are seen in preterm infants, leading to markedly reduced opsonizing capacity. The receptor for C3b001 on neonatal PMNs is also decreased, leading to depressed cell adherence, phagocytosis, mobility and activation of adhesion reactions.

Phagocytosis of microbes by dendritic cells and macrophages triggers both degradation of pathogens and subsequent presentation of pathogen-derived peptide antigen, both to TLR (as above) as well as to naive T cells. This in turn stimulates antigen-specific acquired immunity (see below).

Neonatal sepsis is a highly inflammatory process that culminates in septic shock and multiorgan failure. In newborn infants excessive cytokine concentrations can be measured in the serum, and neonatal phagocytes and monocytes can form large amounts of the cytokines TNF, IL-1, IL-6 and IL-8 in response to infection.<sup>1009,1010</sup> The ability to produce pro-inflammatory cytokines is an initially protective physiological response to microorganisms. However, an immature regulatory response both in production of and response to anti-inflammatory cytokines is reported in both term and preterm infants.<sup>1011</sup> This may predispose preterm

infants to the harmful effects of proinflammatory cytokines including severe organ sequelae during infection.

In contrast to the preserved proinflammatory capacity of neonatal phagocytes, there do appear to be deficiencies in the other key mechanisms required for bacterial elimination: chemotaxis, phagocytosis and intracellular and extracellular bacterial killing. For example, chemotaxis of neonatal polymorphonuclear granulocytes is impaired as a consequence of decreased membrane deformability. Neonatal granulocytes also migrate at reduced speed compared with adult granulocytes. Phagocytosis is further hampered by low serum concentrations of opsonizing complement factors and immunoglobulins, especially so in preterm infants. In order to kill bacteria, toxic oxygen products (superoxide, hydroxyl radicals and hydrogen peroxide) need to be generated. The cationic proteins, lactoferrin and a lysosomal enzyme (myeloperoxidase) interact with hydrogen peroxide to form hypochlorite ions, which are bactericidal. Intracellular oxidative killing is, however, depressed in newborn phagocytes. All these essential functions are depressed further when an infant is stressed by infection. (For a review see ref 1012.)

### Adaptive immune system

B and T lymphocytes use antigen receptors such as immunoglobulins and T cell receptors to recognize microorganisms. Although antigen-specific IgG can be produced early, even in utero, the response in infants is both qualitatively and quantitatively different to that of older children and adults. A gradual maturation of antibody responses is seen over the first 2 years of life and this is reflected in the increasing capacity to mount antibody responses to vaccines. Secretory IgA is present in large amounts in colostrum and breast milk and has a role in preventing mucosal infections but the most important compensation for this immunoglobulin deficiency is the presence of maternal antibody. Maternofetal transport of IgG commences around the 17th gestational week, is at equilibrium around the 33rd week and reaches up to 2-fold higher values in the neonate at term. Fetal levels of IgG at 17–22 weeks' gestation are therefore only 5–10% of maternal levels. This is one major explanation for the increased susceptibility to infection of preterm infants. There are also differences in the four IgG subclasses with preferential transfer of IgG1.<sup>1013</sup> An example of the importance of immunoglobulin is the association between bacterium-specific IgG and susceptibility to infection; infants who lack specific antibody to GBS polysaccharide capsule are more likely to develop invasive GBS disease than those with adequate levels.<sup>1014</sup>

Adult-like antigen-specific T cell responses can be achieved earlier than B cell responses. For example, BCG immunization at birth elicits comparatively stronger IFN-gamma (i.e. T cell) than IL-5 (i.e. B cell) responses that are similar to adult responses.<sup>1015</sup> However, early life T cell responses, like B cell responses, are also subject to immune maturation. For example, stronger purified protein derivative (PPD) responses are seen when BCG vaccination is delayed from birth to 2–6 months of age.<sup>1016</sup> Immaturity of antigen-presenting cells is considered a critical determinant of early infant T cell responses: the response of neonatal dendritic cells to in vitro activation by TLR ligands is incomplete and results in limited IL-12 responses as compared to adult responses.<sup>1017</sup> T cell responses, however, are largely unaffected by the presence of maternal antibody.<sup>1018</sup>

Many aspects of the infant's immune system immaturity will be more pronounced in preterm infants. Even at 8 weeks of age preterm infants have lower absolute counts of lymphocytes, T cells, B cells, and T helper cells and a lower CD4:CD8 ratio than term infants. By the age of 7 months B cell numbers in the preterm group have reached term equivalent, but the reduced absolute lymphocyte count, total T cell count, and T helper count persist.<sup>1019</sup> The range of antigens recognized by preterm B cells may also be limited when compared to term infants because intense development of the B cell receptor repertoire occurs during the third trimester of pregnancy. However, there is intriguing evidence that premature exposure to antigens can accelerate this development. The significance of this is that infants born at 28 weeks' gestation may actually have a more diverse antibody repertoire by the time they reach 'term' than infants who are born at term.<sup>1020,1021</sup>

Another consideration in the immune response of preterm infants is the possible impact of iatrogenic factors. Disruption of the mucosal barrier by medical procedures is mentioned earlier. Additionally, preterm infants may be exposed to corticosteroids, antenatally and/or postnatally, and may receive blood and immunoglobulin transfusions during their neonatal stay. It is conceivable that any of these might impair the immune responses of preterm infants. There is suggestive evidence that steroids administered for chronic lung disease, for example, may suppress antibody responses to diphtheria/tetanus/pertussis (DTP) and Hib vaccines<sup>1022,1023</sup> and in a US study of VLBW infants, those who received a 14 day course of dexamethasone were more likely to develop a bloodstream or cerebrospinal fluid infection than those who received placebo.<sup>1024</sup>

Administration of antenatal steroids does not seem to reduce the responses to meningococcal C conjugate vaccine.<sup>1025</sup> There are no data on the impact of blood transfusions or immunoglobulin infusions on the development of antibody responses of premature infants.

## SEPSIS SYNDROME

As a result of their breakdown by the host inflammatory response, Gram positive bacteria release peptidoglycans and Gram negative bacteria release lipopolysaccharide-A (LPS-A) or endotoxin. These substances can lead to the release of inflammatory mediators as described above. They can also activate the complement, coagulation and fibrinolytic cascades leading to the formation of vasoactive and proinflammatory agents. The net effect is the initiation of a cascade of events that leads to the sepsis syndrome, septic shock, multiple organ failure and death (Fig. 12.63).

## Clinical manifestations

Neonatal infections are caused by a number of organisms (Table 12.98) and can present in many different ways. As described earlier, it is useful to classify them as early onset (EO) and late onset (LO). The advantage of such a classification is that it helps in determining the most probable organism and mode of transmission and thus guides empiric treatment. Whilst most clinicians use this general classification there is no consensus as to the precise definition. Some define EO as infection occurring between birth and 48 hours, 72 hours, 5 days or up to 7 days of life. LO infection occurs up until 3 months of life. EO infection is generally caused by organisms acquired from the mother at or during birth (vertical transmission) whilst LO infection is more likely to be caused by organisms from the environment (nosocomial or community sources).

Maternal chorioamnionitis (e.g. abdominal pain, fever, discharge), PROM and urinary tract infection may provide important clues to early diagnosis of sepsis in the newborn. Signs and symptoms of sepsis in the newborn are often nonspecific (Table 12.99) and may evolve over time. Sepsis may be fulminant, leading to death in several hours from multiorgan failure, or may be more protracted. The most frequent indicators are lethargy, poor feeding, abdominal distention, prolonged capillary filling time, glucose intolerance and unexplained persistent acidosis. Physical examination may not be very helpful but particular note should be made of the baby's responsiveness and the respiratory and heart rates.

## Laboratory investigations

There is no single reliable test for neonatal sepsis. Ultimate proof rests on recovering an infecting organism from a normally sterile body fluid, e.g. blood, CSF, urine or aspirate from an infected lesion or tissue. Even though culture remains the gold standard it is recognized, as described earlier, that clinical sepsis may be evident even in the absence of positive sterile site cultures. The list of tests which may suggest infection is large (Table 12.100).

Table 12.99 Most frequent signs and symptoms in neonatal sepsis

Symptoms	Signs
Lethargy	Temperature instability
Poor feeding	Prolonged capillary filling time (hypotension)
Apnea	'Does not look well'
Respiratory distress	Widening toe-core temperature difference
Pallor	Hepatomegaly
Mottling	Splenomegaly
Cyanosis	Full fontanelle
Abdominal distention	Abnormal neurological reflexes
Vomiting/increasing gastric residue	Glucose intolerance a. Hyper/hypoglycemia b. Glucosuria
Jaundice	Persistent acidosis
Petechiae, purpura, bleeding from prick sites	
Irritability	Painful bones/joints
Seizures	Sclerema

Fig. 12.63 The 'sepsis cascade': DIC, disseminated intravascular coagulation; IL, interleukin; LPS, lipopolysaccharide; MOD, multiple organ dysfunction; RDS, respiratory distress syndrome; TNF, tumor necrosis factor. Table 12.100 Accuracy of diagnostic tests or combinations of tests for early onset neonatal sepsis (from Mishra et al,<sup>1026</sup> with permission)

Test	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
CRP	60–82	93–96	95–100	75–87
CRP, FBC, gastric aspirate	97	61	53	98
Procalcitonin	82–100	87–100	86–98	93–100
CD11b	96–100	81–100	22–100	100
CD64	64–97	72–96	64–88	84–98
CD64, IL-6 or CRP	81–97	71–87	63–74	86–98
GCSF $\geq$ 200 pg/ml	95	73	40	99
Umbilical cord IL-6	87–90	93	93	93–100
IL-6	67–89	89–96	84–95	77–91
IL-6 and/or CRP	93	88–96	86–95	95
IL-8	80–91	76–100	70–74	91–95
IL-8 and/or CRP	80	87	68	93
PCR for genomic DNA in blood culture	100	100	100	100

CRP, C-reactive protein; FBC, full blood count; GCSF, granulocyte colony-stimulating factor; IL-6, interleukin 6; IL-8, interleukin 8; PCR, polymerase chain reaction.

### Microbiological tests

**Blood culture.** Blood cultures remain the mainstay for investigation of neonatal sepsis although results are not immediately available. In one prospective study virtually all cultures growing clinically significant Gram positive and Gram negative organisms were positive by 24–36 h of incubation. Cultures growing *Staphylococcus epidermidis* were virtually all positive after 36–48 h and 88% of cultures growing yeasts were positive by 48 h.<sup>1027</sup> The yield of blood cultures may depend on such things as skin disinfection technique, sample volume and the number of cultures taken as well as technical factors: the dilution of blood to culture medium and the blood culture system used (reviewed in ref 1028).

**CSF culture.** Examination of cerebrospinal fluid (CSF) via lumbar puncture (LP) is the only way to confirm meningitis because clinical signs are nonspecific and unreliable and blood cultures may be negative in 15–55% cases.<sup>1029–1031</sup> An LP should be done in all neonates with suspected meningitis, with suspected or proven late onset sepsis and should be considered in all neonates in whom sepsis is a possibility. The role of LP in neonates who are healthy appearing but have maternal risk factors for sepsis is more controversial; the yield of the LP in these patients is likely to be low.

It is generally believed that the interpretation of CSF tests in the newborn differs from that in older children. Previous studies have suggested average white cell counts of between 3 and 11/mm<sup>3</sup> with an upper limit of 42 white cells/mm<sup>3</sup> to be normal, but it is not clear how 'normal' these infants actually were.<sup>1032</sup> A recent small study of healthy term infants suggested that an upper limit of 5 white cells was more appropriate.<sup>1032</sup> The cell counts in preterm infants are likely to be higher.

**Urine culture.** Uncontaminated urine is difficult to obtain. The best method is suprapubic aspiration. Infection should be considered present if there are more than 10 leukocytes/mm<sup>3</sup> in uncentrifuged well-shaken urine or when more than 10<sup>5</sup> colony-forming units (CFU) of bacteria/ml of urine are cultured. However, the latter figure is a cut-off derived from mid stream or clean catch specimens where specimen contamination from anterior urethral or perineal skin organisms may occur. Thus, where urine is collected by catheterization or suprapubic aspiration, lesser growths of organisms may indicate infection. The yield from urine collections when done as a screen for early onset infection is lower than when it is done as a screen for late onset infection.<sup>1033,1034</sup> Urine culture may also be useful for detecting systemic fungal infections.

**Superficial and other cultures.** Routine cultures from the umbilicus, skin, nose, rectum, pharynx, etc., demonstrate colonization rather than invasive disease and are not generally helpful.<sup>1035</sup> There may be a role for such screening in the context of an outbreak investigation. Positive cultures from other normally sterile sites such as joint fluid will reflect true infection. Positive cultures from tracheal or lower respiratory tract specimens may be useful, especially in the context of a new pneumonia, but otherwise may simply reflect colonization and are common in ventilated preterm infants.<sup>1036</sup>

### Hematological tests

Neutrophil counts are more valuable than total white cell counts. The early 'band' (metamyelocyte and myelocyte) count and its ratio with total neutrophils (I:T ratio) is more important. An I:T ratio greater than 0.2 suggests infection but still has a poor positive predictive value. Other characteristics seen in adults, e.g. toxic granulation, vacuolation, Dohle bodies and decreased leukocyte alkaline phosphatase activity, are not reliable in neonatal sepsis. There may be a coagulopathy but this is not specific. A platelet count less than 150  $\times$  10<sup>9</sup>/L is suggestive of sepsis but may also be caused by other conditions.

### Serological tests

Antibody tests are generally used for diagnosing congenital infections, especially those encompassed by the TORCH acronym: toxoplasmosis, other (such as HIV and syphilis), rubella, cytomegalovirus and herpes simplex virus. Over time many of these are being supplanted by PCR amplification of specific pathogen-related nucleic acid.

Serological assays are dependent on the host response to infection. Recent infection is recognized by a 4-fold or greater rise in titer when acute and convalescent sera are run in the same assay at the same time. The presence of specific IgM is evidence of recent infection and the presence of pathogen-specific IgM in the infant is particularly useful as this will represent the infant's antibody response, as opposed to IgG, which may reflect transplacental transfer of maternal IgG. However, the sensitivity of this test is variable and especially so in the older infant in whom a congenital infection is being retrospectively considered. Similarly, maternal pathogen-specific IgM may be useful although it can persist for long periods of time and thus may reflect prenatal rather than antenatal infection.<sup>1037</sup> The particular assays used are important.<sup>1038</sup> An alternative means of diagnosing antenatal infection is to compare the pathogen-specific IgG titers between early/pre pregnancy and those of late pregnancy, assuming such samples are available. IgG avidity is also used in an attempt to differentiate recent primary infection (low avidity) from recurrent or past infection (high avidity).<sup>1039</sup>

### Other diagnostic tests

There is a great need for a reliable diagnostic test (or combination of tests) for the early diagnosis of neonatal infection. There is considerable antibiotic use on neonatal units because of concern about infection; however, most babies who receive antibiotics will not actually have a bacterial infection. The ideal early diagnostic test for neonatal infection would have 100% sensitivity (all babies with the infection have a positive test) and 100% specificity (all babies without the infection have a negative test). This is unlikely to be achieved as many tests are assessed on a continuous scale where there is overlap between infected and non-infected babies. However, cut-offs can be set at which most infections are detected and most non-infections are defined correctly. In the case

of neonatal sepsis a test with higher sensitivity, i.e. 100%, is probably required because of the implications of missing and not treating a true infection. A large number of tests have been studied although the methodological quality of studies is variable, e.g. often small sample sizes are used. These are summarized in Table 12.100, which is taken from a useful review in this area.<sup>1026</sup> Markers of infection that have been studied include acute phase reactants (such as CRP and procalcitonin), cell surface markers (such as neutrophil CD11 and CD64), granulocyte colony-stimulating factor concentrations, cytokines (such as IL6 and IL8) and nucleic acid amplification techniques (PCR).

## Management

Prompt, effective therapy is important as babies with infection may deteriorate rapidly. Supportive care, antimicrobial therapy and host defense modulation are all important. As highlighted in Figure 12.63, the cascade of sepsis, cytokine and inflammatory cell interaction at the endothelial level leads to CHAOS (cardiovascular instability, hematological abnormalities, increased apoptosis, organ dysfunction and suppression of immunity). Efforts should be made to correct this chaos.

Septic babies may rapidly lose fluid into the extravascular space (*third spacing*). Meticulous attention to fluid balance and blood pressure is required to maintain tissue perfusion. Increased fluids may be necessary as may blood transfusion to maintain an adequate hematocrit. Inotropic support should be started sooner rather than later because systemic hypotension can result in end organ damage, e.g. renal and cerebral. Acid–base balance should be maintained. It is important to maintain tissue oxygenation and nutrition by providing adequate oxygen and calories. Frequently, clinicians stop feeding babies with sepsis although there is no evidence that feeding is harmful in babies with sepsis without intestinal pathology. Calories should be provided parenterally if enteral feeding is not possible. Maintaining tight glycemic control may be important.<sup>1040,1041</sup> Single or multiorgan failure in sepsis is not uncommon and this should be managed accordingly.

## Antimicrobial therapy

Because neonatal pharmacokinetics differs from that in later life, most antimicrobial drugs require modification of dose, dose intervals and duration in the newborn. Slower metabolism and delayed excretion of many drugs in the newborn may prolong their half-life, particularly in the very premature. Other factors include the larger volume of extracellular fluid, the amount of serum protein available for binding and drug competition with bilirubin at protein binding sites. For detailed information about individual antimicrobials the reader should refer to a specialized text.

The specific agent(s) chosen to treat infection are determined by knowledge of local pathogens and their susceptibilities, the nature of the illness and the unit policy. Since initial empirical treatment in suspected sepsis cannot cover all possible pathogens, value judgments have to be made. Use of the narrowest spectrum antibiotics possible is encouraged. Routine use of cephalosporins as first line therapy is discouraged due to the emergence of resistant pathogens<sup>1042</sup> and routine empiric use of vancomycin for late onset sepsis is also discouraged as it is unnecessary and may also promote resistance.<sup>1043</sup> Third generation cephalosporins are particularly useful in the treatment of meningitis due to their antimicrobial spectrum and penetration into the CSF.<sup>1044</sup>

Most antibiotics should be administered intravenously. Intramuscular injections are painful and should be avoided. Absorption after oral therapy in the newborn is erratic and cannot be relied upon. For some antibiotics drug levels must be carefully monitored.

There is no consensus on the duration of therapy. If the baby is well, antibiotics should be stopped as soon as negative culture results are available. If the cultures are positive then at least 7 days of treatment is traditional, and if the clinical suspicion of sepsis is high in the face of negative cultures, at least 5 days of treatment is often recommended. Earlier discontinuation of antibiotic treatment may be possible in selected infants.<sup>1045</sup> One exception is pneumonia where blood cultures are often negative.<sup>985</sup>

There are no controlled clinical trials to guide the recommended duration of antibiotic therapy for neonatal meningitis. Historically, therapy has been continued for 2–3 weeks after sterilization of CSF cultures. This equates to a minimum of 14 days for GBS and *Listeria monocytogenes* meningitis and 21 days for Gram negative meningitis.<sup>1044</sup> Osteomyelitis should be treated for at least 4–6 weeks.

## Adjunctive therapies

As outlined above, the relative immunodeficiency of the newborn infant, which is exaggerated in premature and sick neonates, includes quantitative and qualitative deficits in phagocytes, complement components, cytokines and immunoglobulins. Therapies that modulate or augment these host defenses may attenuate the virulence of neonatal infections. Unfortunately, the evidence for the clinical efficacy of many such therapies is currently lacking.

### Fresh frozen plasma (FFP)

There is no evidence to support the routine use of FFP in sepsis.

### White cell transfusion

Neonates, especially preterm neonates, have an immaturity of granulopoiesis and a limited capacity for progenitor cell proliferation. Neutropenia is a frequent finding in septic neonates and is a risk factor for death. Transfusion of granulocytes to septic neutropenic neonates may therefore reduce mortality and morbidity. However, a Cochrane review concluded that there is inconclusive evidence from randomized controlled trials to support or refute the routine use of granulocyte transfusions in neonates with sepsis and neutropenia. When granulocyte transfusion was compared with placebo or no transfusion, there was no significant difference in all-cause mortality [typical RR 0.89 (95% CI 0.43, 1.86)].<sup>1046</sup>

### Exchange transfusion

There is no evidence to support the routine use of exchange transfusion in sepsis.

### Pentoxifylline

This methylxanthine derivative inhibits TNF- $\alpha$  production, preserves microvascular blood flow, inhibits neutrophil deformability and increases the respiratory burst. Two randomized controlled trials of 140 preterm infants showed an 86% reduction in mortality. The conclusion of a Cochrane review was that given the relatively small numbers of infants and considerable methodological weaknesses, larger studies are required before this therapy can be recommended.<sup>1047</sup>

### G-CSF and GM-CSF

In studies involving newborn babies G-CSF and GM-CSF have been shown to increase neutrophils and granulocyte counts and enhance their functional activity. Studies have been performed using these agents as prophylaxis against sepsis as well as for treatment during sepsis. A Cochrane review analyzed seven treatment studies which included 257 infants with suspected systemic bacterial infection and three prophylaxis studies comprising 359 neonates. From the treatment studies there was no evidence that the addition of G-CSF or GM-CSF to antibiotic therapy reduced immediate all-cause mortality. No significant survival advantage was seen at 14 days from the start of therapy [typical RR 0.71 (95% CI 0.38, 1.33)]. However all seven of the treatment studies were small, the largest recruiting only 60 infants. The subgroup analysis of 97 infants from three treatment studies who, in addition to systemic infection, had clinically significant neutropenia ( $< 1.7 \times 10^9/L$ ) at trial entry, did show a significant reduction in mortality by day 14 [RR 0.34 (95% CI 0.12, 0.92); NNT 6 (95% CI 3–33)]. Prophylaxis studies have not demonstrated a significant reduction in mortality in neonates receiving GM-CSF [RR 0.59 (95% CI 0.24, 1.44)]. The identification of sepsis as the primary outcome of prophylaxis studies has been hampered by inadequately stringent definitions of systemic infection. The authors' conclusions were that there is currently insufficient evidence

to support the introduction of either G-CSF or GM-CSF into neonatal practice, either as treatment of established systemic infection to reduce resulting mortality, or as prophylaxis to prevent systemic infection in high risk neonates. No toxicity was reported in any study included in this review. The limited data suggest that G-CSF treatment may reduce mortality when systemic infection is accompanied by severe neutropenia and should be investigated further.<sup>1048</sup>

### IVIG

Administration of intravenous immunoglobulin provides IgG that can bind to cell surface receptors, provide opsonic activity, activate complement, promote antibody dependent cytotoxicity, and improve neutrophilic chemoluminescence. Intravenous immunoglobulin thus has the potential of preventing or altering the course of neonatal infections. A Cochrane systematic review assessed the effectiveness and safety of intravenous immunoglobulin (IVIG) administration (compared to placebo or no intervention) to preterm (< 37 weeks' gestational age at birth) and/or low birth weight (LBW) (< 2500 g BW) infants in preventing nosocomial infections. When all 19 eligible studies were combined there was a statistically significant reduction in sepsis ( $p = 0.02$ ), RR [0.85 (95% CI 0.74, 0.98)], NNT 33. A statistically significant reduction was found for any serious infection, one or more episodes, when all studies were combined [RR 0.82 (95% CI 0.74, 0.92); NNT 25 (95% CI, 16.7, 50)]. There were no statistically significant differences for mortality from all causes, mortality from infection, incidence of necrotizing enterocolitis, bronchopulmonary dysplasia or intraventricular hemorrhage or length of hospital stay. No major adverse effects of IVIG were reported in any of the studies. The absence of significant impact on these other outcomes, especially mortality, leads the reviewers to conclude that any benefit was marginal.<sup>1049</sup>

In a review of trials of immunoglobulin use in treatment of proven or probable sepsis, six studies ( $n = 318$ ) reported on the outcome of mortality for randomized patients with clinically suspected infection. The results showed a reduction in mortality following IVIG treatment [typical RR 0.63 (95% CI; 0.40, 1.00)]. Treatment with IVIG (seven trials,  $n = 262$ ) in cases of subsequently proven infection did result in a statistically significant reduction in mortality [typical RR 0.55 (95% CI; 0.31, 0.98)]. The authors concluded that there is insufficient evidence to support the routine administration of IVIG to prevent mortality in infants with suspected or subsequently proved neonatal infection. Further studies were encouraged.<sup>1050</sup> A large international study is in

of the benefits reported with dexamethasone treatment in childhood meningitis, corticosteroids were an obvious consideration for the management of neonatal meningitis. In a study from Jordan, 52 cases of neonatal meningitis (84% Gram negative) in full-term neonates were alternately assigned to dexamethasone treatment (0.15 mg/kg every 6 h for 4 d).<sup>1051</sup> The mortality (22% dexamethasone vs. 28% controls) and the morbidity at 2 years (30 vs. 39%) were not significantly different and it was concluded that adjunctive dexamethasone therapy does not have a role in neonatal meningitis.

### Prevention

The source of infection in late onset cases may be nosocomial or community spread. It follows that any steps taken to prevent the spread of organisms in a neonatal unit may reduce the likelihood of late onset infection. Judicious antibiotic use including the use of narrow spectrum antibiotics, stopping antibiotics when cultures are negative and not using antibiotics to treat colonization or as prophylaxis,<sup>1006,1052</sup> as well as enforcement of hand hygiene policies,<sup>1053</sup> are obvious prevention strategies for neonates remaining in the hospital. Breast-feeding appears to be protective against nosocomial infection in general, although its main benefit seems to be in preventing infections due to *Staphylococcus epidermidis*.<sup>1054–1056</sup>

## SPECIFIC NEONATAL INFECTIONS

### Group B streptococcal infection

#### Epidemiology

In Europe, Australasia and North America, GBS is the commonest Gram positive bacterium causing neonatal septicemia. Early onset (EO) GBS disease may be defined as infection presenting in the first 6 days of life (though some use the first 2, 3 or 5 days as the cut-off) and accounts for approximately 60–70% of all GBS disease in the first 3 months of life. Of the 9 serotypes that exist, types III, Ia, II and V are responsible for most EO disease.<sup>1057,1058</sup> Maternal carriage of GBS in the gastrointestinal and/or genital tracts is a prerequisite for EO disease, vertical transmission occurring prior to or during birth. An estimated 20–30% of pregnant women are GBS colonized,<sup>1059,1060</sup> 50% of babies become colonized perinatally and 1% become infected. Late onset (LO) disease appears to have a different pathophysiology. It is predominantly caused by serotype III and is acquired perinatally, nosocomially or from community sources.<sup>981,1057</sup>

Incidence measured by multistate, population-based, active surveillance in 1990 in the USA identified an early onset disease rate of 1.4 per 1000 live births, with a lower rate of 0.4 per 1000 births recorded for late onset infections occurring in infants between 7 and 90 days of age.<sup>1061</sup> This equated to 7600 cases and 310 deaths per year. Both early and late onset GBS disease occurred at significantly higher rates among African American newborns compared with whites, as well as among low birth weight or preterm infants.<sup>1061,1062</sup> In the UK, a study carried out between 1977 and 1978 involving 25 centers in England and one in Scotland observed an incidence of invasive GBS disease in infants < 2 months of age of 0.3 cases per 1000 live births. Through the late 1990s studies from different centers in England reported incidence figures ranging from 0.6 to 1.2 cases per 1000 live births. In 2000–2001, national surveillance was enhanced and cases of invasive GBS disease (culture positive) in infants < 90 days of age were identified through active surveillance involving pediatricians, microbiologists and parents. A total of 568 cases were identified: an incidence of 0.72/1000 live births (95% confidence interval 0.66–0.78), 0.47/1000 (0.42–0.52) for early onset disease and 0.25/1000 (0.21–0.28) for late onset disease.<sup>981</sup> Regional variation was marked; the incidence in Scotland, for example, was 0.42 per 1000 while it was 0.9 per 1000 live births in Northern Ireland. As indicated earlier, the true burden of GBS sepsis (if culture negative cases are included) may indeed be higher.

GBS disease is associated with significant morbidity and mortality. GBS meningitis leaves half those infected with long term neurodevelopmental effects at 5 year follow-up.<sup>990</sup> Neurodevelopmental impairment may also be associated with clinical (i.e. culture negative) neonatal sepsis.<sup>991</sup> Case fatality rates for GBS disease are estimated at between 9% in Oxford (1990–6) and 15% in London (1990–9),<sup>1063</sup> with a UK national figure of 10% (2000–1).<sup>981</sup> In the USA between 1993 and 1998 the case fatality rates for EO and LO disease were 4.7% and 2.8% respectively. GBS is also a well recognized cause of stillbirth, but in the absence of clear case definitions and with variable autopsy rates, this burden is more difficult to quantify.

Risk factors include exposure to a heavy inoculum of GBS and to a strain with a high potential for invasiveness, preterm delivery, maternal chorioamnionitis, rupture of membranes more than 18 h prior to delivery, intrapartum pyrexia, GBS bacteriuria during the current pregnancy and a previous baby with GBS infection. There is a clear correlation between neonatal disease and low levels of maternal antibody to the capsular polysaccharide of the colonizing strain of GBS at the time of delivery.<sup>1014</sup>

#### Clinical features

Signs of EO sepsis may mimic those of RDS, birth asphyxia or cyanotic congenital heart disease. Disease occurs rapidly, being evident at birth or within 12 h in over 90% of cases, and presenting with overwhelming sepsis (60%) or pneumonia (25%).<sup>981</sup> Up to 50% of LO cases present with meningitis but focal infections such as cellulitis, abscesses, arthritis, osteomyelitis, ethmoiditis, fasciitis and conjunctivitis may also occur.

Cultures are diagnostic; rapid diagnosis is possible using antigen detection assays but these may be unreliable.

### Treatment

The combination of a penicillin and an aminoglycoside has been the mainstay of GBS treatment for decades. The rationale for this choice is that in vitro and animal studies suggest improved outcome with the combination over a penicillin given alone.<sup>1064</sup> Cefotaxime is an alternative but broad spectrum. Ceftriaxone could be substituted for cefotaxime for once a day administration, but there is substantially less experience with this drug in neonates, some uncertainty because of its ability to displace bilirubin from plasma protein, and cases of associated cholestasis and gallbladder hydrops have been reported. Once clinical improvement has been documented and the CSF has been sterilized, there is probably no indication for continuing an aminoglycoside. Penicillin alone can be used to complete therapy. Treatment is usually given for 7–10 days. For GBS meningitis it is recommended to use high doses of penicillin for a minimum of 14 days.

### Prevention

Clinical trials during the 1980s assessed the use of antibiotics to reduce transmission from the pregnant woman to her fetus or newborn. Antenatal antibiotics failed to eliminate vaginal colonization, consistent with a persistent gastrointestinal reservoir and/or reinfection from a sexual partner. Postnatal penicillin seemed to reduce the occurrence of infections that were not very early in onset but had no effect on group B streptococcal disease in the low birth weight population where disease occurrence and severity was greatest.<sup>1065</sup> Antimicrobials administered after onset of labor or rupture of the membranes were consistently effective in reducing transmission of infection and, where measured, also reduced early onset disease. A systematic review in 2000, which included five studies, concluded that intrapartum antibiotic prophylaxis (IAP) reduced the colonization rate of newborns [odds ratio (OR) 0.1, 95% confidence limits 0.07–0.14] and reduced the incidence of EO GBS (OR 0.17, 0.07–0.39). The reduction in mortality did not reach statistical significance (OR 0.12; 0.01–2.0), probably reflecting the relatively small sample size of these studies.<sup>1066</sup> The main issue is how to target IAP appropriately. Two strategies emerged, based on clinical risk factors or based on swab-based screening.

**Clinical risk-based strategy for GBS prevention.** The risk-based strategy was based on multiple studies indicating that certain clinical risk factors were overly represented in mothers of infants who went on to develop EO GBS disease. With this strategy prenatal screening cultures are not obtained and IAP is directed to any woman with prolonged membrane rupture, gestation < 37 weeks, or intrapartum fever. Additionally, IAP is given to women with antenatal GBS bacteriuria (a marker of heavy colonization and a risk factor for EO GBS disease) and to those who had experienced a previous delivery of a neonate with group B streptococcal disease.

**Swab-based strategy for GBS prevention.** With a swab screening-based strategy cultures are obtained by swab of both lower vagina and rectum at 35–37 weeks' gestation. Swabbing of both sites significantly increases the yield over one site.<sup>1067</sup> Specimens are then processed with selective broth media containing either nalidixic acid and gentamicin or nalidixic acid and colistin. This is to prevent the overgrowth of other commensal bacteria and again results in a significant increase in GBS isolation over use of nonselective media.<sup>1067</sup> After onset of labor or rupture of membranes, IAP is then given to women who are identified as GBS carriers. If no culture result is available, intrapartum prophylaxis is only given to those women who develop intrapartum fever, threatened preterm delivery (< 37 weeks), or membrane rupture over 18 h. As with the risk-based strategy, IAP is also given to women with antenatal GBS bacteriuria and to those who have experienced a previous delivery of a neonate with group B streptococcal disease.

In the USA, application of either of these prevention strategies was associated with a reduction in the occurrence of GBS disease. Early onset

disease fell from 1.7 to 0.5 cases per 1000 live births between 1993 and 1998, while late onset disease was stable.<sup>1068</sup> Death certificate analysis also documented a steeper decline in early sepsis deaths temporally associated with prevention implementation, without similarly steep declines in other causes of deaths including late sepsis deaths.<sup>1069</sup> A retrospective cohort study was conducted among a birth cohort of more than 600 000, and including 312 early onset GBS cases, to assess the relative effectiveness of the two strategies. Adjusting for confounders, women who were screened for GBS prenatally had more than 50% less risk of delivering a baby with GBS disease than did those exposed to the risk-based strategy (relative risk for EO disease following screening-based versus risk-based IAP 0.46; 95% confidence limits 0.36–0.60).<sup>1070</sup>

In the UK the background rate of culture proven GBS diseases appears lower than that of the USA and the cost effectiveness arguments may be different. Concerns persist about unintended consequences of widespread IAP use such as antibiotic resistance and drug side-effects. National UK guidelines for GBS prevention recommend targeting IAP to mothers based on clinical risk factors ([www.rcog.org.uk](http://www.rcog.org.uk)).

An important issue, about which there are few data to guide practice, is the assessment and management of the baby born to a mother who has received IAP. If the mother receives appropriate antibiotics at least 2 h before delivery and the baby is well and not born prematurely, no further intervention is required. However, if the baby is born prematurely or appears unwell then consideration should be given to performing a full sepsis screen and starting the baby on antibiotics until culture results are available.

### Listeriosis

*L. monocytogenes* is a Gram positive bacillus which causes EO and LO sepsis and meningitis. EO infection is frequently associated with signs of maternal infection and clinical presentation, as with GBS, may be with pneumonia or sepsis. Maternal infection may also result in abortion, stillbirth or preterm delivery. LO sepsis is more likely to present with meningitis. Microabscesses, skin granulomas, hepatosplenomegaly and passage of meconium by preterm infants should arouse the suspicion of *L. monocytogenes* infection.

Diagnosis is based on culture.

*Listeria monocytogenes* is not susceptible to cephalosporins. Ampicillin is the mainstay of therapy. The combination of ampicillin and gentamicin is synergistic in vitro and provides more rapid bacterial clearance in animal models of infection. Thus this combination is favored for initial therapy, with cessation of the aminoglycoside when the patient has improved clinically. The duration of therapy is 14 days for sepsis and at least 14 days for meningitis.

### Neonatal meningitis (see also p. 305)

#### Incidence

The age at presentation with meningitis will suggest both the probable organisms and their likely mode of acquisition. EO infection, particularly in the first two days of life, reflects vertical transmission while LO infection suggests nosocomial or community acquisition. EO meningitis is more likely to be due to GBS, *Escherichia coli* and *Listeria monocytogenes* while LO meningitis may be caused by other Gram negative organisms as well as staphylococcal species. In the majority of cases a bacteremia permits the organism to traverse the blood–brain barrier (BBB). The risk appears to correlate with the magnitude of bacteremia. It is estimated that meningitis complicates 20% of early onset and 10% of late onset sepsis.<sup>1071</sup> Direct infection of the central nervous system via a myelomeningocele, congenital dermal sinus, infected cephalohematoma, osteomyelitis of the skull or otitis media may also occur. The BBB separates vascular and CNS compartments and is composed of brain microvascular endothelium with tight junctions. Penetration of the BBB may occur via the paracellular route, as a result of damage and disruption,

appears to predominate for most bacteria. Generalized inflammation, brain swelling and vasculitis along with cortical thrombophlebitis may cause brain damage. Thrombosis and infarction may occur. At autopsy,

subarachnoid inflammatory exudate is more prominent at the base of the brain than over the cortex. Damage to the choroid plexus and ventriculitis may lead to encephalopathy and blockage of the foramina and aqueduct resulting in hydrocephalus.

Comparison of data from two studies of neonatal meningitis conducted in England and Wales between 1985–7 and 1996–7 suggests that the bacteria responsible for meningitis have changed very little over this decade.<sup>995,996</sup> Group B streptococcus remains the leading pathogen, followed by *E. coli*, other Gram negative rods, *Streptococcus pneumoniae* and *Listeria monocytogenes*. The overall incidence of neonatal bacterial meningitis also has not changed: 0.22 cases/1000 live births (1985–7) versus 0.21 cases/1000 (1996–7). Under-reporting is probably common.

These data are consistent with other UK studies<sup>1072</sup> as well as with data from other industrialized countries.<sup>1071,1073,1074</sup> In developing countries, Gram negative enteric organisms appear to account for the majority of early onset and *Streptococcus pneumoniae* for late onset meningitis.<sup>1000</sup>

Aseptic or viral meningitis is uncommon in the newborn, though adenovirus and enteroviruses have been implicated. Herpes simplex virus is a rare but important cause of meningoencephalitis and aciclovir therapy must be started promptly if the outcome is to be favorable. This pathogen should be considered in all cases of meningitis where the initial Gram stain is negative for bacteria.

### Mortality and morbidity

A reduction in mortality between the 1980s and the 1990s is evident from the two England and Wales studies (from 25% to 10%). A case control study from the 1985–7 national neonatal meningitis cohort has determined the neurodevelopmental outcome at 5 years of age.<sup>990</sup> Surprisingly it showed there to be very little difference between GBS and *E. coli* regarding disability at 5 years of age (~50% each) but a dismal outcome following meningitis due to other Gram negative organisms (78% with disability at 5 years of age). In another study, the neurodevelopmental outcome of VLBW infants with meningitis at 20 months' corrected age revealed a similar figure; 51% had impairment.<sup>997</sup> Comparison with data from older studies<sup>1073–1075</sup> suggests that despite declines in mortality, morbidity has not changed significantly between the 1970s and 1990s.

### Clinical manifestations

Any of the clinical signs and symptoms listed in Table 12.99 may be present in meningitis. Temperature instability, lethargy, feed intolerance, recurrent apnea and bradycardia, sugar intolerance and unexplained hyponatremia are more frequent in VLBW babies. Bulging or full fontanelle and neck stiffness are late manifestations and occur in only 28% and 15% of cases, respectively.<sup>1076</sup>

### Diagnosis

Examination of CSF via LP is the only way to confirm meningitis. See the discussion under microbiological tests, above.

There are few contraindications to performing a LP. Cardiorespiratory compromise during the procedure can be minimized using a modified left lateral position (hip flexion at 90 degrees without flexion or extension of the neck).<sup>1077</sup> In an unstable neonate the procedure can be deferred until stabilization is achieved.

### Management

**Antibiotic therapy.** Appropriate antibiotic therapy is a critical aspect of management. Antibiotic choice is empirical, based on age at onset, likely pathogens and antibiotic susceptibility patterns, with a focus on GBS, *E. coli*, other Gram negative organisms and *Listeria monocytogenes*. A reasonable regimen therefore is a combination of ampicillin, gentamicin and cefotaxime.<sup>1044</sup> Antibiotics are then modified according to culture and antibiotic susceptibility results. Empirical choice in an individual neonatal unit must also consider data regarding pathogens and their susceptibility within that unit. The goal of antibiotic therapy is to achieve sterilization of CSF. Delayed CSF sterilization is a particular feature of Gram negative meningitis and may in part account for its higher

mortality compared with GBS. CSF sterilization is dependent on achieving bactericidal antibiotic concentrations within the CSF. This will be influenced by the dose of antibiotic that can be administered safely, the penetration of the antibiotic into the CSF and the minimum bactericidal concentration (MBC) of the infecting organism. For example, the aminoglycosides have relatively good CSF penetration but the concentrations achieved at standard doses may only be minimally above the MBC of Gram negative organisms. A low margin of error between therapeutic and toxic concentrations means that aminoglycoside doses cannot be safely increased to compensate. In contrast, although the CSF penetration of third generation cephalosporins may be modest, the CSF concentrations usually achieved are many-fold higher than the minimum bactericidal concentrations for Gram negative bacteria, and cephalosporin dosage is not limited by toxicity.<sup>1078</sup>

The antibiotic considerations for GBS and *Listeria* meningitis are discussed above. The treatment of Gram negative meningitis (e.g. *E. coli*, *Klebsiella*, *Enterobacter*, *Citrobacter*, *Salmonella*, *Proteus*, *Pseudomonas* and *Serratia*) has traditionally been with a combination of ampicillin and an aminoglycoside. However, these Gram negatives frequently are resistant to ampicillin, CSF aminoglycoside concentrations often are minimally above their minimum inhibitory concentrations, CSF cultures remain positive longer than with GBS meningitis, and morbidity and mortality from Gram negative meningitis remain high. This led to consideration of intrathecal and intraventricular administration of antibiotics such as gentamicin, but trials have demonstrated these to be unhelpful strategies.<sup>1079,1080</sup> No further trials have been performed. While certain infants with obstructive ventriculitis complicating Gram negative meningitis may require administration of intraventricular aminoglycoside to assist in sterilization of the CSF, this therapy is not recommended routinely. Cefotaxime (or ceftazidime in the case of *P. aeruginosa*) is recommended for therapy in suspected neonatal Gram negative meningitis in combination with an aminoglycoside, usually gentamicin. Once susceptibility is documented, the combination is continued for at least 14 days after CSF cultures have sterilized. Thereafter cefotaxime alone is used to complete a minimum total therapy of 21 days. Meropenem has not been sufficiently studied for safety and efficacy in neonates, and is not recommended unless an extended spectrum beta lactamase-producing organism is identified. In this circumstance, meropenem in combination with an aminoglycoside should be administered for the entire course of therapy.

Coagulase negative staphylococci (CONS) rarely invade the CSF except as a complication of bacteremia accompanying intraventricular hemorrhage in VLBW neonates, in the presence of a foreign body, i.e. a ventriculoperitoneal shunt, or after contamination following neurosurgery or direct entry into the ventricular space, i.e. following ventricular fluid aspiration. Such infections are late onset. Most CONS are resistant to penicillin and flucloxacillin, necessitating the use of vancomycin for proven CONS central nervous system infection.

**Repeat lumbar punctures.** A repeat lumbar puncture 24–48 h into antibiotic therapy should be considered in cases of Gram negative meningitis in order to document CSF sterilization. Persistence of infection may indicate a focus, such as obstructive ventriculitis, subdural empyema or multiple small vessel thrombi. Infants with positive CSF cultures after initiation of appropriate therapy are at risk of these complications as well as a poor outcome. In this situation immediate diagnostic imaging is recommended. The choice and dosage of antibiotics also should be reviewed and (rarely) intraventricular administration considered. Delayed CSF sterilization and/or abnormalities found on neuroimaging may be an indication for prolonging the total course of therapy (see below).

With regard to LP at the end of treatment, Schaad et al reviewed 27 cases of recrudescence and relapse following bacterial meningitis in childhood (including 9 neonates). In the majority recrudescence/relapse could be explained by inadequate dosage of antibiotics, inadequate length of course or persistent infection in meningeal or parameningeal sites, e.g. subdural empyema, brain abscess or ventriculitis. They concluded that an LP at the end of therapy was unnecessary if

the clinical response was otherwise uneventful as they found that normal CSF findings may not exclude a relapse and abnormal CSF findings may not be predictive of relapse.<sup>1081</sup> However, in neonates where abnormal neurological findings persist, especially focal deficits, or where CSF cultures are positive for more than 48–72 h into therapy, prolonging therapy may assist in preventing a relapse of infection. Examination of the CSF as well as neuroimaging in these circumstances may assist in determining an optimal duration of antibiotic therapy.

**Intensive care support.** The appropriate and early use of supportive care including fluid management, inotropes, anticonvulsants and ventilation appears to be a critical part of neonatal meningitis management. There are no clinical trials, however, which address this.

**Imaging.** Neuroimaging is recommended to detect the complications of meningitis. Complications should be suspected when the clinical course is characterized by shock, respiratory failure, focal neurological deficits, a positive CSF culture after 48–72 h of appropriate antibiotic therapy or by infection with certain organisms. *Citrobacter koseri* and *Enterobacter sakazakii* meningitis, for example, are frequently associated with the development of brain abscesses, even in infants who have a benign clinical course.<sup>1082,1083</sup> The most useful and non-invasive method early in the course is ultrasonography, which will provide information regarding ventricular size and the presence of hemorrhage. Computerized tomography will be useful in detecting cerebral abscesses and later in the treatment course in identifying areas of encephalomalacia that may dictate prolonged therapy.

## NOSOCOMIAL INFECTIONS

Nosocomial infections are an important problem in VLBW infants, associated with a number of complications and a risk factor for death and for prolonged hospital stay. Nosocomial means hospital acquired and the majority of late onset infections are likely to be nosocomial in origin. In their most recent surveillance data, the National Institute of Child Health and Human Development Neonatal Research Network included 6215 infants who survived beyond 3 days and 1313 (21%) had one or more episodes of blood culture-proven late onset sepsis.<sup>984</sup> The vast majority (70%) were caused by Gram positive organisms, with CONS accounting for 48% of infections. Other Gram positive organisms included *Staphylococcus aureus*, *Enterococcus* and GBS. The most frequent Gram negative agents were *E. coli*, *Klebsiella*, *Pseudomonas* and *Enterobacter* species. Rate of infection was inversely related to birth weight and gestational age. Complications of prematurity associated with an increased rate of late onset sepsis included patent ductus arteriosus, prolonged ventilation, prolonged intravascular access, bronchopulmonary dysplasia and necrotizing enterocolitis. Infants who developed late onset sepsis had a significantly prolonged hospital stay (mean length of stay: 79 vs. 60 days). They were significantly more likely to die than those who were uninfected (18% vs. 7%), especially if they were infected with Gram negative organisms (36%) or fungi (32%). The mortality associated with CONS infection is probably very low.<sup>993</sup> In the Stoll multicenter analysis, there was considerable center-to-center variability in the incidence of late onset sepsis, with rates ranging from 10.6% to 31.7% of VLBW infants.<sup>984</sup> This may reflect different infection control practices in different centers.

## Coagulase-negative staphylococci (CONS)

Most infants are colonized with *Staphylococcus* by the fifth day of life. Although they may sometimes be culture contaminants there is clear evidence that CONS are also pathogens. They are often associated with the use of vascular catheters. In contrast to *S. aureus* they produce a limited range of virulence factors but it is the ability of CONS to form an adherent multilayered biofilm on polymer surfaces which is considered their main virulence determinant. There are numerous species of CONS but the majority of infections are due to *Staphylococcus epidermidis*.

### Clinical features

Presentation is usually subtle rather than acute. Episodes of apnea or bradycardia, low grade acidosis, pyrexia and increased oxygen

**Table 12.101** Incidence of catheter related coagulase negative staphylococcal infection by duration of catheter insertion<sup>1085</sup>

Duration of insertion	Incidence (%)
0–7 days	5
8–14 days	15
15–21 days	41
22 days or more	58

requirements may be observed. The usual site of infection is a catheter or other intravascular device. The main risk factors for catheter related sepsis are catheter hub colonization, exit site colonization, duration of total parenteral nutrition, ELBW (<1000 g) at the time of catheter insertion and postnatal age (>1 week) at the time of insertion.<sup>1084</sup> Rates of sepsis are related to duration of catheter insertion (Table 12.101).<sup>1085</sup>

### Treatment

Intravascular catheters should be removed if at all possible. Where CONS are isolated from blood cultures, consideration should first be given to their significance. Isolation from two or more blood cultures, a pure growth (vs. mixed growth), growth of organism within 48 h and accompanying clinical signs of sepsis all lend support to the significance of a positive culture. Although a proportion of strains may retain susceptibility to flucloxacillin, most will require therapy with vancomycin. Monitoring of serum concentrations is advised. There is no consensus about duration of antibiotic therapy. Antibiotics should be stopped if the baby is clinically well, has a normal white cell count and a CRP level of <10 mg/dl.

## Staphylococcus aureus

*S. aureus* infections are an increasing problem in neonatal units. Rates of infection have risen over the last decade in all age groups, including neonates, and the proportion of isolates that are methicillin resistant (MRSA) is increasing. In England and Wales in 2001, for example, 13% of all strains in the neonatal period were MRSA as compared with 0–3% between 1990 and 1994.<sup>992</sup> In the USA in particular, community acquisition of MRSA in babies after discharge from hospital is also increasing.<sup>1086</sup> In terms of clinical presentation, MRSA appears to be more likely to present with skin sepsis than methicillin sensitive *S. aureus* (MSSA), although it may also be associated with bacteremia and bone and joint infections as with MSSA.<sup>1086,1087</sup> In one study, babies with MRSA were more likely to be born more prematurely than those with MSSA and the mortality was also higher.<sup>1087</sup>

### Treatment

For local umbilical cord infections, cleaning with alcohol or with chlorhexidine solution may be enough. Systemic infection is best treated with an antistaphylococcal penicillin such as flucloxacillin. MRSA will require vancomycin.

## Pneumonia (p. 250)

In a review of autopsies performed on 111 ELBW infants between 1990 and 1993, the major cause of death was found to be infection of the amniotic fluid leading to pneumonia.<sup>977</sup> Neonatal pneumonia may be acquired in utero (congenital), during birth or nosocomially. Congenital pneumonia may be caused by TORCH group organisms, or be secondary to chorioamnionitis associated with bacteria such as GBS, *E. coli* and *Listeria*. Most infants swallow material during birth but few develop pneumonia. Congenital pneumonia usually presents within the first 24–48 hours of life. Nosocomial pneumonia is a particular problem in ventilated preterm infants. Many of the late onset pathogens described above may be associated with pneumonia and the finding of positive cultures from tracheal or lower respiratory tract specimens may be useful, especially in the context of a new pneumonia, but otherwise may simply reflect colonization.<sup>1036</sup> Respiratory viruses as a cause of pneumonia should also be considered.

*C. trachomatis* is well recognized as a cause of pneumonia but the role of *U. urealyticum* is less clear. A proposed link with the development of bronchopulmonary dysplasia is also controversial.<sup>1088</sup>

### Clinical manifestations

Clinical features include tachypnea, tachycardia, cyanosis and expiratory grunt. Distinction from RDS may be difficult. Symptoms and signs are nonspecific. Babies may show signs of cerebral irritation or be hypotonic and lethargic. They do not feed well and may go into heart failure. *C. trachomatis* infection may produce a staccato cough.

### Diagnosis

This is based on history, blood culture, and Gram stain and culture of the tracheal aspirate. Early chest radiographs may be unhelpful but they may be confirmatory if taken 48–72 h after onset of symptoms. Serology may also be helpful.

### Treatment

Initial therapy should be with ampicillin/penicillin and an aminoglycoside. Flucloxacillin should be used for *S. aureus* but vancomycin is preferred for *S. epidermidis* and methicillin resistant *Staphylococcus*. Azithromycin or erythromycin is the drug of choice for *Chlamydia* infection. There is no consensus regarding duration of therapy but shorter courses may be as effective as longer courses. In one study, 4 days of antibiotic therapy plus a 24 h period of observation for selected cases of neonatal pneumonia was comparable to 7 days of therapy. However, these infants had also received a single dose of penicillin soon after birth as group B streptococcal sepsis prophylaxis. Additionally, only infants who were asymptomatic after 48 h of antibiotic therapy were included.<sup>1089</sup> In a later study, 4 days was again shown to be adequate and better than 2 days of therapy.<sup>1090</sup> Supportive therapy with oxygen, intravenous fluids, suction and physiotherapy is also required. Drainage of pleural effusion or empyema may be necessary. Overall prognosis is good.

### Gastroenteritis

This is uncommon in the newborn but may occur in epidemics. Rotavirus, echovirus and adenovirus infections are the commonest cause. *E. coli*, *Salmonella*, *Shigella*, *Campylobacter* and *Yersinia* are the commonest bacterial agents. There may be vomiting, diarrhea, feed intolerance, dehydration and pyrexia. The mainstay of management is correction of dehydration. Antibiotics should be given if the infection is considered to be invasive.

### Necrotizing enterocolitis (NEC) (see also p. 275)

NEC is a major contributor to morbidity and mortality, particularly in small preterm infants. The precise role played by bacteria remains uncertain but NEC has occurred in endemic and epidemic forms suggesting an infectious origin. Most consistent among predisposing factors are low birth weight and prematurity. Others recorded include hypoxia, persistent ductus arteriosus, umbilical catheterization, rapid advancement of feeding (particularly with hyperosmolar milk), Hirschsprung disease, hyperviscosity syndromes and infective diarrhea. Antenatal Doppler studies showing absent/reversed end-diastolic flow in the umbilical artery may also indicate increased risk. In the majority of cases no organism is isolated. Organisms reported in the literature include *E. coli*, *K. pneumoniae*, *Clostridium butyricum*, *Clostridium perfringens*, *Clostridium difficile*, *Salmonella*, *P. mirabilis* and *Ps. aeruginosa*. Viruses such as adenovirus type 19, coxsackie, corona and enterovirus have also been implicated.

### Clinical manifestations

NEC commonly presents in the first 10 days of life in babies weighing less than 1500 g. There is no sex predisposition. Signs include abdominal distention, increasing gastric residue (may become bile stained), absent bowel sounds, vomiting and passage of blood in the stools. X-ray of the abdomen may show bowel wall edema in the early stages followed by pneumatosis intestinalis, perforation and in severe cases gas in the portal tract. Clinical staging using Bell's criteria (stages 1–3) can be useful.

### Treatment

Medical management consists of withdrawal of enteral feeds, gastric suction and administration of intravenous fluids and parenteral nutrition. Empirically a combination of ampicillin, an aminoglycoside (gentamicin) and metronidazole is given for 7–10 days. Shorter courses are appropriate where NEC is only suspected (Bell's stage 1). Indications for surgery are debatable and are discussed on page 275. Mortality varies from 15 to 30%.<sup>1091</sup> Stoll and colleagues reported that infants with sepsis and NEC were at high risk of later neurodevelopmental impairment.<sup>991</sup>

### Osteomyelitis and septic arthritis

During the first year of life, capillaries perforate the epiphyseal plate providing communication between the joint space and the metaphysis. Thus, septic arthritis and osteomyelitis may often occur together. The source of infection is usually hematogenous but direct trauma during arterial or venous puncture has also been implicated. The commonest organism is *S. aureus*. GBS, *Klebsiella* and *E. coli* are also prominent. In resource limited countries, *Salmonella* is frequent. *S. epidermidis* and *Candida albicans* are emerging as important etiological agents in extremely preterm infants.

### Clinical manifestations

Most cases present insidiously. There may be nonspecific symptoms such as poor feeding, lethargy, decreased activity and low grade fever. Mild unexplained acidosis may be a pointer. Local signs include swelling over the affected area or joint, pseudoparalysis of the limb, and irritability on handling the affected body part.

### Diagnosis

Diagnosis is based on radiological confirmation although changes are not seen for 10–14 days. Technetium-99m scan is highly sensitive. Conventional radiographs may miss early lesions. MRI imaging can be helpful. Whole body scanning is advisable as there may be more than one focus of infection. Repeated cultures should be taken.

### Treatment

Flucloxacillin and a third generation cephalosporin (cefotaxime) should be started until culture and sensitivity results are available. Therapy should be continued for at least 6 weeks (at least 2–3 weeks intravenously). Orthopedic consultation should always be sought and surgical intervention may become necessary if the response to medical treatment is slow. Mortality is low; however, long term growth impairment may occur if the growth plates are affected.

### Urinary tract infection (see also p. 313)

Urinary tract infection occurs in up to 10% of preterm and 1% of term infants. It is more common in males and in infants with kidney or renal tract abnormalities, e.g. obstructive uropathy. It is also seen more frequently in babies whose renal parenchyma may have been damaged, e.g. by asphyxia or dehydration.

The most frequent infecting organism is *E. coli* with *Klebsiella* and other Gram negative bacteria accounting for the rest. In very preterm LBW babies, *C. albicans* is also an important etiological agent.

### Clinical manifestations and diagnosis

Clinical signs and symptoms include poor weight gain, jaundice, hepatomegaly and palpable kidneys. There may be generalized septicemia. Diagnosis is confirmed by urine culture (greater than 100 000 CFU/ml) and > 10 white cells/ml in freshly voided or aspirated urine. (See earlier discussion on urine specimens.)

Further investigation with ultrasound, micturating cystourethrogram and isotope scanning (DMSA) is advisable as abnormalities have been detected in up to 45% of cases.

### Treatment

Empirical therapy with ampicillin and gentamicin is usually adequate but antibiotics must be changed according to urine culture reports.

There is a recurrence rate of up to 10%, so follow-up is essential. With current therapy, prognosis is excellent where there has been no renal parenchymal damage and there are no congenital abnormalities. If there is evidence of reflux uropathy then antibiotic prophylaxis with trimethoprim should be initiated.

### Conjunctivitis (see p. 314)

The incidence of conjunctivitis varies between 7 and 20%. The higher figure comes mainly from premature infants nursed on NICUs.

### Clinical manifestations

In a recent US study the most common isolates in neonates with conjunctivitis were CONS, viridans streptococci, *S. aureus* and *H. influenzae*.<sup>1092</sup> Conjunctivitis usually presents within the first week. *Chlamydia* infections usually, but not always, present later. *N. gonorrhoeae* infection is now rare in the UK but if untreated it may lead to corneal ulceration and perforation, iridocyclitis, anterior synechiae and panophthalmitis. *Chlamydia* infection produces a similar clinical picture but only involves the tarsal aspect of the conjunctiva, sparing the cornea.

### Diagnosis

This is based on the clinical history, timing, and site of the lesion and on cultures of the discharge. *Chlamydia* infection may be diagnosed by obtaining scrapings from the tarsal conjunctiva and staining with Giemsa stain for intracytoplasmic inclusions.

### Treatment

For gonococcus the eye should be cleaned with frequent eye washes of normal saline or water (every 15–30min at first) followed by instillation of penicillin drops. Penicillin should also be given intravenously for a few days.

For chlamydial infection, 0.5% erythromycin ophthalmic ointment is used with systemic erythromycin therapy for 7–14 days. Chloramphenicol and sulfacetamide ophthalmic preparations may be useful for staphylococcal colonization. The instillation of 1% silver nitrate drops to newborns led to the decline in gonococcal conjunctivitis, but this treatment has generally been abandoned as it leads to significant chemical conjunctivitis.

### Otitis media

Examination of the eardrum, particularly in preterm infants, should be a mandatory part of the routine examination of infants with suspected sepsis. The incidence of otitis media in the newborn is 0.6–2.4%. A shorter, widely patent and horizontally placed eustachian tube predisposes to infection. Other factors include chorioamnionitis, asphyxia, prematurity, ventilatory support, cleft palate and Down syndrome. *S. pneumoniae* and *H. influenzae* are the commonest organisms involved. Presentation is nonspecific. Otolaryngologic examination reveals a dull tympanic membrane which is bulging and has reduced or absent mobility on pneumatic otoscopy. Treatment includes appropriate antibiotics. Outcome is usually favorable but the recurrence rate is high and up to 33% develop chronic otitis media.

### Umbilical infection

*S. aureus* and *E. coli* are the most frequent organisms causing infection of the umbilicus. The incidence is between 0.5 and 2%. Periumbilical erythema is usually the only clinical feature though severe omphalitis has been reported from resource limited countries. Simple cleaning with an antiseptic such as chlorhexidine is sufficient, but for more significant infection broad spectrum systemic antibiotics should be given.

## SPECIFIC INFECTIONS

### Syphilis

Congenital syphilis is uncommon in resource rich countries; however, there are concerns that this may change. There has been a 255% increase in the diagnosis of syphilis in UK women between 2000 and 2004.<sup>1093</sup> Coupled with this, two recent case series demonstrate that

screening, referral and management of pregnant women with positive serology is poorly done.<sup>1093,1094</sup> Clinicians must therefore not forget congenital syphilis.

*T. pallidum* is the etiological agent. Transplacental infection rarely occurs before 18 weeks' gestation as the Langhans' layer of the chorion prevents the passage of *Treponema*. Treatment of the mother before the 18th week of gestation will almost always completely protect the fetus. The chances of the fetus remaining uninfected are negligible if the mother is not treated. If the mother has early or latent syphilis the fetus has a 20–70% chance of being infected.

### Clinical manifestations

Hematogenous spread in prenatal life determines which fetal organs and tissues are involved. Abortion, stillbirth and hydrops occur in 40% of pregnancies. There may be severe anemia, hepatosplenomegaly or pneumonia soon after birth. One to three weeks later the stigmata of congenital syphilis become evident, e.g. nasal obstruction with serosanguineous discharge, copper-colored maculopapular rash, perianal condylomata, rhagades (fissures at mucocutaneous junctions), loss of hair, exfoliation of the nails, iritis and choroiditis. Poor feeding and fever may be accompanied by jaundice, generalized lymphadenopathy and signs of pancreatitis or hepatitis. Bone lesions are seen in nearly all infants beyond the neonatal period. Most infants born with congenital disease are free of clinical symptoms at the time of birth, and the problem may not appear for more than 2 years.

### Diagnosis

This is based on either the visualization of *T. pallidum* by dark ground microscopy or serological tests. The two types of serological tests for syphilis are nontreponemal reaginic tests and treponema-specific tests. Screening nontreponemal tests include the rapid plasma reagin (RPR) test and the Venereal Disease Research Laboratory (VDRL) test. The specific tests measure antibodies specific for *T. pallidum* and include *T. pallidum* immobilization (TPI), fluorescent treponemal antibody absorption (FTA-ABS), and microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP).

### Treatment

Infection is suspected with the following: physical or radiographic evidence of active disease; quantitative nontreponemal titer  $\geq 4$  maternal titer; reactive CSF VDRL test or abnormal CSF cell count and/or protein; positive IgM FTA-ABS; positive dark field microscopy or staining for treponemes in placenta or umbilical cord.

In general, for symptomatic or CNS syphilis a minimum 10-day course of a parenteral penicillin is needed. Procaine penicillin (penicillin G procaine) IM, once daily, 50000 u/kg for 10 days; or iv benzylpenicillin (= penicillin G = crystalline penicillin) 50000 u/kg twice daily for 7 days followed by three times daily for a further 3 days to a total of 10 days. For asymptomatic syphilis a single intramuscular injection of benzathine penicillin G 50–10000 units/kg is recommended by some experts (where available). If maternal treatment was given during the last 4 weeks of pregnancy or the treatment was not with penicillin or treatment was inadequate or status is unknown, the infant should be treated. Penicillin-allergic patients can be given cephalosporins.

### Tetanus

This is very unusual in resource rich countries but in some parts of the world neonatal tetanus is responsible for 30–40% of all neonatal deaths. *Clostridium tetani* is a Gram positive anaerobic spore-forming bacillus which produces a toxin, tetanospasmin, that causes muscle spasms and convulsions. The toxin, once fixed to the nervous tissue, cannot be neutralized by antitoxins. Mothers who are immunized protect the fetus through the active transport of antitoxin antibodies across the placenta.

### Clinical manifestations

The incubation period is between 3 days and 3 weeks. Most neonatal cases occur between 3 and 10 days after birth. The umbilicus is the main

route of entry. The infant usually presents with difficulty in sucking (due to upper lip spasm), excessive irritability and trismus. This is followed very soon by generalized muscle spasms, convulsions, rigidity and fever. There may also be cardiorespiratory difficulties.

### Diagnosis

This is usually easy but meningitis, metabolic disorders and ingestion of phenothiazines must be considered in countries where tetanus is unusual.

### Treatment

This is based on the provision of an adequate airway and ventilation, neutralization and elimination of toxins, prevention of spasms and convulsions and maintaining hydration and nutrition. Diazepam, either as a bolus (0.1–2 mg) or as a continuous infusion (10–140 mg/kg/d), is useful in reducing muscular spasm. Paraldehyde or barbiturates may also be used. Human tetanus immune globulin should be given if possible as a single dose but equine tetanus antitoxin may also be used. There is evidence that intrathecal administration is superior to intramuscular administration.<sup>1095</sup> Parenteral penicillin 100 000–1 500 000 IU should be given for at least 10 days. Fluid, electrolytes and nutrition should be maintained. Where facilities are available, mechanical ventilation and neuromuscular blockade have improved the outcome, which remains gloomy in resource limited countries.

### Tuberculosis

It is rare to see tuberculosis (TB) during the first month of life. It may be congenitally or postnatally acquired, although the former is very rare. The source of congenital infection will be the placenta or genitourinary lesions with acquisition via the bloodstream or via the inhalation or ingestion of infected amniotic fluid. Acquisition via airborne spread from adults in the environment is the most common route of postnatal infection. Symptoms include poor weight gain, respiratory distress, fever, lethargy, jaundice, lymphadenopathy and hepatosplenomegaly. The diagnosis may be suspected from seeing a primary focus, a miliary pattern or hilar lymphadenopathy on a chest X-ray, or on the basis of maternal history. Placental histology and culture of gastric washings, bronchoalveolar lavage fluid or bone marrow aspiration from the infant may help.

It would appear that the basic principles of TB treatment would apply to neonates as much as to older children with active TB, thus quadruple therapy with rifampicin, isoniazid, ethambutol and pyrazinamide is recommended. In the setting where the mother has active TB but there is no evidence of disease in the infant then the infant should receive isoniazid prophylaxis (INH 10 mg/kg/d) for 3 months, after which a tuberculin test should be done. If this is negative, bacille Calmette–Guérin (BCG) should be given. If the tuberculin test is positive and there is no evidence of active disease, then INH is continued for 6 months. If the mother has active lesions, the infant should be separated from the mother until treatment has commenced.

## FUNGAL INFECTIONS

### Candidiasis

Up to 33% of pregnant women have vaginal colonization with *Candida* species. Invasive neonatal fungal infection, however, is very uncommon and predominantly seen in low birth weight or preterm infants. In a recent UK surveillance study the incidence of invasive fungal infections in VLBW infants was 10.0 (95% CI 8.0–12.0) cases per 1000 live births. The majority (86%) of the infants were of extremely low birth weight (< 1000 g) and the incidence in this ELBW group was 21.1 (95% CI 16.5–25.7) per 1000 live births.<sup>982</sup> These figures are much lower than those found in other countries, especially the USA. For example in the NICHD Neonatal Research Network, invasive candidiasis was documented in 7.7% of ELBW infants.<sup>1096</sup> Fungal colonization is an important risk factor for systemic infection. In one US study of VLBW infants, around 27% of infants were colonized (two thirds during the first week of life), one third developed mucocutaneous candidiasis and 8% developed invasive infection.<sup>1097</sup> Colonization is inversely correlated with gestational age at birth, usually occurs in the first 2 weeks of life, and occurs

on the skin and gastrointestinal tract before the respiratory tract.<sup>1098</sup> Other risk factors for fungal infection include antibiotic therapy, intravenous alimentation with fat emulsions and use of postnatal steroids. The commonest fungal pathogens are *C. albicans* and *C. parapsilosis*.

Infection in the newborn may be congenital or late onset and may be local or disseminated. Congenital candidal infections are acquired in the birth canal and usually present within the first 24 h of life as an intense desquamating rash. Pustules and satellite lesions are common, and may be confused with staphylococcal scalded skin syndrome. In late onset mucocutaneous infections, skin lesions appear between the 7th and 10th day as a rash of small papules which coalesces to form cheesy white patches in the mouth, diaper (nappy) area, groin or axillae. Occasionally oral thrush may extend to cause esophagitis.

Clinical signs and symptoms of invasive candidiasis are indistinguishable from bacterial sepsis. Affected infants often develop hyperglycemia and thrombocytopenia. There is a high incidence of renal and central nervous system involvement in systemic candidiasis.<sup>1099</sup> There may be endophthalmitis and the eyes should be examined for white fluffy retinal deposits which can progress to involve the vitreous humor, resulting in blindness. Occasionally *Candida* may cause skin abscesses, osteomyelitis and pneumonia.

### Diagnosis

The diagnosis of local disease can be confirmed by microscopy and culture of scrapings from the margins of lesions. Systemic candidiasis is diagnosed by growing fungi from blood, CSF or urine, but cultures may be negative even when multisystem disease is seen at autopsy. Urine microscopy may show yeasts or hyphae. Ultrasound of the kidneys may reveal fungal balls and eye examination may show retinal deposits.

### Treatment

Local lesions may be treated by nystatin, 100 000 IU four times a day for 5 days, or with miconazole gel (orally) or cream (for the perineum and buttocks). Nystatin with corticosteroid ointment may be used in severe cases of *Candida* dermatitis.

Systemic candidiasis is best treated by removing all central lines and indwelling catheters and starting the infant on intravenous antifungal agents. Amphotericin B has a long half-life and good penetration into the CSF. The starting dose is between 0.5 mg/kg and 1 mg/kg per day given as an infusion over 4–6 h. Principal adverse effects are nephrotoxicity, marrow suppression and hepatotoxicity. Liposomal amphotericin B is less toxic. The dose of liposomal amphotericin B is 1 mg/kg/d to a maximum of 3–5 mg/kg/d. Treatment should be given for 4–6 weeks. 5-Flucytosine (5-FC) is synergistic with amphotericin and some recommend combined treatment, particularly in the presence of CNS infection. Fluconazole is a broad spectrum antifungal agent that is well absorbed enterally and is a suitable alternative for susceptible *Candida*. Side-effects include hepatotoxicity, skin rashes and thrombocytopenia.

In the recent UK surveillance study, death occurred in 41% of the infected infants before 37 weeks' postconceptional age.<sup>982</sup>

### Other fungi

*Aspergillus* and *Trichophyton* species may cause cutaneous disease. *M. furfur* is responsible for intralipid induced fungemia, since it is a lipophilic fungus that often colonizes skin. Treatment consists of removal of lines, discontinuing lipid infusion and instituting antifungal therapy with any of the above antifungal drugs.

## VIRAL INFECTIONS

See Chapter 28.

## PARASITIC INFECTIONS

### Malaria

Congenital malaria is rare in resource rich countries but increasingly reported among babies born to mothers continually residing in endemic

areas. The clinical presentation may be indistinguishable from sepsis; the infant may present with hepatosplenomegaly or jaundice due to hemolysis.

Diagnosis is made on identifying malarial parasites in the blood film. Treatment should be with quinine.

## Toxoplasmosis

See Chapter 28.

## NEONATAL NEOPLASIA

Of those rare tumors that present at birth or in the neonatal period less than half will be malignant. It is important to know the natural history as even huge tumor masses or apparently disseminated disease may regress completely and spontaneously. As survival from childhood cancer has improved, death certificate data have become progressively less accurate as an indicator of frequency. Estimates of incidence vary because most reports are referral center rather than population based and some exclude benign tumors. In the USA the best estimate of different malignancies is based on an analysis of 10% of the total population over a 3 year period. This suggests an overall incidence of 1 per 27 000 live births (Table 12.102, column 5 for proportions of different tumors). In the UK a prevalence of 1 per 12 500–17 500 has been found but this included benign neoplasia (Table 12.102, column 1). Approximately 1.9% of childhood malignancies will present in the first 28 days of life: 43% of these will present on the first day; 66% by the end of 1 week;<sup>1103</sup> and 0.6% of pediatric malignant deaths will occur during this period. There is some suggestion that the incidence is increasing.<sup>1106</sup>

## ETIOLOGY

1. Transplacental metastases of maternal choriocarcinoma, melanoma and leukemia are well described but very rare.
2. Transplacental carcinogenesis. This is definite for the use of maternal stilbestrol which leads to vaginal adenocarcinoma – the latent period is 10–15 years – it has not been reported neonatally.

Transplacental carcinogenesis is also probable for infantile neuroblastoma in the fetal phenytoin syndrome and it is possible for hepatoblastoma when the mother has been taking estrogens in the first trimester.

3. Genetic
  - a. Chromosomal
    - Down syndrome 21X3 – acute myelogenous and occasionally acute lymphoblastic leukemia presents neonatally. Leukemoid reactions are comparatively common in the neonatal period; they are difficult to distinguish and 15% will go on to develop leukemia later.
    - Klinefelter syndrome XXY – breast cancer (not reported neonatally), and recent reports of a higher incidence of leukemia.
    - Gonadal dysgenesis 46XY, 45X/46XY, other mosaics – dysgerminomas (not reported neonatally).
    - 13q (retinoblastoma) – may present neonatally. This is the only known inheritable malignancy.
    - Mutations of genes on chromosome 11 (and possibly on other sites) are common in Wilms' tumors.
    - Fanconi anemia – leukemia (not reported neonatally).
    - Bloom syndrome – leukemia (not reported neonatally).
    - Ataxia telangiectasia – lymphoma and gastric carcinoma (not reported neonatally).
  - b. Malformation syndromes
    - Aniridia – nephroblastoma (possible neonatally).
    - Hemihypertrophy syndrome – nephroblastoma and hepatoblastoma (not recorded neonatally).
    - Beckwith–Wiedemann syndrome – nephroblastoma and hepatoblastoma (not recorded neonatally).
    - Cryptorchidism – testicular tumors (not recorded neonatally).
    - Other syndromes – chondrosarcoma (not recorded neonatally).
4. Environmental. In 1992 Golding reported an association between intramuscular vitamin K at birth and later (not neonatal) development of cancer.<sup>1107</sup> Many more recent epidemiological and case-control studies have failed to confirm this association.<sup>1108–1100</sup>

<sup>6</sup> Represents 0.6% of childhood deaths from malignancy.

## GENERAL MANAGEMENT

The variety of neonatal neoplasia makes it extremely important that all patients are referred to recognized specialist centers with facilities for diagnostic imaging, expert pediatric and molecular pathology, surgery, radiotherapy, chemotherapy and hematology. Tumor markers have an increasingly important role in both diagnosis and monitoring the response to treatment (Table 12.103). Large tumors may be problematic, more from their size interfering with organ function than from tumor load. Surgery can frequently be more conservative than is generally appreciated and may be curative. Back-up with postoperative intensive care is essential. Neonatal tissue (especially brain, bone, lungs, liver and kidneys) is very sensitive to radiotherapy and the anxieties of infection secondary to immune suppression, interference with growth leading to long term musculoskeletal morbidity, or the development of second malignancies means that this therapy should be avoided if possible. Cytotoxic chemotherapy may reduce the infant's effective immune response with in consequence a higher incidence of complications and particularly infection. Chemotherapy can potentially affect a child's subsequent development but small doses will often reduce tumor size very significantly. Centralization of referral also allows more realistic parental and family support.

## SPECIFIC DIAGNOSIS AND MANAGEMENT

See Table 12.104.

## NEONATAL METABOLIC DISORDERS

### HYPOGLYCEMIA

#### Glucose homeostasis in the fetus and newborn

The fetus receives a constant supply of glucose across the placenta and this largely determines blood glucose concentrations. Fetal metabolism is directed towards synthesis with insulin as the principal anabolic hormone. Hepatic glycogen accumulates during the third trimester and mobilization of this reserve is the principal source of glucose for the first postnatal hours. At delivery, the constant transplacental glucose supply is interrupted, blood glucose falls and the processes of glycogenolysis and gluconeogenesis are activated mainly by catecholamines and cortisol and a concomitant decrease in insulin levels until milk feed intakes increase to levels where this is the main source of glucose precursors.

The maintenance of normoglycemia during the newborn period is dependent on adequate fetal glycogen reserves, effective glycogenolysis and gluconeogenesis, an appropriate balance of insulin:glucagon and an increasing postnatal nutritional intake. Hypoglycemia will result if any of these processes are inadequate.

#### Neuropathology

Glucose is an essential primary fuel for the brain and cerebral glucose consumption is proportionately high. It seems likely that the term infant brain can utilize ketones, lactate or amino acids as an alternative to glucose. This may explain the vulnerability of infants with nonketotic hypoglycemia to cerebral damage. Neurones and glial cells are susceptible to hypoglycemia, and vulnerable areas are the cerebral cortex, particularly posteriorly in the parieto-occipital region. Less commonly involved are neurones of the hippocampus, caudate nucleus and putamen but any level of the central nervous system may be involved including anterior horn cells of the spinal cord.

#### Definitions of hypoglycemia

Hypoglycemia was defined as a glucose concentration less than two standard deviations below the mean for a particular population; in the preterm it was defined as  $< 1.1$  mmol/L during the first week of life but in full-term infants the corresponding value was  $< 1.7$  mmol/L for the first 72 h of life and  $< 2.2$  mmol/L after 72 h of age. These criteria imply that preterm infants compared to term are less prone to neurological impairment secondary to hypoglycemia and that resistance to hypoglycemia

is greatest in the immediate postpartum period. A more satisfactory approach is to define hypoglycemia in the context of acute or chronic neurological dysfunction, e.g. moderate hypoglycemia,  $< 2.6$  mmol/L, in preterm infants is associated with reduced mental and motor developmental scores.<sup>1126</sup>

The *symptomatic* response of the neonate to low blood glucose is variable with nonspecific features including pallor, feeding difficulties, hypotonia, tachypnea, abnormal cry, jitteriness, apnea, irritability, coma and convulsions. This lack of symptomatic specificity can make the interpretation of biochemical hypoglycemia difficult such as the intensively cared for infant where comorbidities can cause similar clinical features or where symptomatic responses may be masked with therapeutic muscle paralysis, severe birth asphyxia or extreme prematurity. Hypoglycemia may be intermittent and it is important to check blood glucose at times of vague but suspicious symptoms.

Some otherwise well infants with low blood glucoses are *asymptomatic* suggesting that alternative substrates are available for brain metabolism. Such infants in general have a favorable prognosis. However, acute cerebral dysfunction, as measured by auditory and somatosensory evoked potentials, occurs in the majority of neonates when blood glucose levels fall below 2.6 mmol/L even though 50% of them were still asymptomatic.<sup>1127</sup>

As a consequence of these relationships between blood glucose levels and acute and chronic neurological dysfunction, *blood glucose levels  $< 2.6$  mmol/L are accepted as indicating hypoglycemia* which requires treatment regardless of gestation or postnatal age.

On a practical basis, hypoglycemia can be subclassified into two main groups: *transient* and *persistent* hypoglycemia.<sup>1128</sup>

### Transient neonatal hypoglycemia

#### IUGR

Infants with asymmetric growth retardation are particularly prone to hypoglycemia; the etiology can be multifactorial with metabolic demands of a relatively large brain, depleted glycogen, fat and protein reserves as well as limited gluconeogenic and ketogenic responses which in some are secondary to poorly coordinated counter-regulatory mechanisms.<sup>1129</sup> The presence of prematurity, birth asphyxia or polycythemia can compound the problem.

Enteral feeds should start within an hour of birth. Blood glucose should be monitored frequently, usually hourly, until normoglycemia is attained, when the interval can be extended to 2- then 4-hourly. If normoglycemia cannot be established, then a background intravenous infusion of dextrose is required, starting around 5 mg/kg/min but increasing if necessary the volume per kg and dextrose concentration. Enteral feeds are gradually increased in volume with reciprocal decreases in intravenous dextrose if normoglycemia is maintained. With the discontinuation of intravenous dextrose, the frequency of enteral feeds can be sequentially increased to 2-, 3- and 4-hourly if normoglycemia is established. In a minority of infants where sustaining normoglycemia is problematic and intravenous glucose requirements are high or prolonged, despite established enteral nutrition, concurrent pathology should be considered. Hypoglycemia in growth restricted infants may produce psychomotor delay<sup>1130</sup> and the problems of persistence of hypoglycemia beyond the neonatal period may be underdiagnosed in asymptomatic infants.<sup>1131</sup>

#### Prematurity

The immaturity of gluconeogenesis, glycogenolysis and limited glycogen and fat reserves make this group vulnerable to hypoglycemia. Early hypoglycemia, within 1 h of delivery, occurs in up to 70% of infants  $< 30$  weeks' gestation before intravenous dextrose infusions are established and thereafter glucose homeostasis can be unstable in sick premature infants. Hypoglycemia is usually transient and correctable with dextrose infusions of 5 mg/kg/min but a higher caloric intake to meet energy demands, either parenterally or enterally, should also be established early. Preterm infants will only partially suppress endogenous glucose production with glucose infusions but also fail to inhibit proteolysis, and early introduction of complete parenteral nutrition (day 1) improves not

Table 12.103 Features of tumors presenting in the neonatal period

Tumor	Presentation	Investigations	Markers	Treatment	Incidence per 100 000 live births in UK	Notes
<i>Teratoma</i>						
a. Sacrococcygeal b. Head and neck	1. Prenatal US 2. Obvious mass at birth a. On buttocks: may be so large as to obstruct delivery b. On neck: may lead to airway obstruction	CT/MRI	1. Alpha-fetoprotein: raised malignant, normal benign 2. Beta human chorionic gonadotrophin often raised	1. Benign: surgery (remove coccyx or local recurrence common) 2. Malignant: surgery then chemotherapy (etoposide/bleomycin/carboplatin) UKCCSG results (Huddart et al <sup>1111</sup> ) 3. Significant recurrence rates mandates long term follow-up (using AFP)	0.27	1. At birth 90% benign, 10% malignant (if presents after 2 yr, 90% malignant) 2. 4:1 females:males 3. 20% of those with intra-abdominal extension are malignant (Altman et al <sup>1112</sup> ) 4. AFP raised in 70% malignant variety 5. Solid tumors are more likely to have malignant elements 6. Teratomas rarely present as retroperitoneal (abdominal) mass
<i>Leukemia</i>						
a. Acute myelogenous (nonlymphocytic)	1. Hepatosplenomegaly 2. Petechiae + bruising 3. Skin infiltration (nodules) 4. Respiratory distress (infiltration) 5. Bone pain 6. Meningeal involvement	1. WBC variable, blasts+++ platelets reduced 2. Bone marrow ± biopsy 3. Biopsy skin plaque	1. Enzymes 2. Monoclonal membrane markers 3. Chromosomes (Burmeister & Thiel, <sup>1113</sup> Robinson <sup>1114</sup> )	Invariably fatal despite modern chemotherapy ± intrathecal methotrexate	0.29	1. 25% cases are Down syndrome 2. Differential = hemolytic disease, congenital infection, disseminated neuroblastoma 3. Skin lesions may suggest monocytic leukemia 4. Null ALL may rarely present neonatally
b. (Leukemoid reactions)	Down syndrome child with leukemoid blood reaction	1. WBC 2. Marrow		Spontaneous remission, support with platelets, blood, antibiotics, etc.		1. Down syndrome frequent but may be normal karyotype and phenotype 2. Indistinguishable from leukemia but regresses over 1–3 months
<i>Neuroblastoma</i>						
	1. Abdominal mass 2. SVC obstruction 3. Respiratory obstruction 4. Leukoerythroblastic anemia 5. Bluish subcutaneous nodules 6. Spinal cord compression with pain and paraplegia 7. Horner syndrome from cervical chain involvement	Stage i – confined to structure of origin ii, local unilateral spread iii, bilateral spread iv, remote disease ivs, i or ii with remote disease 1. 24 h catecholamine, VMA–HVA excretion 2. Calcification on X-ray 3. CT/MRI	1. VMA–HVA up in 95% 2. Vasointestinal peptide 3. Neurone specific enolase (Kintzel <sup>1117</sup> ) 4. MYCN gene amplification (Schmidt et al <sup>1118</sup> )	Stage i – total excision ii – maximal excision + chemotherapy iii – chemotherapy + excision iv – chemotherapy ivs – spontaneous regression usual Chemo usually etoposide and carboplatin	0.45	1. 1:40 neonatal autopsies (Guin et al <sup>1115</sup> ) 2. Spontaneous regression common (Bolande <sup>1116</sup> ) 3. 60% occur in abdomen or pelvis 4. Prognosis excellent – compare later childhood 5. Accounts for 30–50% neonatal malignancy 6. Mostly stage ivs 7. Associated congenital abnormalities are common (Isaacs <sup>1119</sup> )

Tumor	Presentation	Investigations	Markers	Treatment	Incidence per 100 000 live births in UK	Notes
<i>Soft tissue sarcomas</i>						
Fibro-, spindle cell, leio-, myo-, rhabdomyo-, hemangiopericytomas	1. Mass – particularly in head and neck and extremities	1. Biopsy 2. CT/MRI	Gene markers allow better management and prognostication	1. Excision if possible 2. ± Cytotoxics at reduced dose	0.3	1. If benign soft tissue sarcomas are included the incidence is greater than either leukemia or neuroblastomas 2. Locally aggressive 3. Metastases rare (compare older age groups)
<i>Renal (Bove<sup>1120</sup>)</i>						
a. Nephroblastoma [Wilms' tumor (WT)]	1. Prenatal US 2. Postnatal abdominal mass 3. Hematuria (rare)	1. US 2. CXR (pulmonary metastases) 3. CT/MRI	1. Increased inactive renin (Johnston et al <sup>1121</sup> ) 2. Gene markers (Bown et al <sup>1122</sup> )	Stage 1, surgery + vincristine Stage 2, surgery + vincristine + actinomycin (chemo at 50% dose)	0.13	1. A neonatal renal mass is not likely to be malignant 2. True WTs are associated with aniridia, hemihypertrophy, Beckwith syndrome and UG abnormalities 3. Nephroblastomatosis is present in 1:400 autopsies (Machin <sup>1123</sup> )
b. Congenital mesoblastic nephroma (more common – Bolande <sup>1124</sup> )	1. Prenatal US 2. Postnatal abdominal mass 3. Hematuria (rare)	1. US 2. CXR (pulmonary metastases) 3. CT/MRI	1. Increased inactive renin (Johnston et al <sup>1121</sup> ) 2. Gene markers (Bown et al <sup>1122</sup> )	Stage 1 – surgery Stage 2 – surgery		1. Commoner than WT and do not metastasize 2. Outlook extremely good
<i>CNS</i>						
Astrocytomas, teratomas, ependymomas, oligodendrogliomas, craniopharyngiomas, medulloblastomas	1. Prenatal US 2. Hydrocephalus with cephalopelvic disproportion 3. Bulging fontanelle and suture separation 4. Increased ICP with vomiting 5. Convulsions	1. US 2. CT/MRI		1. Surgery 2. Probably not radiotherapy 3. ± Shunt 4. Chemotherapy	0.2	1. High incidence of teratomas 2. Predominantly supratentorial 3. Often large at diagnosis with frequent hemorrhage 4. Prognosis poor 5. Avoid RT until > 2 yr
<i>Hepatoblastoma and hemangioendotheliomas</i>						
	1. Hepatosplenomegaly 2. ± Respiratory distress 3. ± Gastrointestinal symptoms	1. US 2. CT/MRI	1. Alpha-fetoprotein	1. Surgery 2. ± Preoperative chemotherapy 3. ± low dose RT preop 4. Postop chemotherapy in low dose	0.05	1. A neonatal liver mass is more likely to be a hemangioma or mesenchymal hamartoma and present with cardiac failure or DIC 2. Secondary neuroblastoma or leukemia is commoner than hepatoblastoma in causing hepatomegaly 3. May be associated with hemihypertrophy or Beckwith syndrome

(Continued)

Table 12.103 Features of tumors presenting in the neonatal period—cont'd

Tumor	Presentation	Investigations	Markers	Treatment	Incidence per 100 000 live births in UK	Notes
<i>Retinoblastoma</i>	1. White eye and squint 2. Heterochromia iridis 3. Abdominal mass	1. CT/MRI head and eye 2. CT/MRI – body	1. Operation – enucleation 2. If bilateral – laser photo-coagulation and RT			1. 40–50 new cases per year UK 2. Family history in 10–25%, and this usually bilateral 3. Abnormality of chromosome 13 common 4. Note an orbital mass may be an orbital teratoma
<i>Langerhans' cell histiocytosis</i> (no longer considered a neoplastic process – Chu et al <sup>1125</sup> )	1. Skin rash, particularly groins, axillae, neck, and behind the ears. Occasionally trunk. Usually brown–red raised macules which may coalesce or even ulcerate in the skin folds 2. A cradle cap-like skin lesion on the scalp 3. Respiratory distress from infiltration 4. Hepatosplenomegaly 5. Lymphadenopathy 6. Usually little systemic upset	1. Skin biopsy 2. Chest X-ray 3. Skeletal survey for punched out bone lesions 4. Osmolality of urine for diabetes insipidus		1. Spontaneous remission 2. If systemic upset/progression, steroids ± vincristine or vinblastine ± VP16		1. Proliferation of tissue macrophages. T-suppressor lymphocytes normally control the macrophages

ALL, acute lymphoblastic leukemia; SVC, superior vena cava; VMA, vanillylmandelic acid; HVA, homovanillic acid; UG, urogenital; US, ultrasound; CT, computerized tomography; MRI, magnetic resonance imaging; ICP, intracranial pressure; RT, radiotherapy; DIC, disseminated intravascular coagulation.

only energy–nitrogen balance but reduces the frequency of hypoglycemic episodes.<sup>1132</sup> Hypoglycemia in preterm infants is common and this may impair the early detection of underlying metabolic abnormalities or genetic disorders affecting glucose homeostasis.<sup>1133</sup>

### Birth asphyxia

Perinatal stress will deplete glycogen reserves and mitochondrial damage may uncouple oxidative phosphorylation with subsequent anaerobic glycolysis and generation of lactate. Hypoglycemia is usually transient and correctable with an intravenous infusion of dextrose at around 5 mg/kg/min. Hyperglycemia should be avoided as it may exacerbate existing metabolic acidosis and compound the hyperosmolar state. Prematurity, IUGR, adrenal hemorrhage and transient hyperinsulinism are common associations.

### Neonatal sepsis

Hypoglycemia and sepsis are commonly associated. Pyrexia may increase the metabolic rate, caloric intake may be decreased and insulin sensitivity may be increased.

### Neonatal hypothermia

Hypoglycemia is a common feature and glucose homeostasis should be established as part of the resuscitative measures.

### Starvation

Failure to establish adequate enteral intake in full-term infants can result in hypoglycemia and this effect is exaggerated by IUGR, prematurity or birth asphyxia.

### Congenital heart disease

Hypoglycemia per se can result in transient cardiomegaly. An association exists between hypoglycemia and acute congestive cardiac failure; the etiology of this may be multifactorial with decreased caloric intake, increased metabolic rate, decreased hepatic perfusion or even focal hepatic necrosis. Hypoglycemia has also been observed in children with severe congenital heart disease without cardiac failure. Management consists of restoration of normoglycemia with intravenous glucose and, in the longer term, adequate caloric intake.

### Transient hyperinsulinemia Infant of diabetic mother

Fetal blood glucose uptake is directly related to maternal blood glucose levels, and fetal hyperglycemia results in hyperplasia of the islets of Langerhans, increased peripheral insulin receptors, a decreased glucagon response to postnatal hypoglycemia and delayed evocation of hepatic gluconeogenic pathways. Meticulous control of maternal diabetes in pregnancy and labor can prevent or reduce the severity and frequency of neonatal hypoglycemia and the incidence of macrosomia, RDS, hyperbilirubinemia, polycythemia and hypocalcemia. The incidence of congenital malformations is higher and includes congenital heart disease, central nervous system abnormalities, vertebral anomalies and the caudal regression syndrome which may present in various forms including sacral agenesis, femoral hypoplasia or sirenomelia. Careful control of maternal diabetes preconceptually and in the early weeks of pregnancy reduces the incidence of malformations.

In the majority of infants, hypoglycemia is transient, <6 h, and asymptomatic. Blood glucose is usually monitored at birth, 1, 2, 4 and 6 h.

Table 12.104 Causes of neonatal hypoglycemia

Transient hypoglycemia	Persistent hypoglycemia
Intrauterine growth retardation	Hyperinsulinism Nesidioblastosis Insulinoma
Prematurity	Inborn errors of metabolism Glycogen storage disease
Birth asphyxia	GSD types I, III, IV Galactosemia
Neonatal sepsis	Hepatic gluconeogenic deficiencies Fructose-1,6-diphosphatase
Neonatal cold injury	Pyruvate carboxylase Phosphoenolpyruvate carboxylase
Starvation	Defects in amino acid metabolism Maple syrup urine disease
Congenital heart disease	Methylmalonic acidemia HMG-CoA lyase deficiency
Hyperinsulinism	Beckwith–Wiedemann syndrome Propionic acidemia
Infant of diabetic mother	Tyrosinemia type I
Erythroblastosis fetalis	Mitochondrial fatty acid oxidation defects
Maternal drugs	MCAD deficiency
Maternal glucose infusions	LCAD deficiency
Idiopathic hyperinsulinism	Electron transport defects
	MAD-S deficiency
	MAD-M deficiency
	RR-MAD deficiency
	Hormonal deficiencies
	Congenital hypopituitarism
	Cortisol deficiency
	Congenital glucagon deficiency

LCAD, long chain acyl-CoA dehydrogenase; MAD-M, mild multiple acyl-CoA dehydrogenase; MAD-S, severe multiple acyl-CoA dehydrogenase; MCAD, medium chain acyl-CoA dehydrogenase; RR-MAD, riboflavin responsive multiple acyl-CoA dehydrogenase.

Enteral feeds are established within the first hour and thereafter 2-hourly until normoglycemia is established. In the minority of infants hypoglycemia may be more prolonged, up to 3 days, and if normoglycemia is not maintained the infants may become symptomatic. In asymptomatic infants who fail to establish normoglycemia with enteral feeds, a single dose of glucagon (0.03–0.1 mg/kg) may prevent recurrence. In the sick infant, or those intolerant of enteral feeds or where hypoglycemia is prolonged, normoglycemia should be maintained by intravenous infusions of dextrose (4–8 mg/kg/min). Symptomatic hypoglycemia requires an initial bolus of intravenous dextrose (0.25–0.5 g/kg) and thereafter a constant intravenous infusion. Enteral feeds are introduced when appropriate with reciprocal reduction in intravenous infusion rates maintaining normoglycemia and avoiding abrupt changes, which can result in reactive hypoglycemia. Rarely, in prolonged hypoglycemia unresponsive to the above measures, hydrocortisone 5 mg/kg 12-hourly has been used.

### Erythroblastosis fetalis

An association exists between moderate to severe erythroblastosis fetalis and hypoglycemia secondary to hyperinsulinism. It is estimated that around 20% of infants with cord Hbs <10 g/dl will have significant hypoglycemia.

### Beckwith–Wiedemann syndrome

Affected infants may have exomphalos, macroglossia, visceromegaly, gigantism, parallel creases on the ear lobes, hyperinsulinemic hypoglycemia and an increased risk of Wilms' tumor and other malignancies.<sup>1134</sup> All features may not be present and infants with only gigantism or exomphalos should have blood glucose levels monitored.

The majority of cases are sporadic with a female predominance but in familial forms possible patterns include autosomal dominant, multifactorial and autosomal dominant sex-dependent inheritance. This multigenic disorder is caused by dysregulation of the expression of imprinted genes in the 11p15 chromosomal region with close associations to insulin-like growth factor (IGF)-2 and tumor suppressor genes<sup>1135</sup> and genes implicated in regulation of insulin release.<sup>1136</sup>

Hypoglycemia is usually transient but may be prolonged and severe and occasionally persists into adulthood. Symptomatic hypoglycemia is estimated to occur in around 50% of individuals and may contribute to the mental deficiency recognized as part of this syndrome. The management of persistent hyperinsulinemia is discussed below.

### Maternal drugs

Neonatal hyperinsulinemic hypoglycemia has been reported after maternal administration of chlorpropamide. Thiazide diuretics probably stimulate beta-cell function. Beta-mimetics stimulate insulin production and also reduce fetal hepatic glycogen deposition. Maternal valproate has been associated with infant hypoglycemia and features of withdrawal.

**Intrapartum glucose infusion.** Fetal insulin secretion can be induced by intrapartum maternal glucose infusions. The incidence of resultant neonatal hypoglycemia is related to maternal blood glucose levels particularly when above 6.6 mmol/L or when maternal glucose infusions are greater than 20 g/h.

### Idiopathic transient neonatal hyperinsulinism

The etiology of hypoglycemia in growth retarded infants is multifactorial but in some infants where normoglycemia is not established by 72 h, in spite of adequate nutrition, the possibility of hyperinsulinism should be considered and investigated. This syndrome also occurs in full-term, appropriate for gestational age infants after normal pregnancies and deliveries, without maternal diabetes or drug ingestion. The resolution of transient hyperinsulinemia may take days, weeks or in some instances months, and on occasions diazoxide is required to control hypoglycemia. The etiology of transient hyperinsulinism is unknown; it is regarded as a temporary imbalance in the regulatory development of insulin secretion.

### Persistent hypoglycemia

#### Persistent hyperinsulinemia

Recurrent or persistent hyperinsulinemia is the commonest cause of prolonged severe hypoglycemia during the first year of life. The majority of cases present with early neonatal hypoglycemia and are recognized causes of neonatal death and sudden infant death. Most are caused by loss of function of the beta-cell  $K_{ATP}$  channel function and causative mutations are found in related genes on chromosome 11 (11p15.1) with both autosomal recessive and dominant inheritance.<sup>1137</sup> Dominantly inherited activating mutations in the glutamate dehydrogenase (GLUD1) gene are associated with hyperammonaemia.<sup>1138</sup> There are mutations in the genes for glucokinase, L-3-hydroxyacyl-CoA dehydrogenase and carbohydrate-deficient glycoprotein syndrome type 1b.<sup>1137</sup> However, no genetic etiology has yet been determined for as many as 50% of the cases. In the neonatal group, the underlying pathology is usually diffuse hyperplasia of the endocrine pancreas whereas in older children solitary islet cell adenomas predominate. However, congenital islet cell adenomas are described in neonates and hyperinsulinemic hypoglycemia, whilst the features of diffuse hyperplasia have also been described in adults. Histological features vary widely. In most instances there is an increase in pancreatic beta-cells, either organized in groups or as individuals. Somatostatin cells are usually decreased.

### Diagnosis of hyperinsulinism

Normoglycemia, >2.6 mmol/L, may only be attained in infants with hyperinsulinism with increased glucose infusion rates (>8 mg glucose/kg/min and in individual cases sometimes >20 mg glucose/kg/min).

Insulin secretion is inappropriately high in comparison to simultaneously measured blood glucose. Insulin prevents ketogenesis by inhibiting lipolysis and in hyperinsulinism there is no increase in blood ketones. Insulin increases hepatic glycogen reserves and liver size may increase due to glycogen deposition. The measurement of blood ammonia is essential to exclude hyperammonemic hyperinsulinemia.<sup>1138</sup>

### Management

Immediate management is to attain normoglycemia by intravenous infusion of dextrose, which may require rates > 15 mg/kg/min, and the establishment of a normal feed volume in content and volume for age. Hypostop and/or glucagon may be useful as a temporary measure, e.g. resiting intravenous sites. Diazoxide inhibits insulin release, acting as a specific  $K_{ATP}$  channel opener, and hence the therapeutic effects are variable and unpredictable, some infants showing initial benefit with a subsequent return to hypoglycemia. Diazoxide in oral dosage up to 5–20 mg/kg/day orally 8-hourly is usually combined with chlorothiazide 7–10 mg/kg/day in two divided doses, which potentiates its effects and reduces the associated water retention. Both these agents activate potassium channels by different mechanisms, the diuretic also being given concurrently for its ability to overcome the fluid-retaining effects of diazoxide. Other complications of diazoxide therapy include edema, nonketotic hyperosmolar coma, blood dyscrasias and generalized hypertrichosis. Nifedipine 0.25–2.5 mg/kg/day may be of value as an adjuvant therapy but the precise role of calcium channel blockers has not been defined. The advantages of the above treatments are that they can be given orally and second line drugs require intravenous or subcutaneous infusions. Glucagon infusions at rates between 5 and 10 mcg/kg/h in isolation, or at 1.0 mcg/kg/h combined with the synthetic somatostatin analogue octreotide 10 mcg/kg/h may be useful. Surgery may have to be considered in infants where hypoglycemia is still a significant problem despite adequate medical treatment. There is no diagnostic metabolic or endocrine test to distinguish a diffuse pancreatic disorder from an adenoma in a newborn or infant. In older children, distinguishing an adenoma from diffuse hyperplasia is now potentially possible using percutaneous transhepatic pancreatic venous sampling for insulin, glucose and C-peptide to identify 'hot spots' of insulin hypersecretion. Where no tumor is localized pre- or perioperatively, subtotal or total pancreatectomy may have to be considered, balancing the detrimental effects of hypoglycemia against postpancreatectomy diabetes. The management recommended above is consistent with the consensus view of the European Network for Research into Hyperinsulinism.<sup>1137,1139</sup>

## Inborn errors of metabolism

### Glycogen storage disease

Type I glycogen storage disease, glucose-6-phosphatase deficiency and associated transporter defects, may present in its severest form in the neonatal period with hepatomegaly, profound hypoglycemia and lactic acidosis.<sup>1140</sup>

### Hepatic gluconeogenic enzyme deficiencies

Fructose-1,6-diphosphatase (p. 344) deficiency causes fasting hypoglycemia, lactic acidosis, ketosis, hyperuricemia and hyperlipidemia and hepatomegaly.

Phosphoenolpyruvate carboxykinase converts oxaloacetic acid to phosphoenolpyruvate. Defects of the enzyme restrict the utilization of lactate and gluconeogenic amino acids and this results in hypoglycemia, lactic acidosis and hyperalaninemia.

Pyruvate carboxylase converts pyruvate to oxaloacetic acid and deficiency limits gluconeogenesis from lactate and alanine. Hypoglycemia may not be a prominent feature as other gluconeogenic amino acids can enter the tricarboxylic acid cycle and be converted through oxaloacetic acid to glucose.

### Galactosemia

Galactosemia commonly presents in the neonatal period with vomiting, diarrhea, failure to thrive, cataracts, hyperbilirubinemia and hypoglycemia.

### Defects in amino acid metabolism

Maple syrup urine disease (p. 344) in neonates may present with vomiting, failure to thrive, a characteristic odor and hypoglycemia with a rapid progression to severe neurological symptoms.

3-hydroxy-3-methylglutaryl-CoA lyase deficiency (HMG-CoA lyase deficiency) has features of hypoglycemia, hyperammonemia and metabolic acidosis without ketonuria. Initial presentation may be in infancy, early childhood or the neonatal period.

Methylmalonic acidemia and propionic acidemia can present in the neonatal period with hypoglycemia and ketoacidosis.

### Mitochondrial defects of fatty acid oxidation

**Medium chain or general acyl-coa dehydrogenase (MCAD) deficiency** (p. 337). This is the commonest of the inborn errors of mitochondrial fatty acid catabolism and crises are commonly precipitated by infectious episodes with fever, diarrhea, vomiting, poor feeding, lethargy and coma. Hepatomegaly is inconsistently present secondary to fatty infiltration. Hypoglycemia is always present. Plasma ammonia may be normal or slightly elevated. Ketonuria is classically absent or inappropriately low. MCAD deficiency has been reported as a cause of sudden and unexpected death in infants. The diagnosis of MCAD deficiency can be made by DNA molecular analysis (90% have a common allelic variant) and/or plasma acylcarnitines. The severity of clinical symptoms can be prevented by frequent meals, additional carbohydrate intake during stress and supplements of carnitine if required.

**Long chain acyl-CoA dehydrogenase (LCAD) deficiency** (p. 337). Attacks of hypoglycemia and hypotonia occur with hepatocardiomegaly during episodes of exacerbation. In a few infants a sensorimotor neuropathy or pigmentary retinopathy has been described. LCAD deficiency may initially present in the newborn infant.<sup>1141</sup>

### Hormone deficiencies

**Congenital hypopituitarism.** Infants are usually at term, normally grown and without other central nervous system defects but there may be a conjugated or unconjugated hyperbilirubinemia. In affected males external genitalia may be small with micropenis. A few infants have associated midline defects including cleft lip and palate or septo-optic dysplasia. Pituitary hormone deficiencies may be partial or complete and are usually multiple. Cortisol and thyroid replacement may be required from the newborn period.

**Cortisol deficiency states.** Hypoglycemia may be seen in congenital adrenal hyperplasia, bilateral adrenal hemorrhage and congenital adrenal hypoplasia.

**Congenital glucagon deficiency.** Two cases have been reported and hypoglycemia described in both.

### Investigation of hypoglycemia

The majority of infants will have transient hypoglycemia associated with a clinical risk factor (Table 12.104) and do not require extensive investigation. If hypoglycemia persists or is recurrent the infant should be investigated. The priority of investigations may be determined by clinical features or a family history of inborn errors of metabolism or sudden infant death syndrome.

Hypoglycemia should always be confirmed by formal laboratory analysis using a glucose oxidase method. Glucose requirements of the infant should be calculated in mg/kg/min.

Investigations include a full blood count to exclude polycythemia, a blood gas to determine the presence of a metabolic acidosis and plasma electrolytes, essential if adrenal dysfunction is suspected.

Plasma should be collected at the time of hypoglycemia for insulin, C-peptide, ketone bodies (usually beta-hydroxybutyrate), amino acids, lactate, growth hormone, cortisol and ACTH levels. Prior discussion with the investigating laboratory is essential.

Urine should be collected at around the time of hypoglycemia and screened for pH, reducing compounds (Clinitest), ketones and keto acid with 2,4-dinitrophenylhydrazine and for the variety of compounds that

react with ferric chloride. Urine should also be analyzed for amino acid and organic acids.

Acylcarnitine profiles using tandem mass spectrometry on dried blood spots are increasingly being used as a diagnostic tool for disorders of intermediate metabolism. Complete characterization of a metabolic defect may require provocation or loading tests or enzyme studies on fibroblasts, leukocytes or tissue biopsies or analysis of DNA.

## HYPERGLYCEMIA

Hyperglycemia in the newborn is defined as blood glucose  $> 7$  mmol/L after a 4 h fast and this value may be used in the diagnosis and subsequent management of the rare phenomenon of transient neonatal diabetes mellitus.

### Hyperglycemia in preterm infants

Hyperglycemia is commonly seen in nonfasting preterm infants where blood glucose concentrations  $> 10$  mmol/L are not uncommon, may occasionally exceed 20 mmol/L and are most frequently associated with either dextrose infusions or parenteral nutrition. The pathogenesis of this hyperglycemia is uncertain and may include failure to suppress endogenous glucose production, an attenuated insulin release or a decrease in end-organ sensitivity to insulin.<sup>1142</sup> Some regimens for parenteral nutrition include insulin to control not only the hyperglycemia but to improve anabolism and activate lipid clearance.

The adverse effects of hyperglycemia include osmotic diuresis and dehydration, an increase in plasma osmolality and generation of a metabolic acidosis through lactate production.

Blood glucose values that constitute hyperglycemia in preterm infants are not well defined. Most consider it desirable to maintain blood glucose  $< 10$  mmol/L, either by decreasing the amount of dextrose infused or prescribing insulin 0.05–0.1 IU/kg/h. Whether to control moderate hyperglycemia, 5–10 mmol/L, depends on clinical circumstances. Renal glucose thresholds can be as low as 5 mmol/L in extremely preterm infants and a glucose-induced osmotic diuresis might be an indication to treat with insulin.

Hyperglycemia is also associated with infection, intracranial hemorrhage, severe RDS, NEC, or pain. Aminophylline and dexamethasone may exacerbate hyperglycemic tendencies.

### Hyperglycemia in full-term infants

Early postnatal hyperglycemia has been described in association with compensatory responses to birth asphyxia probably involving rapid mobilization of hepatic glycogen by a combination of glucagon and epinephrine secretion and suppression of insulin release. Early hypoglycemia is much more common in this group although late hyperglycemia and instability of glucose homeostasis is seen in severely birth asphyxiated infants who often have associated hepatic damage.

### Transient diabetes mellitus

The onset of permanent diabetes mellitus is rare in infants less than 6 months of age. A transient form of diabetes mellitus may present as early as the first postnatal day or as late as 6 weeks of age. The infants are usually small for gestational age and present, in spite of adequate nutrition, as failure to thrive with wasting and dehydration but with a characteristic 'alert appearance'. Blood glucose levels are variable and may be as low as 1.3 mmol/L or as high as 110 mmol/L. Glycosuria leads to dehydration, which may be rapid in onset and severe. Ketonuria is absent or minimal, in contrast to later onset permanent diabetes mellitus. Insulin levels are inappropriately low for blood glucose concentrations. Management consists of correction of the dehydration and insulin to achieve normoglycemia. A few infants can be managed without continuation of insulin but the majority require regular insulin in dosage varying from 1 to 3 IU/kg/day for periods as short as 14 days or as long as 18 months. These infants are extremely insulin sensitive. After initial correction of dehydration and establishment of enteral feeds

they can usually be managed on a once or twice daily insulin regimen. In the majority, the dose of insulin can be tapered slowly before completely stopping.

In most instances, the condition is sporadic in occurrence although familial cases are reported with a few infants born to diabetic mothers. The etiology of transient diabetes mellitus is thought to be a temporary delay in maturation of beta-cell function and control. A few infants have been reported where there was an initial period of hypoglycemia, but within 3–14 days this gave way to hyperglycemia and transient diabetes mellitus. Permanent diabetes mellitus or later recurrence has been reported in a few individuals.

**Leprechaunism.** A constellation of mutations in the insulin receptor gene gives rise to this syndrome of IUGR with minor dysmorphic features and characterized by insulin resistance, elevated plasma insulin levels and glucose intolerance. Infants usually die in the first year of life.

## DISORDERS OF CALCIUM AND MAGNESIUM METABOLISM

### Normal fetal and neonatal calcium homeostasis

In utero, there is an active movement of calcium from mother to fetus such that by term fetal blood levels are approximately 10% higher than maternal values. This relatively hypercalcemic state suppresses fetal parathormone secretion and stimulates calcitonin release, conditions which favor fetal mineral deposition. After birth, the infant parathyroid remains suppressed and this transient hypoparathyroid state results in a fall in plasma calcium. In the normal term infant, the plasma calcium decreases during the first 24–72 h after birth, reaching values as low as 1.75–2.0 mmol/L. This state of relative hypocalcemia stimulates parathormone release and suppresses calcitonin secretion. Calcium levels gradually increase to within the normal range for infants by 4–5 postnatal days. This transition in calcium metabolism is usually without clinical features but symptomatic hypocalcemia develops if these mechanisms are delayed or exaggerated.

### Hypocalcemia

Mild functional asymptomatic hypocalcemia occurs normally within the first few days of life but levels which constitute biochemical hypocalcemia can be defined as a corrected plasma calcium  $< 1.75$  mmol/L or an ionized calcium  $< 0.625$  mmol/L. Such infants are at risk of symptomatic hypocalcemia. The ionized state is the metabolically active form but dynamic equilibrium and interchange occurs between calcium in the various plasma fractions. Approximately 80% of protein-bound calcium is attached to albumin and the remaining 20% to globulin: binding to albumin is pH sensitive and acidosis results in an increased ionized calcium and alkalosis a decrease in ionized calcium. Clinical assessment of ionized calcium can be made by electrocardiographic observations of the corrected QT interval (QTc interval); it is prolonged  $> 0.19$  s in full-term infants and  $> 0.20$  s in preterm infants who have a low ionized calcium value.

There are a number of clinical conditions where hypocalcemia is the presenting feature (Table 12.105) but the commonest of these is early neonatal hypocalcemia.

### Early neonatal hypocalcemia

The onset of early neonatal hypocalcemia is typically in the first few days of life and most often between 24 and 48 h. At greatest risk are LBW infants, both premature and growth retarded, birth asphyxiated infants and the infant of the diabetic mother.

**Pathogenesis.** The etiology of early neonatal hypocalcemia is usually multifactorial. Most symptomatic infants will have had suboptimal postnatal calcium intake. The postnatal rise in parathormone may be delayed in preterm infants, and indeed most infants with early neonatal hypocalcemia have low or undetectable levels of immunoreactive parathormone. Calcitonin levels are normally elevated in the early newborn period but exaggerated concentrations have been documented in premature as well

**Table 12.105** Causes of neonatal hypocalcemia

Neonatal hypocalcemia
Early
Late (neonatal tetany)
Primary hypoparathyroidism
Sporadic
X-linked, autosomal dominant or recessive
DiGeorge syndrome
Maternal hyperparathyroidism
Vitamin D deficiency
Vitamin D dependency
Rickets/osteopenia of prematurity
Primary hypomagnesemia

as in asphyxiated hypocalcemic infants. Hyperphosphatemia as a result of hypoxemic tissue damage or excessive catabolism releasing phosphate may lead to hypocalcemia. An intracellular movement of calcium can occur after hypoxic cell injury with depression of plasma calcium levels. Acute respiratory alkalosis can occur in ventilated infants resulting in reduced ionized calcium. Sodium bicarbonate administration or the use of citrated blood in exchange transfusions may create a metabolic alkalosis. Elevated plasma fatty acids generated from intravenous lipid infusions have been reported to lower ionized calcium levels.

Insulin-dependent diabetic mothers tend to have lower plasma magnesium levels throughout pregnancy, and infants have lower cord and 24 h postpartum plasma levels of calcium and parathormone. Chronic maternal hypomagnesemia may cause relative hypoparathyroidism in both mother and fetus. The majority of infants of diabetic mothers are asymptomatic but may show biochemical evidence of hypocalcemia and/or hypomagnesemia. In symptomatic infants with both biochemical abnormalities, the hypocalcemia and hypomagnesemia can be corrected with magnesium treatment.

**Clinical features and course.** The symptoms and signs of early neonatal hypocalcemia occur when the calcium falls to  $< 1.75$  mmol/L and can be difficult to differentiate from those of associated pathologies, e.g. HIE or intraventricular hemorrhage, or those of other metabolic abnormalities such as hyponatremia or hypoglycemia.

**Management.** Early enteral calcium supplementation has been shown to prevent early neonatal hypocalcemia in preterm infants. Gastrointestinal irritation and increased stool frequency are the only significant side-effects. The vitamin D metabolites 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol are also effective in raising plasma calcium levels but are rarely used.

Infants whose only pathology is early neonatal hypocalcemia and who have neurological symptoms should be treated as described for late neonatal hypocalcemia. Calcium gluconate 10% (1 ml/kg) can be given intravenously but cautiously over 10 min with ECG monitoring. Decreases in heart rate require slowing of the intravenous infusion or discontinuation. Maintenance calcium gluconate can be given continuously intravenously or orally (75 mg/kg/day). If peripheral intravenous infusions extravasate they may result in skin slough, tissue necrosis and calcification. The preferred method of maintenance, where there is no central line, is by the enteral route and calcium gluconate 10% 1–2 ml/kg 4- or 6-hourly is usually tolerated.

### **Late neonatal hypocalcemia (neonatal tetany)**

Late neonatal tetany can be regarded as a form of transitory hypoparathyroidism but usually symptomatic hypocalcemia and tetany are only problematic in infants subsequently exposed to high phosphorus intake.

**Pathogenesis.** Primary maternal hyperparathyroidism complicating pregnancy is rare but a temporary maternal hyperparathyroid state, secondary to vitamin D deficiency, may be more common. That this type of neonatal hypocalcemia is related to maternal vitamin D

deficiency is supported by nutritional studies and a seasonal incidence in spring and early summer in the northern hemisphere related to low sunshine exposure in the later months of pregnancy, with low levels of 25-hydroxycholecalciferol in both mothers and infants. Enamel hypoplasia is frequently found in affected infants and is indicative of disordered enamel formation during the last trimester of pregnancy.

Occurrence of neonatal tetany in a susceptible population is largely determined by the nature of the milk feed in the newborn period. Cows' milk contains 3–4 times as much phosphorus as human milk. Partially modified cows' milk formulae (particularly tinned evaporated milks), which still had high phosphorus content, were used routinely until the mid 1970s when the incidence of neonatal tetany was as high as 1% of formula-fed infants. With the introduction of feeds with a calcium and phosphorus content approximating to that of human breast milk, neonatal tetany is now rare.

**Clinical features.** Late neonatal tetany usually occurs from the second half of the first week up to several weeks, classically in full-term infants born after a normal labor and delivery who are artificially fed. Although affected infants may have appeared a little jittery or tremulous with increasing tactile irritability of muscles, usually they have been otherwise well, feeding normally, responding normally and with a normal cry, before the sudden onset of convulsions.

Fits are usually transitory, lasting for a few seconds and usually focal in nature, and between convulsions the infant is alert. Jitteriness is evident on stimulation, the tendon reflexes are increased and increased muscle tone with extension, in the legs particularly, is usual. Trousseau's sign is seldom positive and Chvostek's sign, which can be elicited freely in the newborn infant, is of little value. Recovery may occur spontaneously, but in others fits may continue for several weeks unless treated.

**Diagnosis.** The diagnosis is based on a low serum calcium,  $< 1.75$  mmol/L, and a high serum phosphorus,  $> 2.6$  mmol/L. Occasionally the serum calcium is not markedly lowered and the raised phosphorus level is probably a more important diagnostic criterion. There is usually an associated hypomagnesemia but this is moderate in degree, in the range 0.5–0.6 mmol/L.

The differential diagnosis of neonatal tetany from other types of convulsions usually rests on the absence of an abnormal birth history, the normal behavior of the infant between the attacks, apart from muscular irritability, the absence of other signs which would indicate intracranial birth injury and the presence of normal or increased deep tendon reflexes.

**Treatment.** Treatment consists of calcium intravenously or orally, usually in the form of calcium gluconate 10% solution 5 ml/kg/d. Vitamin D has also been used in a dosage of 5000 IU/d orally. Although hypocalcemia is the most obvious biochemical abnormality, the most effective treatment is intramuscular magnesium sulfate (0.2 ml/kg 50% solution per dose), particularly when convulsions are occurring; this can be followed with a further one or two doses at 12-hourly intervals. Intramuscular magnesium controls hypocalcemic tetanic fits more effectively than calcium, and calcium more effectively than phenobarbital.

**Prognosis.** The prognosis of neonatal tetany per se is good, most cases making a full recovery without sequelae. Where the hypocalcemia is secondary to an underlying disorder, the prognosis will be of that disorder.

### **Hypoparathyroidism**

Primary hypoparathyroidism is a rare cause of hypocalcemia in the newborn. The diagnosis is confirmed by absent or low parathormone levels in the presence of hyperphosphatemia, hypomagnesemia and low alkaline phosphatase. Sporadic cases occur but most have a genetic basis, usually X-linked recessive, but autosomal recessive and dominant forms have been described.

DiGeorge syndrome is usually sporadic in occurrence and results from an embryological defect of the 4th branchial arch and derivatives of the 3rd and 4th pharyngeal pouches. The pattern of defects includes hypoplasia or absence of the parathyroids, hypoplasia or absence of the thymus and cardiovascular anomalies including aortic and truncal abnormalities with minor facial anomalies. The severity

of the congenital heart disease usually determines the early prognosis. The degree of hypoparathyroidism may be variable and transient forms have been described. The etiology is heterogeneous. Several different chromosomal abnormalities have been described but deletions at 22q11.2 are most frequent. Teratogenic causes including retinoic acid and fetal alcohol syndrome are also described. Treatment of hypoparathyroidism consists of supplementation with vitamin D<sub>3</sub> or its analogs 1 alpha-hydroxycholecalciferol or 1,25-dihydroxycholecalciferol.

### Maternal hyperparathyroidism

Primary maternal hyperparathyroidism is a rare complication of pregnancy. Parathyroid adenomas are usually responsible but carcinoma has been described. The maternal diagnosis depends on the demonstration of persistently high plasma calcium, elevated plasma parathormone and low urinary calcium and phosphorus. Complications in pregnancy include hyperemesis gravidarum, weakness, renal calculi, spontaneous abortion and late fetal death. The most common neonatal complication is hypocalcemic tetany, observed in around 50% of infants born to mothers with untreated disease. The unexpected occurrence of neonatal tetany may provide the initial clue to the diagnosis of unsuspected maternal hyperparathyroidism. The etiology of neonatal hypocalcemia is thought to reflect prolonged parathyroid suppression from the chronic hypercalcemic state of mother and fetus. However, some infants have normal or elevated parathormone levels and the etiology may be more complex.

The clinical features are those of neonatal tetany. Hypomagnesemia is a frequent occurrence. Most cases of neonatal hypocalcemia secondary to primary maternal hyperparathyroidism are transient but long term congenital hyperparathyroidism has been described.

### Maternal medullary carcinoma of the thyroid

Maternal medullary carcinoma of the thyroid is associated with high calcitonin levels. In the one reported case of this disease, several children born prior to maternal diagnosis exhibited radiological features of osteopetrosis.

### Hypercalcemia

Plasma calcium levels > 2.75 mmol/L (corrected) are generally regarded as constituting hypercalcemia. Clinical manifestations include weakness, irritability, hypotonia, poor feeding, weight loss, polyuria, polydipsia, constipation and vomiting. The major causes are idiopathic infantile hypercalcemia, hyperparathyroidism, benign familial hypercalcemia, and vitamin D intoxication, and hypercalcemia associated with inadequate phosphorus intake in extremely immature infants.<sup>1143</sup>

### Hypomagnesemia

Plasma magnesium levels in the newborn infant are relatively constant through the first week of life (range 0.59–1.15 mmol/L). Hypomagnesemia, < 0.6 mmol/L, does not usually occur during the first few days of life, nor in association with asphyxia, but most commonly occurs towards the end of the first week and later.

Isolated hypomagnesemia can occur as a primary cause of convulsions but is usually associated with concomitant lowering of the plasma calcium as in late neonatal hypocalcemia. Milk formulae with high phosphorus loads predispose to hypocalcemia and also to hypomagnesemia. Neonatal hypomagnesemia is also associated with maternal malabsorption, with parathormone deficiency in the infant, with a primary defect of magnesium absorption in the infant (p. 336) or with magnesium binding by citrate in exchange transfusions.

Treatment of hypomagnesemia is by intramuscular injection of magnesium sulfate 50% 0.2 ml/kg dose. This can be repeated for one or two further doses at 12-hourly intervals. If both hypomagnesemia and hypocalcemia are present, treatment with calcium alone may be ineffective. Improvement may only be achieved after magnesium is prescribed and this often results in the spontaneous rise in serum calcium level. The role of magnesium in relieving the symptoms of hypocalcemia may be due to its capacity to release ionized calcium for effective parathyroid function.

## METABOLIC BONE DISEASE IN PRETERM INFANTS

Defective bone mineralization has been recognized in preterm infants for many years but the terminology used to describe this is confusing. The terms *rickets of prematurity* and *osteopenia of prematurity* have been used synonymously. *Osteopenia of prematurity* refers to skeleton hypomineralization of the preterm infant compared to that resulting from in utero accretion of minerals.<sup>1144</sup> *Rickets of prematurity* implies the presence of radiologically detectable abnormalities, appearances which are historically related to vitamin D deficiency in children, but similar appearances can occur in preterm infants with severe metabolic bone disease. The term osteoporosis has been used to describe radiological rarefaction of bone; where this occurs without obvious rachitic changes it represents a less advanced stage of metabolic bone disease. Substantial demineralization, quantified sensitively by means of photon absorptiometry or dual energy radiographic densitometry, can occur before radiological changes are obvious.

### Pathogenesis

The etiology of metabolic bone disease in preterm infants is probably multifactorial but a major component is as a consequence of a deficiency of calcium and phosphorus.

The vitamin D status of the infant at birth largely depends on the adequacy or otherwise of maternal vitamin D metabolism. In humans, 25-hydroxycholecalciferol crosses the placenta with a close correlation between maternal and cord blood levels both in term and preterm infants.

The preterm infant may not have full expression of hepatic 25-hydroxylation of vitamin D but the majority of studies would support the concept that this ability appears to be achieved very early in postnatal life. Adequate serum levels can be achieved using vitamin D supplements as low as 400–500 IU/day for the first 1–3 months of life. Preterm infants are also capable of 1 alpha-hydroxylation of vitamin D, based on serum estimation of 1,25-dihydroxycholecalciferol, which rises sharply during the first week of life when infants are supplemented with very high vitamin D intakes. On more physiological dosage regimens of vitamin D, 500 IU/day, lower increments of 1,25-dihydroxycholecalciferol are seen over the first week of life but gradually reach maximal values around 3–4 weeks' postnatal age.

Calcium, unlike phosphorus, is not well absorbed from formula milks. The higher bioavailability in human milk can result in 70% absorption provided that phosphorus and vitamin D contents are adequate. In term milks, the absorption of calcium is in the range of 30–60%, and 80–95% of this absorbed calcium can be retained. Calcium absorption increases with both gestational age and postnatal age. Absolute calcium retention increases with the amount of calcium ingested and with higher calcium intakes can be greater in preterm infants than occurs in utero. The concentration of calcium in the formula is therefore important, as is the quantity of milk consumed.

Preterm infants absorb phosphorus very efficiently (86–97% of intake) independent of the type of milk or the calcium or phosphorus concentration of that milk. Retention of absorbed phosphorus appears to be directly related to the rates of calcium and nitrogen retention. Calcium and phosphorus absorption are relatively independent. The renal absorption of phosphorus can be almost complete in preterm infants but fractional phosphorus excretion can be increased if phosphorus is supplied in excess, either in absolute terms or in conditions of relative excess, if calcium is deficient.

The in utero accretion of calcium rises exponentially in the last trimester from 114 to 125 mg/kg/day (2.89–3.12 mmol/kg/d) at 26 weeks to 119–151 mg/kg/day (2.97–3.77 mmol/kg/d) at 36 weeks' gestation. Phosphorus accretion over this gestational age range is 60–85 mg/kg/d (1.94–2.74 mmol/kg/d).

The calcium and phosphorus contents of human milk or term formulae cannot meet the requirements of the preterm infants if accretion of these elements is to continue at intrauterine rates. For example, an extreme preterm infant fed a commercial term formula at 150 ml/kg/d

would have a calcium intake of 65 mg/kg/d (1.6 mmol/kg/d) and a phosphorus intake of 40 mg/kg/d (1.6 mmol/kg/d). If the infant typically absorbed 50% of the calcium intake and 90% of the phosphorus intake, then this would give absorbed calcium of only 32 mg/kg/d (0.8 mmol/kg/d) and phosphorus of 36 mg/kg/d (1.2 mmol/kg/d) available for retention. Comparison of these figures with the in utero accretion rates shows how wide the deficits can be between prenatal and postnatal life.

Copper deficiency in preterm infants can easily be confused where the radiological findings are of osteoporosis, flaring of anterior ribs, cupping and flaring of metaphyseal regions of long bones and subperiosteal new bone formation. It is equally possible that deficiencies in other nutrients may contribute to metabolic bone disease in preterm infants.<sup>1145</sup>

### Clinical features

The largest number of reports of metabolic bone disease is in extreme preterm infants.<sup>1146</sup> Skeletal mineralization may be compromised by prolonged intravenous nutrition with its inherent limitation of mineral intake as well as concerns about aluminum contamination, fluid restriction resulting in decreased intakes of calcium and phosphorus, prolonged immobility, chronic acidosis, treatment with dexamethasone or furosemide and the use of nonsupplemented human breast milk. Many of these factors are common to infants receiving prolonged intensive care.

In the majority of infants with metabolic bone disease there are no overt findings on clinical examination. Occasionally, clinical features are present in preterm infants with well-established and severe rachitic disease (Fig. 12.64). Metabolic bone disease in preterm infants can be

Fig. 12.64 X-ray grading of changes of rickets of prematurity at the wrist: (a) grade 0 = normal; (b) grade 1 = osteopenia only; (c) grade 2 = cupping and fraying of ulnar metaphysis; (d) grade 3 = spontaneous fracture in association with grade 2 changes. (X-rays by kind permission of Professor N McIntosh.)

associated with impairment of linear growth, spontaneous fractures and chronic respiratory distress.

### Investigation and monitoring

Bone mineral content, usually of the forearm, can be measured directly with photon absorptiometry which, when specifically calibrated for small infants, can be precise and accurate.<sup>1147</sup> Bone mineralization is assessed relative to body weight or ulnar length and compared to a gestational age curve which represents in utero mineralization.<sup>1148</sup>

Photon absorptiometry is both sensitive and precise but it is expensive and the equipment bulk makes it impractical for routine use. Dual energy radiographic densitometry overcomes these difficulties.<sup>1149</sup> Radiographic densitometry has the advantage that bone mineral content can be assessed along the length of a bone or comparison easily made between bones. This may be important as bone mineralization is not uniform and wider assessment of the state of mineralization could be a major advantage.

The radiological changes of rickets in preterm infants are cupping and fraying of the metaphyses together with the loss of the provisional zone of calcification (Fig. 12.64). Periosteal reactions and fractures of bone may also occur. Substantial demineralization has to occur before radiological changes become apparent and a dependence solely on radiological methods will seriously underestimate the extent of the spectrum of metabolic bone disease.

In formula-fed infants, plasma calcium and phosphorus values are not good indicators of early metabolic bone disease with plasma calcium only falling significantly in the most severely affected infants with overt radiological rickets and phosphorus values often remaining unchanged. In infants fed human milk, phosphorus depletion is commonly recognized and characterized by hypophosphatemia, hypercalcemia, hypercalciuria, hypophosphaturia and elevated levels of plasma alkaline phosphatase.

Measurement of vitamin D metabolites has limited value in the diagnosis or management of rickets of prematurity.

The use and interpretation of plasma alkaline phosphatase activity as a marker of bone metabolism can be difficult in preterm infants; reference values have been established in cord blood from preterm and term infants and it appears that the bone alkaline phosphatase is the predominant isoenzyme.<sup>1150</sup> The liver isoenzyme is undetectable in preterm and term infant plasma. Plasma fetal intestinal alkaline phosphatase increases dramatically in preterm infants in the postnatal period, peaking at around 2 weeks of age when it may contribute up to 30% of the total activity in plasma. Thereafter peak plasma fetal intestinal alkaline phosphatase activity declines to negligible levels by 6–7 weeks' postnatal age. In preterm infants, total plasma alkaline phosphatase activity in the third trimester decreases with gestational age in infants 5–10 days postnatal age and total alkaline phosphatase has been correlated with the radiological features of rickets and used to monitor the effects of metabolic studies. The wide variability between individual infants makes its usefulness limited on single samples<sup>1151</sup> but sequential measurements from an infant increase its diagnostic value.

In spite of these constraints, the radiological appearances of rickets crudely correlate with total plasma alkaline phosphatase measurements although not with osteopenia or with bone mineral content as measured by photon absorptiometry. Equally high total plasma alkaline phosphatase activity, representing metabolic bone disease in preterm infants, has been related to slower growth rates in the neonatal period and to a significant reduction in attained length at 12 years.<sup>1152</sup> A combination of the criteria serum total alkaline phosphatase activity above 900 IU/L and serum inorganic phosphate concentrations below 1.8 mmol/L yields a sensitivity of 100% at a specificity of 70%. This is probably the best available screening method for low bone mineral density in preterm infants.<sup>1153</sup>

### Management

The key to management of this disorder must be prevention, with a sufficient nutritive intake from early postnatal life to allow mineralization to proceed in a manner that avoids clinical and overt radiological rachitic

changes. Whether we should go further than this goal and attempt to achieve 'normal' mineralization in all preterm infants using in utero mineral accretion rates is an unresolved question.<sup>1154</sup>

Although vitamin D deficiency is not a major factor in the etiology of metabolic bone disease of preterm infants, it facilitates normal mineralization with intakes of around 500–1000 IU/day. In established metabolic bone disease, modest increases in vitamin D intake, 1000–2000 IU/day, are used for short periods in conjunction with mineral supplementation.

Postnatal retention of calcium and phosphorus can approximate intrauterine accretion in term infants fed formulae with a calcium and phosphorus content similar to that of human milk.<sup>1155</sup> In contrast preterm infants approaching term may have a bone mineral deficit of as much as 30% when compared with full-term infants but have a rapid phase of mineral accretion between 40 and 60 weeks' postconceptional age which reduces perinatal mineralization deficits that might otherwise persist into childhood.<sup>1148</sup> Ziegler<sup>1156</sup> discusses this dilemma and emphasizes that the avoidance of overt bone disease should be the criterion for calcium and phosphorus need, rather than the necessity to achieve fetal accretion rates or in utero rates of mineralization. On this basis the requirement of the preterm infant for calcium and phosphorus is probably greater than the intake from human milk but less than that needed to achieve intrauterine accretion rates. The problem is how much calcium and phosphorus is required to avoid overt bone disease and how this need should be assessed.

A premature infant fed breast milk at 150 ml/kg/d receives an intake of around 55 mg/d (1.3 mmol/d) of calcium and 22 mg/d of phosphorus (0.5 mmol/d) and the postnatal increase in bone mineral content is significantly less than that expected in utero. Supplementation of maternal milk has been attempted with calcium or phosphorus or both, addition of skimmed components of donor human milk, mixing maternal milk with formula containing high concentration of calcium and phosphorus and the use of proprietary powdered fortifiers. Indiscriminate fortification of human milk is to be avoided and reserved for extreme preterm infants where this type of nutrition is the major dietary source. Phosphorus supplements of up to 9 mg/dl (13 mg/100 cal) have been used to maintain the plasma phosphorus greater than 1.5 mmol/dl and avoiding excess urinary calcium losses. Calcium supplements should not be given without a proportionate amount of phosphorus in order to maintain the calcium:phosphorus ratio in the range of 1.4–2.0. Simultaneous additions of calcium and phosphorus salts to milks may result in precipitation. This can be avoided by adding the phosphorus first (usually disodium phosphate) and then calcium (usually calcium gluconate/glibionate).

The American Academy of Pediatrics,<sup>1157</sup> on the basis of estimated fetal requirements, has advised enteral intakes of calcium 185–210 mg/kg/d (4.6–5.2 mmol/kg/d) and phosphorus 123–140 mg/kg/d (4–4.6 mmol/kg/d) for infants between 26 and 31 weeks' gestation. To achieve these intakes, assuming a fluid intake of 150 mg/kg/d, milk formulae would have calcium content of 126–140 mg/dl (3.1–3.5 mmol/dl) and phosphorus 82–93 mg/dl (2.7–3.1 mmol/dl). A more cautious approach has been adopted by the ESPGAN Committee on Nutrition,<sup>1154</sup> representing European opinion, where the recommended calcium content of formulae would be between 56 and 112 mg/dl (1.4–3.8 mmol/dl) with a phosphorus content 40–72 mg/dl (1.3–2.3 mmol/dl). LBW formulae currently available in the UK have calcium contents in the range 70–110 mg/dl (1.7–2.7 mmol/dl) and phosphorus 35–60 mg/dl (1.2–2.0 mmol/dl), compositions not optimal to meet mineral requirements if intrauterine accretion rates are to be attained but levels which should avoid overt bone disease. Excess dietary calcium can cause supermineralization in preterm infants, impede fat absorption as well as that of other minerals and lead to the risk of nephrocalcinosis.

Parenterally fed preterm infants are at particular risk of inadequate supply of calcium and phosphorus.<sup>1158</sup> The solubility and stability of mineral substrate in parenteral solutions depends on a number of factors and precipitation of salts can occur readily, resulting in blocked lines and the potential for microembolization of crystalline particles.

Most parenteral nutrition regimens can routinely achieve intakes of calcium of 1.5 mmol/kg/d and phosphorus 1.0 mmol/kg/d. By prescribing increased amounts of calcium and phosphorus only when fluid and amino acid intakes are appropriate, avoiding prolonged standing times, using the more soluble calcium gluconate rather than the chloride and only adding calcium and phosphorus to already diluted parenteral solutions, precipitation can be avoided and intakes of calcium around 2.0 mmol/kg/d and phosphorus 1.7 mmol/kg/d can be achieved. Further increments may be possible using monobasic potassium phosphate.<sup>1159</sup>

## NEONATAL PRESENTATION OF INBORN ERRORS OF METABOLISM

Major advances have been made in the recognition and understanding of many inborn errors of metabolism. Prenatal diagnosis is available for a number of conditions, allowing parents to avoid recurrence of serious disease or early management and treatment to avoid deleterious effects on the developing fetus or neonate. Increasingly successful treatment regimens are being devised but the outcome may depend on the earliest possible recognition and institution of therapy. Only a minority of inborn errors of metabolism are routinely screened for in the newborn and early recognition is often dependent on maintaining a high index of clinical suspicion and a low threshold for sometimes basic and sometimes complex biochemical investigations. This is particularly true where inborn errors can present as acute and serious illness in the newborn period.

The aim of this review is to consider what inborn errors of metabolism can present in the newborn period and their clinical features. Although investigation and management will be discussed, details of individual inborn errors of metabolism are to be found in Chapter 26 and will be cross-referenced, as well as the relevant chapters of *The Metabolic and Molecular Bases of Inherited Disease*.<sup>1160</sup>

### Acute metabolic disorders

A number of metabolic disorders can present with acute overwhelming symptoms in the newborn period, particularly the urea cycle defects, organic acidemias and certain aminoacidopathies (Table 12.106). The majority of these disorders have no detrimental effects on fetal

**Table 12.106** Inborn errors of metabolism which may present as acute illness in the newborn period – see also Table 12.104 for metabolic diseases where hypoglycemia is a prominent feature

<i>Disorders of amino acid metabolism</i>
Maple syrup urine disease
Phenylketonuria
Tyrosinemia type I
Nonketotic hyperglycinemia
Hyperbeta-alaninemia
Sulfite oxidase deficiency
5,10-Methylene tetrahydrofolate reductase deficiency
Methylmalonic acidemia
Propionic acidemia
Isovaleric acidemia
Beta-methylcrotonylglycinuria
Multiple carboxylase deficiency
Hydroxymethylglutaryl-CoA lyase deficiency
Beta-ketothiolase deficiency
2-Methylacetoacetyl-CoA thiolase deficiency
<i>Urea cycle defects</i>
N-acetylglutamate synthase deficiency
Carbamyl phosphate synthetase deficiency
Ornithine transcarbamylase deficiency
Citrullinemia
Argininosuccinic aciduria
Arginase deficiency

development because placental perfusion can correct the disordered metabolic accumulation. As a consequence, the majority of infants are full-term, of normal growth, without dysmorphic features and asymptomatic at birth. An exception to this generalization is where the primary defect is in cerebral metabolism as occurs in nonketotic hyperglycinemia (p. 303). These infants may be born with established brain damage and have clinical features of hypertonia, lethargy, poor feeding and seizures, both grand mal and myoclonic. Other similar conditions include primary lactic acidosis, pyridoxine dependent seizures and primary molybdenum deficiency.

Fetal disorders of fatty acid oxidation can predispose the mother to acute fatty liver of pregnancy and the HELLP syndrome of hemolysis, elevated liver enzymes and low platelet count.<sup>1161</sup>

Many of the disorders are inherited as autosomal recessives and there may be a family history of consanguinity, previous perinatal loss or sudden and unexpected death in infancy. Autopsy findings may have been nonspecific and unrevealing unless specific biochemical investigations were done. A few inborn errors of metabolism have other patterns of inheritance, for example X-linked recessive in ornithine transcarbamylase deficiency.

### Clinical features

The initial symptoms are usually nonspecific with lethargy, poor feeding, poor weight gain and vomiting. Diarrhea is less common but occurs in galactosemia (p. 338), and hereditary tyrosinemia (p. 282).

In the case of the infant who is well at birth, the onset of symptoms may be within a few hours of the first milk feed or may be delayed several weeks. The relationship to milk feeds and protein load may be further emphasized when the initial symptoms resolve with a period of intravenous fluids to recur again when milk feeds resume.

Progressive accumulation of intermediate metabolites may have neurotoxic effects and encephalopathic symptoms may accompany the presentation with apnea, periodic respirations, hypotonia, hypertonia, decerebrate rigidity, seizures and coma.

The clinical features may mimic the presentation of an acute neonatal infection. Indeed sepsis is a common accompaniment of acute exacerbations of metabolic disease as occurs in maple syrup urine disease (p. 338) galactosemia (p. 338) or the mitochondrial disorders of fatty acid oxidation (p. 338). Certain metabolic disorders may predispose to the risk of infection, for example infants with type I glycogen storage disease.

Clinical examination may be unrevealing. Tachypnea may indicate an underlying metabolic acidosis. Hepatomegaly, if present, classically occurs in the glycogen storage disorders, galactosemia and fructose-1,6-diphosphatase deficiency (p. 338), but has been described in some infants with urea cycle defects, disorders of mitochondrial fatty acid oxidation and some aminoacidopathies. Cataracts can occur in newborn infants with galactosemia. Dislocated lens, characteristic of homocystinuria and sulfite oxidase deficiency have been described in the first month of life. Abnormal hair fragility can be present in some infants with argininosuccinic aciduria.

The majority of infants with acute metabolic disease do not have congenital anomalies but dysmorphic features are characteristic of some metabolic disorders such as multiple acyl-CoA dehydrogenase deficiency. Ambiguous genitalia occur in association with congenital adrenal hyperplasia.

Abnormal urinary odors may accompany metabolic disorders: phenylketonuria, mousy or musty; maple syrup urine disease, maple syrup or burnt sugar; isovaleric acidemia and glutaric acidemia type II, sweaty feet; beta-methylcrotonylglycinuria, cat urine.

### Initial laboratory investigations

Infants suspected of acute metabolic disease require basic investigations not only for clinical management and resuscitation but to begin to determine the nature of the inborn error. Initial investigations should include blood gases, plasma electrolytes, plasma calcium and magnesium, blood glucose and lactate, blood ammonia and a full blood count.

Valuable information can be gained by urine screening tests for pH, glucose (Clinistix), reducing compounds (Clintest), ketones and keto acids with 2,4-dinitrophenylhydrazine and for the variety of compounds that react with ferric chloride. Urinary creatinine may be useful for standardization of subsequent investigations. These basic investigations should be available in all laboratories and be completed rapidly.

The differential diagnosis and the diseases which may be detected by Clintest, ferric chloride and 2,4-dinitrophenylhydrazine testing of urine are discussed in Chapter 26.

**Metabolic acidosis.** This is frequently present in acutely ill infants with galactosemia, gluconeogenic disorders, glycogen storage disease and particularly the organic acidemias (Tables 12.106 and 12.107). Infants with organic acidemias may have a significant anion gap. Secondary lactic acidosis is commonly seen in neonatal medicine secondary to infection, hypoperfusion syndromes, or indeed secondary to other metabolic disorders such as the organic acidemias, urea cycle disorders and fatty acid oxidation defects. Primary lactic acidoses occur in disorders of pyruvate metabolism and mitochondrial respiratory chain disorders.

**Hyperammonemia.** High blood ammonia is present in the primary enzyme defects of the urea cycle (Table 12.106) and is exacerbated by high protein loads whether from milk or endogenous catabolism. Secondary hyperammonemia is often seen in the defects of mitochondrial fatty acid oxidation and the organic acidemias and in glutamate dehydrogenase associated hyperinsulinemia. Delayed ontogeny of the urea cycle in preterm infants, particularly those receiving high protein loads, may result in severe hyperammonemia. Blood urea may be inappropriately low in the presence of defects of the urea cycle.

**Hypoglycemia.** This is the predominant feature of the primary defects of carbohydrate metabolism and of mitochondrial fatty acid oxidation but can be present in disorders of amino acid metabolism or organic acidemias. Hypoglycemia is frequently present as part of the acute metabolic derangements in maple syrup urine disease, methylmalonic acidemia, glutaric acidemia type II and hydroxymethylglutaryl-CoA lyase deficiency (Tables 12.106 and 12.107). The list is not exhaustive but illustrates the overlap in presentations and the importance of blood glucose estimations in the investigation, monitoring and treatment of suspected metabolic disease.

**Liver transaminases and direct hyperbilirubinemia.** Elevated plasma alanine or aspartate aminotransferases are secondary to hepatotoxicity and may be found in galactosemia, type III glycogen storage disease, disorders of mitochondrial fatty acid oxidation and the urea cycle defects (Tables 12.106 and 12.107). Indirect hyperbilirubinemia is a common

accompaniment to a wide range of newborn illnesses. A direct hyperbilirubinemia occurs in those diseases that damage the liver, in particular galactosemia, fructose intolerance and tyrosinemia, but is also seen in the later stages of the presentation of urea cycle defects, mitochondrial respiratory chain disorders and alpha1-antitrypsin deficiency.

**Thrombocytopenia and neutropenia.** These can be features of methylmalonic acidemia, propionic acidemia, isovaleric acidemia and lysinuric protein intolerance. In addition neutropenia has been described in carbamyl phosphate synthetase deficiency and nonketotic hyperglycinemia and glycogen storage disease type Ib. Defective platelet function and bleeding may be a feature of type I glycogen storage disease (Tables 12.106 and 12.107). The presence of neutropenia and/or thrombocytopenia can be indices of sepsis in the newborn infant without an underlying inborn error of metabolism.

**Anemia.** Anemia can be found in association with methylmalonic aciduria and some of the aminoacidopathies.

### Detailed laboratory investigation

If hyperammonemia, unexplained metabolic acidosis or hypoglycemia is present then it must be assumed that the symptoms are secondary to an inborn error of metabolism and the infant thoroughly investigated.<sup>1162</sup> This may require urine and plasma samples to be sent to a specialist laboratory. In general the full range of tests described below may have to be performed, but a priority order of investigations can be made on the basis of clinical features and the results of initial laboratory investigations, e.g. in the case of a vomiting infant with hypoglycemia and a urine positive for reducing substances, urine sugar chromatography will be the first priority to exclude galactosemia. Collaboration and discussion with personnel in a specialist center or laboratory is essential and investigations can be organized for each specific patient. Not all sick newborn infants with metabolic disease need have hypoglycemia, metabolic acidosis or hyperammonemia. For example, infants with nonketotic hyperglycinemia may have severe encephalopathic features but unrevealing initial investigations. Detailed metabolic investigation can be worth pursuing even when initial laboratory results are unresponsive.

Semiquantitative analysis of urinary amino acids can be made relatively rapidly by thin layer or paper chromatography complemented by a complete quantitative amino acid analysis of plasma, CSF or urine. Thin layer chromatography of sugars is semiquantitative but rapid and usually diagnostic. Urinary organic acids may initially be analyzed by gas-liquid chromatography but preferably by gas chromatography-mass spectrometry which can be analyzed from a dried blood spot. Lactate and pyruvate are generally measured in plasma but urinary lactate measurements have been advocated for the differentiation of a primary from a secondary lactic acidosis. Acylcarnitine profiles using tandem mass spectrometry on dried blood spots are increasingly being used as a diagnostic tool.

These investigations may give a definitive diagnosis or one where there is a high index of suspicion of a known inborn error to allow specific treatment to begin. Complete characterization of an inborn error of metabolism may require enzyme studies on fibroblasts, leukocytes or tissue biopsies including DNA analysis.

### Acute management of severe metabolic disease

Cardiorespiratory homeostasis and the correction of biochemical abnormalities are the priorities. The extent of resuscitative measures will depend on the clinical state of the infant and often must be instituted before a definitive diagnosis has been established.

Intravenous fluids are given as 10% dextrose solutions; the volume/kg/h will depend on the state of hydration and the presence of renal dysfunction. Hypoglycemia and hypocalcemia should be corrected. Hyperglycemia can potentiate the generation of lactate and should be avoided. This is particularly important for patients with pyruvate dehydrogenase complex defects where a high carbohydrate load can dramatically accentuate the acidosis.

If the infant has a metabolic acidosis with no respiratory acidosis or a compensatory respiratory alkalosis, the metabolic acidosis should be

**Table 12.107** Metabolic storage disorders which may be suspected in neonates

#### Glycogen storage diseases

- Type I, glucose-6-phosphatase system deficiencies
- Type II, Pompe disease, alpha-1,4-glucosidase deficiency
- Type III, debrancher deficiency
- Type IV, brancher deficiency

#### Lipid storage diseases

- GM1 gangliosidosis type I
- Gaucher disease
- Niemann-Pick disease
- Wolman disease
- Farber disease

#### Mucopolysaccharidoses

- Type I, sialidosis
- Type II, I-cell disease

#### Mucopolysaccharidoses

- Type VII, beta - glucuronidase deficiency

#### Glycoprotein storage disease

- Fucosidosis

corrected with sodium bicarbonate, initially with boluses to raise the pH to around 7.25 and then maintained if necessary by a slow intravenous infusion. If the infant has a combined respiratory and metabolic acidosis with hypoventilation secondary to cerebral depression, the respiratory component is firstly corrected by ventilatory support and then the metabolic acidosis corrected. Oxygen should be given as required to maintain normal arterial saturation. Muscle paralysis with ventilatory support may have a specific role in severe lactic acidosis reducing the peripheral production. Blood gases and electrolytes should be monitored frequently.

Good tissue perfusion and oxygenation is essential to avoid secondary lactic acidosis. In correction of hypotension it may be more appropriate to use an inotropic agent such as dopamine rather than a high protein load of plasma or blood. As perfusion improves, the metabolic acidosis may worsen as peripheral lactate is brought into the circulation. Convulsive episodes may accentuate anaerobic metabolism and should be treated initially with intravenous phenobarbital.

Vitamins are essential cofactors for some enzymes and in certain conditions where cofactor function is abnormal reduced enzyme activity will result. Prescribing vitamins in doses approximately 10–100 times the daily requirement can increase enzyme activity in some instances. In the situation of the critically ill infant without as yet a specific diagnosis, the empirical use of multivitamins is justified but restricted to biotin (5–10 mg/d) and vitamin B<sub>12</sub> (1–2 mg). Secondary carnitine deficiency is common in many metabolic disorders, especially fatty acid oxidation defects and organic acidemias, and should be given 100–200 mg/kg/d intravenously by continuous infusion or in divided doses orally.

Protein catabolism can exacerbate most of these disorders and once the infant's condition is stable and the acute metabolic derangements have been corrected, calories can be increased by gradual increments of intravenous 20% dextrose. Hyperglycemia is to be avoided as it may exacerbate metabolic acidosis, and insulin 0.05–0.1 IU/kg can be used to maintain blood glucose < 10 mmol/L. Insulin may also increase anabolism and can be used regularly 4- to 6-hourly. Once the infant is stabilized on this regimen and to maintain anabolism, protein and lipids are introduced either by the enteral or parenteral route. Protein can be commenced at 0.25–0.5 g protein/d and if tolerated increased by the same amount daily to reach 1.5 g/kg/d with an aimed caloric intake of 120 kcal/kg/d.

### Specific treatments

Where investigations have led to a definitive diagnosis or where there is a high index of suspicion of an inborn error, specific treatment can be instituted. In urea cycle defects a combination of dietary therapy and the use of drugs to provide alternative pathways for nitrogen excretion can be successful. Arginine functions as an essential amino acid and supplementation will allow excretion of additional nitrogen. Amino acid nitrogen can be excreted as hippuric acid if sodium benzoate is given or as phenylbutylglutamine after administration of phenylbutyrate. The use of medications alone may be sufficient, but dialysis may also be necessary. Hemodialysis and hemodiafiltration are more effective than peritoneal dialysis, and the methods of choice in the initial treatment of urea cycle defects, maple syrup urine disease and the organic acidemias. Exchange transfusion should be reserved for exceptional circumstances.<sup>1163</sup>

Dietary modifications have been particularly successful in phenylketonuria and galactosemia. Supplementations of vitamin B<sub>12</sub> in methylmalonic aciduria, carnitine in organic acidemias, biotin in carboxylase deficiencies and pyridoxine in homocystinuria have been successful in some individuals. Alterations of the ratio of fat:carbohydrate:protein in the diet or the frequency of feeding have been used in the management of type I glycogen storage disease, fructose-1,6-diphosphatase deficiency and the mitochondrial disorders of fatty acid oxidation.

### Investigations where death is inevitable

The situation may arise where death is inevitable but the exact definitive diagnosis of an inborn error of metabolism has not been conclusively

established. In these circumstances it is important that the fullest information be obtained to advise parents of the risks of recurrence in subsequent pregnancies. An autopsy is vital and should preferably be performed soon after death. The majority of parents, with skilled counseling, will give postmortem permission before the infant dies. At autopsy liver, kidney, skeletal muscle, cardiac muscle and areas of brain thought to be involved should be fixed for light and electron microscopy. Duplicate frozen tissue samples suitable for cryostat sections should be obtained. Skin or pericardial fibroblast cultures should be established. A substantial amount of each tissue should be snap frozen as 0.5 cm<sup>3</sup> cubes in liquid nitrogen and stored at –70 °C for subsequent enzyme analysis. Certain disorders, particularly those of membrane associated enzymes where there is a transport function or where the membrane is important for regulatory function or where the enzyme itself is sensitive to freeze-thaw, may best be analyzed on fresh tissue. Specialist advice should be sought. Some parents will agree only to a limited postmortem, for example wedge biopsy or needle biopsy of liver with skin samples for culture from the incision site. In these circumstances all available urine and plasma should be frozen and stored at –70 °C. Blood should be taken into EDTA tubes for subsequent DNA extraction, and a blood spot on a screening card for tandem mass spectrometry.

### Suspected metabolic storage disorders

Metabolic storage disorders that may present in the newborn period are shown in Table 12.107 but often symptoms and a diagnosis may be delayed into infancy or childhood depending on the severity of the enzyme deficiency or the rate of expression of pathognomonic features. Infants with glycogen storage disease may have hepatomegaly with or without obvious hypoglycemic symptoms. Pompe disease, type II glycogen storage disease, is not associated with hypoglycemia but infants may have macroglossia, hypotonia, hepatomegaly and cardiomegaly with cardiac failure. In addition to type II glycogen storage disease, cardiac failure and cardiomyopathy may suggest a mitochondrial respiratory chain defect, or a long chain fatty acid oxidation disorder, and Barth syndrome in the presence of neutropenia.<sup>1164</sup>

The clinical features of the mucopolysaccharidoses are rarely fully expressed in the newborn period and a Hurler-like phenotype with coarse facies, macroglossia, limited growth and skeletal abnormalities is more likely to be a lipid or mucolipid storage disorder, particularly GM1 gangliosidosis type I or I-cell disease.

The acute infantile variant of Niemann–Pick disease, Gaucher disease and Wolman disease may present in the newborn period with hepatosplenomegaly, feeding difficulties, vomiting, choking, cyanotic episodes, failure to thrive and disorders of tone. Gastrointestinal symptoms are particularly marked in Wolman disease with diarrhea and abdominal distention in addition to vomiting.

Congenital disorders of glycosylation are rare and involve abnormal glycosylation of certain glycoproteins. The features are variable with cardiomyopathy, pericardial effusions, failure to thrive, abnormal fat distribution and facial dysmorphism.

### Metabolic disorders associated with dysmorphic features

Inborn errors of metabolism may be associated with dysmorphic features suggesting that metabolic derangements in utero have disrupted normal fetal ontogeny, for example congenital adrenal hyperplasia in females is associated with ambiguous genitalia.

### Peroxisomal disorders

Disorders of peroxisomal biogenesis as well as deficiencies in peroxisomal enzymes may present in the newborn period.<sup>1165</sup>

**Zellweger syndrome (cerebrohepato-renal syndrome).** This autosomal recessive condition has a number of characteristic clinical features. Craniofacial abnormalities may include a high forehead, flat occiput, wide sutures and fontanelle, absent orbital ridges, micrognathia, redundant neck skinfolds, external ear abnormalities and a high arched palate. The neurological features include hypotonia, poor feeding, nystagmus,

hypo- or areflexia, psychomotor retardation and seizures. The brain is abnormal with disordered neuronal migration. Hepatomegaly is characteristic with prolonged jaundice, elevated transaminases and a progression to cirrhosis. The kidneys may show multiple cysts. Ocular abnormalities include cataracts, retinal pigmentation, optic disc pallor and Brushfield spots. Radiologically stippled calcification of the patella or acetabulum may be present. The clinical expression includes milder forms of the disorder.

**Neonatal adrenoleukodystrophy.** The clinical syndrome and symptoms may be indistinguishable from Zellweger syndrome.<sup>1165</sup> The presence of skeletal stippling or renal cysts at autopsy has not been encountered in neonatal adrenoleukodystrophy.

**Infantile Refsum disease.** This condition was originally described as an association between elevated plasma phytanic acid in infants with craniofacial dysmorphism, ocular abnormalities, hepatomegaly and psychomotor retardation with peroxisomes absent or deficient.

**Rhizomelic chondrodysplasia punctata.** This condition is inherited as an autosomal recessive and is characterized by short stature, symmetrical rhizomelia with marked shortening of the humerus and femur and punctate calcification around the epiphysis with coarse irregularity of the metaphyses. Severe psychomotor retardation, hepatomegaly and craniofacial dysmorphism with cataracts and corneal changes complete the clinical picture.<sup>1165</sup>

**Hyperpicopolic acidemia.** This syndrome is characterized by elevated picopolic acid in plasma, minor dysmorphic features, optic disc pallor, retinal pigmentation, psychomotor retardation and hepatomegaly with abnormal liver function progressing to cirrhosis. The postmortem findings show adrenal abnormalities, renal cysts, normal neuronal migration in the brain and normal peroxisomes in liver but a disturbance in multiple peroxisomal function.

**Zellweger-like phenotype with structurally intact peroxisomes.** The biochemical defect in this group is confined to disorders of very long chain fatty acid oxidation or bile salt metabolism but with intact peroxisomes. It includes peroxisomal 3-oxoacyl-CoA thiolase deficiency, peroxisomal acyl-CoA oxidase deficiency and peroxisomal bifunctional enzyme deficiency.

### Mitochondrial electron transport chain defects

**Multiple acyl-CoA dehydrogenase deficiencies (MAD) or glutaric acidemia type II.** MAD deficiency is classified into two variant forms: a severe (MAD-S) neonatal form or glutaric aciduria type II and a mild (MAD-M) variant with later onset.

In the severe neonatal form (MAD-S) two subgroups have been identified: those with congenital abnormalities and those without congenital abnormalities. In MAD-S deficiency with congenital abnormalities, characteristically the infants are born prematurely and may be growth retarded but develop a metabolic acidosis in the first 24 h of life with

a characteristic odor of 'sweaty feet'. All patients have died in the first week of life. Neonatal MAD-S deficiency is associated with congenital abnormalities including facial dysmorphism, polycystic kidneys or some form of cystic dysplasia, cerebral abnormalities including disorders of migration, pulmonary hypoplasia, hypospadias and minor abnormalities of nail or palmar creases. At autopsy fatty infiltration of the liver, heart and kidneys is present. In MAD-S deficiency without congenital abnormalities the clinical course is similar with acidosis, hypoglycemia and odor; death occurs rapidly. Both types are a result of deficiencies of electron transport chain flavoprotein or its oxidoreductase. In MAD-M deficiency the clinical presentation is heterogeneous with first symptoms in the neonatal period, childhood or adulthood and characterized by vomiting, acidosis and hypoglycemia.

**Riboflavin responsive defects of beta-oxidation or riboflavin responsive multiple acyl-CoA dehydrogenase deficiencies (RR-MAD).** Some patients presenting with a Reye-like syndrome or hypoglycemia in the first years of life with defects in beta-oxidation have been shown to be responsive to riboflavin. The biochemical etiology remains to be confirmed but a therapeutic trial with riboflavin should be attempted in all patients presenting with an organic aciduria suggesting an MAD deficiency.

### Disorders of cholesterol biosynthesis

**Smith-Lemli-Opitz syndrome.** Smith-Lemli-Opitz syndrome is a syndrome of mental retardation and multiple congenital malformations. The defect is thought to be in the gene coding for the enzyme 3beta-hydroxysteroid-delta7-reductase with the consequence of reduced conversion of 7-dehydrocholesterol to cholesterol and a reduction in plasma and tissue levels of cholesterol with an increase in 7-dehydrocholesterol. The common dysmorphic features are hypospadias, ambiguous genitalia, syndactyly of the toes, microcephaly, blond hair, anteverted nares, low set ears, palatal abnormalities, micrognathia, congenital heart disease and renal abnormalities. Severe feeding problems are common requiring nasogastric or gastrostomy feeding. Cholesterol supplementation of the diet may increase plasma cholesterol and in some has beneficial effects. Other disorders of cholesterol biosynthesis can result in dysmorphic features but are not as well characterized as Smith-Lemli-Opitz syndrome.<sup>1166</sup>

### Miscellaneous conditions with newborn presentations

These include Crigler-Najjar syndrome; cystic fibrosis, alpha1-antitrypsin deficiency; Menkes' kinky hair syndrome, hypophosphatasia; hereditary orotic aciduria; glucose-6-phosphate dehydrogenase deficiency; pyruvate kinase deficiency; pyridoxine dependent convulsions; congenital erythropoietic porphyria; and aminolevulinic acid dehydratase porphyria (Ch. 26).

### INTRODUCTION

Promoting, protecting and supporting optimal nutrition is relevant to life-long health and requires not only an understanding of physiological and biochemical facets but an appreciation of the strong social and cultural influences.

### BREAST-FEEDING

#### INCIDENCE OF BREAST-FEEDING

Over the past 15 years the proportion of mothers initiating breast-feeding in the UK has risen (Table 13.1), particularly in areas and social groups with historically low uptake. However the UK is still some way from matching initiation rates typical in Scandinavia and Australasia. Factors that affect the incidence of breast-feeding in the UK are shown in Table 13.2.<sup>1</sup> Social class, educational and geographical gradients are particularly marked. The chosen method of infant feeding is therefore a strong marker of social and educational inequality.

#### DEFINITION AND PREVALENCE OF 'BREAST-FEEDING'

Because breast-fed babies may receive other fluids and foods it is necessary to define epidemiologically the meaning of 'breast-feeding'. World Health Organization terminology has now been widely adopted (Table 13.3).<sup>2</sup> In the UK the term 'prevalence' has been used in national surveys to describe the proportion partially or exclusively breast-fed at specified ages. A consistent trend has been the rapid decline during the first 6 weeks of life, particularly the first 2. Socially and educationally disadvantaged mothers are more likely to give up. About 80% who stop in the first 2 weeks say that they wanted to breast-feed for longer, the commonest reasons being 'insufficient milk/baby hungry' (44%), 'sore nipples or breasts' (36%) and 'baby would not suck' (20%). As these reflect errors of technique and failure to recognize the normal feeding pattern of the breast-fed baby, better professional education on the management of breast-feeding could help.

### CONTRIBUTION OF BREAST-FEEDING TO HEALTH

#### Infectious and allergic disease

Breast-feeding is crucial to survival in less resource-rich countries: a pooled analysis of data from six countries showed that infants not breast-fed were 2–6 times more likely to die of infections (mainly respiratory and diarrheal disease) in the first 6 months.<sup>3</sup> Risks of not breastfeeding were greatest for those whose mothers were the least educated and for the youngest infants. In Ghana supplementing breast milk with liquids or solids was associated with a fourfold increase in neonatal death; it has been estimated that early establishment of exclusive breast-feeding could reduce neonatal mortality by about one fifth in such circumstances.<sup>4</sup>

The effect size of breast-feeding on maternal and child health in industrialized countries has been harder to confirm: most evidence comes from case-control and cohort studies. Methodological problems include: the variable duration of breast-feeding, imprecise definition of the term 'breast-feeding' (Table 13.3), dependence on recall rather than prospective monitoring of feeding method, confounding by sociocultural factors (Table 13.2), 'ascertainment bias' and inadequate definition of disease outcomes. Although randomized allocation to artificial feeding is clearly unethical, cluster randomization of an intervention increasing the prevalence of breastfeeding, particularly exclusive breastfeeding (the Baby Friendly Initiative, vide infra) has provided level 1 evidence confirming the effect of breastfeeding on child health in an industrialized country setting, Belarus. Infants born in control hospitals were less likely to be breast-fed (either at all or exclusively) and at increased risk of atopic and diarrheal disease, despite a relatively low background prevalence of both.<sup>5</sup>

#### Breast-feeding and cardiovascular health

Meta-analyses have shown that breast-fed infants in industrialized countries have lower plasma cholesterol in adult life,<sup>6</sup> lower systolic blood pressure<sup>7</sup> and are less obese.<sup>8,9</sup> There are indications that exclusive breast-feeding exerts strongest effects but it has not proved possible to confirm this partly because of imprecise definition (particularly in the largest studies) and partly because of the frequency with which supplementation has been practiced.

**Table 13.1** Incidence of mothers initiating breast-feeding in the UK, 1975–2000<sup>53</sup>

	England & Wales	Scotland	Northern Ireland
1975	51	n/a	n/a
1980	67	50	n/a
1985	65	48	n/a
1990	64	50	36
1995	68	55	45
2000	70	77	63
2005	70	54	63

**Table 13.2** Factors affecting the incidence of breast-feeding in the UK

<b>Favor breast-feeding</b>
Social class I
Mother educated beyond 18 years of age
Mother over 24 years of age
Live in South-East England
First baby
Breast-fed previous baby
<b>Hinder breast-feeding</b>
Smoking

### Breast-feeding and neurological development

Numerous studies have found a statistically significant association between breast-feeding and mental development in infancy and childhood, but potential confounding influences are numerous, e.g. parental alcohol intake, smoking behavior and intelligence. Differences are most marked in preterm infants and in most studies persist after adjustment for confounders.<sup>10</sup> Although attributed to differences in the fat composition of formula and breast milk this is currently unproven.

### Breast-feeding and the mother's health

Exclusive breast-feeding assists child spacing by inducing lactational amenorrhoea. Globally this may be its most important benefit to maternal health. There is strong evidence that breast-feeding significantly reduces a mother's risk of breast cancer, regardless of menopausal status.<sup>11</sup> Breast-feeding does not adversely influence the mother's bone health.<sup>12</sup> Although some demineralization occurs during lactation there is remineralization on weaning. These events are not preventable by calcium supplementation.<sup>13</sup>

**Table 13.3** World Health Organization definitions of 'breast-feeding'<sup>12</sup>

<b>Breast-feeding</b>
Infant has received any breast milk, expressed or from breast
<b>Exclusive breast-feeding</b>
Infant has received only breast milk and no other liquids or solids except vitamin/mineral supplements and medicines
<b>Predominant breast-feeding</b>
Breast milk the predominant source of nourishment but other drinks (e.g. water, herbal drinks, teas, etc.) may have been given
<b>Full breast-feeding</b>
Exclusive or predominant breast-feeding
<b>Complementary feeding</b>
Infant has received breast milk and solid or semi-solid foods
<b>Bottle feeding</b>
Infant has received liquid or semi-solid food from a bottle with a teat

## ESTABLISHING AND MAINTAINING BREAST-FEEDING

### Breast milk production

Progesterone, prolactin and human placental lactogen induce hyperplasia and hypertrophy of the ducts and acini of the breast during pregnancy. By the second half of pregnancy the breast can secrete small amounts of milk. This preparatory growth period is termed 'lactogenesis stage 1'. At birth the inhibitory influence of maternal progesterone is removed and prolactin released in response to sucking drives milk synthesis. Thus infant demand regulates breast milk supply. Pregnancy is not an essential prerequisite and lactation can be induced to an extent after adoption by infant sucking ('*adoptive lactation*' or '*relactation*').

During the first 3–5 d of life the output of milk increases.<sup>12</sup> This period is termed 'lactogenesis stage 2'. Early milk ('colostrum') is rich in protein, particularly secretory immunoglobulin A. As the output rises protein and electrolyte content falls and carbohydrate and fat content increase. By the fifth day the breasts typically produce more milk than the infant chooses to take. When the breasts were presented in random order (left/right or right/left), 5-day-old babies took significantly less milk from the second breast than the first at a feed, confirming the breasts were not actually 'empty' and the baby chose to leave milk behind.

Other experiments show that the *yield* (or volume obtainable by expressing the breasts over a 24-hour period) usually exceeds the baby's *intake*. In one study it was 7% greater than average intake measured by test weighing and in another an average 'residual volume' of over 100 ml/d (range 0–457 ml/d) could be extracted from the breast in addition to normal intake. Regular pumping increases yield and an increment of 20% has been reported.

It is therefore hard to understand why mothers in the early weeks of life often believe they have 'insufficient milk'. They (and sometimes health professionals) probably fail to recognize differences in the feeding patterns of breast- and bottle-fed babies. Breast-fed babies feed frequently, particularly during the early weeks as production is rapidly increasing; this must not be interpreted as undersupply. The amount of time a baby spends sucking may not reflect the baby's intake as there is very pronounced variation between individual mother–baby pairs.

### Breast-feeding management

Important features of breast-feeding management are shown in [Table 13.4](#). Evidence supporting the 'Ten Steps' has been published<sup>14</sup> and supported by a more recent systematic review of interventions increasing duration of breast-feeding.<sup>15</sup> They form the basis for accrediting health care facilities as '*Baby Friendly*' (currently 53 accredited maternity

**Table 13.4** Steps that help to establish breast-feeding in hospital

Every facility providing maternity services and care for newborn infants should:
1. Have a written breast-feeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help mothers initiate breast-feeding as soon as possible after delivery.
5. Show mothers how to breast-feed and how to maintain lactation, even if they should be separated from their infants.
6. Give breast-fed newborn infants no food or drink unless medically indicated.
7. Practice rooming-in – allow mothers and infants to remain together 24 h a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or dummies (pacifiers) to breast-feeding infants.
10. Foster the establishment of breast-feeding support groups and refer mothers to them on discharge from the hospital.

Modified from WHO/UNICEF 1989<sup>54</sup>

hospitals and seven primary care facilities in the UK). The effectiveness of the 'Baby Friendly Hospital Initiative' in promoting initiation and maintenance of lactation has been confirmed in a cluster randomized trial performed in Belarus.<sup>5</sup> Babies born in Baby Friendly Hospitals were significantly more likely to be exclusively breast-fed at 3 months and 6 months; similar effects were seen in a randomized study in Brazil.<sup>16</sup> Scottish audit data have also shown that babies born in Baby Friendly Hospitals are more likely to be breast-fed at the end of the first week.<sup>17</sup> It is essential, however, that skilled support for breastfeeding mothers is provided in primary care once the mother has left hospital. There is evidence that *proactive* support is more effective than waiting for the mother to ask for help.<sup>15</sup>

### Early feeding, positioning and attachment

Babies should be given an opportunity to breast-feed as soon as possible after birth whilst alert and active. New mothers need to learn that babies do not always cry when hungry, but show signs such as rooting activity. Early feed supervision helps to facilitate correct *positioning* (i.e. baby's body facing mother's body) and *attachment*.

Understanding the mechanics of breast-feeding (Fig. 13.1)<sup>18</sup> helps to ensure correct *attachment* (relationship between baby's mouth and mother's breast). As the baby attaches the nipple and surrounding

Fig. 13.1 Mechanism of sucking. (From Woolridge 1986<sup>18</sup> with permission) The figure shows a complete 'suck' cycle; the baby is shown in median section. The baby exhibits good feeding technique with the nipple drawn well into the mouth, extending back to the junction of the hard and soft palate (the lactiferous sinuses are depicted within the teat though these cannot be visualized on scans). In ultrasound scans it appears that compression by the tongue, and negative pressure within the mouth, maintain the tongue in close conformation to the nipple and palate. Events are portrayed here rather more loosely to aid clarity.

breast tissue are drawn into the mouth, retained by suction; the nipple is thus elongated to about three times its former length. The lateral margins of the tongue curve upwards to enclose it in a cup formed by tongue and hard palate. Milk is then stripped by a peristaltic wave running anteroposteriorly along the tongue. In this way milk is ejected from the ducts under the positive pressure created by nipple compression; negative pressure retains the nipple in the mouth and draws milk into the stripped ducts. This process is frictionless and the nipple should not be traumatized if the baby attaches correctly.<sup>18</sup> The mechanics of breast- and bottle-feeding are different and many believe babies develop 'nipple confusion' if switched from one to the other (see later).

Incorrect attachment is a common cause of feeding problems.<sup>19</sup> The mother may complain that she has 'insufficient milk' because her baby seems fretful and hungry yet will not suck, or that the nipple is sore, even bleeding. Such symptoms should prompt observation of a feed to check the physical signs of correct attachment, which include:

- baby's chin touching breast;
- baby's lower lip turned out;
- mouth wide open;
- cheeks rounded, not drawn in;
- swallowing seen or heard;
- slow, rhythmical jaw movements with few pauses, not bursts of rapid sucking.

Doubts should prompt expert midwifery assessment of technique rather than resort to ineffective remedies such as creams, sprays or nipple shields. The last may even hinder milk flow. The midwifery skills required are outside the scope of this chapter.

### Supplementary feeds

Supplementary feeds of formula or water are unnecessary for healthy, term breast-fed babies. Supplementary water or dextrose feeds are of no value in neonatal jaundice. If anything they *increase* the incidence.<sup>20</sup>

Healthy breast-fed term babies do not require routine blood glucose monitoring. 'Symptomatic' hypoglycemia in a breast-feeding baby should never be attributed to starvation alone; there is likely to be an underlying illness such as infection. Simple supplementary feeding is not therefore the solution.<sup>21</sup>

In some cultures (e.g. south Asian) it is believed that colostrum is detrimental, and 'prelacteal' feeds (e.g. teas, or formula in the UK) are used. It is widely but erroneously believed that this practice has a religious basis; it is contrary, for example, to Islamic teaching and should be discouraged.<sup>22</sup>

### Demand feeding

Babies should be allowed to feed until satiated. Limiting sucking time does not reduce the incidence of nipple trauma, which is more likely to be attributable to poor attachment (see earlier). It is impossible to make rules about feed frequency because babies vary greatly. They may feed only a few times in the first 24 h, becoming more active and hungry on the second and third days.

The duration of a breast-feed bears little relationship to the amount consumed. Although a cross-sectional study suggested that, *on average*, 90% of the feed is consumed in the first 4 min, subsequent studies have shown pronounced interindividual variation. It is therefore impossible to formulate a rule applicable to all.

It is not necessary for babies to take both breasts at every feed. Babies can adjust milk intake to allow for variation in fat (i.e. energy) content. Babies extracted more hindmilk, thereby consuming more fat and maintaining a constant total daily energy intake, when mothers offered only one breast at each feed.<sup>23</sup> If the mother curtails feeding at the first breast to offer both routinely, there is a risk that the baby will consume excessive volumes of low-energy foremilk and lactose, producing explosive, watery stools and 'colic'.

### Maintaining lactation

Well babies should be with their mothers continuously ('rooming-in'; Table 13.4) in the postnatal period. All breast-feeding mothers should

be taught how to express milk by hand, though many prefer to use a pump. If so there is good evidence that pumping both breasts simultaneously (rather than sequentially), coupled with breast massage, increases yield.<sup>24</sup> A mother should express milk at least six times each day if separated from her baby, commencing as soon as possible after the birth. Expressed milk can be given by gavage, bottle or cup, the last being practicable for some babies of 30 weeks' gestation upwards. Cup feeding increases the chances of full breast-feeding at discharge, but may prolong hospital stay.<sup>25</sup>

## CONTRAINDICATIONS TO BREAST-FEEDING

There are few absolute contraindications to breast-feeding. Galactosemia is one, and disorders of long-chain fatty acid oxidation another, though with phenylketonuria it is usually possible to continue, supplementing with a low phenylalanine formula according to blood concentrations. Formula supplements may be prescribed in medium chain acyl co-A dehydrogenase deficiency to prevent fasting hypoglycemia during the establishment of lactation. Maternal infections such as hepatitis B and tuberculosis do not contraindicate breast-feeding though the baby should be immunized and treated with appropriate prophylaxis. Maternal hepatitis C infection does not contraindicate breast-feeding.<sup>26</sup>

## Human immunodeficiency virus (HIV) infection

In mothers infected antenatally the additional risk of vertical transmission attributable to breast-feeding has been estimated as about 15%, rising to about 30% if the mother is infected whilst breastfeeding. Mothers in the UK known to be HIV antibody positive and those at risk of infection are counseled not to breast-feed. In countries where the risk of malnutrition or infection associated with replacement feeding outweighs the risk of vertical transmission, mothers should be counseled about the risks and benefits, and given specific advice relevant to their circumstances.<sup>27</sup> This may encourage exclusive breastfeeding for the first 6 months with rapid weaning once safe complementary feeding has been established. Breast-feeding support is important as mastitis (including 'subclinical mastitis') significantly increases transmission risk.

## Drugs in breast milk

Very few maternal drugs preclude breast-feeding; the decision should be based upon the toxicity of the drug, the quantity that the infant is likely to ingest, and the capacity of the infant to detoxify or excrete. Specific guidance is available from regularly updated texts.<sup>28</sup> The balance of benefit and risk must be considered; highly toxic drugs such as anti-mitotic agents and some retinoids contraindicate breast-feeding even though the amount ingested may be small. The quantity of a drug passed into milk may be measured or estimated from its lipid solubility and pKa. The more ionized the drug at milk pH 7.2 the less likely it is to pass into milk: thus drugs with higher pKa are generally safer. Helpful general guidance is to choose drugs with a shorter half-life and advise that they be taken immediately after a feed: as milk and plasma concentrations are in equilibrium, peak milk concentration will have declined by the next feed.<sup>28</sup>

## GROWTH OF BREAST-FED BABIES

Historical growth references such as those of the National Center for Health Statistics (NCHS) and Tanner did not describe accurately the growth of breast-fed infants. In both industrialized and developing countries breast-fed babies grow rapidly in the first 2 months by comparison with those formula-fed, slowing thereafter.<sup>29</sup> Thus charts displayed an apparent slowing of weight velocity, once described as 'growth faltering' of the breast-fed baby and speculatively attributed to energy deficiency.<sup>30</sup> Likewise there was an appearance of rapid early weight gain, which should not be interpreted as 'overfeeding'. These deviations from charts reflected choice of an inappropriate reference population, not suboptimal growth patterns.

The UK 1990 growth reference may better reflect the growth of breast-fed babies, particularly a chart based on the growth of a subset

of Cambridge breast-fed babies.<sup>31</sup> A reference based on the growth of healthy babies in six countries born at term to nonsmoking mothers with uncomplicated pregnancies and fed according to World Health Organization recommendations has recently been published.<sup>32</sup> The mean birthweight of this multi-country population was lower than that of babies born in the UK but the charts indicate, as expected, that breast-fed babies are in general heavier in the first 6 months and lighter in the second with respect to the existing UK reference. Differences in length and stature are less marked, but those in weight persist into later childhood.

## COMPLEMENTARY FEEDING OF BREAST-FED BABIES

Following systematic review of the evidence, the World Health Organization recently recommended exclusive breast-feeding for the first 6 months of life, with introduction of complementary foods and continued breast-feeding thereafter. By comparison with babies fed exclusively for the first 4 months of life, those exclusively fed for 6 months experienced less diarrheal disease. Maternal postpartum weight loss and duration of lactational amenorrhea were also increased.<sup>33</sup> There have been few randomized studies of the appropriate timing of complementary feeding among breast-fed babies. One in Honduras showed that total daily energy intake and growth rate were comparable in early and late-weaned infants, though breast milk intake simply fell in those given solid food intake earlier.<sup>34</sup> There remains a need to examine the effect of energy density of weaning diets on this relationship.

In England the Department of Health recommends exclusive breast-feeding for the first 6 months with introduction of complementary foods and continued breast-feeding thereafter.<sup>35</sup> This is a population recommendation, within which there may be subgroups (such as those of low birth weight) at potential risk of iron or trace mineral deficiency resulting from low stores at birth. As such it is not a rule to be applied inflexibly to all individuals, but guidance. Differences in the social and cultural preferences of mothers mean that complementary foods are introduced for many reasons, for example the need to return to work.

## SUPPLEMENTS FOR BREAST-FED BABIES

### Vitamin K

Deficiency of vitamin K may result in hemorrhagic disease of the newborn (HDN) (see Chapter 12, Hematologic problems of the newborn). Human milk contains less vitamin K than cows' milk or formula (Tables 13.5 and 13.6) and supplementation from birth has long been recommended. An i.m. injection of vitamin K (1 mg phytomenadione) offers effective prophylaxis but was associated in one study with an increased incidence of childhood malignancy. Although several other studies have not confirmed this association, some parents still prefer oral supplementation. In England the Department of Health recommends that parents are offered this choice, and an information leaflet is available. A preparation licensed for oral administration to healthy term babies (Konakion MM Paediatric, Roche) is now available. It may be given parenterally (i.m./i.v.) to preterm babies or to those with other risk factors (for example instrumental delivery, mother taking anticonvulsants). Some ill babies (for example those with liver disease, malabsorption or on prolonged broad-spectrum antibiotic therapy) require continued supplementation in higher doses. An oral dose (2 mg) given at birth will need to be repeated: the datasheet advises a second 2 mg dose at 4–7 d and further monthly doses during the period of exclusive breast-feeding. Alternative schedules have been recommended but there are no comparative data on safety or efficacy as randomized trials of oral and parenteral dosage have not been performed.<sup>36</sup>

### Vitamin D

Young babies meet their vitamin D requirements from stores at birth and sunshine exposure but nutritional rickets is seen in the UK, apparently with increasing frequency. It is associated with late introduction of complementary foods, Asian or black ethnic minority origin, and

iron deficiency.<sup>37</sup> A high proportion of young children (between 20 and 35% in a national study of Asian infants and toddlers) have low plasma 25-OH-vitamin D concentrations, particularly during the winter.<sup>38</sup> Preventing rickets requires action before and after birth; a reference nutrient intake (RNI) of 10 mcg/d is set for pregnant and breast-feeding women in the UK, yet very few take a supplement and a high proportion of pregnant women from minority ethnic groups show biochemical evidence of severe deficiency.<sup>39</sup> Breast-fed babies should be given a supplement of 280 iu (7 mcg/d) from 6 months onwards, or from about 2 months in groups at increased risk by virtue of ethnic origins or culture. Other babies should commence vitamin D supplements when no longer receiving fortified infant formula, usually from about 12 months of age. In the USA supplementation with 200 iu/d (5 mcg) vitamin D should start before 2 months of age in all breast-fed babies and in those consuming less than 500 ml formula per day.<sup>40</sup>

**Iron**

Breast milk contains little iron though bioavailability is high. Birth stores are the principal source in young infants. Thus breast-fed babies do not require iron supplements unless additional risk factors are present, such as low birth weight. There may be adverse effects of iron supplements in babies who do not need them. In one study weight gain was impaired<sup>41</sup> and there are other concerns where malaria is endemic.<sup>42</sup> Moreover iron, copper and zinc compete for absorption, so other trace mineral deficiencies (particularly zinc) might be precipitated.

**Water**

Breast-fed babies do not need supplementary water: the solute load (vide infra) of breast milk is low enough to permit free water availability even in tropical climates.

**INADEQUATE MILK PRODUCTION**

Physiological failure of milk supply is rare. Faulty breast-feeding technique usually underlies slow weight gain and expert breastfeeding support is essential. Assessment of the adequacy of breastfeeding should not be made on weight alone. Frequency of feeding, frequency and amount of stools and urine should also be established. A history of early feeding difficulty or nipple pain may be obtained, the baby eventually becoming undemanding. Breast engorgement or mastitis may have occurred, again indicating ineffective drainage. Physical illness in the baby needs to be excluded, particularly if change has been sudden.

Attention to technique and increasing the frequency of feeds, sometimes combined with expression may increase supply. There is no evidence that metoclopramide, domperidone or other galactogogues offer additional benefit.

Test weighing underestimates intake. Electronic scales improve weighing precision but may still undermine the mother's confidence and raise problems of interpretation. Firstly, test weighing must last at least 48 h to take account of day-to-day and circadian variation. Secondly, the range of normal is very wide and the baby's milk consumption less than the mother's potential yield; the intake of one group of 3-month-old babies varied from 523–1124 g/d but, on average, a further 100 g could be obtained by expression. Finally, the baby's energy intake cannot be derived from weighed milk intake as the fat content of breast milk varies, tending to be inversely proportional to the volume of milk consumed. Test weighing therefore has little clinical value. Observation of breast-feeding technique (p. 369) and referral to a competent breastfeeding supporter is more likely to help.

**BREAST MILK SUBSTITUTES**

If a mother cannot breastfeed, or chooses not to, a replacement feed is required. The term '*breast milk substitute*' describes 'any food marketed or otherwise represented as a partial or total replacement for breast milk, whether or not suitable for the purpose.' '*Infant formula*' is a breast milk substitute formulated in accordance with Codex Alimentarius standards

and the replacement feed of choice where feasible. In Europe '*infant formula*' is legally defined as 'a product that by itself meets the nutritional requirements of normal healthy infants in the first 6 months of life'. Its composition is determined by European and UK legislation. '*Follow-on formula*' is intended for normal healthy infants over 6 months of age as 'the principal liquid element in a progressively diversified diet'. It is not legally required to meet by itself the infant's nutritional needs.

Unmodified milks from cows, sheep, goats and other animals are unsuitable for infants. Amongst other things they generate a high *renal solute load*, have inappropriate calcium:phosphorus ratios, and are low in iron and other micronutrients. Historically the composition of human milk has guided the nutrient content of infant formula, except where significant differences in bioavailability exist (e.g. iron and protein [see later]). More recently it has been proposed that innovations should also strive to approximate health outcomes characteristic of the healthy breast-fed infant. This reflects appreciation of the superiority of human milk and its molecular complexity, and the development of novel processes (such as recombinant DNA technology) to manufacture human milk constituents. Adequately controlled studies must document both the efficacy and safety of such developments.<sup>43</sup>

**COMPOSITION OF HUMAN MILK**

The composition of expressed human milk has been extensively studied. Table 13.5 shows the composition of mature human milk expressed by UK mothers.<sup>44</sup> It is worth noting briefly some factors that affect milk composition and important qualitative nutritional differences between human milk and formula.

**Table 13.5** Composition of mature human milk

Total nitrogen	2.1 g/L
Protein	10.7 g/L
Casein	41% of total protein
α-lactalbumin	28% of total protein
Lactoferrin	14% of total protein
Serum albumin	2% of total protein
Lysozyme	1% of total protein
Secretory IgA	14% of total protein
Nonprotein nitrogen	0.4 g/L
Fat	42 g/L
Cholesterol	0.42 mmol/L
Carbohydrate	74 g/L
Total energy	700 kcal/L
Sodium (23)	6.5 mmol/L
Potassium (39)	15.4 mmol/L
Calcium (40)	8.8 mmol/L
Magnesium (24)	1.2 mmol/L
Phosphorus (31)	4.8 mmol/L
Chloride (35)	12.3 mmol/L
Iron (56)	13.6 μmol/L
Copper (64)	6 μmol/L
Zinc (65)	45 μmol/L
Vitamin A (retinol)	600 μg/L
Vitamin D	0.1 μg/L
Vitamin E	3500 μg/L
Vitamin K	15 μg/L
Thiamin (B <sub>1</sub> )	160 μg/L
Riboflavin (B <sub>2</sub> )	310 μg/L
Nicotinic acid	2300 μg/L
Pyridoxine (B <sub>6</sub> )	59 μg/L
Vitamin B <sub>12</sub>	0.1 μg/L
Folic acid	52 μg/L
Pantothenic acid	2600 μg/L
Biotin	7.6 μg/L
Vitamin C	38 mg/L

After DHSS 1977.<sup>55</sup> Atomic weights of minerals in parentheses.

## Factors affecting milk composition

### *Gestation of baby*

The milk of mothers delivering prematurely tends to be higher in protein and sodium content but lower in lactose. Differences can be partly explained by reduced milk output, but serum leakage due to immaturity of mammary epithelial integrity might also be relevant.

### Maternal diet and nutritional state

The effect of energy intake on the output and macronutrient content of breast milk has been overstated. Milk production is relatively unaffected by maternal body mass index (BMI). The fat content does, however, reflect qualitatively the amount and type of fat the mother consumes in her diet and her body stores.

### *Stage of lactation*

Stage of lactation affects all milk constituents. Early milk is arbitrarily classified as *colostrum* (0–5 d) or *transitional* milk (5–10 d). Thereafter it is termed *mature*. Protein concentration changes greatly in the early stages. The immunoglobulin content of colostrum falls about 50-fold in the first week but total output of immunoglobulin A changes little because the milk output increases. Sodium concentration similarly falls in early lactation as the lactose concentration rises. Amongst the micro-nutrients, iron and copper concentrations fall slowly during lactation but zinc drops about 10-fold over a year. The changes in protein, lactose and sodium content reverse at weaning so that colostrum, weaning milk and 'preterm milk' show similarity in composition.

### *Changes within a feed*

Fat concentration changes most, more than doubling during a feed. This may be a simple physical effect as it can to an extent be mimicked by squeezing milk from a sponge.

### *Time of day*

Fat concentration shows most change and is related to the interval since the last feed: the longer it is, the lower the foremilk fat. Variation in nursing patterns affects circadian changes in fat concentration for this reason.

### *Protein and nonprotein nitrogen*

Estimates of human milk protein concentration vary between 0.8 and 1.3 g/d for methodological reasons. The *crude protein* content is total nitrogen (g)  $\times$  6.38. It is higher than the true figure as 25% of total nitrogen is *nonprotein nitrogen*. Some of this, including urea, is incorporated into body protein together with the principal nutritional proteins, alpha-lactalbumin and casein. Many milk proteins (e.g. secretory immunoglobulin A, lactoferrin) have important functions other than nutrient provision; they can be recovered from the stool though digestibility increases with age. The differing digestibility of human and cows' milk proteins partly explains why the crude protein content of infant formula does not equate with that of human milk.

A further reason is the difference in *protein quality*, i.e. the relative match between the amino acid content of dietary protein and the requirement for growth and metabolism. Protein quality can be expressed numerically either by essential 'amino acid score' or 'net protein utilization', the proportion of ingested protein that is retained. Human milk is used as a reference protein in both cases, e.g. by regulating an infant formula must be based on soya or cows' milk protein. The latter has broadly two classes: whey (or acid-soluble) proteins and caseins (acid-precipitable curd). As whey and casein differ in amino acid composition the quality of cows' milk protein can be manipulated by changing the whey:casein ratio from 20:80 to 60:40. Such formulae are known as *whey dominant*. The claim that casein dominant formula 'satisfies hungry babies' has no justification, though UK babies commonly change to it within the first 6 weeks.<sup>1</sup>

The plasma amino acid concentrations of babies fed formulas containing 1.25 or 1.3 g/100 ml cows' milk protein as opposed to

the usual 1.5–2.0 g/dl (Table 13.6) more closely approximate those of breast-fed babies. The whey:casein ratio also has less effect at these intakes. Thus the protein content of current formulae might be higher than necessary. It is possible that the higher protein intake of formula-fed babies explains the differences in growth and body composition observed during infancy. However breast-fed babies also self-regulate energy intake at lower levels, and have lower levels of energy expenditure.

### *Fat*

Breast milk contains long- (LCT) and medium-chain triglycerides (MCT). In recent years it has been speculated that provision of the polyunsaturated fatty acid (PUFA) precursors linoleic (C<sub>18</sub>–20:6) and linolenic acid (C<sub>18</sub>–3:3) in formula is insufficient to meet the demands of the growing nervous system for the long-chain polyunsaturated fatty acid (LCPUFA) docosahexaenoic acid (C<sub>22</sub>–6:3) but there is no conclusive evidence that the addition of LCPUFAs to formula is of significant short- or long-term health benefit for term infants.<sup>45</sup>

### *Iron*

Cows' milk contains less iron than human milk and, furthermore, cows' milk iron is less bioavailable. Formulae are therefore enriched with iron salts. Formulae sold in the USA vary widely in iron content; so-called 'regular' formula contains 1 mg/L iron whereas 'iron-fortified' formulae contain > 10 mg/L. A US randomized trial showed superior iron status and psychomotor development among infants fed 'iron-fortified' formula.<sup>46</sup> Formulas sold in the UK contain 5–7 mg/L iron and it is not possible to extrapolate the results of the US study to UK practice. If the mother is not breast-feeding, continued use of infant formula to at least 12 months of age is important in building iron stores and preventing iron deficiency in the toddler years. 'Follow-on' formulas offer no advantage over infant formulas in this respect, though either is preferable to cows' milk.

## MANUFACTURE OF INFANT FORMULA

Manufacture of infant formula in simple terms changes the composition of cows' milk (Table 13.6) as follows:

1. The protein and electrolyte content of cows' milk (see 'solute load' later) are reduced.
2. The whey:casein blend may be altered to improve protein quality and digestibility.
3. The calcium and phosphorus content is reduced and the Ca:P ratio altered.
4. The carbohydrate content is increased by addition of lactose or maltodextrins (glucose polymers).
5. The fat blend is changed using vegetable oil to reduce saturated fat intake and increase intake of polyunsaturated fat, thus improving fat absorption.
6. Trace minerals are added, particularly iron and copper.
7. Vitamins are added.

### 'RENAL SOLUTE LOAD'

Both glomerular filtration rate and tubular concentrating power are reduced in the newborn (Ch. 12, Special care – sodium and potassium), limiting the clearance and elimination of solute surplus to growth demands. The *potential renal solute load* (PRSL) of a feed is the amount of solute that would need to be excreted in urine if none were deposited in new tissue or excreted through nonrenal routes.<sup>47</sup> It can be calculated by summing the expected urea production from protein oxidation (approximately 4 mosmol/g protein), sodium, potassium, phosphorus and chloride content. Note that the true renal solute load (RSL) presenting to the kidneys is normally lower than PRSL because a variable proportion of dietary solute, relatively high in the case of human milk, is deposited in new tissue during growth. RSL can be estimated by subtracting from PRSL an amount given by  $0.9 \times$  weight gain (in grams per day).

Table 13.6 Composition of cow's milk and infant formula in europe

	Cow's milk	Units	Infant formula		Units
			Minimum	Maximum	
Energy			60	75	kcal/100 ml
Protein	33	g/L	1.8	3	g/100 kcal
Carbohydrate	48	g/L	7	14	g/100 kcal
Fat	38	g/L	4.4	6.5	g/100 kcal
Linoleic acid			300	1200	mg/100 kcal
Linolenic acid			50		
Sodium	59 (35–90)	mg/dl	20	60	mg/100 kcal
Potassium	150 (110–170)	mg/dl	60	145	mg/100 kcal
Chloride	95 (90–110)	mg/dl	50	125	mg/100 kcal
Calcium	120 (110–130)	mg/dl	50	#	mg/100 kcal
Phosphorus	95 (90–100)	mg/dl	25	90	mg/100 kcal
Ca:P ratio	1.2:1		1.2	2	
Magnesium	12 (9–14)	mg/dl	5	15	mg/100 kcal
Iron	50 (30–60)	µg/dl	0.5	1.5	mg/100 kcal
Zinc	350 (200–600)	µg/dl	0.5	1.5	mg/100 kcal
Copper	20 (10–60)	µg/dl	20	80	µg/100 kcal
Vitamin A	31 (27–36)	µg/dl	60	180	µg RE /100 kcal
Vitamin D	0.02	µg/dl	1	2.5	µg/100 kcal
Vitamin E (a tocopherol)	0.09	mg/dl	0.5	#	mg/g of polyunsaturated fatty acid
Vitamin K	1–8.5	µg/dl	4	#	µg/100 kcal
Vitamin C	2	mg/dl	8	8	mg/100 kcal
Thiamine	40 (30–60)	µg/dl	40	#	µg/100 kcal
Riboflavin	190 (150–230)	µg/dl	60	#	µg/100 kcal
Nicotinamide	80 (60–130)	µg/dl	0.8	#	mg/100 kcal
Pyridoxine	40 (21–72)	µg/dl	35	#	µg/100 kcal
Vitamin B <sub>12</sub>	0.3	µg/dl	0.1	#	µg/100 kcal
Pantothenic acid	0.35 (0.2–0.5)	µg/dl	300	#	µg/100 kcal
Biotin	2 (1.0–1.3)	µg/dl	1.5	#	µg /100 kcal
Folic acid	5	µg/dl	4	#	µg /100 kcal

†Data from DHSS 1980;<sup>46</sup> \*Infant formula regulations 1995;<sup>47</sup> # no value stated.

Human milk has a PRSL of 93 mosmol/L and unmodified cows' milk 308 mosmol/L. A nongrowing infant with maximal tubular concentrating power of 600 mosmol/L of urine would therefore require at least 513 (or 308/600 × 1000) ml of water to eliminate the solute load generated by 1 L of cows' milk. This explains why infants fed unmodified cow's milk may become hypernatremic. During illness a high nonrenal water loss caused by diarrhea or fever may particularly constrain water available for solute excretion. Energy density also has a bearing on solute load because it affects milk intake, and thus water available for urine formation.

**MILK CONSUMPTION**

The intake of both breast- and bottle-fed babies is extremely variable and the oft-quoted 'requirement' of 150 ml/kg/d merely a guideline. The intakes of healthy American formula-fed infants 0–2 months old fed ad libitum were 169 ± 25 (1 standard deviation [SD]) ml/kg/d (boys) and 157 ± 22 ml/kg/d (girls).<sup>48</sup> Similarly, although the average breast milk intake of 3-month-old infants is 700–800 ml/d, there is approximately 100% difference between the extremes.

Consequently the 'normal' milk intake for an individual infant cannot be predicted. Acceptable intake is reflected in satisfactory growth. If the baby is not growing, the baby should be fed ad libitum or intake increased to the upper end of the normal range (mean + 2 SD) before seeking other causes.

**SOYA FORMULA AND OTHER MILKS**

Soya formula is unsuitable for the prophylaxis or treatment of cows' milk protein allergy because cross-sensitivity to soya protein occurs in

15–43% of affected children. A formula based on cows' milk protein hydrolysate is preferable both in proven cows' milk protein intolerance (CMPI) and post gastroenteritis lactose intolerance because CMPI often coexists. Concern about the very high phytoestrogen content of soya formula underpins Department of Health advice that soya formulas should not be used. However they have advantages in the management of galactosemia (Ch. 26) because they are lactose free and more palatable than alternatives.

**COMPLEMENTARY FEEDING – 'WEANING'**

The term 'weaning' is commonly used to describe the gradual introduction of foods (or 'solids') other than breast milk or formula, though it more correctly describes a reduction in the number of breast-feeds. The phrase 'complementary feeding' is therefore preferred, to indicate the important role played by continued breast-feeding.

Nutritionally, complementary feeding increases the energy, vitamin and mineral (especially iron) density of the diet as demands outstrip milk supply. However it should be considered in the wider context of development because it encourages tongue and jaw movements in preparation for speech, introduces new tastes and textures, and increases social interaction with carers. It is important that complementary feeding is paced to accord with developmental changes in gross, fine motor and oral motor function. Infants must not be 'pushed' if later behavioral eating problems are to be avoided.

By custom most British mothers have commenced complementary feeding by offering relatively bland (unseasoned), single ingredient foods (such as thinly puréed rice, fruit or vegetables) once- or twice-daily from a spoon after breast-feeds. As the spoon is accepted, thicker purées may be offered, with progression to lumps and small finger foods as fine motor skills progress. Such an approach may be less appropriate for infants

Table 13.7 Suggestions for vegetarian weaning diets. After Poskitt<sup>49</sup>

Nutrient	Problem	Solution
Energy	Energy density reduced by water absorption and fiber content. Most fruit low in energy	Use oils in cooking and spreading fats on food. Cereals, pulses, bananas and avocados are energy dense
Protein	Quality variable	Mix complementary food groups to achieve balanced intake, i.e. milk (dairy), legumes, grains, green vegetables
Vitamins	Low B <sub>12</sub> , D and riboflavin	Use eggs, vitamin D-supplemented margarine or fish oils (if permissible). Consider oral B <sub>12</sub> supplement
Minerals	Phytates reduce availability (especially of iron). Zinc and calcium intakes may be low	Green leaf vegetables rich in iron. Vitamin C increases uptake. Dairy products important as calcium/zinc source

weaned from 6 months in line with current advice. Oral and manual manipulative skills are more dexterous at this age, suggesting that dietary texture might be more rapidly advanced. However the acceptability of alternative regimens has not been systematically studied. By about 1 year of age the infant should be receiving (chopped) family foods at about three main meals with intervening snacks. Breast milk should remain the principal source of fluid, though formula (in amounts of no more than 500–600 ml/d) may now be replaced by pasteurized whole cows' milk.

## WEANING PROBLEMS

### Vegetarian and ethnic minority diets

Certain minority ethnic groups (e.g. vegans, Rastafarians) have limited choice of weaning foods threatening protein quality, zinc, iron and vitamin B<sub>12</sub> intake. Phytates may reduce mineral availability (especially calcium and iron) and increase dietary bulk, compromising energy intake. Suggestions for a suitable vegetarian weaning diet are summarized in Table 13.7.<sup>49</sup>

Asian babies in the UK, particularly those of Bangladeshi and Pakistani background, tend to be weaned later than Caucasian ones.<sup>50</sup> They are more likely to be breast-fed initially, but also more likely to receive cows' milk in the first year of life, often with complementary foods such as rusk added to the feeding bottle. Amongst children of Indian background 38% of 9-month-olds in a national survey had never eaten meat, which may help to explain the higher incidence of iron deficiency anemia. Early supplementation with vitamin D, coupled with supplementation for the mother during pregnancy and breast-feeding is also important (vide supra). Although more Asian mothers (> 50% at 9 months) than Caucasian ones (20%) give vitamins,<sup>50</sup> there is room for improvement. There has been no national study of black, Afro-Caribbean babies in the UK but they are likely to be at increased risk of vitamin D deficiency also, particularly if Rastafarian.

## VITAMIN SUPPLEMENTS

Formula is fortified with vitamins, and supplementation is unnecessary until cows' milk is introduced at about 1 year of age. Breast-fed babies

should receive vitamin supplements (e.g. *Abidec*<sup>™</sup>, *Dalavit*<sup>™</sup>) from 6 months of age or in some cases earlier (vide supra). Vitamin supplements should be continued until at least 2 years of age, and preferably until the age of 5. Under the *Healthy Start* scheme (which has recently replaced the Welfare Food Scheme<sup>51</sup> in the UK), parents on income support can obtain vitamin supplements free of charge until their child is 4 years old.

## DENTAL HEALTH

Caries in pre-school children is strongly linked to socioeconomic status; by the age of 5 years children living in the most deprived areas have three times more caries than those in the most affluent areas. Fluoridation of the water supply is an effective public health measure but fluoride supplements (other than toothpaste) should only be used on an individual basis as prescribed by a dentist. Brushing after drinking or eating should commence with emergence of the first teeth, using a smear of fluoridated toothpaste. Excessive dosing may cause enamel mottling. Drinks containing nonmilk extrinsic sugars (including natural juices) should be avoided, especially between meals, and water or milk given instead. Using a cup from about 6 months also helps to prevent caries; infants must never be left unsupervised or left to sleep with a bottle or feeder cup.<sup>52</sup>

## DRINKS AND WATER

Boiled tap water is sufficient, if required, for formula-fed babies under 6 months of age. Flavored drinks are unnecessary. Natural mineral water, or water drawn through a domestic softener may be of unsuitable electrolyte content and should not be given to babies. Displacement of milk with flavored drinks during weaning is a common cause of failure to thrive; it is important to ensure that adequate milk intake (breast-feeds or about 500–600 ml formula) is maintained.

## PASTEURIZED COWS' MILK

Pasteurized whole cows' milk should not be given to infants under 1 year of age (see Ch. 16) and semi-skimmed milk should be avoided in children under 2 years. Other milk products, such as cheese and yoghurt, may be used from 6 months onwards.

### INTRODUCTION

There has been an exponential increase in the understanding of human genetics and it would not be possible to discuss all genetic disorders in children, so the purpose of this chapter is to present some of the basic concepts of genetics in relation to pediatric practice.

Traditionally diseases were divided into those due to ‘nature’ and those due to ‘nurture’ but it is more fruitful to consider human disease as a spectrum from those conditions like Duchenne muscular dystrophy and Down syndrome, which are purely genetic, through to those which are purely environmental such as scurvy and tuberculosis (Fig. 14.1).<sup>1,2</sup> Between the two extremes are many common diseases like diabetes mellitus, ischemic heart disease and congenital malformations in which both genetic and environmental factors are involved. Such conditions may be referred to as multifactorial. Disorders at the genetic end of the spectrum are due either to changes in a single gene or to visible changes in the chromosomes.

### EPIDEMIOLOGY

The frequency of genetic disorders has not increased, but they have become relatively more important with the decline in mortality from infectious diseases and the rapidly increasing knowledge of medical genetics. The number of human chromosomes was only established in 1956 and since then our knowledge of genetics has advanced at an exponential rate with the first draft of the human genome being completed in 2001. Prenatal diagnosis has offered the opportunity of preventing an increasing number of serious handicaps, and the developments in DNA technology have meant that many of the genes that predispose to common adult disorders such as heart disease and cancer have now been identified and play a role in identifying predisposition and developing strategies for the prevention of these disorders.

Genetic disorders are a major component in childhood mortality with up to half of childhood deaths in hospital having a genetic or partly genetic cause. In addition to mortality, genetic disorders produce a substantial morbidity. They often require frequent hospital admissions

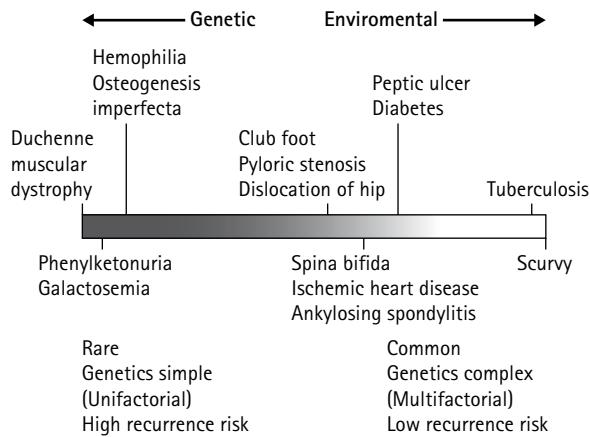

Fig. 14.1 Human disease may be seen as being on a spectrum from those diseases which are exclusively genetic to those which are exclusively environmental. (From Emery & Mueller 1988'.)

or complex surgery and the incidence of genetic or partially genetic disease amongst pediatric inpatients has been found to be between 11 and 27%.<sup>3</sup> It should also be noted that many chronic genetic disorders may place a considerable financial strain on health resources.

In the field of intellectual disability the genetic contribution is even greater. Chromosome abnormalities are the most significant cause and with newer chromosome techniques coming into diagnostic testing the proportion of intellectual disability due to visible chromosome abnormalities or microdeletions will increase. There is also an increasing number of X-linked forms of intellectual disability in which genes are being identified and these may account for the excess of males affected.

The same situation applies in visual handicap and profound childhood deafness. In previous generations retrolental fibroplasia and ophthalmia neonatorum contributed significantly to childhood blindness but the frequency of these disorders is declining with improved medical care. One survey<sup>4</sup> conducted in a national school for children who are registered blind has shown that about 50% of childhood blindness has a genetic basis and that this is largely due to single gene disorders (Table 14.1).<sup>3</sup> In studies on congenital sensorineural deafness around 50% has been attributed to genetic factors and over half of these are due to autosomal recessive genes (Fig. 14.2).

Even before birth, chromosome abnormalities are a major cause of fetal wastage with between 15 and 30% of all human conceptions having an abnormal karyotype and being spontaneously aborted or failing to implant.

The overall incidence of genetic disorders is roughly comparable in different parts of the world, but the frequency of specific disorders may vary for reasons such as inbreeding, selective advantage and genetic isolation.<sup>2</sup> The frequency of malaria since carriers of sickle cell disease mirrors the frequency of malaria since carriers of sickle cell trait have a greater resistance to *Plasmodium falciparum* malaria. This frequency has taken many generations to develop from a relatively small selective advantage and will remain in those racial groups for a very considerable

Table 14.1 99 Children in blind school, Edinburgh (1988). (Modified from Philips et al 1987')

Genetic = 50%	Nongenetic = 50%
Congenital cataract	Birth asphyxia
Anophthalmos	Optic nerve hypoplasia
Leber's amaurosis	Cortical blindness
Laurence - Moon - Biedl	Retrolental fibroplasia
Retinitis pigmentosa	Hydrocephalus
Retinal dystrophy	Non-accidental injury

Fig. 14.2 Etiology of deafness. AD, autosomal dominant; AR, autosomal recessive.

Table 14.2 Racial and geographic differences in the frequency of genetic disease

Disease	Racial/geographic group	Birth incidence
Sickle cell disease	African	1 in 50
Thalassemia	Mediterranean	1 in 100
Oculocutaneous albinism	Hopi Indians	1 in 250
	N. Europeans	1 in 40 000
Congenital adrenal hyperplasia	Yupik Eskimos	1 in 500
	N. Europeans	1 in 10 000
Cystic fibrosis	N. Europeans	1 in 2000
	Oriental	Very rare
Tay-Sachs disease	Ashkenazi Jews	1 in 3600
Neural tube defects	N. Ireland	1 in 300
Ellis-van Creveld syndrome	Amish	1 in 200
	N. European	1 in 60 000

number of generations even after they have moved to countries without malaria. Cystic fibrosis is one of the most frequent single gene disorders in Western Europe, and although this is probably attributable to a selective advantage in gene carriers, the mechanism has yet to be demonstrated. For other recessive disorders in small isolated communities the frequency of affected children may be increased by inbreeding, e.g. oculocutaneous albinism in the Hopi Indians, congenital adrenal hyperplasia in the Yupik Eskimos and Ellis-van Creveld syndrome in the Amish community (Table 14.2). It should be noted that genetic disease may pose a major health problem even in resource limited countries where infections are still a major cause of childhood deaths, e.g. in Thailand up to 500 000 children suffer from variable degrees of chronic ill health due to the interaction of different thalassemia genes.

## MITOSIS AND MEIOSIS

Chromosomes are the means whereby the genes are transmitted from one cell generation to the next. This transmission of genetic information must be precise and accurate and is achieved via one of the two mechanisms of cell division, either mitosis which is the division of somatic cells resulting in the growth of specific organs or the overall body, or meiosis which is the specialized cell division resulting in gamete formation and may be referred to as 'reduction division' since it involves the reduction

of the original *diploid* (2n) complement of 46 chromosomes to the *haploid* (n) complement of 23 chromosomes.

### MITOSIS: CELL DIVISION

Somatic cell division is a cyclical procedure, the length of the total cycle varying from organism to organism and between cell types. Essentially the cell cycle can be divided into a number of steps. During the resting or *interphase* stage the chromosomes are not visible other than as a mass of chromatin. At *metaphase* the chromosomes are maximally contracted with two sister chromatids held together at the centromere and aligned along the equatorial plate of the cell. At this stage the chromosomes can be visualized and examined under the microscope. The chromatids are then separated by the 'spindle apparatus' to opposite ends of the cell, where they are included in separate daughter nuclei (*telophase*). The products of mitotic division, therefore, are two daughter cells identical in all respects with the parent cell from which they have arisen.

### MEIOSIS: PRODUCTION OF GAMETES

Meiosis comprises a reduction of the diploid chromosome number (46) to a haploid chromosome number (23) through two successive nuclear divisions. In the early stages the homologous chromosomes pair closely with one another, and exchange segments of genetic material in a process known as *meiotic recombination* (Fig. 14.3). This recombination ensures the individuality of the offspring in much the same way as shuffling a pack of cards in each game ensures that the players will receive a different combination of cards. After recombination the paired chromosomes separate and eventually two daughter chromosomes of differing genetic constitution from each parent are formed (*metaphase I*). The second stage is a straightforward mitotic division in which the centromeres of the daughter chromosomes divide and their attached chromatids travel to opposite cell poles.

The outcome of this two-stage division process is a quartet of nuclei, each with half (n) the original number (2n) of chromosomes, and with new combinations of parental genes.

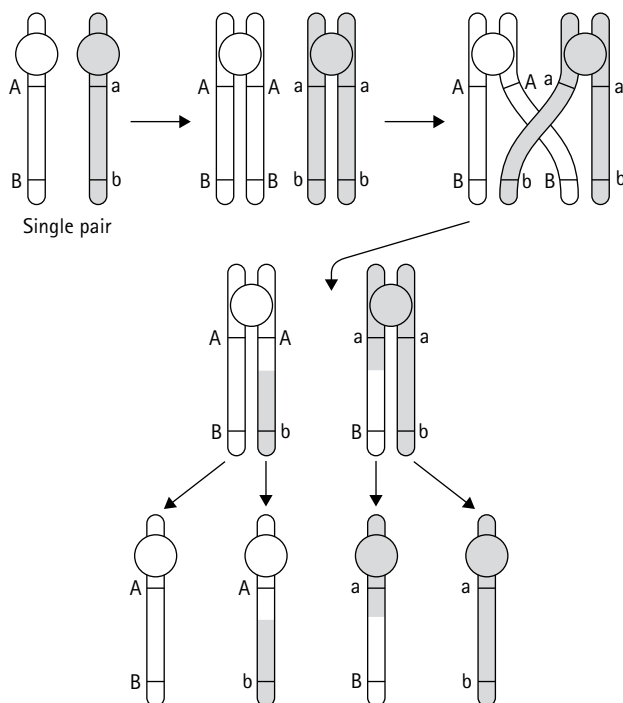

Fig. 14.3 'Crossing over' – the exchange of genetic material between homologous chromosomes.

### Spermatogenesis and oogenesis

The basic pattern of chromosome behavior is the same during meiosis in both male and female gametogenesis, but there are differences in timing of the various stages. Spermatogenesis begins around puberty and continues throughout life, with spermatozoa produced by continuing meiotic division of primary spermatocytes. On the other hand, oogenesis commences in intrauterine life but is arrested at a very early stage in meiosis I, with completion of the cycle only when ovulation occurs, anything up to 50 years later.

Spermatogenesis and oogenesis also differ in that, while the former gives rise ultimately to four functional sperm, the latter normally yields only a single functional ovum, with the other three products of the division process forming 'polar bodies', each with its haploid chromosome constitution, but with only a relatively small amount of cytoplasm. The polar bodies are nonfunctional and do not contribute to the future offspring.

### CHROMOSOMES

#### PREPARATION OF BLOOD CHROMOSOMES

The original demonstration that there are 46 chromosomes in the human cell was made using fibroblast cultures from fetal lung.<sup>5</sup> In routine clinical practice, however, it is human lymphocytes that are used for the standard chromosome analysis since a blood sample is convenient to obtain and relatively easy to prepare.

The standard preparation of chromosomes from a blood sample is illustrated in Figure 14.4. The first stage of the process (i) is to separate the white cells from the rest of the blood sample. This is done by centrifugation using a medium such as Ficoll, which leaves the lymphocytes in a buffy coat at the top of the tube. The second stage (ii) is to cultivate the lymphocytes in vitro. The lymphocyte rarely divides in circulation but when a *mitogen* (a chemical which stimulates mitosis or cell division) such as phytohemagglutinin is added the lymphocytes undergo a cell division in about 48–72 h. The third stage (iii) is to arrest the cell division in metaphase when the chromosomes are at their most contracted and are best visualized. This is done by adding colchicine to the culture at 69–70 h. The fourth stage (iv) is to release the chromosomes from the nucleus and spread them on a microscope slide. This is carried out by placing the cultured cells in hypotonic saline and dropping the solution carefully onto a microscope slide from a sufficient height to give a reasonable spread of chromosomes. The fifth stage (v) is to fix and stain the spread for microscopic analysis. The normal staining process is using a Giemsa stain that shows a light and dark banding appearance (Fig. 14.5). Most of the analysis is carried out under the microscope, but a photograph of the spread may be taken and a mounted karyotype prepared as a permanent record or for further analysis. It is usual to analyze several cells in preparing a report.

Fig. 14.4 Preparation of a chromosome karyotype from a blood sample.

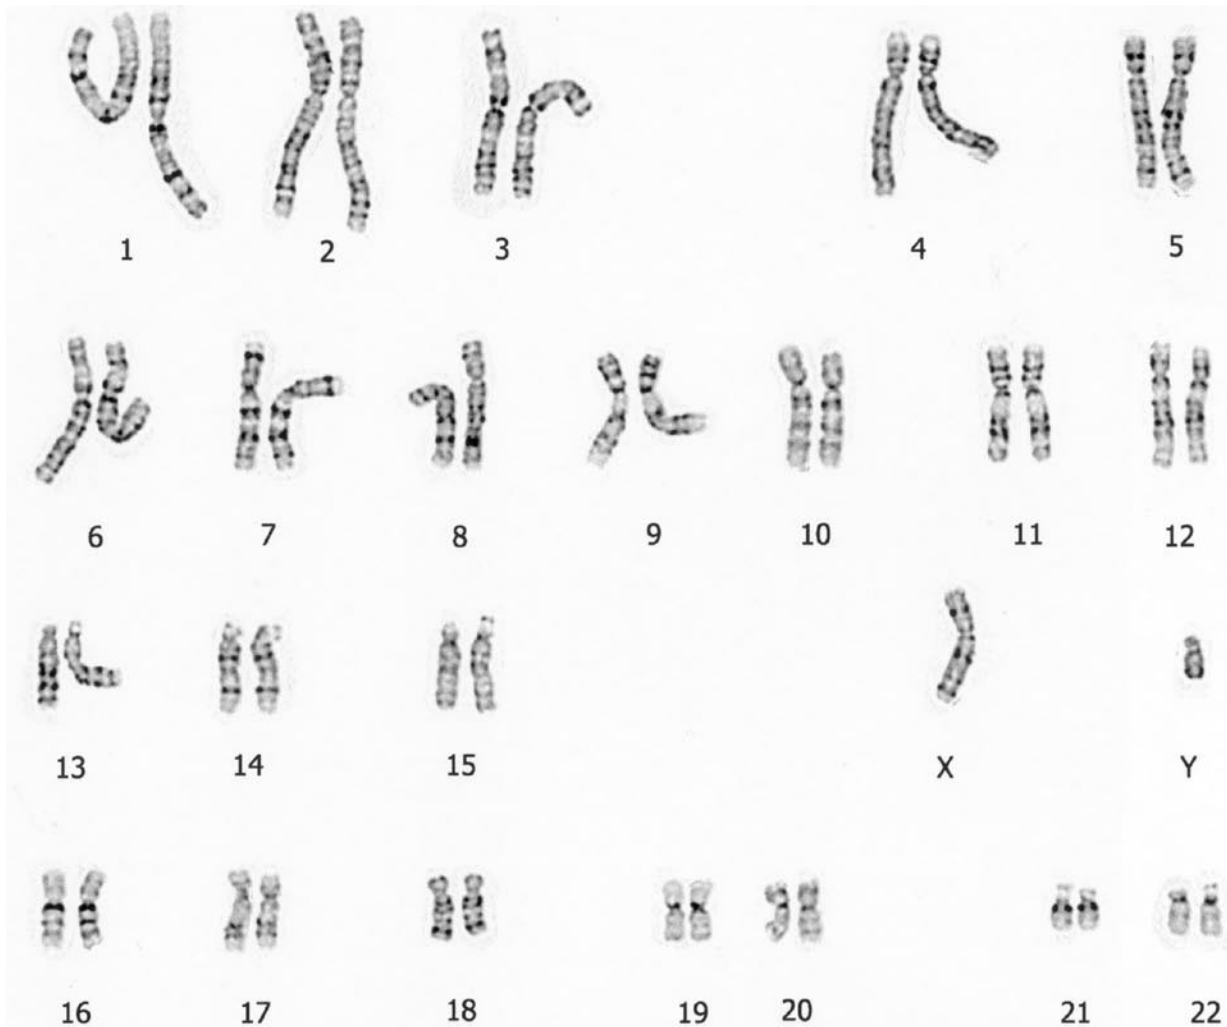

Fig. 14.5 Standard chromosome karyotype.

### BONE MARROW

Bone marrow contains many rapidly dividing cells. It is therefore possible to locate cells that are already in metaphase and thus a direct preparation may be obtained. However, short term culture is generally performed and is used in leukemias where chromosome abnormalities may be of value both for diagnosis and prognosis.

### FIBROBLASTS

Culture of connective tissue *in vitro* will result in the growth of fibroblasts, which may be used for chromosome culture. The most common source of fibroblasts is from a skin biopsy. It may be useful to look for mosaicism in a different tissue from blood. At postmortem connective tissue may be obtained from many different sources, but usually it is adequate to take a sample of skin under sterile conditions for culture.

### AMNIOCENTESIS

Fluid taken at amniocentesis between 12 and 16 weeks' gestation contains skin cells shed from the fetus and amniotic membranes. These cells are not very numerous in the sample but may be cultured up in a similar way to fibroblasts. It takes 2–3 weeks to culture and analyze the cells.

### CHORIONIC VILLUS SAMPLES

Another approach to prenatal diagnosis is to obtain a sample of chorionic villi from the membranes surrounding the fetus at 9–11 weeks' gestation. This material is fetal in origin, but has to be separated from maternal tissue under the dissecting microscope before analysis. Chorionic villi are rapidly dividing and it is possible to obtain direct preparations without culture. However, because of the possibility of maternal contamination and mosaicism, most diagnostic laboratories prefer to wait until culture is also available at 1–2 weeks before giving a definitive result.

### FLUORESCENT IN SITU HYBRIDIZATION (FISH)

There has been a considerable gap between cytogenetic analysis at the microscopic level and molecular genetics at the gene level, but it is now possible to combine a gene specific probe with a fluorescent dye and to demonstrate the location of that gene on the chromosome spread.

The FISH technique has wide applications. It has been very valuable in looking for small chromosome deletions such as in Williams syndrome and DiGeorge syndrome (Fig. 14.6) and has greatly extended the ability to make such diagnoses. It has also been used with chromosome specific probes on the uncultured cells to get rapid chromosome diagnosis, e.g. in prenatal diagnosis or for a rapid diagnosis of chromosome abnormalities in the neonatal unit. Another role has been to develop

**Fig. 14.6** Fluorescent in situ hybridization using probes for chromosome 22q. On chromosome A both the control and the 22q probe show fluorescence, but on chromosome B only the control probe shows up indicating a deletion of 22q seen in DiGeorge syndrome. (Courtesy of Dr J. Taylor.)

'chromosome paints' with fluorescent gene probes specific to individual chromosomes. Initially this technique was limited by the relatively small number of fluorescent dyes but by using the spectral division of color and computer enhancement it is now possible to assign a separate color to each chromosome and make the analysis of complex chromosomal translocations easier.

One area of the chromosome that is relatively difficult to visualize is the end or telomere, and as a consequence chromosome deletions at the subtelomeric region may be missed on conventional analysis. Knight & Flint<sup>6</sup> developed a range of subtelomeric gene probes that have in clinical practice allowed the identification of chromosome abnormalities in another 7% of children with mental retardation and apparently normal chromosomes on routine analysis.

FISH techniques also have an important role in gene mapping and the identification of chromosome imbalance in malignancy.

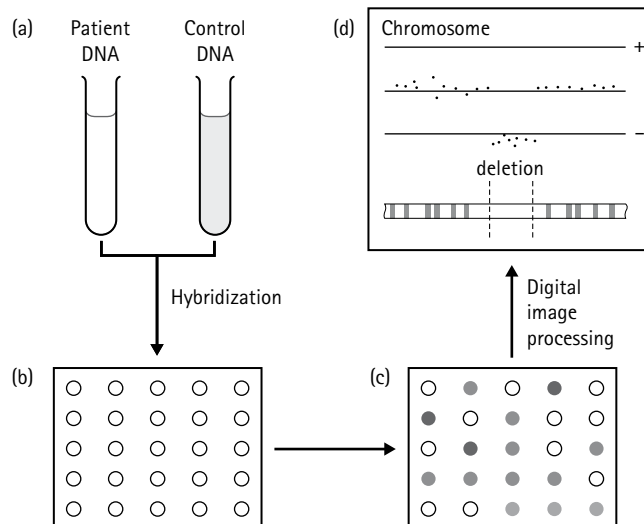

### COMPARATIVE GENOMIC HYBRIDIZATION MICROARRAY

A new technique that has great promise for future diagnostic work is the comparative genomic hybridization (CGH) microarray. The technique depends on the relative hybridization between the green fluorescent labeled patient's DNA and the red fluorescent labeled reference DNA (Fig. 14.7). Where hybridization takes place a standard yellow fluorescent color will appear; if there is a deletion in the patient's DNA then only the red color will appear; if there is a duplication in the patient's DNA then a green color will appear. This process can be repeated for up to 3000 known markers spread at 1 Mb intervals across the chromosomes. As the microarray is very small it has to be read by a scanning microscope and the image translated into an overview of the chromosome karyotype. Preliminary studies have suggested that it may pick up *de novo* abnormalities in up to 15% of children with previously undiagnosed mental retardation.<sup>7</sup>

### INDICATIONS FOR CHROMOSOME STUDIES

The indications for chromosome studies in pediatric practice include:

1. Intellectual disability, especially when associated with physical abnormalities. It should be borne in mind that there are specific tests now for some forms of mental handicap, e.g. fragile X, Prader-Willi syndrome, Williams syndrome, and these will need to be requested separately with appropriate samples.
2. Multiple congenital abnormalities as many of the malformation syndromes have a chromosomal basis.

**Fig. 14.7** Comparative genomic hybridization (CGH) microarray is a recent technique that will greatly increase our resolution in chromosome analysis. (a) Single stranded fluorescent labeled DNA from the patient (green) is mixed with single stranded control DNA (red) and mixed on a slide (b) with up to 3000 DNA clones covering all the chromosomes at 1 Mb intervals. Where hybridization takes place a yellow color will appear, but where there is a deletion of the patient's DNA only the red color of the control appears (c). The slide is then scanned by an automated microscope and the image processed to show the spread of hybridization reactions across each chromosome and presented against the chromosome karyotype. A small interstitial deletion is seen in (d).

3. Intersex conditions manifesting as the presence of ambiguous genitalia in the newborn, inguinal herniae in a girl or the failure of development of secondary sexual characteristics at adolescence. Cryptorchidism or minor degrees of hypospadias alone are unlikely to be manifestations of a chromosome abnormality.
4. Congenital lymphedema may be a manifestation of Turner syndrome and Noonan syndrome, and part of the investigation should include chromosome analysis.
5. Gross failure to thrive which is prenatal in origin may be due to a chromosome abnormality, especially when accompanied by minor physical abnormalities or intellectual disability.
6. Childhood leukemias and malignancies will often reveal major chromosomal rearrangements in the cancerous cells and these may be an indicator of the prognosis.

### TYPES OF CHROMOSOME ABNORMALITY

The chromosome abnormalities fall into two categories: (a) abnormalities of number, and (b) abnormalities of structure.

#### NUMERICAL ABNORMALITIES

*Euploidy* describes chromosome constitutions which are multiples of the haploid (n) number (23 in man), thus diploid,  $2n = 46$ , triploid,  $3n = 69$ , or tetraploid,  $4n = 92$ . Multiples greater than  $2n$  are designated by the general term *polyploidy*. In clinical practice these are exceptionally rare but *triploidy* is occasionally seen with severe abnormalities at birth. It usually arises from the fertilization of a single ovum by two spermatozoa (*dispermy*).

*Aneuploidy* refers to those karyotypes in which the chromosome complement is not an exact multiple of the haploid number and includes both the trisomic and monosomic states.

*Nondisjunction* is the term used to describe the failure of homologous chromosomes or sister chromatids to separate and migrate to opposite poles of the nucleus during cell division and is the major mechanism

by which monosomic and trisomic states originate. The consequences of nondisjunction vary depending on whether the event occurs during meiosis or mitosis. Nondisjunction occurring in meiosis will give rise to trisomy or monosomy, but nondisjunction taking place in mitosis in the early embryo will give rise to mosaicism with a mix of abnormal and normal cell lines.

There seems no doubt that in some families there is a predisposition towards nondisjunctional events. The number of families in which aneuploidy recurs and the occurrence of individuals who possess two different aneuploidy states, e.g. both Down and Klinefelter syndromes, are suggestive evidence of this predisposition. The mechanism for this is not understood.

## STRUCTURAL ABNORMALITIES IN CHROMOSOMES

Structural chromosome abnormalities include those involving a definite loss or gain of genetic material, and those in which the existing genetic material is rearranged in some way. Structural rearrangements arise from one or more breaks in the chromosomes. Figure 14.8 presents in diagrammatic form the mechanisms of origin of the common structural abnormalities.

### Deletions

Deletions (Fig. 14.8a) result when one or more breakages occur along the chromosome with subsequent loss of the resulting fragment, and may be either terminal or interstitial.

### Ring chromosomes

Ring chromosomes (Fig. 14.8b) result from simultaneous breakage in both long and short arms of a chromosome with subsequent fusion of the ends of the remaining centric fragment and loss of the acentric terminal segments. Ring chromosomes are notoriously unstable during cell division and break down readily so that the proportion of cells with a clear ring may vary considerably in cultures from the same individual, as also may the actual form and number of the rings observed.

### Inversions

Inversions (Fig. 14.8c), as their name suggests, result from a reversal of the sequence of genes in a segment of chromosome lying between two points of breakage. Inversions may be either *paracentric* involving double breakage in only one arm of a chromosome without any alteration in arm ratio, or *pericentric* involving breakage on either side of the centromere.

The clinical significance of inversions is a subject for debate. The vast majority of paracentric inversions are likely to be harmless; however, the risk of having an unbalanced rearrangement in offspring would be increased if there were a family history of recurrent miscarriage or congenital malformations. Small pericentric inversions, including the relatively common pericentric inversions of chromosomes 2 and 9, also seem to be associated with a relatively small risk of unbalanced chromosome arrangements in offspring, and in some cases might be regarded as normal variants. However, the effects of inversions can be unpredictable and the risks in the individual case should be assessed in the light of the family history and cumulative experience from the medical literature.

### Isochromosomes

An isochromosome is a chromosome in which the two arms are genetically and structurally identical, e.g. two short arms from the same chromosome. Such chromosomes are thought to arise as a direct result of misdivision of the centromere in the transverse rather than the longitudinal plane, with subsequent reunion of the centric elements of sister chromatids (Fig. 14.8d). In clinical practice this may be seen when an isochromosome X causes Turner syndrome.

### Translocations

A translocation is a transfer of genetic material from one chromosome to another. When there is a mutual exchange of segments with

no associated loss of genetic material this is termed a *balanced reciprocal translocation*. Such translocations may involve either homologous or nonhomologous chromosomes and can be the result of no more than two breaks, one in each of the chromosomes involved (Fig. 14.8e).

Provided that the translocation does not result in the loss or gain of genetic material there will be no harm to the carrier, although the potential effect for the offspring of carriers may be considerable. Many carriers are first identified following the detection of one or other product of a reciprocal rearrangement in an abnormal infant, in a stillbirth, or in an early abortus. Family studies frequently uncover a history of previously unexplained miscarriages in phenotypically normal individuals, who are found subsequently to be carriers of the rearrangement. Such translocations can often be traced through many generations of a large pedigree. Translocations involving chromosome 9 and those between chromosomes 11 and 22 appear to carry a particularly high risk of an unbalanced defect.

One of the most commonly occurring structural rearrangements in man is the centric fusion or Robertsonian translocation, involving, by definition, only acrocentric chromosomes. The breakpoints occur close to the centromere, either one in the short arm and one in the long arm, in which case the metacentric chromosome formed has a single centromere, or in both short arms with a resultant dicentric chromosome (Fig. 14.8f). The deleted short arm material is generally lost without any apparent effect on phenotype, presumably because it is heterochromatin without structural genes.

A Robertsonian translocation between chromosomes 13 and 14 is thought to be one of the most common structural rearrangements in man, with a frequency of 0.05–0.08% in the newborn population. This rearrangement usually functions more or less normally during meiosis but there is a small risk of trisomy 13 in the offspring of carriers.

Robertsonian translocations involving chromosome 21 such as 14,21 translocations are of considerable clinical significance since they may give rise to Down syndrome and have a high chance of recurrence. There are differences in the risk of recurrence of Down syndrome depending on the sex of the carrier parent. Recurrence is higher if the carrier is female (10–15%) and lower if the carrier is male (< 5%).

## MOSAICISM

*Mosaicism* occurs where there are two or more genetically different cell lines in an individual derived from a single zygote, *chimerism* where an individual has arisen from the fusion of two zygotes or exchange of cells between two zygotes. Chimerism is extremely rare and not usually of clinical significance whereas mosaicism is relatively frequent and may be a cause of diagnostic difficulty.

Significant levels of chromosome mosaicism may be demonstrated by examining a reasonable number of cells. The examination of 30 metaphases will be sufficient to demonstrate mosaicism at the 10–15% level, but many more metaphases would be needed to exclude lower levels of mosaicism. It may be difficult to completely exclude mosaicism as a diagnosis, and failure to demonstrate mosaicism in blood need not necessarily exclude the diagnosis as a possibility in other less available tissues. One of the clinical indicators of chromosome mosaicism is the appearance of linear areas of pigmentary abnormality in the skin. In such cases a skin biopsy including both normal and abnormal skin may be used to look for mosaicism.

## NOMENCLATURE<sup>8</sup>

Chromosomes can be arranged in pairs on the basis of certain morphological features. Such morphological features include size, centromere position, and the presence of satellites or secondary constrictions.

The *centromere* is the point of union of the two chromatids. The position of the centromere in relation to the *telomeres* (or chromosome ends) determines the actual shape of the chromosome and divides it into two *arms* which vary in length, being either short (p), or long (q). Where

**Fig. 14.8** Structural rearrangements in chromosomes. (a) Deletions may be (i) terminal or (ii) interstitial. (b) Ring chromosome. (c) Inversions may be (i) paracentric or (ii) pericentric. (d) Isochromosome formation: (i) normal mitosis with longitudinal division of the centromere; (ii) misdivision of the centromere in the transverse plane leading to the products (iii) of either isochromosome of the short arm. (e) Balanced reciprocal translocation. (f) Robertsonian or centric fusion translocation.

the centromere is median in position and the arms are of approximately equal length, the chromosome is described as *metacentric*. Where the arms are of unequal length, the chromosome is described as *submetacentric*. Where the centromere is more nearly terminal so that the short arms are minute, the chromosome is described as *acrocentric*. Small

condensations of heterochromatin or satellites may occur on the short arms of acrocentric chromosomes.

The International Conferences on Standardization in Human Cytogenetics provide a standardized system of chromosome nomenclature and symbols (Table 14.3).<sup>8</sup> The conventions which apply in use of

Table 14.3 Table of nomenclature symbols<sup>9,10</sup>

1–22	The autosome numbers
X, Y	The sex chromosomes
Diagonal (/)	Separates cell lines in describing mosaicism
Plus sign (+) or minus sign (–)	When placed immediately before the autosome number or group letter designation indicates that the particular chromosome is extra or missing; when placed immediately after a symbol it means an increase or decrease in length of the chromosome
cen	Centromere
dic	Dicentric (presence of two centromeres)
h	Secondary constriction or negatively staining region
i	Isochromosome
inv	Inversion
mar	Marker chromosome
mat	Maternal origin
p	Short arm of chromosome
pat	Paternal origin
q	Long arm of chromosome
r	Ring chromosome
s	Satellite
t	Translocation
del	Deletion
der	Derivative chromosome
dup	Duplication
ins	Insertion
inv ins	Inverted insertion
rep	Reciprocal translocation
rec	Recombinant chromosome
rob	Robertsonian translocation ('centric fusion')
ter	Terminal or end (pter = end of short arm; qter = end of long arm)
:	Break (no reunion, as in a terminal deletion)
::	Break and join
–	From – to

All symbols for rearrangements are placed before the designation of the chromosome or chromosomes involved and the rearranged chromosome or chromosomes should always be placed in parentheses.

this nomenclature are as follows. The number of chromosomes is given first followed by the sex chromosome constitution, e.g. 45X in Turner syndrome and 47XXY in Klinefelter syndrome. Autosomal aneuploidies are indicated by a numerical alteration, the extra or deficient chromosome being designated by a + or – before the chromosome involved, e.g. 47XX,+21, a female with Down syndrome, or 45XX,-21, a female missing a 21 chromosome. When placed after a symbol a + or – means an increase or decrease in the length of a chromosome, e.g. 18p– represents deletion of the short arm of chromosome 18. Diagonals are used in the description of mosaicism, e.g. 45XO/46XX represents a Turner mosaic and 46XX/47XX,+21 a female with mosaic Down syndrome. Translocation is designated by the letter t followed in parentheses by an indication of the nature of the translocated chromosome. An isochromosome is indicated by the letter i before the chromosome arm involved, e.g. 45X,i(Xq) represents an isochromosome for the long arm of one X chromosome. Ring chromosomes are designated by the letter r placed before the chromosome involved, e.g. 46X,r(X). Bands on chromosomes are numbered outwards from the centromere and are represented by a number written after p or q representing the short or long arms, e.g. 8q24 represents a region on the long arm of chromosome 8 and t(8;14)(q24;q32) a translocation between chromosome 8 and 14 involving region 24 on the long arm of chromosome 8 and region 32 on the long arm of chromosome 14.

## CHROMOSOMAL SYNDROMES

### DOWN SYNDROME

#### Incidence

Since the original description of the condition by Langdon Down in 1866, this disorder has been recognized to be the commonest single cause of mental handicap, occurring in approximately 1 in 700 of all live births in all populations. However, the incidence varies with the age of the mother: the incidence for mothers aged 25 years is 1 in 1400 and increases to reach an incidence of 1 in 46 for mothers aged 45 years (see Fig. 14.9).

#### Clinical features

In most instances Down syndrome is recognizable at birth by the craniofacial features (Fig. 14.10). The head circumference is small with a brachycephalic skull. The neck is short and thick. The palpebral fissures slope upwards (i.e. the outer canthus is higher than the inner canthus) and there may be marked epicanthic folds. Brushfield's spots (whitish spots scattered round the periphery of the iris) are found more frequently in Down syndrome than in the general population. There is an increased incidence of lens opacities. The ears are small with an overfolding helix. The nasal bridge is flat. The tongue appears large and may protrude because the mouth is relatively small. Eruption of the teeth is frequently delayed with abnormalities in dental positioning. The hair may be fine and sparse.

The hands are short and broad. The fifth finger is short and incurved (clinodactyly). Radiologically this feature is accompanied by shortening of the shaft of the middle phalanx. A single transverse palmar crease (or simian crease) is seen in both hands in at least 50% of children with Down syndrome. A unilateral transverse palmar crease may be demonstrated in 2–5% of chromosomally normal infants. A deep plantar crease ('sandal gap') between the first and second toe may also be a helpful diagnostic sign.

Congenital heart disease occurs in between 40 and 60% of infants with Down syndrome. Atrioventricular canal and ventricular septal defects are the commonest types of cardiac lesion seen. Intestinal atresia, in particular duodenal atresia, is also considerably more common in Down syndrome. One third of cases of congenital duodenal atresia occur in Down syndrome.

Initially a child with Down syndrome may be hypotonic, but the early developmental milestones are eventually reached. The ultimate

Fig. 14.9 The frequency of Down syndrome increases with maternal age.

Fig. 14.10 Facial features of Down syndrome.

**Cytogenetics**  
**Full trisomy 21**

Approximately 95% of children with Down syndrome have a full trisomy 21. Trisomy 21 arises as a result of meiotic nondisjunction, usually from the maternal side.

**Translocation as a cause of Down syndrome**

Translocations account for 2–3% of Down individuals. The most frequent cause is from a Robertsonian 14,21 translocation (Fig. 14.11). In this form the carrier would have one 14 chromosome, one 21 chromosome and one fused 14,21 chromosome giving a total of 45 chromosomes and would be phenotypically normal. However, when a carrier produces offspring there is a risk of producing an unbalanced karyotype.

In Figure 14.11, when an individual with a 14,21 translocation produces offspring with an individual with a normal karyotype then three viable chromosome arrangements may be produced: (i) a normal karyotype, (ii) a balanced translocation and (iii) an unbalanced translocation giving 46 chromosomes with trisomy 21. Other arrangements can be produced, but these will be nonviable or lead to early miscarriage, e.g. monosomy 21, monosomy 14 or trisomy 14. While in theory it may appear that one third of pregnancies would produce an unbalanced translocation with trisomy 21, this does not take into account the selective disadvantage that acts on gametogenesis, fertilization or the early zygote. From analysis of pooled family data the likelihood of a female carrier producing an unbalanced trisomic child is 15%, and the likelihood of a male carrier producing an unbalanced trisomic child is 2.5%. The different risks may be explained by selective disadvantage in the sperm carrying the extra 21 chromosome.

A 21,22 Robertsonian translocation may also give rise to Down syndrome in a similar way. Very rarely a 21,21 translocation may arise. Carriers of this 21,21 translocation can only produce zygotes that are either monosomic or trisomic for chromosome 21, and since monosomy 21 would almost always be lethal their risk of producing a child with trisomy 21 is 100%.

IQ ranges from 20 to 75 with a mean around 50. The earlier assessment of development tends to be more favorable than the formal measurement of IQ in later childhood. Children with Down syndrome are often affectionate and good humored but like all stereotypes this tends to underestimate the range of personality and behavioral traits seen in a defined group.

Intellectual function shows a decline with age in adults with Down syndrome due to an increased incidence of early onset dementia of the Alzheimer type. Decline may start in the third decade of life but becomes frequent by the fifth decade.<sup>11</sup> The neuropathology in Down syndrome is similar to Alzheimer disease with the presence of amyloid plaques and neurofibrillary tangles. Gene mapping studies have found mutations in the amyloid precursor protein gene on chromosome 21 in some early onset familial cases of Alzheimer disease suggesting a causative link with Down syndrome.

The development of secondary sexual characteristics is delayed in Down syndrome. Adult males with Down syndrome are infertile and in females there may be delayed puberty but they will usually be fertile. The incidence of leukemia, but not other malignancies, is greater in Down children. A transient leukemoid reaction may occur in newborns with Down syndrome. In the first year of life acute nonlymphoblastic leukemia predominates, but in older children it is predominantly acute lymphoblastic leukemia. Overall the incidence is 10–18 times greater than that in the general childhood population.

A generation ago, two thirds of children with Down syndrome died in early childhood, usually from the associated congenital abnormalities. Now only about 20% die in the first year and 45% of individuals with Down syndrome will survive to 60 years of age.<sup>12,13</sup> This improved survival will represent a greater burden of care for those families facing the diagnosis today.

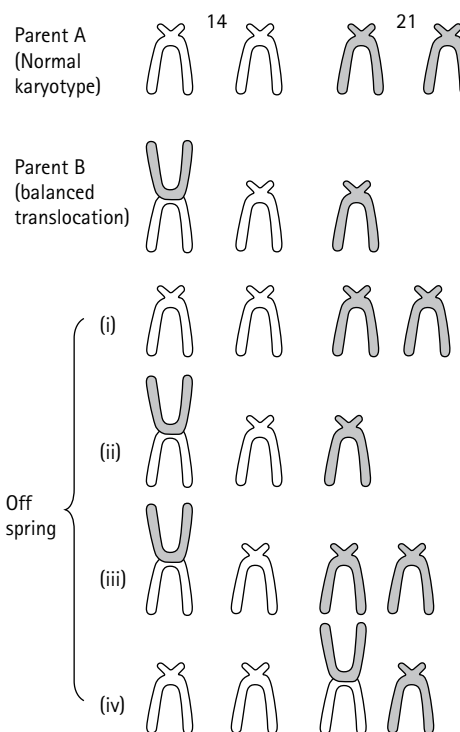

Fig. 14.11 Segregation of a 14,21 translocation. Four combinations may be produced: (i) normal karyotype; (ii) balanced translocation; (iii) unbalanced trisomy 21; (iv) unbalanced trisomy 14 (lethal).

### Mosaic trisomy 21

In about 2.5% of individuals with Down syndrome there is a mosaic combination of cells with a normal karyotype and cells with trisomy 21. The phenotypic variation produced may range from apparently normal individuals to those with typical Down syndrome.

### Genetic counseling and screening

It is essential to determine the chromosome karyotype in the affected child prior to genetic counseling, since the recurrence risks are different for standard trisomy 21 and translocation trisomy 21.

In the case of a child with a standard trisomy 21 the chance of recurrence in further children is 1% in mothers under 35 years and twice the maternal age risk in mothers over 35 years.

When Down syndrome has arisen as a result of an unbalanced translocation, it is necessary to check both parents' chromosomes and if one is found to be a carrier, then further family studies are necessary to determine if other members of the family are also carriers. The recurrence risks for carriers of a 14,21 translocation carrier are given above. In some instances neither parent is found to be a translocation carrier and the unbalanced translocation has arisen *de novo*. In such situations the chance of recurrence in further pregnancies is equivalent to the population risk.

Since Down syndrome is a major cause of mental handicap, pregnancy screening and chromosome analysis have been incorporated into various public health programs. Since the incidence of Down syndrome increases with increasing maternal age, amniocentesis was initially offered to mothers aged 35 and above. This approach, if fully taken up by all mothers, would diagnose 30% of all pregnancies with Down syndrome, and the remaining 70% would occur in younger mothers. The next refinement was to use maternal blood markers that indicated a higher risk of Down syndrome and offer amniocentesis to those at higher risk. The blood markers used were alpha-fetoprotein, estriol and human chorionic gonadotrophin. Now most centers use earlier ultrasound scanning as the preliminary screen. If there is an increased amount of thickening over the back of the neck or *nuchal translucency* then there is a greater risk of chromosome abnormalities and chorionic villus sampling may be carried out. This approach will diagnose up to 80% of Down syndrome in the early stages of pregnancy.

### TRISOMY 18 (EDWARDS SYNDROME)

This was first described by Edwards.<sup>14</sup> Although much rarer than Down syndrome, it is the second commonest autosomal trisomy with an incidence between 1 in 3500 and 1 in 7000. It is also associated with increased maternal age. Of the affected infants some 80–90% die within the first week, usually from cardiopulmonary failure. A few cases have been reported surviving into the teens, but they have all been profoundly retarded.

There is often polyhydramnios and intrauterine growth retardation. The cranium is long and narrow with a prominent occiput. The ears are low set and frequently underdeveloped. The facies characteristically shows micrognathia and narrow sloping palpebral fissures. The hands are clenched with the second and fifth fingers overlapping the third and fourth fingers (Fig. 14.12a). There may be other flexion deformities. The nails are hypoplastic. The feet show a 'rocker bottom' appearance like the shape of the runners of a rocking chair (Fig. 14.12b).

A variety of congenital malformations are present. Anomalies of the gastrointestinal tract are particularly common, e.g. intestinal atresias, malabsorption and exomphalos. Around one third of cases of exomphalos detected prenatally on ultrasound have trisomy 18. Renal abnormalities are also frequent with renal hypoplasia or cystic dysplasia being one of the commoner and more serious abnormalities. Congenital heart defects, ocular abnormalities and neural tube defects can also occur.

In the past a number of conditions which clinically appeared similar to trisomy 18 but showed normal karyotypes were described as pseudotrismy 18. Some of these cases were probably Pena–Shokeir

(a)

(b)

Fig. 14.12 The typical appearance of the (a) hands and (b) feet in trisomy 18 (Edwards syndrome).

syndrome<sup>15</sup> which is autosomal recessive. It presents with a combination of microcephaly, joint contractures, pulmonary hypoplasia and cataracts, and should be considered in the differential diagnosis when the karyotype is normal.

The vast majority of cases arise as a result of primary nondisjunction and have a regular trisomy 18. Like trisomy 21, it is associated with increased maternal age and thus may be diagnosed on screening prenatally. After the diagnosis of one affected pregnancy the chance of recurrence is 0.5% in younger mothers.

### TRISOMY 13 (PATAU SYNDROME)

This syndrome has an incidence of around 1 in 6000. The majority of affected children have multiple malformations and die shortly after birth. The few cases reported with longer survival have all been severely retarded. There is some maternal age effect, but probably not as significant as that seen in trisomy 21 or trisomy 18.

The affected children show intrauterine growth retardation. There may be marked microcephaly. Structural malformations of the brain are common and this may alter facial development. Instead of two cerebral hemispheres with lateral ventricles, a single forebrain with a single ventricle may form. This malformation sequence is known as holoprosencephaly (Fig. 14.13). The process alters the development and separation of optic vesicles from the forebrain and the migration of the median process from the forehead to form the nose. In its most extreme form the optic vesicles may fuse to give cyclopia. More usually (Fig. 14.14) there is marked hypotelorism with a small nose and cleft lip and palate. Ocular abnormalities such as microphthalmos are common, often reflecting the underlying cerebral abnormality.

In the hands, postaxial polydactyly is frequent. Flexion contractures and 'rocker bottom' feet may also be present. Scalp defects may be helpful diagnostically as they rarely appear in other abnormalities. Internally, in addition to cerebral malformations, renal and cardiac abnormalities are also frequent.

The majority of cases of trisomy 13 arise as a result of primary nondisjunction and there is a low chance of recurrence (0.5%).

**Fig. 14.13** Holoprosencephaly sequence. The forebrain divides into two hemispheres and the optic vesicles develop from these to form the eyes. In holoprosencephaly the forebrain divides incompletely and the optic vesicles develop in close proximity, leading to hypotelorism or cyclopia.

It may occasionally arise from an unbalanced chromosome translocation  $t(13q,14q)$ . In the vast majority of cases carriers of a  $t(13q,14q)$  do not produce unbalanced progeny, but in practice it is appropriate to counsel such carriers with a small recurrence risk and offer amniocentesis.

### 1p36 DELETION

This small telomeric deletion is being increasingly recognized with newer laboratory techniques and gives rise to a severe neurological phenotype with severe intellectual disability and seizures. There are deep set eyes and straight eyebrows and there may also be congenital heart disease.<sup>16</sup>

**Fig. 14.14** Facial features of trisomy 13 (Patau syndrome).

### 4p<sup>-</sup> (WOLF-HIRSCHHORN) SYNDROME

This syndrome gives a clearly recognizable phenotype. The features include microcephaly, hypertelorism, low set simple ears, coloboma (25%), cleft palate (30%), renal abnormalities, heart defects (50%) and intrauterine growth retardation. The facial features (Fig. 14.15) are described as resembling a Greek helmet since the flat nasal bridge appears to run in continuity from the glabella in much the same way that the protective nosepiece is incorporated into a Greek helmet.

The natural history is known.<sup>17</sup> Death usually occurs in early childhood (at least one third die in the first year of life) and survivors invariably show profound mental retardation with seizures. As 10% arise from balanced translocations it is important to examine the parents' chromosomes. The deletion required to produce this syndrome may be very small and may require specific cytogenetic tests to identify it.

### 5p<sup>-</sup> (CRI DU CHAT) SYNDROME

This was one of the first autosomal deletions to be recognized. The syndrome derives its name from the striking cat-like cry that is heard in infancy. This cry is related to the hypoplastic larynx and tends to lessen with increasing age and growth of the larynx. In the newborn the face is round with microcephaly, micrognathia and down-slanting palpebral fissures. With further growth the microcephaly remains but the face becomes long and narrow. Survival into adult life with severe mental retardation has frequently been described.

The deletion may involve a variable amount of the short arm of chromosome 5 but band 5p15 is invariably involved.<sup>18</sup> About 15% of cases arise from a balanced reciprocal translocation.

### DELETIONS OF 13q

Deletions of 13q14 (Fig. 14.16) are associated with retinoblastoma. The dysmorphic features associated with this deletion are variable. Further genetic analysis of the interstitial 13q14 deletions has led to recognition that this chromosomal region contains an anti-oncogene responsible for inhibiting the proliferation of embryonic retinal cells. In the presence of a homozygous deletion or a deletion in one allele with a mutation in the other allele, retinal cells continue to proliferate in a malignant fashion producing a retinoblastoma. Inherited forms of retinoblastoma are usually bilateral whereas isolated cases of retinoblastoma are usually unilateral and are the result of a somatic mutation in the retinoblastoma gene that has arisen in one eye.

Terminal deletions of 13 may also produce eye abnormalities but not retinoblastoma. These children also characteristically have hypoplastic thumbs and anal atresia. Most die in the neonatal period.

**Fig. 14.15** Facial features of 4p<sup>-</sup> (Wolf-Hirschhorn) syndrome.

Fig. 14.16 Deletions of the long arm of chromosome 13.

### DIGEORGE SYNDROME (22q11 DELETION)

Prior to the discovery of the underlying chromosome defect this disorder was described with different emphasis and with different names, e.g. velocardiofacial syndrome, Sphrintzen syndrome or CATCH 22. With the advent of fluorescent gene probes this has become one of the commonest chromosomal microdeletion syndromes.

About 75% of patients with 22q11 deletion will have significant congenital heart defects.<sup>19</sup> The range of defects is wide but tetralogy of Fallot and abnormalities in the main arteries are most frequently seen. About 50% of patients will have defects of the palate. This is often velopharyngeal insufficiency rather than overt cleft palate. Hypocalcemia may also occur and is a cause for fits. Developmental delay tends to be mild and a significant number of affected children have normal development. In the original description of this syndrome there was severe immunodeficiency with T cell depletion and although this is infrequent, care should be given with live immunization.<sup>20</sup>

The main indication for requesting a 22q deletion test is the presence of congenital heart defect or facial clefting but it is appropriate to consider it with any feature of the syndrome. The facial features include a long bulbous nose and a small mouth but are relatively subtle. When a deletion is identified it is important to carry out testing in the parents as around 30% of cases are inherited.

By dissecting out the critical region of the deletion it has been possible to identify a T box developmental gene as the primary cause of heart defects in the syndrome.<sup>21</sup>

### WILLIAMS SYNDROME

Williams syndrome was initially referred to as infantile hypercalcemia as the biochemical change was the usual presentation. It is now recognized to be a more generalized syndrome with 'elfin facies', short stature, supravalvar aortic stenosis, hyperacusis and developmental delay. After autosomal dominant supravalvar aortic stenosis was recognized to be due to a defect in elastin, it was found that there is a deletion of elastin and contiguous genes in Williams syndrome. It is now easily diagnosed by a FISH probe for elastin on chromosome 7, but obviously the features such as learning difficulties and the characteristic behavior are due to the adjacent genes in the deletion rather than elastin alone.<sup>22</sup>

### ANIRIDIA-WILMS

The association of bilateral aniridia and Wilms tumor is due to a deletion of chromosome 11p13. It is a good example of a contiguous gene deletion in which a gene involved in eye development (Pax 6) is deleted together with an oncogene WT1. There is often developmental delay and growth retardation as well due to deletion of other genes in the area. This concept of a contiguous gene deletion syndrome will probably be found to be a cause of many other apparently unrelated features in malformation syndromes.

### ANGELMAN SYNDROME AND PRADER-WILLI SYNDROME

Although these are very different clinical disorders it is important to consider these two syndromes together as they can both be due to deletions of chromosome 15 and illustrate an important biological principle known as genetic imprinting.

Prader-Willi syndrome usually presents with neonatal hypotonia with feeding difficulties and in males undescended testes.<sup>23</sup> As the affected child becomes older the muscle tone and feeding difficulties improve but the child develops a voracious appetite (hyperphagia) and becomes obese. Affected children will also have developmental delay and in later life may suffer from the complications of obesity. Angelman syndrome presents with severe developmental delay, inappropriate laughter and complex seizures. There may be a characteristic electroencephalogram (EEG) in early life<sup>24</sup> and later absence of speech and ataxia.

The commonest cause of these syndromes is deletion of 15q11-13 but it was found that Prader-Willi syndrome was due to paternal deletions and Angelman syndrome was due to maternal deletions. This phenomenon would not be predicted by Mendelian inheritance, where the parental origin of a mutation does not usually matter, and is an example of *genetic imprinting*. It appears that both paternal and maternal chromosome 15s are required in early embryonic development and that paternal and maternal chromosome 15q12 have different functions. Thus genetic imprinting may be defined as the determination of gene expression depending on the parental origin.

The situation became more complex with analysis of other cases. In some cases there was no deletion but two copies of chromosome 15 from the same parent, which is referred to as uniparental disomy.<sup>25</sup> In the case of Prader-Willi syndrome this would have started with trisomy 15 in which there were two copies of the maternal 15 and one of paternal 15; then, if the paternal chromosome 15 is lost, the child effectively has two maternal chromosome 15s and no paternal 15. The net effect is the same as a deletion on the paternal chromosome 15. The situation is now more complicated as there can also be mutations affecting the imprinting mechanism and in Angelman syndrome point mutations in the UBE3A gene at 15q12.

A number of other genetic disorders involve genetic imprinting, e.g. transient neonatal diabetes, Russell-Silver syndrome and Beckwith-Wiedemann syndrome.

### KILLIAN-PALLISTER SYNDROME

Most chromosomal disorders can be diagnosed on blood analysis. However this is not the case in the Killian-Pallister syndrome. It is unusual in that a mosaic cell line containing tetrasomy 12p is found in the skin fibroblasts but not in the blood. Although the mosaicism is relatively tissue specific the effects are generalized.<sup>26</sup> There is severe mental retardation with coarse facial features and a characteristic bitemporal loss of hair growth (Fig. 14.17).

Fig. 14.17 Killian-Pallister syndrome is caused by a mosaic isochromosome 12p, which is present in skin culture but not in blood culture. The syndrome has a characteristic coarse facies.

## OTHER AUTOSOMAL ABNORMALITIES

Many other aberrations involving the autosomes have been described. As a general rule they are associated with low birth weight, mental retardation and physical malformations. In many instances a specific phenotype cannot be delineated because gene dosage will depend on the exact breakpoints and, in the case of unbalanced translocations, which other chromosome is involved. It is recommended that the reader refers to a chromosomal atlas such as de Grouchy & Turleau,<sup>27</sup> Gardner & Sutherland<sup>28</sup> or Schnizel<sup>29</sup> for details of other autosomal abnormalities.

## SEX CHROMOSOME ABNORMALITIES

### TURNER SYNDROME

The syndrome was first described in 1938 and subsequently became the first disorder recognized to have a chromosomal basis. It is a frequent finding in first trimester abortions, but, as many 45X conceptuses are non-viable, the frequency at birth is 1 in 3000 live-born females.

#### Clinical features

At birth there is lymphedema (Fig. 14.18) especially in the dorsum of the hand and there may be redundant skin over the back of the neck. Hydrops and cystic hygroma are seen in utero and may occasionally be present in the neonate.

In childhood, Turner syndrome may present with short stature. There is a short webbed neck with low posterior hairline. The chest is shield shaped with widely spaced nipples. The carrying angle at the elbow is increased (cubitus valgus). Pigmented nevi and a tendency to keloid scarring are frequently found. Coarctation of the aorta may also be present. Around 60% will have renal tract abnormalities, which include horseshoe kidneys and duplex ureters, but these do not usually compromise renal function. Mental development is normal although detailed psychometric testing may demonstrate a minor defect in spatial perception.

At puberty Turner syndrome may present for the first time with primary amenorrhea and failure of secondary sexual development. Streak gonads are found with ultrasound and at laparotomy. The patients are usually infertile, but menstruation and secondary sexual development may be induced by estrogen replacement (see Ch. 15).

Girls with Turner syndrome have a normal life span. It is now recognized that hypertension may be a complication in adult life, and in the absence of hormone replacement osteoporosis may also develop.

#### Cytogenetics

Although 60% of patients with Turner syndrome have a 45X karyotype, a variety of chromosome abnormalities are seen with the syndrome (Table 14.4).

Mosaic cell lines arise from mitotic nondisjunction in early embryogenesis. On the whole the phenotype with mosaicism is similar to the classic features of Turner syndrome. When the mosaicism involves an XY cell line there is an increased risk of gonadoblastoma, and the streak ovaries should be removed. In the rare situation of an unbalanced X: autosome translocation and in some cases of ring X, mental retardation may occur.

Turner syndrome is not associated with increased maternal age and as it usually arises from mitotic rather than meiotic error is not associated with an increase of recurrence in further pregnancies.

#### 47XXX

The majority of girls with triple X (47XXX) will not have been brought to medical attention and have had their chromosomes tested. However prospective studies have identified some potential differences. Their height tends to be greater than average and in statistical terms there is a slight lowering of mean IQ, but no specific abnormal behavioral patterns. Fertility is normal. In theory there should be an increased risk of sex chromosome aneuploidy in the offspring of these girls, but in practice the risk appears to be insignificant.

Fig. 14.18 Turner syndrome in the neonate may present with edema of the hands and feet.

Table 14.4 Chromosome abnormalities in Turner syndrome

Chromosome abnormality	Percentage
45X0	60
Mosaic XX/X0	20
Isochromosome Xq or Xp	5
46X del (X)	5
46X ring (X)	5
With Y chromosome	5

## KLINEFELTER SYNDROME (47XXY)

Klinefelter syndrome of gynecomastia, small atrophic testes and absent spermatogenesis (azoospermia) in phenotypic males is associated with an abnormal karyotype (47XXY). The incidence is around 1 in 1000 live-born males.

The clinical features are not usually evident in the first few years of life although it may be discovered coincidentally in apparently normal male infants. When the syndrome is diagnosed early there are often considerable parental anxieties and careful counseling will be required. At puberty, however, the secondary sexual characteristics develop poorly and body fat tends to take on a feminine distribution with gynecomastia. Beard growth is minimal and in adult life patients will rarely need to shave more than twice a week. The testes remain small and infertility may be the presenting feature in adult males. Sexual function is normal although the libido is reduced. The testosterone levels are low and the gonadotrophin levels elevated, and testosterone replacement may be helpful. Testicular histology shows an increase in Leydig cells and interstitial fibrosis. Height is usually increased with relatively long limbs. The mean intelligence is on average slightly reduced in Klinefelter syndrome, but this rarely poses a problem.

### Cytogenetics

The extra X chromosome usually arises from disjunctional errors during oogenesis. As would be predicted from this, the incidence of Klinefelter syndrome increases with maternal age. In about 15% of patients with Klinefelter's there is a mosaic XY/XXY form but even in mosaic forms infertility would usually occur.

## 48XXXY AND 49XXXXY

These sex chromosome abnormalities are more severe than Klinefelter syndrome and should not be referred to as Klinefelter syndrome. Mental retardation is frequent and there may be skeletal abnormalities, especially radioulnar synostosis (leading to inability to supinate the forearm). The facies may also be dysmorphic with hypertelorism, epicanthic folds, broad nose and large open mouth.

## XX MALES

Very rarely patients have been identified who have an essentially male phenotype with an apparently normal 46XX karyotype. This has led to further basic research into the embryological determination of sex. On molecular analysis these males will almost invariably be found to have the SRY gene. This gene is now known to be the main genetic switch in determining whether a fetus becomes male or female. After the SRY gene has been expressed there may still be other hormonal and genetic factors which will modify the sexual phenotype. Amongst the hormonal factors are congenital adrenal hyperplasia in which an overproduction of androgens will lead to virilization, and testicular feminization in which the absence of testosterone receptors prevents the development of the external genitalia. There are also other modifying genes on the autosomes found through the analysis of malformation syndromes, e.g. the gene responsible for sex reversal in camptomelic dysplasia is the SRY related gene SOX9,<sup>30</sup> and the gene responsible for ovarian dysgenesis in blepharophimosis-ptosis syndrome is the forkhead transcription factor FOXL2.<sup>31</sup> A good review of the role of SRY in sexual differentiation is given by Goodfellow & Lovell-Badge.<sup>32</sup>

## XYY SYNDROME

The initial reports of males with 47XYY came from studies of males in institutions for mentally ill criminals and this biased ascertainment initially distorted the understanding of this chromosomal abnormality.

It is relatively common with an incidence of 1 in 1000 males. In order to obtain a truer picture of the syndrome a number of prospective studies have been carried out looking, for example, at the karyotypes of all newborn children in a particular area and following those with sex

chromosome abnormalities through childhood.<sup>33</sup> The XYY karyotype is associated with a normal birth weight but increased growth in early to mid-childhood. About a third are in the 90th centile for height. Intelligence is not significantly different from their chromosomally normal siblings. Detailed psychological testing does reveal a tendency to compulsive behavior, which in certain settings may lead to socially deviant behavior, but in the presence of a stable family background this can be more appropriately channeled. It should be remembered that the vast majority of males with 47XYY remain undetected in the community.

## FRAGILE X MENTAL RETARDATION

It has long been recognized that there is a considerable excess of males in the mentally handicapped population, and it is now realized that this is due to a considerable number of X-linked forms of mental retardation. Systematic research studies of these families have revealed a large number of new genes but as yet testing for the genes is not available. There are a number of good reviews available.<sup>34,35</sup> At present the most significant form of X-linked mental retardation is fragile X mental retardation.

In 1969 Lubs demonstrated a fragile site on culture of the X chromosome in a family with mental retardation, but it was initially regarded as an isolated curiosity. Around the same time Dr Gillian Turner studied a number of X-linked mental retardation families in a mental handicap institution and described their relatively 'normal looking' appearance together with large testes. Lubs had described the cytogenetic finding and Turner the phenotypic appearance of fragile X mental retardation. Several years later the connection between the clinical and laboratory findings was firmly established and the condition is now recognized as the second commonest cause of mental handicap in males after Down syndrome. The incidence of fragile X mental retardation is 1 per 1000 males. In a study of autism 5% of the male patients were found to have fragile X mental retardation.

### Clinical features

The phenotype of fragile X mental retardation is not as striking as that of Down syndrome, but with experience can be recognized (Fig. 14.19). Fragile X males have a large forehead, large head, long nose, prominent chin and long ears. The facial phenotype, however, becomes more obvious with age and is not easily recognizable in younger children.

Fragile X males tend to be larger at birth and taller than other children, but do not achieve the full growth predicted by the centile chart. In adult life fragile X males tend to be short. The head circumference is increased, with many having a head circumference greater than the 97th centile. Similarly the ear length is increased. This is an extremely useful clinical sign and may be measured and compared with a centile chart prepared from a normal population.<sup>15</sup>

Macro-orchidism is present in 80% of adult fragile X males and 15% of prepubertal fragile X boys. The size of the testes may be considerably enlarged. In one series the range was 15–127 ml (the standard orchidometer can only be used for testicular volumes up to 25 ml!). The large testes are functionally normal and the increased size may be due to an increase in interstitial edema or connective tissue. Large testes are a relatively rare feature in other syndromes with mental handicap.

It has been suggested that there may be a connective tissue abnormality in fragile X. There is a slight increase in the frequency of mitral valve prolapse. More striking clinically is the soft skin and joint hypermobility, which may be helpful diagnostically.

The range of intellectual handicap in fragile X males varies but most are moderately to severely retarded. Females tend to be more mildly affected. There is also a suggestion that intelligence may decline with age. Speech development is particularly affected in fragile X males and behavioral changes and seizures may occur.

### Molecular genetics

The fragile site in the X chromosome was initially used to diagnose this disorder but in affected males only 5–20% of cells will

Fig. 14.19 Facial features of fragile X mental retardation (reproduced with permission).

demonstrate the fragile site and in female carriers only half of the carriers could be detected by the cytogenetic test. It is now recognized that the fragile site is a marker for the disease rather than its cause.

The diagnostic difficulties were resolved by the identification of the FMR-1 gene at Xq27. The gene has within it a repeating sequence of three nucleotides CCG. Normal individuals have up to 45 copies of the nucleotide repeat. If the number of repeats is greater than 45–55 it becomes unstable in meiosis and can then increase in repeat number. The initial increase to between 55 and 200 repeats is referred to as the *premutation*. It may be found in intellectually normal males and female carriers. However, after passing through meiosis in the female the size of the repeats increases to the *full mutation* of greater than 200 repeats and can then produce learning difficulties in both males and females. Repeat number may increase or decrease in the full mutation during somatic cell division and therefore somatic mosaicism can be detected in some affected individuals. The full mutation affects the methylation of the DNA and this in turn switches off the FMR-1 gene and will affect both intellectual function and the cytogenetic fragility.

In terms of inheritance therefore it appears very similar to X-linked recessive inheritance as the condition is passed through females and will affect males, but up to a third of carrier daughters may also be affected with learning difficulties and the mutation can arise from unaffected males.

The discovery of the FMR-1 gene has meant that accurate follow-up and counseling of families is possible (Fig. 14.20). Prenatal diagnosis using chorionic villus sampling (CVS) and molecular analysis is possible in the first trimester of pregnancy.

Fig. 14.20 Autoradiograph of Southern blot looking for fragile X. The DNA has been digested by the restriction enzyme Eco R1 and probed with FMR-1 probe OX1.9. The normal fragment size is seen in lanes 1, 2 and 5. In lane 3 there is an expanded fragment (<500 repeats) indicating an affected boy. In lane 4 there is a female with a normal band and a slightly larger band above, indicating a carrier of a premutation. (Courtesy of R. Taylor.)

### SINGLE GENE DISORDERS: INHERITANCE

Distributed amongst the 46 chromosomes, there are approximately 45 000 structural genes, which code for specific proteins. The position at which the gene lies on the chromosome is referred to as the *locus*. At the locus there is a pair of alleles. If an individual possesses two alleles that are the same, the individual is said to be *homozygous* for that particular trait. If the two alleles are different, the individual is said to be *heterozygous*. A gene which is manifest in the heterozygote is *dominant*, whereas a gene which is only manifest in the homozygote is *recessive*. These terms do not refer to the characteristics of the genes, but only to their manifestations. It is, therefore, more correct to refer to a ‘dominant disorder’ rather than a ‘dominant gene’.

A trait or disorder which is determined by a gene on an *autosome* is said to be inherited as an autosomal trait and may be dominant or recessive. A trait or disorder that is determined by a gene on one of the *sex chromosomes* is said to be sex linked and may also be either dominant or recessive.

### DRAWING THE PEDIGREE

The first stage in analyzing the pattern of inheritance in a family is to draw up a pedigree. This is a shorthand method of putting all the relevant family information together in a systematic way. The symbols used in drawing up a pedigree are illustrated in Table 14.5. Each individual

Table 14.5 Pedigree symbols

□	Male unaffected
○	Female unaffected
■	Male affected
●	Female affected
◻	Deceased unaffected
◊	Sex unknown
⊙	Miscarriage or termination
⊖	Dizygotic twins
⊗	Monozygotic twins
◻◻	Heterozygote
◻◻	Propositus or index case
◻◻	Consanguineous marriage
◻◻	Illegitimate or adopted
○	Female without offspring
②	Two unaffected females

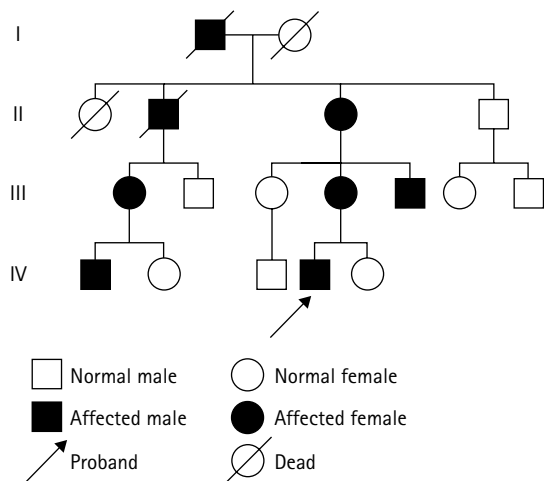

Fig. 14.21 Pedigree pattern of an autosomal dominant trait.

in a pedigree is identified from his generation (Roman numerals) and his location in the generation (Arabic numerals). Thus the index case or proband in Figure 14.21 is IV.4. It is usually necessary to ask specifically about consanguinity and miscarriages as most patients will not realize that these details are relevant.

### AUTOSOMAL DOMINANT INHERITANCE

In an autosomal dominant disorder an affected individual possesses the abnormal (mutant) gene and its normal allele. When an affected individual marries a normal person, on average half their children will be affected. This is because an affected person produces gametes that have either the mutant allele for the disorder or the normal allele. If the normal allele is represented as 'a' and the abnormal allele as 'A' then the various combinations are illustrated in Table 14.6.

Classically an autosomal dominant disorder can be traced back through several generations, but if the condition is severe, affected individuals may not survive to have children and transmit the disease to subsequent generations. In such cases the affected individual is 'sporadic', as the condition in the individual has arisen as a new mutation and they will not live to reproduce. The frequency of new mutations arising varies from condition to condition, e.g. about 50% of cases of neurofibromatosis arise from new mutations whereas new mutations are rare in Huntington disease.

Autosomal dominant traits affect both males and females (Fig. 14.21). They may show great variation in severity (= *expressivity*) as in neurofibromatosis, which may range from being a relatively mild pigmentary skin disorder to a cause of severe deformity. Sometimes the gene may not express itself at all, in which case it is said to be nonpenetrant. This phenomenon explains apparent skipped generations in certain pedigrees. The *penetrance* of the trait is the proportion of heterozygotes who express a trait.

Table 14.6 Autosomal dominant inheritance

		Affected parent (Aa)	
		↓ gametes	
		A	a
Normal parent (aa) → gametes	a	Aa affected	aa normal
	a	Aa affected	aa normal

Some autosomal genes are expressed more frequently in one sex than in the other. This is referred to as sex-influenced inheritance or, in the extreme case in which only one sex is affected, as *sex-limited inheritance*. Possible examples of sex-influenced autosomal traits include hemochromatosis, gout and male pattern baldness. The underlying difference in expression may be due to the different hormonal background.

In myotonic dystrophy it was suggested that the severity of the condition tended to increase with each generation, e.g. the grandparent could have had cataracts only, while the mother had myotonia and muscle weakness and the affected child had the disorder in its congenital form with developmental delay. This was referred to as *anticipation*. It was initially thought that the cause of this was a bias in ascertainment but it is now clear that the underlying mutation is a triplet repeat in the myotonin kinase gene. Triplet repeats within a gene may become unstable at a critical size and at this point there may be an increase in the repeat size number during meiosis leading to an increasing severity in the next generation.

Occasionally it is known that a particular disorder is autosomal dominant and fully penetrant, and yet an unaffected parent will have two affected offspring. It is very unlikely that this was due to two independent *de novo* mutations and the most likely explanation is *germinal* or *gonadal mosaicism*. In this situation the unaffected parent carries the mutation only in the testis or ovary and not in the other tissues of the body.

### AUTOSOMAL RECESSIVE INHERITANCE

Autosomal recessive traits affect both sexes and only homozygotes are affected. The affected individuals in a family are all in one sibship, i.e. they are brothers and sisters (Fig. 14.22). The parents of an affected child or children are both heterozygotes and are perfectly healthy. It is, therefore, not possible to trace the disease through several generations unless there is complex inbreeding. With rare recessive traits the parents of affected individuals are often related, the reason being that cousins are more likely to carry the same genes because they inherited them from a common ancestor.

When parents have a child affected by an autosomal recessive disorder the likelihood of the next pregnancy being similarly affected is 1 in 4. The risk remains 1 in 4 for each successive pregnancy no matter how many children may be affected in the family. If the normal allele is represented as 'A', and the abnormal allele as 'a', then the possible combinations are illustrated in Table 14.7.

Nowadays, since families tend to be small, it frequently happens that an autosomal recessive condition appears sporadic with only one affected person in the family.

The majority of inborn errors of metabolism are due to deficiencies of specific enzymes and are inherited as autosomal recessive traits. In some instances it may be possible to demonstrate that individuals are heterozygotes in these disorders by finding an intermediate level of enzyme activity.

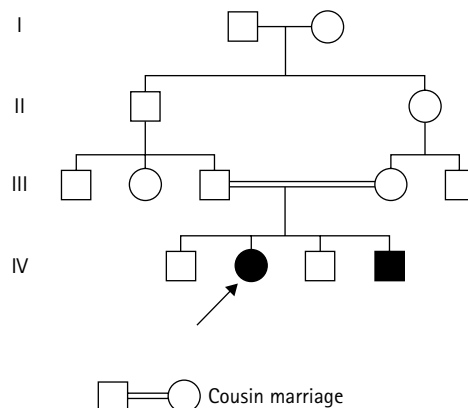

Fig. 14.22 Pedigree pattern of an autosomal recessive trait.

Table 14.7 Autosomal recessive inheritance

		Normal heterozygous parent (Aa) gametes	
		↓ gametes	
		A	a
Normal heterozygous parent → (Aa) gametes	A	AA normal	Aa unaffected heterozygote
	a	Aa unaffected heterozygote	aa affected

Where a number of different mutant alleles exist it is occasionally possible to find an individual who is heterozygous for two different mutant alleles. An example of this is seen in the hemoglobinopathies. An individual may be heterozygous for both HbS and HbC. Such double heterozygotes or 'genetic compounds' have a disease intermediate in severity between sickle cell disease and HbC disease.

**CODOMINANCE**

Codominance is the term used for two traits, which are both expressed in the heterozygote. An example of codominance is the inheritance for the blood groups A and B. An individual with both alleles will have the blood group AB.

**X-LINKED RECESSIVE INHERITANCE**

In theory sex-linked inheritance could be either X-linked or Y-linked, but as there are no structural genes other than those determining sexual development on the Y chromosome, sex linkage is effectively the same as X linkage.

An X-linked recessive trait is one which is due to a mutant gene on the X chromosome, and is carried by females to affect males (Figs 14.23 and 14.24). The affected males are *hemizygous* (with the mutant gene on their single X chromosome) while the carrier females are heterozygous and are usually perfectly healthy. X-linked disorders may also be transmitted by affected males through their daughters unless the disorder is so severe that affected males do not survive to have children (e.g. Duchenne muscular dystrophy). Hemophilia is an X-linked recessive disorder in which improvements in medical treatment and surgical techniques have led to affected males often surviving into adult life. If an affected male marries a normal female

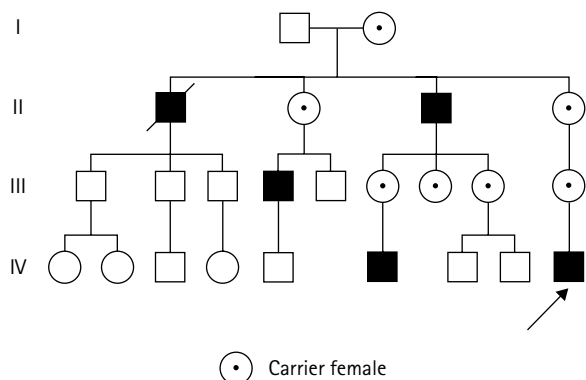

Fig. 14.23 Pedigree pattern of an X-linked recessive trait in which affected males reproduce.

Fig. 14.24 Pedigree pattern of a severe X-linked recessive trait in which affected males do not survive to have children.

and if the hemophilia gene is represented as X<sup>h</sup> and the normal gene as X, then the various gametic combinations that can occur are represented in Table 14.8. Thus, all daughters of an affected male are carriers and all his sons are normal. In the case of a woman who is a carrier (XX<sup>h</sup>) and who marries a normal male then half her sons will be affected and half her daughters will be heterozygote carriers (Table 14.9).

Quite often in serious X-linked conditions there is only one affected boy in a family. Such a sporadic case may be the result of a new mutation in the affected boy's X chromosome and in such cases recurrence would not occur in the family. It is also possible that the mother might be a carrier, and by chance the mutant gene has not been transmitted to any of her other male offspring. In families with predominantly female offspring an X-linked mutation may be inherited through the female line for a few generations without affected males. In one third of isolated cases of Duchenne muscular dystrophy the mutation occurs in the affected boy, and in two thirds of cases the mother is a carrier. It is obviously of vital

Table 14.8 X-linked inheritance: the offspring of affected males

		Affected male (X <sup>h</sup> Y)	
		↓ gametes	
		X <sup>h</sup>	Y
Normal female (XX) → gametes	X	XX <sup>h</sup> carrier daughter	XY normal son
	X	XX <sup>h</sup> carrier daughter	XY normal son

Table 14.9 X-linked inheritance: the offspring of affected females

		Normal male (XY)	
		↓ gametes	
		X	Y
Carrier female (XX <sup>h</sup> ) → gametes	X	XX normal daughter	XY normal son
	X <sup>h</sup>	XX <sup>h</sup> carrier daughter	X <sup>h</sup> Y hemophiliac son

importance to determine if the mother is a carrier in order to provide accurate information about recurrence risks. The probability of the mother being a carrier can be calculated using knowledge of the numbers of unaffected males in the family (the more unaffected males the less chance the mother is a carrier), the level of creatine kinase (female heterozygotes have slightly higher levels than female controls from the general population) and using information from DNA studies.

In a number of special circumstances a female may exhibit manifestations of an X-linked recessive trait. It may occur as a result of random inactivation or *lyonization* of the X chromosome. In early embryogenesis in the female zygote one of the X chromosomes is inactivated in each cell. This process is random so that on average half the cells in a female will have one X chromosome inactivated and half will have the other X chromosome inactivated. However, occasionally by chance the majority of cells will have the X chromosome with the normal allele inactivated and the mutant allele will be partially expressed. This situation is seen in female carriers of Duchenne muscular dystrophy where about 5% of female carriers may show some muscle weakness. It may also occur in the rare situation when a female is both a carrier of an X-linked mutation and has a 45X karyotype (Turner syndrome). Finally it can also occur in common X-linked disorders such as red-green color blindness where an affected male marries a female heterozygote and produces a daughter in whom both X chromosomes possess the mutant allele.

### X-LINKED DOMINANT INHERITANCE

An X-linked dominant disorder is one which is manifest in the heterozygous female as well as in the hemizygous male. The pedigree pattern superficially resembles that of autosomal dominant inheritance, but in an X-linked dominant disorder an affected male transmits the disease to all his daughters and to none of his sons. Affected females transmit the disease equally to sons and daughters, half of whom, on average, will be affected (Fig. 14.25).

There are relatively few X-linked dominant disorders. One example is vitamin D-resistant rickets (hypophosphatemia). In some X-linked dominant disorders the condition is lethal in males and so only females are affected (e.g. incontinentia pigmenti, Rett syndrome).

### MITOCHONDRIAL INHERITANCE

While the vast majority of genes are located in the nuclear genome there are a small number of genes located on the mitochondrial DNA (mtDNA). The mitochondrial DNA consists of 16.5 kb of circular DNA and accounts for 1% of the total DNA. mtDNA encodes for the proteins essential for aerobic respiration, and defects in mtDNA reflect abnormalities in this function.<sup>36</sup> Each cell contains between 1000 and 100 000 copies of mtDNA. In the vast majority of cells the functional mtDNA will be identical. This is referred to as *homoplasmy*. However, where there is a mutation in the mtDNA it will not usually be present in all mitochondria and cells will have a mixture of mitochondria with the 'wild type' gene and mitochondria with the mutation. This is referred to as *heteroplasmy*. The proportion of the mitochondria with the mutation will determine

whether there is a phenotypic effect from the mutation. In practice over 85% of the mitochondria would need to have the mutation before there was a phenotypically significant defect in the enzymes of the respiratory chain.

In mitochondrial diseases there may also be variation among tissues in the body. This may have considerable practical implications in diagnosis since a blood sample may not give an accurate reflection of abnormalities in other tissues. For this reason muscle biopsy is the mainstay of diagnosis of mitochondrial diseases rather than blood sampling. In many mitochondrial diseases there will be characteristic 'ragged red fibers' on Gomori staining and a nonspecific elevation of lactate and pyruvate in the blood. It also follows from these tissue differences that prenatal diagnosis may be difficult, as the proportion of a mitochondrial mutation in a chorionic villus sample may not reflect the proportion of the mutation in other parts of the fetus.

The segregation of mitochondrial genes does not follow Mendelian inheritance. Mitochondrial genes are not passed paternally as the mitochondria are in the tail of the sperm and only the nucleus of the sperm penetrates the ovum at fertilization. The ovum on the other hand has a relatively large volume of cytoplasm and thus contains many mitochondria. The exact proportion of offspring affected will depend on the proportion of mitochondria containing the specific mutation in the fertilized ovum. It is thus very difficult to give accurate recurrence risks for mitochondrial disorders and the best guide at present is to rely on the statistical data from family studies.

Another complication in mitochondrial disease is that some of the enzymes in the respiratory chain and hence some of the mitochondrial functions are not coded for in the mtDNA but are coded for in the nuclear DNA. Mutations in these genes affecting mitochondrial function are inherited in a Mendelian pattern. One example of such a disorder is Barth syndrome (endocardial fibroelastosis, neutropenia and muscle weakness) which is due to a mutation in the G-45 gene on the X chromosome and is therefore inherited as an X-linked recessive disorder.<sup>37</sup>

There are a number of characteristic mitochondrial disorders which are important in clinical practice:

- Kearns-Sayre syndrome: this is a progressive external ophthalmoplegia with ptosis and muscle weakness.
- MERRF: myoclonic epilepsy with ragged red fibers.
- MELAS: mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes.
- Leber's hereditary optic neuropathy (LHON) which presents as acute or subacute visual failure in the second or third decade.<sup>38</sup>

However in many cases the clinical phenotype will not fit into a characteristic presentation and the possibility of mitochondrial disease should be considered in cases of lactic acidosis, muscle weakness, cardiomyopathy, deafness or pigmentary retinopathy.

In clinical practice pathological mutations are most significant, but there is also a wide range of harmless variation in the mtDNA. Such genetic variations are similar to the variation seen in blood groups and are known as *polymorphisms*. The mitochondrial polymorphisms have been used to study human evolution and the spread of different populations.<sup>39</sup>

## DNA AND GENE ACTION

### STRUCTURE AND FUNCTION OF GENES

The genetic material that is capable of providing a perfect replica in cell division is in the form of a molecule of DNA. While it is possible to study chromosomes at a microscopic level, the genes are well below the resolution of the microscope. Looking at the chromosomes under the microscope is rather like looking at the wrapping around the genes. In rough terms a 5 cm length of DNA is compressed into a chromosome 10 000 times smaller by tight coiling and packing with proteins called *histones*.

DNA consists of long chains of molecules called *nucleotides*. Each nucleotide consists of a nitrogenous base (*adenine, thymine, guanine* or

Fig. 14.25 Pedigree pattern of an X-linked dominant trait.

*cytosine*), a pentose sugar and a phosphate group. The pentose sugar in DNA is deoxyribose. The DNA (unless denatured) is in the form of two polynucleotide chains arranged in a double helix (Fig. 14.26a). The arrangement of the bases in the double helix is not random since adenine in one chain always pairs with thymine, and in the other cytosine always pairs with guanine. Thus the arrangement of nucleotides in the two chains is *complementary*, and in cell division using one chain a complementary chain may be synthesized, thus preserving the sequence of bases in each daughter cell.

The sequence of bases is important, because the arrangement of the bases provides the genetic code from which proteins may be made (Fig. 14.26b). The genetic information in the DNA is first *transcribed* with messenger ribonucleic acid (mRNA) and this in turn is *translated* into the synthesis of a polypeptide chain. RNA is very similar to DNA in structure except (i) the thymidine is replaced by uracil, (ii) the deoxyribose is replaced by ribose and (iii) it is a single-stranded rather than a double-stranded polynucleotide chain.

The DNA, which is responsible for the synthesis of specific proteins, forms the structural genes. The information is in the form of a *triplet code*, a sequence of three bases or a *codon* determines one amino acid. Since there are four bases involved the possible combination that could be provided is  $4^3 = 64$ . Since there are only 20 amino acids this code is said to be degenerate and most amino acids can be coded for by more than one triplet sequence. The code also provides codons to initiate and terminate synthesis.

In the first stage of protein synthesis the DNA sequence between the initiation codon and the stop codon is transcribed into mRNA. The mRNA then moves from the nucleus to the ribosomes in the cytoplasm. Here the second stage takes place, viz. the translation of mRNA into a polypeptide chain. The ribosome binds to the initiation site on the

mRNA and for each codon an amino acid is added on using transfer RNA (tRNA). Transfer RNA is another form of RNA, which because of its molecular configuration is able to carry an amino acid and match it to the appropriate codon.

It has become apparent that the majority of DNA does not code for proteins and is not transcribed at all. The total amount of human DNA is 3 billion bases and if each gene were around 2000 bases in length this would allow for 1.5 million genes. Instead it is estimated that there are around 45 000 structural genes and 90% of the genome is DNA which does not code for proteins. Much of this is highly repetitive in its sequences and may have some as yet undefined function in the control of gene action. There are various classes of noncoding DNA. One form of the highly repetitive DNA known as microsatellite DNA is widely distributed throughout the genome and also because it is variable between individuals it can be used by researchers in mapping genes in family linkage studies. In another form there are also copies of genes which are nonfunctional and are known as pseudo-genes. There are also inactivated DNA sequences known as transposable sequences which resemble the sequence found in retroviruses and indeed may have entered the human DNA from viral infection.

The structural gene has an ordered sequence that is illustrated in Figure 14.27. Upstream of the structural gene there is highly repetitive DNA and within this there are two promoter regions which regulate gene transcription. The beginning of the structural gene is marked by an initiation codon, AUG, which indicates where transcription begins. Within the region that is transcribed, the DNA may be divided into *exons* and *introns*. The exons mark the regions of DNA that code for the amino acids in the translated protein, whereas the introns or intervening sequences are spliced out of the processed RNA before it migrates to the cytoplasm as mRNA. The introns probably have a role in gene

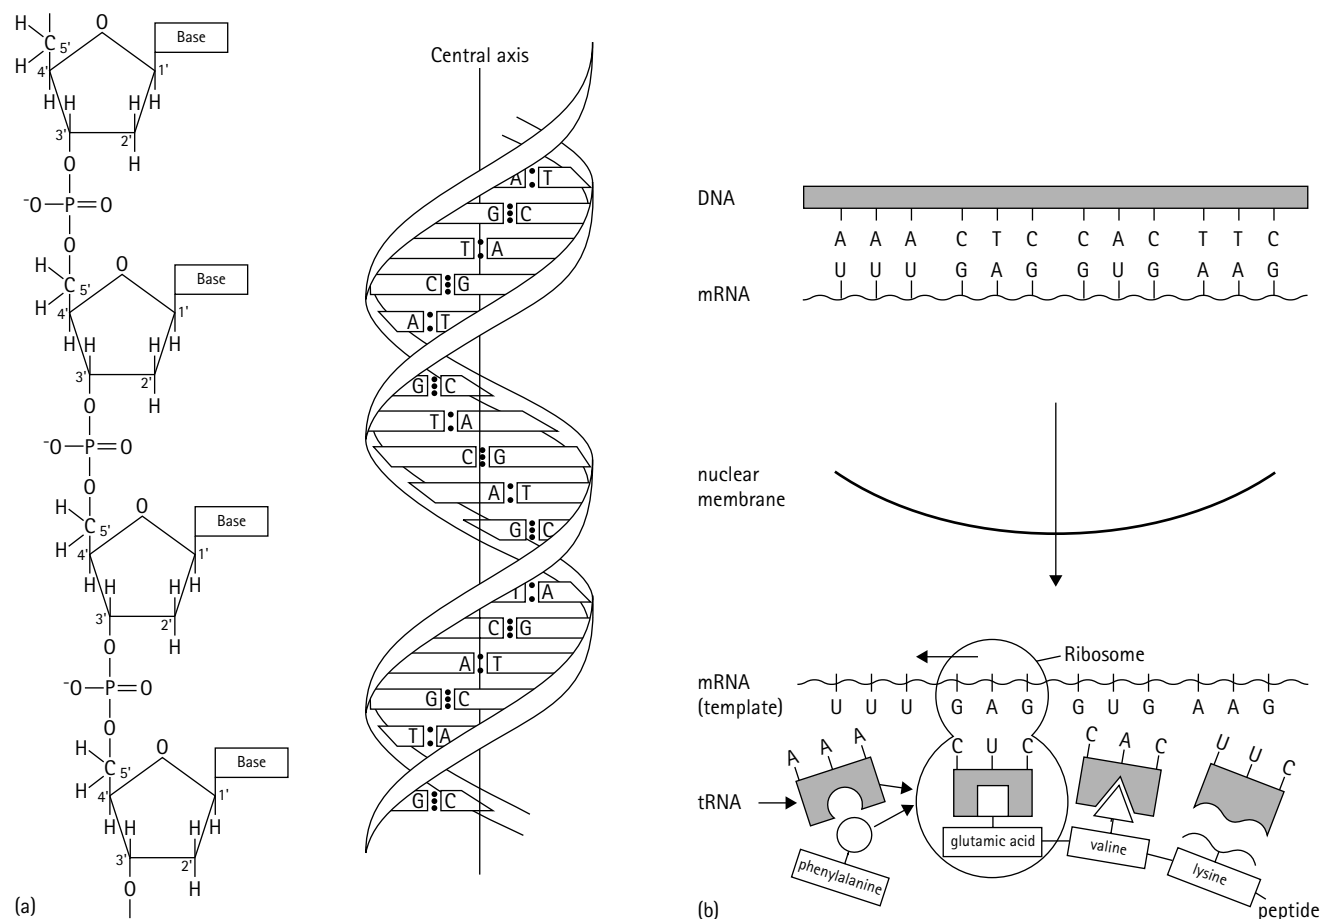

Fig. 14.26 (a) The structure of DNA. (From Weatherall 1986<sup>40</sup> with permission.) (b) The production of proteins from DNA. (Modified from Emery 1983<sup>41</sup> with permission.)

Fig. 14.27 The structural gene consists of promoter and terminator sequences that are located at either end of the gene. The coding sequence of the gene is made up of exons and introns (the mRNA of which will eventually be spliced out before translation into a protein).

regulation. The complexity of genes varies, e.g. insulin has two introns, whereas some collagen genes may have as many as 50 introns. At the end of the transcribed gene there is a stop codon and further downstream an AATAAA sequence that allows the release of the RNA.

This description of one gene producing one protein has been derived from biochemical studies in bacteria and it is often more complex than this in human genetics. In some cases such as the hemoglobin genes or some developmental genes there is a cluster of genes closely positioned together and the genes will work together to produce a complex protein or sequence of changes. In the case of the muscle protein dystrophin involved in Duchenne muscular dystrophy there is a very large gene measuring 2.5 million bases and within this gene there are several tissue specific promoters which produce different forms of dystrophin in different tissues. With immunoglobulins there is enormous diversity that comes from the alternative splicing of the RNA and DNA. With insulin the gene produces a precursor protein, preproinsulin, which is subsequently cleaved enzymatically after protein translation leaving the physiologically active insulin and its protein precursors.

At a disease level there are now many examples of one gene being associated with more than one disease. Most mutations in the androgen receptor gene will cause differing degrees of androgen insensitivity, but a CAG repeat mutation in the same gene produces X-linked spinocerebellar atrophy and gynecomastia. Similarly, different mutations in the cystic fibrosis transmembrane receptor (CFTR) gene may produce the classic features of cystic fibrosis at one end of the spectrum and bilateral absence of the vas deferens without respiratory disease at the other end of the spectrum.

## MUTATIONS AT A MOLECULAR LEVEL

A *mutation* represents a change in the genomic material. Mutations may occur in somatic cells or germinal cells. Somatic cell mutation may predispose to malignancy but will not be inherited. Mutations in the germinal cells, on the other hand, may be transmitted in the form of genetic disease. Mutations may be in the form of large chromosomal rearrangements as described in the earlier part of the chapter or may occur at molecular level in a single gene.

At a molecular level the main types of structural mutation are:

1. *Single base substitutions ('point mutations')*. These involve the substitution of one base for another but may have different effects.
  - Missense mutations: the replacement of one amino acid for another in the gene product. A good example of such a mutation is sickle cell disease in which an A to T substitution in the 6th codon of the globin gene changes GAG to GTG and hence leads to the substitution of valine for glutamic acid and the subsequent physiological effects on the hemoglobin molecule.
  - Nonsense mutations: the replacement of an amino acid codon with a stop codon (UAA or UAG or UGA) which leads to a truncation of the gene product.
  - Splice site mutations: a single base substitution which creates or destroys an intron–exon splice site.
2. *Deletions*. Deletions may vary in size from single bases to megabase lengths of DNA. There are many examples of molecular deletions, e.g. over 60% of mutations in Duchenne muscular dystrophy are due to deletions in the dystrophin gene. One specific type of deletion is that which occurs in the promoter sequence of the gene;

these will affect the rate of synthesis of the gene product rather than its structure, e.g. promoter deletions have been reported in thalassemia.

3. *Insertions and duplications*. These mutations may arise from unequal crossing over at meiosis and can disrupt the gene.
4. *Frameshift mutations*. These can be produced by deletions or single base substitution and as a result all the subsequent codons in the gene are misread as the nucleotides must be read in 'threes'.
5. *Dynamic mutations*. When there are trinucleotide or triplet repeats in a gene the transmission of the exact number of repeats may become genetically unstable and may increase further in subsequent generations, e.g. fragile X mental retardation, myotonic dystrophy and Huntington disease.

In addition to the structural classification for mutations it is possible to classify mutations in functional terms. Some mutations will produce no change in the function of the gene and thus will not be selected against in evolutionary terms. These nonpathological changes become variations or *polymorphisms* in the population. When a new change is found in a gene it is important to determine whether it is pathological or simply a polymorphism.

Mutations may produce loss of function. In many cases this loss of function is not critical unless both alleles have a loss of function and then the level of the gene product becomes critically low. This is the situation in autosomal recessive disorders. Other genes may serve a more critical role and the loss of function in one allele will be sufficient to produce an effect. This is referred to as haploinsufficiency and is the situation that is found in autosomal dominant inheritance. If a chromosome deletion in the same area produces the phenotype then haplosufficiency of critical genes is likely to be the molecular mechanism.

Collagen is made up of three strands of procollagen polypeptides in a triple helix. The procollagen polypeptides are produced by several collagen genes. A heterozygous mutation in one of these collagen genes may produce serious abnormalities in collagen because the abnormal procollagen polypeptide produced binds abnormally with the other procollagen polypeptides and leads to major disruption in the final collagen product. The effect of this mutation has been described as 'protein suicide' or a dominant negative effect. This is the underlying molecular pathology in some forms of osteogenesis imperfecta.

Mutations can produce a gain of function. The gain of function may be due to the overproduction of a protein such as the peripheral myelin protein (PMP22) in Charcot–Marie–Tooth disease or the accumulation of protein aggregates in Huntington disease. It may also be due to a receptor being switched on permanently, such as the GNAS subunit of the G protein in McCune–Albright syndrome.

Genetic heterogeneity underlies much of the complexity of inherited disease. The term may be used to describe how similar conditions may have different patterns of inheritance, e.g. Noonan syndrome and Turner syndrome both have short stature and a webbed neck but Noonan syndrome is autosomal dominant and Turner syndrome is chromosomal. It may also apply at the molecular level. *Locus heterogeneity* describes the situation where the same disease may be caused by mutations in different genes, e.g. osteogenesis imperfecta may be caused by mutations in either the COL1A1 on chromosome 17 or the COL1A2 gene on chromosome 7. *Allelic heterogeneity* describes the situation where the same disease may be caused by different mutations in the same gene, e.g. there are now over 700 recognized mutations in the CFTR gene causing cystic fibrosis.

Fig. 14.28 DNA may be damaged but has a capacity to repair itself. (From Bunday 1985<sup>42</sup> with permission.)

Mutations usually produce a permanent change in the gene, but DNA has some ability to repair itself. This has been studied largely from disorders where DNA damage leads to malignancy. Ultraviolet exposure leads to the formation of pyrimidine dimers binding the nucleotide bases. In the rare skin disorder xeroderma pigmentosum such abnormal dimers cannot be repaired because of an enzyme deficiency and ultimately skin tumors develop. The stages in normal repair are illustrated in Figure 14.28. Firstly, the single strand of DNA with the dimer formation is excised and removed, then using a DNA replicase a new strand is synthesized using the complementary strand as a template; finally the new strand is fixed into strands of the original using a DNA ligase. Some of the other inherited disorders leading to premature aging are also due to defects in DNA repair.

## THE HUMAN GENOME MAPPING PROJECT

One of the most important events in human biology has been the mapping of genes to their chromosome location which started in the mid-1980s; by February 2001 the first draft of the human genome was published.<sup>43,44</sup> To understand the process it is necessary to look at the classic approaches to gene mapping and also the more automated approach.

## TRADITIONAL GENE MAPPING

Gene mapping has depended on finding gene loci that are linked. When two genetic loci are close together on the same chromosome they are said to be *linked*. If two loci are at different ends of the chromosome then it is very likely that they will be separated during meiosis since there are two or three crossovers for each chromosome (see Fig. 14.3). The closer together they are, the less likely that they will be separated during meiosis. Thus a measure of how close gene loci are to each other is the frequency of recombination. This is measured in *map units* or *centiMorgans* where 1 centiMorgan is equivalent to a 1% chance of recombination.

Gene mapping has been of considerable practical value in medical genetics as it has been possible to progress from gene localization to sequencing the gene and to identifying the gene product. A good example of this was the research that led to the discovery of dystrophin as the altered gene product in Duchenne muscular dystrophy.<sup>42,45</sup> This approach is known as *reverse genetics*, since it reversed the traditional approach of identifying the gene mutation from the enzyme or protein abnormality.

Genes have sometimes been mapped by finding an association between a disorder and a specific chromosome rearrangement, then the gene for that disorder may be located at the chromosome breakpoints. For example, patients were found with retinoblastoma and deletions of 13q14, and further research has identified the gene responsible for retinoblastoma to be located in this region.

The other technique commonly used is *linkage analysis*. If a specific genetic marker segregates in a family with a single gene disorder, then the gene for that disorder will be located on the same chromosome as the marker and the position of two genes can be estimated from the frequency of crossovers. For example, in Figure 14.29, a large family with an autosomal dominant disorder is studied with a DNA polymorphism which gives four alleles, A, B, C and D. In the first generation the disease is inherited with the B allele from the grandfather (I.1) to his son (II.1).

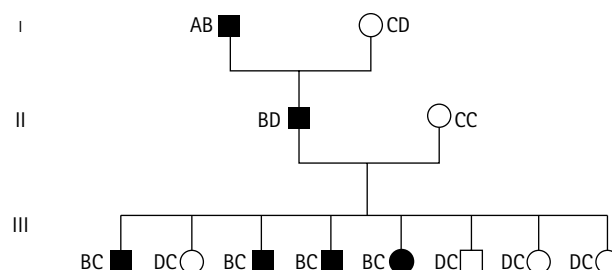

Fig. 14.29 Gene mapping by linkage analysis. In this pedigree the polymorphic marker B is segregating with the disease, with the exception of III.7 where a meiotic recombination between the polymorphic marker and the disease has occurred.

In other words the DNA polymorphism B and the disease allele are on the same particular chromosome and the linkage phase is established. In the third generation it is possible to see if any recombination takes place. In all but one of the eight children the B polymorphism segregates with the disease and the D polymorphism segregates with the normal allele. The exception is III.7 in whom there has been a recombination. Thus there has been one recombination out of eight meioses and the recombination rate is 12.5% or 0.125. Obviously not all families are so obligingly large and informative, but it is still possible to carry out linkage analysis with smaller families because the number of meioses may be added together.

The usual way of expressing linkage is as the log of the odds of linkage or the *lod score*, and this is expressed in terms of genetic distance by the recombination fraction  $\theta$ . A recombination fraction of 0.05 represents a 5% chance of recombination. A lod score of 3 or over, for a recombination fraction of 0.05 or less, is significantly close linkage for prenatal diagnosis.

## AUTOMATED APPROACH

While the traditional approaches have continued to prove useful in mapping diseases it was realized that a more industrialized approach using banks of automated gene sequencers could be used to systematically identify all the genes. The DNA is basically cut into small sections and cloned and then the fragments are sequenced. The order of the fragments can be worked out if they have overlapping sequences and eventually all the DNA in the human genome can be sorted into these overlapping fragments. The structural genes can be identified by relating the DNA to expressed sequences (ESTs) and from this the total number of genes can be identified. One of the first surprises from the Human Genome project was the finding that humans did not have 100 000 genes, as had been previously predicted, but probably only have 45 000 genes or less. This gives us only twice as many genes as the nematode worm and might be taken to indicate we are not as complex or advanced in evolutionary terms as we had thought. It is, however, probably not correct to equate biological complexity with the number of genes. An analogy could perhaps be taken from literature. Everyone writes with the same number of letters in the alphabet but that does not stop Shakespeare from writing great sonnets. In the same way it may be the complexity of gene expression that distinguishes humans from other species. One of the most challenging questions that comes from the genome project is the fact that the difference between some primates and humans comes down to a mere 1% of genes. Perhaps determining what difference this makes will help to define the essential qualities that make the human species different and define the biological basis of humanity.

At present there is only a draft of the genome available and many gaps to fill in with further sequencing. At the time of writing about 17 000 disease genes have been identified. This is just a beginning and there will need to be an enormous amount of research to determine the clinical significance of the genes in relation to disease and normal function.

Already there are a number of new developments in human genetics which will develop the discoveries of the human genome:

- **Bioinformatics.** The amount of information that has to be analyzed is staggering, and making sense of the interrelationship between genes will be even more challenging. This has led to the development of new information technology systems to handle the data.
- **Comparative genomics.** The genome mapping project is not confined to analyzing the human genome and the genomes of other species are being analyzed using the same technology. This has already meant that the location of human diseases can be identified by finding a similar defect in the mouse and working back from the knowledge of the position of the defect on the mouse chromosomes to the homologous position on the human chromosome.
- **Transgenic animals.** It is often necessary to test out treatments in animals but difficult to find the appropriate animal model. Now it is possible to take a gene mutation causing human disease and to insert the mutated human gene into a mouse embryo and construct a transgenic mouse model that matches the human disease very accurately.
- **Gene expression and proteomics.** Having found a disease causing gene it is then necessary to see how that gene is expressed and what the protein it produces is like. The studies will therefore move from the gene (genomics) to the protein (proteomics).
- **Pharmacogenomics.** At present it costs up to £500 million to develop a new drug and along the way there will be many potential drugs which might be effective but cannot be used because a small number of people will develop severe side-effects from the potential drug. It has been discovered that many of these side-effects are determined by genetic variation. Therefore if those who might develop side-effects could be identified genetically before the drug was used then it would be possible to bring many new drugs safely to the market and possibly to reduce the enormous cost of development. Another approach that might be used in pharmacogenomics is to define the heterogeneity within a disease and to target drug treatment more specifically, e.g. rather than treating all individuals with high blood pressure with the same drugs it might be possible by genetic analysis to identify those with abnormal salt metabolism from those with abnormal vascular responses.
- **Gene therapy.** Although gene therapy is the ultimate aim for genetic research it is likely to take some time for this to be more widely successful. There are many technical problems to solve. At present the correct gene is usually introduced into the patient using a viral vector, but this is relatively inefficient and even when it does correctly enter the disease tissue it is lost rapidly. There are also problems about using a virus even when it has been biologically inactivated and the use of a viral vector would probably never be acceptable in the treatment of neurological disease since it might well cause serious complications. There is considerable knowledge of the genetic defect in cystic fibrosis and a number of attempts have been made to use gene therapy to treat cystic fibrosis with rather disappointing results so far.<sup>46</sup> Because of the risks involved it may well be malignant disease rather than chronic genetic disease where the first major successes take place.

## THE USE OF MOLECULAR GENETICS IN DIAGNOSIS

The recent rapid advances in medical genetics have come about largely because of the development of DNA technology. Some knowledge of the technology is helpful in understanding its practical application in the diagnosis of genetic disease. A more detailed review of the laboratory techniques may be found in Strachan & Read.<sup>47</sup>

### DNA extraction

DNA may be extracted from many different tissues. In most clinical work blood samples will be used as a source of DNA but in population studies

buccal scrapes or mouthwashes may be useful for limited DNA testing. It may also be possible to extract DNA from the dried blood spots used for neonatal screening and this may be a source of archival DNA from a child who has subsequently died. Pathology samples are more difficult to analyze as the DNA is often broken down in the fixation process and only short DNA sequences may be analyzed. In prenatal diagnosis chorionic villi provide the best source of DNA.

The DNA is obtained by lysing the cells, digesting the proteins by a proteinase and purifying the DNA by serial extractions with phenol and chloroform. The purity of the DNA obtained is then determined by spectroscopy and running an electrophoretic gel. Extracted DNA may be stored for many years at  $-80^{\circ}\text{C}$ .

### Southern blotting

The first widespread use of DNA hybridization was Southern blotting, but this is now being superseded by new techniques. The DNA is extracted and cut into small fragments with a *restriction enzyme* which will recognize specific DNA sequences and cleave the DNA at these points. The DNA may then be separated by electrophoresis so that the smallest fragments move fastest through the gel. If this is compared to a control sample, the specific size of the DNA fragment may be estimated. Throughout the genome there will be variations or polymorphisms in the cutting sites for the restriction enzymes [*restriction fragment length polymorphisms* (RFLPs)] and therefore it will be possible to study the pattern of inheritance of these RFLPs within a family. If a particular RFLP is located close to a disease gene locus, it will be possible to follow the segregation through the family and make use of this in predicting whether or not a disease has been passed on within the family. The main disadvantages of using Southern blotting are that it takes relatively large amounts of DNA and involves the use of radioisotopes, which require some days to develop on the X-ray plate.

It should be noted that this technique is named after its originator (Southern<sup>48</sup>), but rather confusingly a geographical nomenclature has been applied to other techniques, e.g. a DNA–RNA blot is known as a Northern blot, and a protein–monoclonal antibody analysis is known as a Western blot!

### Polymerase chain reaction

The polymerase chain reaction (PCR) is now the most frequently used technique in molecular biology. It is used to study a specific area of DNA using short complementary sequences of DNA (*oligonucleotides*) from both the 3' and the 5' ends of the DNA to be studied. These oligonucleotides build copies of the DNA using a *heat stable polymerase* (Taq 1). It is then possible to heat the mixture and the DNA strands will separate. On cooling, the DNA can once more be duplicated and the process repeated again and again leading to an exponential increase in the copies of the two fragments. The main advantages of this technique are that it is very quick, highly sensitive and very robust and it can be used to study mRNA as well as DNA. It can also be used to study very small amounts of almost any tissue, e.g. the blood spots on a Guthrie card or the cells found in a mouthwash sample. The technique is widely used in molecular diagnosis of genetic disease (Figs 14.30 and 14.31). It is also being used in infectious disease to confirm the presence of infectious agents and in immunology to identify the human leukocyte antigen (HLA) haplotype.

### Gene sequencing

There are a number of techniques available to decode or sequence a gene into its component nucleotide bases. Originally the process of sequencing a gene might have taken a PhD student 3–4 years but now semi-automated sequencers are available. In theory it may appear that the best way to identify gene mutations is to fully sequence the gene but this is still a major task and full exclusion of mutations causing the disease will still be very difficult, expensive and time consuming. Figure 14.32 illustrates the use of a gene sequencer in identifying a mutation in the ROR2 gene in a patient with Robinow syndrome and shows a point mutation in the gene sequencer printout.<sup>49</sup>

Fig. 14.30 PCR of exon of CFTR gene. Lanes 1 and 4 show homozygous normal individuals. Lanes 2 and 3 show heterozygous carriers of the  $\Delta$ F508 mutation and lane 5 shows an affected homozygous  $\Delta$ F508 individual. (Courtesy of R. Taylor.)

Fig. 14.31 Multiplex PCR testing for deletions in the dystrophin gene. The third lane from the left shows a band missing in amplifying exons from the 3' end of the gene, indicating a patient affected with Duchenne muscular dystrophy. (Courtesy of R. Taylor.)

Fig. 14.32 Gene sequencing of the ROR2 gene in Robinow syndrome. The bases are labeled fluorescently and scanned. The upper printout shows the normal sequences and the lower printout shows two point mutations: (a) is a 550C  $\rightarrow$  T and (b) is a 565C  $\rightarrow$  T change. (Courtesy of Dr Afzal.)<sup>49</sup>

A different strategy is to take a two step approach and to carry out a screen for mismatch between the known DNA sequence and the patient's DNA first and then to look at any areas of mismatch with full sequencing. A number of techniques have therefore been evolved to screen for mismatching between the known gene sequence and the patient's DNA. Single stranded conformation polymorphism (SSCP) analysis is relatively inexpensive but has limited sensitivity. Another technique known as denaturing high performance liquid chromatography (HPLC) requires relatively expensive equipment but is very sensitive and can be used with a high throughput of samples. A protein truncation test may be used to screen for mutations that lead to terminating mutations which shorten the gene product.

Some researchers have looked to the computer industry for inspiration and have tried to develop a DNA chip consisting of a microarray of literally thousands of individual DNA hybridization reactions on a small silicon wafer (see [CGH microarray](#)). Each reaction would cause a color change and the whole chip would be read by an automated scanning microscope. By further analogy with the computer industry, further development may increase the number of reactions per chip and bring the cost per test down.

**Table 14.10** Single gene disorders with their chromosome locations and approaches to diagnostic testing

Disease	Location(s)	Molecular tests
Adrenoleukodystrophy	Xq27	Mutation or biochemical
Adult polycystic kidney disease	16p13, 4q13	Clinical or mutation
Alpha thalassemia	16p13	Mutation
Beta thalassemia	11p15	Mutation
Charcot-Marie-Tooth disease	17p11, 1q21, Xq13	Mutation
Color blindness	Xq27	Research
Congenital adrenal hyperplasia	6p21	Mutation
Cystic fibrosis	7q31	Mutation
Duchenne muscular dystrophy	Xp21	Mutation or FISH
Emery-Dreifuss muscular dystrophy	Xq27	Mutation
Facioscapulohumeral muscular dystrophy	4q34	Linkage
Fragile X mental retardation	Xq27	Mutation
Friedreich's ataxia	9q13	Mutation
Galactosemia	9p13	Biochemical
Hemophilia A & B	Xq28	Mutation/hematological
Hypertrophic cardiomyopathy	14q12	Mutation
Marfan syndrome	15q21	Mutation or linkage
Myotonic dystrophy	19q13	Mutation
Neurofibromatosis type 1	17q11	Clinical or mutation
Neurofibromatosis type 2	22q11	Mutation
Noonan syndrome	12q23	Mutation
Oculocutaneous albinism	11q14	Mutation
Osteogenesis imperfecta	7q21, 17q21	Radiological or mutation
Phenylketonuria	12q24	Biochemical/mutation
Polyposis coli	5q21	Mutation
Sickle cell disease	11p15	Mutation
Tuberous sclerosis	9q34, 16p13	Mutation
Von Hippel-Lindau syndrome	3p25	Mutation
Werdnig-Hoffmann disease	5q13	Mutation

The techniques of molecular genetics have moved out of the research laboratory into the diagnostics laboratory. There are now many diseases in which gene analysis may help in diagnosis, but it is still necessary to recognize the limitations of the present technology. A summary of these is given in [Table 14.10](#). The tests roughly fall into two groups:

1. *Fully diagnostic*. In these diseases there is only one mutation and analysis of this will give a clear and conclusive result which may be used to confirm or exclude the disorder. Examples of these are sickle cell disease where the only mutation is the point mutation in position 6 of the beta globin chain, and in myotonic dystrophy and fragile X where there is an expansion of a triplet repeat sequence.
2. *Partially diagnostic*. In these disorders there is more than one mutation that may cause the disorder and while it may be possible to make a clear positive diagnosis it is more difficult to exclude the diagnosis without fully sequencing the whole gene. There are many examples of this, but two will illustrate the point.
  - In cystic fibrosis around 70–80% of patients have a deletion of the codon for phenylalanine at position 508 ( $\Delta F508$ ) and if a patient is found to be homozygous for this mutation the diagnosis is confirmed ([Fig. 14.30](#)). If, however, the patient without a family history of cystic fibrosis is tested for  $\Delta F508$  and is found not to have it, the diagnosis is not completely excluded as it is possible to have any one of several hundred other mutations. Rather than trying to test for such a large number of mutations it is possible to test for the commonest 32 mutations using a multiplex PCR test and this will give a 95% exclusion which is sufficient in most cases. The problem also exists if the patient is found to be heterozygous for  $\Delta F508$ . The patient might be an unaffected heterozygote carrier or could be an affected homozygote with another rarer mutation on the other chromosome 7.
  - The other example is Duchenne muscular dystrophy. By using a combination of gene probes it is possible to look for several possible deletions in the dystrophin gene. If a deletion is found the diagnosis is confirmed ([Fig. 14.31](#)). However, the absence of the deletion only provides a 60% exclusion of the diagnosis.

## MULTIFACTORIAL INHERITANCE

Many common disorders, including congenital malformations, show some increase in frequency within families, but follow no simple Mendelian pattern of inheritance. In these disorders the condition becomes manifest when there is a sufficient combination of genetic predisposition and environmental factors. These disorders are thus referred to as multifactorial.

One way of understanding multifactorial inheritance is to consider an individual's *liability* to a particular disorder to be a combination of genetic and environmental factors. Liability in the general population will have a normal distribution and it is only those whose liability goes beyond a certain threshold who will show the disease or malformation ([Fig. 14.33](#)). This would be a relatively small proportion of the general population. First degree relatives of those who manifest the disorder will have half the genes in common with their affected relatives and therefore have a greater proportion of the genetic predisposition than the general population. If one then looked at the distribution of liability in first degree relatives it would be shifted away from the distribution in the general population, so that a greater proportion of first degree relatives would be affected than in the general population ([Fig. 14.33](#)).

While the mathematical model of liability may be helpful in understanding the principles of multifactorial inheritance, it is not of practical value in providing information on recurrence risks for genetic counseling. These are best provided by the statistical analysis of family studies. For example the recurrence of neural tube defects in those families who have already had an affected child is around 5% or 15 times the risk for the general population. Similar studies looking at the offspring of those affected by spina bifida have shown a 5% risk for their offspring. [Table 14.11](#) gives some of the empiric risks

Fig. 14.33 Hypothetical curve of liability in the general population and in relatives for a hereditary disorder in which the genetic predisposition is multifactorial.

for common disorders calculated from family studies. With new techniques in molecular biology it may become possible to identify the genetic factors in multifactorial disorders. This has to some extent already been achieved in Hirschsprung disease where many of the predisposing genes have been identified.<sup>50</sup>

With multifactorial inheritance there are some general rules which are helpful.

1. The risk for sibs is approximately equal to the risk for offspring. On the whole the risks are lower than those for Mendelian inheritance.
2. The risk for second degree relatives (uncles, aunts, nephews and nieces) is considerably smaller than for first degree

relatives. The risks for third degree relatives (cousins) are for practical purposes more or less the same as those for the general population.

3. If the frequency of a multifactorial disorder is  $q$ , then the risk for first degree relatives is approximately the square root of  $q$ , e.g. esophageal atresia occurs in 1 in 10 000 births; the risk for further offspring is the square root of  $0.0001 = 1/100$ .
4. If there is a sex difference in the frequency of the disorder, then the risks are greater for further relatives of the rarer sex. For example, with pyloric stenosis males are affected five times as frequently as females. After an affected male the risk of further affected children is 2%, but after an affected female the risk is 9%.
5. The risks increase with the number of affected individuals in the family. The risk after a second affected child is more than twice the risk after a single affected child. For example after one child with a cleft lip and palate the risk is 4%, but after two affected children it is 10%.
6. In theory the recurrence data collected from family studies are only relevant for the same racial group and geographical area. If there are differences in the incidence of a disorder in different racial groups and countries, then care must be taken in applying the data, e.g. the recurrence risk for anencephaly and spina bifida is less in blacks than whites.

The epidemiological studies in neural tube defects have shown the value of looking at both the environmental and genetic aspects of multifactorial disease. The studies looked at the geographic variation of spina bifida and also looked at environmental factors that might explain this variation. It was suspected that dietary factors and especially vitamin intake were important. Eventually trials with periconceptual supplementation of folic acid to pregnant mothers at higher risk of having a child with a neural tube defect demonstrated that the predicted rate of the malformation could be reduced by 60%. This, together with the use of rubella vaccination, is an excellent example of the primary prevention of congenital abnormalities.

Table 14.11 Recurrence risks (%) for some common disorders. (From Emery 1983<sup>41</sup> with permission)

Disorder	Incidence	Sex ratio M:F	Normal parents having a second affected child	Affected parent having an affected child	Affected parent having a second affected child
Anencephaly	0.20	1:2	5*	–	–
Asthma	3–4	1:1	10	26	–
Cleft palate only	0.04	2:3	2	7	15
Cleft lip ± cleft palate	0.10	3:2	4	4	10
Club foot	0.10	2:1	3	3	10
Congenital heart disease (all types)	0.50	–	1–4	1–4	–
Diabetes mellitus (early onset)	0.20	1:1	8	8	10
Dislocation of hip	0.07	1:6	4	4	10
Epilepsy ('idiopathic')	0.50	1:1	5	5	10
Hirschsprung disease	0.02	4:1	–	–	–
Male index			2	–	–
Female index			8	–	–
Mental retardation ('idiopathic')	0.30–0.50	1:1	3–5	–	–
Profound childhood deafness	0.10	1:1	10	8	–
Pyloric stenosis	0.30	5:1	–	–	–
Male index			2	4	13
Female index			10	17	38
Renal agenesis (bilateral)	0.01	3:1	–	–	–
Male index			3	–	–
Female index			7	–	–
Schizophrenia	1–2	1:1	10	16	–
Scoliosis (idiopathic, adolescent)	0.22	1:6	7	5	–
Spina bifida	0.30	2:3	5*	3*	–

\*Anencephaly or spina bifida.

## MALFORMATION SYNDROMES

The majority of single congenital malformations has a multifactorial inheritance and a relatively low risk of recurrence. In the case of multiple malformations or the combination of mental handicap and congenital abnormalities, considerable care needs to be exercised since a proportion of such cases are caused by single gene mutations and consequently have a high risk of recurrence.

Another reason why it is important to recognize when a malformation is part of a syndrome is that it may give a better indication of the ultimate prognosis or likelihood of subsequent complications. For example, Stickler syndrome is an autosomal dominant disorder with variable expression. It may present in the newborn with a cleft palate and micrognathia and a characteristic facial appearance with a flat nasal bridge (Fig. 14.34). There is often severe myopia and possibly retinal detachment; by anticipatory follow-up the retinal detachment can be prevented by early treatment.

The clinical approach to the diagnosis and study of malformations and birth defects is known as *dysmorphology*.<sup>15</sup> There are a number of concepts that are useful in delineating patterns of malformation.

1. A *syndrome* is a recognized pattern of clinical abnormalities that have a single cause, e.g. Meckel syndrome is an autosomal recessive disorder in which postaxial polydactyly, encephalocele, cystic dysplastic kidneys and hepatic fibrosis occur together.
2. An *anomalad* is a recognized pattern of congenital abnormalities that may have several different causes, e.g. the Robin anomalad of micrognathia, cleft palate and posteriorly displaced tongue may

Fig. 14.34 Stickler syndrome.

be a feature of Stickler syndrome, fetal compression, cerebrocostal syndrome and others.

3. An *association* is a combination of congenital abnormalities that occur together at a frequency greater than by chance alone, but do not appear to recur in families, e.g. the VATER association is a combination of Vertebral abnormalities, Anal atresia, TracheoEsophageal fistula, Radial and Renal abnormalities. The combination of abnormalities might represent an insult at a specific point in embryonic development which affects all systems developing at that particular time in embryogenesis.
4. A *sequence* is a series of malformations that arise secondary to one specific developmental incident, e.g. in the prune belly sequence urethral or bladder neck obstruction leads to bladder distension which in turn leads to abdominal distension, hydronephrosis and possibly interference with testicular descent and the iliac blood supply. When the pressure is sufficient to overcome the obstruction the bladder may deflate leaving the characteristic wrinkled prune belly appearance.
5. A *deformation* arises not from an error in embryological development but because normal fetal growth is restricted, e.g. the low set ears, micrognathia and joint contractures seen with oligohydramnios in utero.

## THE CLINICAL APPROACH TO THE DIAGNOSIS OF A DYSMORPHIC SYNDROME

With the exception of radiological and cytogenetic investigations the diagnosis of a dysmorphic syndrome rarely depends on laboratory investigations. It is primarily a clinical diagnosis based on the assessment of the clinical signs and knowledge of the pattern of abnormalities seen in the dysmorphic syndromes.

In trying to weigh up the significance of specific dysmorphic features it is helpful to consider whether they are relatively common or rarely seen outside the context of a dysmorphic syndrome. Abnormalities such as a single palmar crease or partial syndactyly between the second and third toes are commonly seen in the general population and therefore are relatively minor clinical signs. Features like retinitis pigmentosa, cleft lip and polydactyly are rare in the general population as single abnormalities, and are frequently a feature of syndromes and therefore are relatively major clinical signs. Occasionally there is a specific feature that is diagnostic such as the 'hitchhiker thumb' seen in the autosomal recessive diastrophic dwarfism (Fig. 14.35).

Fig. 14.35 'Hitch-hiker thumb' in diastrophic dwarfism.

**Table 14.12** Descriptive terms used in dysmorphology

Hypertelorism	Increased distance between the eyes
Hypotelorism	Decreased distance between the eyes
Blepharophimosis	Narrowed palpebral fissures
Synophrys	Medial fusion of the eyebrows
Nasal bridge	Upper part of nose between eyes
Alae nasi	Lateral border of nostril
Columella	Medial part or septum of nostril
Philtrum	Vertical folds on upper lip
Pterygium	Webbing, e.g. webbing of neck = pterygium colli
Syndactyly	Fusion of digits
Preaxial polydactyly	Extra digit(s) on lateral border of limb
Postaxial polydactyly	Extra digit(s) on medial border of limb
Clinodactyly	Incurving usually of 5th digit
Brachydactyly	Short fingers or toes
Camptodactyly	Bent and contracted digits
Ectrodactyly	Cleft hand or foot
Symphalangism	Fusion of phalanges
Phocomelia	Absence of limb
Rhizomelia	Shortening of proximal segment of limb
Mesomelia	Shortening of middle segment of limb
Acromelia	Shortening of distal segment of limb
Dysplasia	Generalized abnormality of development, e.g. skeletal dysplasia

In trying to describe dysmorphic features, in particular facial characteristics, everyday language may be very imprecise and subjective so it is helpful to use defined terms (Table 14.12) as far as possible and to keep photographic records. The objectivity may also be improved by anthropometric measurements. There is a considerable literature on the use of anthropometric measurements in dysmorphology but some of the more useful measurements are listed in Jones.<sup>15</sup>

The diagnosis of a dysmorphic syndrome depends primarily on pattern recognition and knowledge. The task has been helped by the publication of some excellent photographic atlases.<sup>51</sup> As there are now over 2000 malformation syndromes described, a computerized database is a great asset in the recognition of rare syndromes which may have been described on only a few occasions.<sup>52,53</sup>

The subject of dysmorphology has proven itself in identifying the genes that control normal development. Genetic studies in Waardenburg syndrome (deafness, heterochromia and depigmentation) have led to the identification of a developmental gene responsible for the migration of cells from the neural crest.<sup>54</sup> Studies on craniosynostosis syndromes such as Pfeiffer and Apert syndrome have identified a group of genes such as fibroblast growth factor or fibroblast growth factor receptor which play a very significant part in skeletal development.<sup>55</sup>

## COUNSELING AND GENETIC SERVICES

### ORGANIZATION OF SERVICES

While all pediatricians and other doctors will be involved in providing some genetic information and counseling to their patients, the increasing complexity of medical genetics has led to the development of a new specialty which links the clinical and laboratory aspects. In England each regional health authority (population 1.5–4.5 million) has a regional genetic service, which combines clinical and laboratory skills. One of the important aspects of such a service is that it is orientated towards the extended family rather than the individual, and as such can provide the follow-up required for chromosome translocations or single gene disorders. Separate family records are kept on a long term basis as opposed to the relatively short periods for which individual records are kept in most general hospitals. In addition to this, DNA may be ‘banked’ from

family blood samples and be available for family studies in the future. Coordinating this may require a computerized follow-up or genetic register. The philosophy of family orientated screening can provide a highly personalized service which is very cost effective in terms of preventing handicap.

### APPROACHES TO GENETIC COUNSELING

As in all areas of medicine the first stage of genetic counseling is to establish an accurate diagnosis. Without accurate diagnosis the counseling may be erroneous. There are a number of problems in establishing a diagnosis which are unique to medical genetics. The first is the enormous number of genetic disorders which have now been described. There are over 17 000 single gene traits or disorders.<sup>56</sup> In addition to this, there are many chromosomal abnormalities and malformation syndromes, and the number of disorders described is increasing exponentially. The second problem is that the disorders are often very rare and thus even a specialist covering a relatively large population cannot rely solely on his own personal experience, but must be familiar with the medical literature. A third problem is heterogeneity. *Heterogeneity* may be at the clinical or molecular level. At the clinical level it means that two or more disorders may have the same phenotype, e.g. both Marfan syndrome and homocystinuria have dislocation of the lenses with a similar physical habitus, but Marfan syndrome is autosomal dominant, whereas homocystinuria is autosomal recessive. At a molecular level it means that a number of different allelic mutations can cause the same disease. This point is of considerable practical significance if a specific DNA diagnosis is to be made. Fourthly, the individuals who come to the genetic clinic may not themselves have any clinical features of the genetic disorder in question and so clinical examination will not necessarily provide the appropriate diagnosis. It is essential before seeing the individual in the clinic to obtain as much background medical information about the family as possible. This may mean a careful search of hospital records and considerable ingenuity in tracking the results of autopsies or laboratory investigations.

Having established the correct diagnosis it is then necessary to discuss the prognosis and likelihood of recurrence. It is particularly important to discuss the prognosis in the case of parents whose experience of a disorder may be limited because, for example, the disease has not yet progressed to any significant extent in their affected child. It should also be remembered that some conditions, such as neurofibromatosis, may show a considerable range of expression and this should be taken into account in giving advice. The risk of passing on the gene for neurofibromatosis is 1 in 2, but as only about one third of patients have serious medical complications from the disease the risk of serious complications in offspring is  $1/2 \times 1/3$  or 1 in 6.

Having diagnosed the disorder and given guidance about recurrence and prognosis, the next stage is to discuss the options that may be available to the couple (Table 14.13). It must be stressed that these reproductive discussions are personal choices rather than medical decisions and the counselor’s approach should remain nondirective. The immediate aim of genetic counseling is to inform and support families faced with genetic disease rather than reduce the frequency of genetic handicap per se.

**Table 14.13** Options which may be available for couples receiving genetic counseling

No further action
Restrict family size
Adoption
Artificial insemination by donor
Ovum donation or preimplantation diagnosis

With advances in technology accurate prenatal diagnosis can be offered for most genetic disorders and malformations. This may be by ultrasound or by an invasive test such as amniocentesis or chorionic villus sampling. For severe handicaps the option of termination of pregnancy is welcomed by many couples but in some cases prenatal diagnosis may also be used to guide and improve early neonatal treatment such as corrective surgery. In these instances it is very helpful for the couple to have the opportunity to discuss the surgical management with the pediatric surgeon when a diagnosis is made during pregnancy.

Choosing the right time for genetic counseling is very important. The couple whose child has just died from a major congenital malformation will usually want to come to terms with their loss before considering the recurrence in further pregnancies. On the other hand, leaving genetic counseling until pregnancy is advanced may produce an emotional crisis that could have been avoided by anticipation. It is to the advantage of the family and the geneticist if the initial referral is made before pregnancy.

While the above description outlines one approach to genetic counseling, it is important that the counselor's approach should be flexible. It is important to allocate sufficient time for the counseling session and to be able to elucidate the couple's feelings with open ended questions. It should be noted that a report from a working party of the Clinical Genetics Society in the UK (endorsed by the Royal College of Paediatrics and Child Health) regarded genetic screening of children for late onset disorders when there is no treatment for the disorder screened (e.g. Huntington disease) to be unethical.<sup>57</sup>

It has been shown that a patient's comprehension of the genetic information is limited by anxiety and the counselor must ensure that the patient is given every opportunity to express feelings and be put at ease as far as possible. It is often helpful to follow the session with a letter to the family outlining the important pieces of information and give them the opportunity of a further session or sessions to discuss the matter further. The consequences of genetic counseling can be profound and far reaching and so such advice should not be given lightly. Further information on genetic counseling is given elsewhere.<sup>58</sup>

## GENETIC SCREENING IN THE POPULATION

The usual provision of genetic services is on an individual or family basis. The follow-up in families may be extended to the wider family and may be on a long term basis. This approach is difficult using the normal hospital record systems, and a computerized genetic register may be developed. The genetic register can program follow-up for screening tests and make appointments for counseling when children grow up and want to make their own decisions.

It has also been recognized that genetic testing might be very effective for public health screening and the prevention of inherited disease. The development of genetic services for population screening requires a different approach (Ch. 10). The development of a population screening program should meet certain criteria:

1. The screening test should allow a useful outcome either because early diagnosis will improve treatment or because genetic testing allows reproductive choice.
2. The testing should be socially and ethically acceptable which means that issues of consent and discrimination need to have been fully considered.
3. The screening test must be accurate with a high sensitivity and specificity.
4. The screening program should be cost effective with the benefits outweighing the costs.

In many inherited diseases the rarity of the condition will not justify specific screening in the population but there is the possibility of adding many other tests onto the present neonatal blood spots as many different PCR tests can be undertaken with the same sample. Such an approach would widely increase the opportunity for screening but would require a great deal more information to be given with a consent process. There is

considerable debate at present about the possibility of neonatal screening for cystic fibrosis. It appears that early diagnosis will improve the prognosis, so there is a benefit, but there is no consensus on the most appropriate approach to testing.<sup>59</sup> It is relatively easy to include a DNA test on the Guthrie card but the genetic tests for cystic fibrosis cannot be used alone as they are relatively expensive and only pick up 90% of the known mutations. The pilot studies are evaluating using IRT (immunoreactive trypsin) measurement on the Guthrie card as the first step of screening. This may be followed by a DNA test for cystic fibrosis mutations. One of the problems with this is that the test cannot easily distinguish between a heterozygote carrier and an affected child with a known mutation and a second rare unidentified mutation. Further help may come from a second IRT measurement as the level of trypsin declines with age in the first few weeks of life and a persistently high level is strongly suggestive of cystic fibrosis. Neonatal screening for cystic fibrosis is being piloted in a number of studies at present and is likely to become universal across the UK when the testing dilemmas are resolved.

Several screening tests are routinely used in pregnancy (see also Ch. 11). Screening for rubella, venereal disease and rhesus incompatibility has long been established. Screening for Down syndrome is also widely used although different approaches may be taken. The use of fetal ultrasound has also allowed many fetal malformations to be recognized at an early stage, but there may be difficulties in considering this as a screening test. The test is usually used to monitor normal fetal growth, and formal consent for screening for malformations is not always requested. This may be a problem for couples who would not consider the option of termination of pregnancy. Similarly some of the ultrasound findings are also difficult to interpret and unnecessary anxieties may be raised.

With carrier screening for genetic disorders there is often difficulty in knowing which stage of life is best for screening. The neonatal period may be relatively easy from the organization point of view but the knowledge of carrier status is not needed at that stage and results will often be lost before the individual starts a family. Premarital counseling and testing may seem to be the best option but not all pregnancies are planned and such programs have had very low levels of recruitment. Testing in pregnancy may also seem relatively easy as all mothers come to the antenatal clinic but it may be a very emotional time to test and puts a great time pressure on the laboratory for rapid test results.

Many genetic screening programs will take a two stage approach. One example of this would be to take a family history asking about bowel cancer and only to offer screening to those with a first degree relative whose cancer came on before the age of 45 years. The family history is easy to take and only identifies those with a 10% or greater risk of bowel cancer, and then the use of resources for colonoscopy or gene testing is concentrated on those with highest risk. A similar approach in screening for Down syndrome in pregnancy is to use maternal age as the first risk stratification and then use biochemical or ultrasound screening as a second risk stratification with chromosome testing only offered to those at highest risk.

In some populations the risk of genetic disease may be confined to specific ethnic groups and knowing ethnic origin may be the first stage in screening. Such programs need to be carefully designed to avoid discrimination issues. Often the best approach is to make screening 'bottom up' rather than 'top down'. Rather than impose a program with government directives it is better to provide the screening resources to the specific ethnic group so that they may organize their own program. This approach has worked very successfully in screening for Tay-Sachs disease in the Ashkenazi Jewish populations.

Another two stage approach is *cascade screening*. This is effectively a systematic follow-up from the procedure already used in the genetic clinic. For example children with cystic fibrosis are identified and genotyped and counseling is offered to their immediate family. From this the screening can be offered to members of the extended family out to cousins. This means that the population that is screened is at high risk of being carriers and there is already knowledge of the disorder within the population screened. It obviously falls short of comprehensive population screening but can still be very economic and effective.<sup>60</sup>

## MECHANISMS OF HORMONE ACTION

### DEFINITION

Hormones are chemical substances secreted directly into the bloodstream that affect the specific functioning of a cell or system in some other part of the body. They are produced from endocrine glands. The integration of hormone activity is of vital importance for the maintenance of a stable and appropriate internal environment and for the response to external environmental changes. Few hormones have unique actions and few bodily processes are determined by one hormone.

### TYPES OF HORMONE

Hormones can be divided into four distinct broad categories in terms of glands of origin, basic chemical nature, mode of synthesis, transport in the circulation, half-life, mode of action, metabolism and excretion. The properties of these groups – peptides, steroids, iodothyronines and catecholamines – are summarized in [Table 15.1](#). Actions at cellular level are summarized in [Figures 15.1 and 15.2](#).

## ORGANIZATION OF THE ENDOCRINE SYSTEM

The biological effects of hormones are regulated within well-defined physiological limits by a complex system of stimulation, inhibition and feedback control – secretion, delivery to target cells, recognition by receptors, exertion of a specific biological action, appropriate degradation and feedback to secretory cells to inhibit further production. Control mechanisms are complex and may involve other hormones (facilitative, additive or antagonistic), neurotransmitters and metabolic substrates. The principles are summarized schematically in [Figure 15.3](#).

Interrelationships between environment and endocrine and central nervous systems are close. Physiological states, such as sleep, are important in the hypothalamic control of growth, and sex steroids modify behavior at puberty. The hypothalamus, situated between brain and pituitary gland, has an important integrative and regulatory role, exerting effects on the pituitary adenohypophysis via a series of small peptides secreted from the ventromedial nucleus near the median eminence. Their synthesis and release is determined by neurotransmitters such as dopamine, serotonin and noradrenaline, and others such as acetylcholine, melatonin and gamma-aminobutyric acid (GABA) may

Table 15.1 Categories of hormone

	Peptides	Steroids	Iodothyronine	Catecholamines
Synthesis	From large precursors (prohormones) via enzymatic reactions	From common precursor (cholesterol) via enzymatic reactions	In thyroid gland from iodine and tyrosine via enzymatic reactions	In adrenal medulla and in sympathetic and central nervous tissues and chromaffin tissue from phenylalanine and tyrosine via enzymatic reactions
Storage (gland of origin)	High proportion	Very little	High proportion	Very little
Solubility	Aqueous	Lipid	?	?
Circulation	Unbound	Plasma protein bound	Plasma protein bound	Unbound
Half-life	Minutes	Hours	Days	? (short)
Periphery	Little transformation	Transformation ++ increasing biological activity	Little transformation	Little transformation
Action	Via specific plasma membrane receptors and cyclic AMP (cAMP)	Via binding to cytoplasmic receptors and stimulating nuclear messenger ribonucleic acid (mRNA) and protein synthesis	As steroids (no cytoplasmic receptor for T <sub>3</sub> )	Via alpha-, beta- and dopaminergic cell surface receptors

cAMP, cyclic adenosine monophosphate.

Fig. 15.1 Cellular mechanism of action of peptides.

Fig. 15.2 Cellular mechanism of action of steroids.

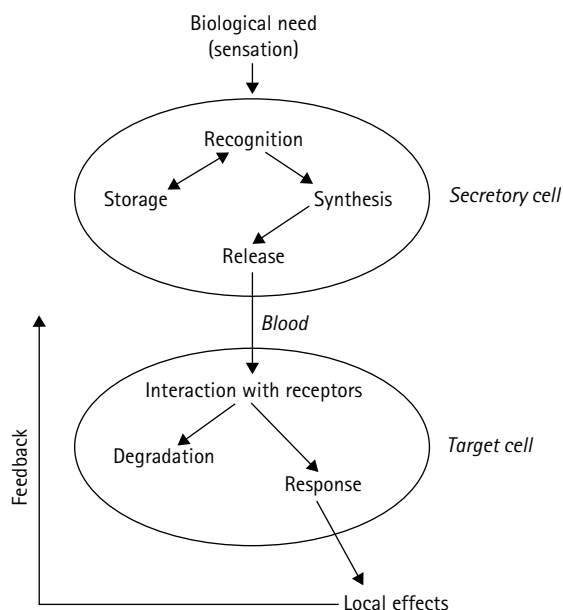

Fig. 15.3 Organization of the endocrine system.

also be important. Some peptides have stimulatory and some inhibitory activity in terms of pituitary hormone secretion.

Neurosecretory cells producing neurotransmitters are in close anatomical relationship with hypothalamic secretory neurones whose axons anastomose with portal blood vessels traversing the pituitary stalk and transporting hypothalamic peptides to the pituitary. Blood-borne anterior pituitary hormones in turn control secretion by a number of glands – thyroid, adrenals and gonads – as well as physiological processes such as growth and lactation. The ontogeny of fetal pituitary hormone secretion and brain – hypothalamo – pituitary connections is discussed on p. 415. Other endocrine systems are independent of hypothalamo-pituitary axis control – serum calcium is the major controlling mechanism for parathyroid hormone (PTH) secretion as is plasma glucose for pancreatic insulin secretion.

Hormone receptors on cell surfaces mediate the activities of water soluble protein hormones (e.g. growth hormone, IGF-1, ACTH) by signal transduction through second messenger systems. Lipid soluble hormones (e.g. thyroid hormones, steroids) act through nuclear receptors where ligand-bound receptors act at target gene promotor sequences to activate gene transcription. There are three classes of cell surface receptors: those with intrinsic tyrosine kinase activity (e.g. insulin receptor), those that recruit tyrosine kinase activity (e.g. GH receptor) and G-protein coupled receptors (e.g. ACTH receptor).

Biorhythms are a common feature of endocrine systems with periodicities of minutes or hours (e.g. LH, testosterone), a day (cortisol), weeks (menstrual cycle), seasons and life span.

Laboratory-based advances are having important impacts on endocrine practice: protein chemistry is increasing understanding of how GH regulates growth, differentiation and metabolism; transmembrane signaling can now ‘explain’ such pediatric endocrine disorders as McCune–Albright syndrome, pseudohypoparathyroidism (PHP) type 1, acromegaly, and many thyroid, adrenocortical and ovarian granulosa cell tumors as disorders of heterotrimeric ‘G’ (G $\alpha$ ) proteins which are important for GTP binding and hydrolysis that amplifies hormonal signals. In particular, two G proteins have been identified which are susceptible to naturally occurring mutations: G $\alpha$ , the activator of adenyl cyclase, and G $\beta$ , involved in adenyl cyclase inhibition and ion channel modulation. The gene encoding G $\alpha$  (GNAS1) may be altered by functional loss or gain mutations. Thus heterozygous inactivating germ line mutations cause PHP type 1a in which physical features of Albright’s hereditary osteodystrophy (AHO) are associated with resistance to several hormones, i.e. PTH, TSH and gonadotropins, that activate Gs-coupled receptors, or pseudopseudohypoparathyroidism in which AHO is the only clinical manifestation.<sup>1</sup>

Advances in molecular genetics are enabling recognition of the genetics and biochemistry of sex determination and there appears to be a major susceptibility locus for sex reversal/gonadal dysgenesis on Xp.<sup>2</sup> New disease mechanisms are being described – mosaicism in pseudoachondroplasia and McCune–Albright syndrome, placental mosaicism in some forms of IUGR; imprinting (parental origin effects) in Prader–Willi and Angelman syndromes, PHP, Beckwith–Wiedemann syndrome, and, possibly, Silver–Russell syndrome. Whilst genetic defects have ‘explained’ many eponymous syndromes, it is clear that genotype/phenotype correlations are often poor: one gene abnormality may only explain a minority of cases and mutations in one gene can cause different syndromes. Indeed even very disparate syndromes can share a common molecular genetic defect.<sup>3</sup>

In addition, it is clear that fetal and childhood growth may have important implications not only for the child but also for adult health and disease (see pp. 416–7).

Endocrine disorders may be due to subnormal hormone production or hormone deficiency, hormone excess, production of abnormal hormones, resistance to hormone action, abnormalities of hormone transport or metabolism or multiple hormone abnormalities. A working classification of pediatric endocrine disorders is available.<sup>4</sup>

## HISTORY TAKING AND EXAMINATION

### FAMILY HISTORY

Many endocrine disorders are familial with clear mendelian patterns of inheritance and a history of unexplained neonatal deaths may be significant in this context, particularly in parts of the world where neonatal pediatric services are poorly developed.

Genetic contributions may be less clear cut as for example in insulin dependent diabetes where the HLA identical sibling of an already affected child has about a 90-fold increased risk of developing the disease before 15 years. However, less than 1% of genetically susceptible children in the general population will ever develop diabetes. Autoimmune processes are important in pathogenesis and a family history of autoimmune disease (e.g. candidiasis, pernicious anemia, alopecia or vitiligo) should alert the clinician to disorders such as diabetes mellitus, Addison's disease, hypothyroidism or hypoparathyroidism. Growth hormone (GH) deficiency can be familial.

A family history of early or late puberty may be relevant (ask about age of menarche in mother and older girl siblings; ask fathers whether they were growing fast after they left school and when they started shaving) but there is considerable variation in the timing of puberty amongst normal family members.

Sometimes a child of normal stature is short for the parents (e.g. a girl with Turner syndrome and tall parents). An unusually short parent can have an undiagnosed disorder such as GH deficiency, skeletal dysplasia or pseudohypoparathyroidism (Fig. 15.4) which the child has inherited.

### PREGNANCY

Maternal illness during pregnancy may have significant effects on endocrine function in the fetus and neonate. Neonatal hyperthyroidism is seen in about 1.5% of infants born to mothers with Graves' disease. This relates to placental transfer of human thyroid-stimulating immunoglobulins. In the first trimester, 19-norprogesterone (e.g. norethisterone) for recurrent abortion are associated with masculinization of a female fetus. In the second or third trimesters, carbimazole and thiouracil are associated with neonatal goiter and hypothyroidism; chlorpropamide may cause neonatal hypoglycemia.

Fig. 15.4 Pseudohypoparathyroidism in mother and child (see also Fig. 15.6).

### NEONATAL HISTORY

Breech delivery, micropenis, hypothermia and hypoglycemia are all commoner in infants with GH insufficiency or panhypopituitarism. Birth asphyxia may be associated with subsequent precocious puberty.

Ambiguous genitalia suggest congenital adrenal hyperplasia (CAH, most commonly 21-hydroxylase deficiency in a genotypic female) or an androgen biosynthetic defect (in a phenotypic male). Severe vomiting, hyponatremic dehydration and excessive urinary sodium loss suggest a form of CAH, hypoplasia or pseudohypoadosteronism (or renal disease). Hypertension can develop in the 11beta-hydroxylase form of CAH.

Prolonged jaundice is a clue to congenital hypothyroidism. Other clinical signs may not be present until later. Even where screening programs are in operation false negatives can occasionally occur.

### PAST MEDICAL HISTORY

Very poor feeding in infancy may be associated with prolonged intrauterine growth retardation and later short stature. Recurrent hypoglycemia may be due to GH deficiency, panhypopituitarism or adrenal problems (e.g. Addison's disease). Insidious fall off in school performance is often a feature of acquired hypothyroidism.

### CLINICAL EXAMINATION

Accurate height measurements (Fig. 15.15; p. 430), repeated to determine growth velocity, are important in the diagnosis of endocrine (and many other) childhood disorders. Many cause slow growth (and, ultimately, short stature) and are associated with mild or moderate obesity (best assessed using skinfold calipers (Fig. 15.5) in addition to weighing to calculate body mass index (BMI). In contrast, obesity due to an excessive food intake causes rapid growth and tall stature in childhood. Endocrine causes of abnormally rapid growth in childhood include precocious puberty, thyrotoxicosis and gigantism.

Disproportionate stature (abnormal body proportions) is seen in long-standing panhypopituitarism, hypothyroidism and GH deficiency, skeletal dysplasias and some inborn metabolic errors. Short fourth and fifth metacarpal bones are characteristic of pseudohypoparathyroidism (Fig. 15.6) and Turner syndrome.

Delayed puberty in girls may be due to Turner syndrome. Primary amenorrhea may be associated with CAH, Turner syndrome or rarer disorders of sexual differentiation.

Hirsutism (reviewed by Rosenfield<sup>3</sup>) may be due to a variety of causes of adrenal and ovarian dysfunction including CAH, obesity-related polycystic ovarian syndrome (PCOS) and Cushing syndrome. The last is often associated with temporarily rapid growth, truncal obesity, striae

Fig. 15.5 Skinfold calipers.

and moon face. Secondary hypertension can be due to endocrine disease (usually adrenal cortical mineralocorticoid excess).

Fundal examination and visual fields assessment is vital in any child with abnormal growth or recurrent headache. Craniopharyngioma (see Ch. 24) commonly presents in this way. Dysmorphic features (especially midline abnormalities) may be associated with hypothalamic-pituitary or other endocrine disorders.

## ENDOCRINE TESTS

Diagnosis can often be suspected on the basis of history and clinical findings. In puberty, clinical staging of secondary sexual characteristics is an excellent 'bioassay' of hormone function. A girl of 14 years with stage

2<sup>6</sup> breast development can be reassured that puberty is underway, without measuring estradiol or LH – indeed a 'random' clinic measurement would suggest the opposite (see below).

Nevertheless, biochemical assessment is often necessary, either to confirm or refute a diagnosis or to assess the appropriateness and effectiveness of treatment but the information obtained must be assessed critically if misleading conclusions are not to be drawn (see Appendix).

As many hormones are secreted episodically in pulses or may vary diurnally, a single measurement may be meaningless or misleading. Dynamic tests to assess maximum secretory capacity will give different normal values to physiological secretory profiles.

## BLOOD

Stress from cannulation (or the thought of it) will affect levels of hormones such as cortisol, GH and prolactin (PRL). Baseline samples must be obtained before suppression or stimulation tests commence. A sample 30 min before baseline may, for example, help to quantify and reduce stress effects or indicate that a spontaneous pulse of growth hormone has just been secreted which will result in a blunted response to a stimulus because of the lack of a readily releasable GH pool.

It may be necessary to measure simultaneously hormones at both ends of a feedback system: ACTH levels will be inappropriately high for the normal cortisol levels in untreated CAH; raised TSH levels with normal T4 levels indicate developing (compensated) primary hypothyroidism.

Overnight fasting does not preclude day case tests if the family live nearby. Those traveling far are best admitted the previous evening. Fasting from midnight (water only allowed) is generally safe in the older child provided testing starts before 9 a.m. but is dangerous in a child with GH deficiency or panhypopituitarism. If this is suspected blood glucose levels should be checked at regular intervals overnight. Younger children are particularly vulnerable to fasting hypoglycemia.

## URINE

Urine sampling is atraumatic in children (less so in infants). 24-h collections can reflect overall production of (e.g.) steroids more accurately than isolated plasma samples but can be difficult to obtain, even in hospital. Expressing results per 24 h per gram excreted creatinine may not control for incomplete timed collection<sup>7</sup> and even distort results.

## SALIVA

Many hormones (e.g. peptides) cannot be assayed in saliva but the technique is useful for steroids, e.g. cortisol, progesterone and testosterone – concentrations are independent of flow rate and reflect free plasma levels. Most children over about 6 years can produce saliva. Specimens can be collected easily and non-invasively, serially or during dynamic tests.

## ERRORS

### Specimen collection, labeling, transport

Liaise with the laboratory beforehand if samples need special handling such as for example ACTH assay samples which must be collected in cooled lithium heparin tubes, centrifuged immediately at 4°C and plasma stored at 20°C until assay.

### Interpreting results

For larger polypeptides, including many hormones (whose structure cannot be physicochemically characterized), values are sometimes reported in terms of 'units' calibrated in terms of 'standards' derived from specific assays from material that may have different biological or immunological properties.

Hypersecretion is easier to diagnose than hyposecretion – a concentration half the mean of values in the normal population is more likely to fall within the 'normal range' than a concentration that is twice normal (Fig. 15.7) and it is more difficult analytically to measure low hormone levels.

Fig. 15.7 Hypo- and hypersecretion – see text. (After Jeffcoate 1981<sup>8</sup>)

This is important for screening tests (e.g. T4 or TSH for congenital hypothyroidism) or choosing particular assay techniques – TSH immunoradiometric assays (IRMA) give added precision at low levels compared to radioimmunoassay (RIA) (helpful in managing thyroxine replacement) and make the TRH test obsolete. LH and FSH IRMA and ultrasensitive immunofluorometric assays (IFA) are providing insights into the evolution of the hypothalamo-pituitary-gonadal axis during childhood and puberty control mechanisms for puberty (see pp. 447–9).

The prevalence of a condition is important in determining the likely significance of an abnormal result in individual patients. Screening for congenital hypothyroidism (1 in 4000) with a TSH assay with 0.1% false positive rate will yield 4 out of 5 positive results in babies without the disease.

## HORMONE ACTION AND MEASUREMENT

Many assays measure total hormone plasma levels of which only a small amount may be free, unbound and metabolically active. Direct measurement of the free, active hormone is of more value in diagnosis and treatment and abnormal hormone levels due to abnormalities of the binding protein can be more easily detected. It is invalid to extrapolate from isolated plasma samples to overall secretion or production rates. Circulating hormone levels may not reflect activity at tissue level. Many hormones have paracrine activity locally at tissue level and are not released in measurable quantities into the peripheral circulation.

Many laboratory assays are based on immunoassay techniques. These have, in many areas, replaced pre-existing bioassay (in vivo) techniques. However many commercial immunoassays are less than ideally reliable because of cross-reactivity or matrix effects and, for steroid analysis for example, liquid chromatographic/tandem mass spectrometry techniques will often be preferable.

What is measured in an immunoassay may not always have biological significance. For example, in mild acromegaly GH levels as measured by RIA may be very high, suggesting that GH molecular forms with low biological activity may be present.

## CIRCULATING HORMONE LEVELS AND RECEPTORS

Endocrine disorders may not only result from hormone under- or over-production but also from lack of tissue response to normal

circulating concentrations. Receptor or postreceptor defects ('end-organ unresponsiveness') may be important, e.g. bone or renal unresponsiveness to PTH in pseudohypoparathyroidism, pseudohypoaldosteronism, partial insensitivity of androgen-dependent structures causing incomplete masculinization in some genotypic males or, as seems increasingly possible, in some children with 'idiopathic' growth failure.

Receptor assays, when available, may provide an indicator of biological activity. However structural and functional properties of receptors may not be the same: in a given disorder they could be abnormal in number, function or both. In clinical practice, many defects must be inferred from finding functional inadequacy in clinical terms with abnormally high circulating levels of the hormone(s) that stimulate that tissue activity.

## FETAL ENDOCRINOLOGY

### FETAL ENDOCRINE FACTORS

Profound perinatal changes occur in many endocrine glands. Progress in understanding fetal endocrine functioning has come from increased access to wide ranges of abortus material from normal pregnancies, animal studies (which must be interpreted carefully in applying results to man), tissue culture experiments, advances in non-invasive (ultrasound) assessment of fetal growth and techniques such as fetoscopy.

Although fetal growth is ultimately controlled by genetic endowment, it is influenced by a number of fetal factors (including hormones and growth factors), uterine environment and other environmental factors. Control of fetal growth is by complex interaction between an evolving central nervous system, endocrine maturation, local tissue (paracrine) growth factors and placental and maternal hormone secretion – within environmental constraints which may impair fetal growth (Table 15.2).

Organogenesis occurs at a variety of times and tempos: organ embryogenesis and functional cell differentiation during the first trimester; rapid growth largely due to cell hyperplasia during the second; further functional maturation during the third. It is likely that endocrine factors, fetal, maternal and placental, are more involved with nonspecific growth stimulation or maturation and that specific stimuli to growth in individual cells and cell systems result from paracrine peptide growth factors derived locally. Positive and negative feedback loops are important in the dynamic regulation of developmental signaling and feedback failure can cause disease.<sup>9</sup> Measurable hormone levels in fetal circulation do not necessarily indicate a functional role at that time; target organ receptors may only appear later.

Table 15.2 Factors reducing fetal growth

## ONTOGENY OF FETAL HORMONE SECRETION

### Anterior pituitary

The anterior pituitary is of ectodermal origin arising from Rathke's pouch, an evagination from the roof of the primitive buccal cavity appearing from about 3 weeks post conception. After 2 months, pouch anterior wall cells proliferate and differentiate to form the pituitary anterior lobe. Growth hormone (GH) is found in the fetal pituitary and circulation by 10 weeks' gestation and levels are very high (greater than 200 mU/L) by mid-pregnancy.<sup>10</sup>

Extrinsic and intrinsic signaling gradients determine expression patterns of pituitary-specific factors in the developing anterior pituitary gland.<sup>11</sup>

In man, no anterior pituitary hormone crosses the placenta in physiologically significant amounts. Fetal growth continues relatively normally with absent GH secretion – anencephalics are only slightly small for gestational age (SGA).<sup>12</sup> However there is a small reduction in birth length for weight in babies with congenital GH deficiency<sup>13</sup> – postnatal growth failure is more marked. GH receptors do not appear before the second trimester. In vitro, GH stimulates insulin-like growth factor 1 (IGF-1) release from isolated fetal hepatocytes by 12 weeks' gestation<sup>14</sup> but has no effect on fetal muscle growth. GH promotes beta cell replication and insulin release in pancreatic islet cell cultures from 12 to 25 week fetuses<sup>15</sup> and any effects of GH in utero may be via insulin (see below). Nevertheless, the human growth hormone (hGH)/human placental lactogen (hPL) gene family, which consists of two GH and three PL genes, is important in the regulation of maternal and fetal metabolism and the growth and development of the fetus.<sup>16</sup> However it seems that prenatal IGF-1 production is largely independent of GH and that IGF-1 (and not GH) is the major factor in intrauterine growth regulation.

PRL [198 amino acids structurally related to GH, molecular weight (MW) 22 500] is synthesized by the fetal anterior pituitary from about 7 weeks postmenstrual age<sup>17</sup> and the pituitary content increases subsequently. Fetal plasma levels rise during the third trimester to peak just before term. Cord blood levels are higher than maternal and normal in anencephalics (cf. GH). Its physiological role in man (other than in the initiation and maintenance of lactation in women) is unknown.

ACTH is present in fetal pituitary by 10 weeks and responsible for adrenal cortical steroidogenesis and growth.<sup>18</sup>

LH and FSH may be present from as early as 5 weeks.<sup>19</sup> At each stage, gonadotrophin (GT) levels are higher in female than male fetuses. They are probably more important for later gonadal development than for early sexual differentiation.

The cytokine receptors for growth hormone (GH), prolactin and leptin probably have a critical role in regulating embryo, placental and fetal development.<sup>20</sup>

### Posterior pituitary

In the 6-week embryo, a downward extension of neural tissue from the floor of the diencephalon has formed the infundibulum. This gives rise to the stalk and neurohypophysis (posterior pituitary). From 12 weeks, the 9-amino-acid peptides vasopressin and oxytocin are synthesized in and secreted from the supraoptic and paraventricular hypothalamic nuclei and transported via axons in the supraopticohypophyseal tract to capillaries drained by inferior hypophyseal veins. They have no known fetal function. Vasotocin seems to be concerned with water shifts across fetal membranes.

### Thyroid

Fetal thyroid is active from mid-gestation and develops autonomously from the mother. Thyroxine (T<sub>4</sub>) is present at low but increasing levels from about 20 weeks but the more physiologically active metabolite tri-iodothyronine (T<sub>3</sub>) is present only in persisting low levels from about 30 weeks. Reverse T<sub>3</sub> (rT<sub>3</sub>) levels are high due to active conversion from T<sub>4</sub> in fetal liver, and placenta which also deiodinates T<sub>4</sub> and T<sub>3</sub> to inactive rT<sub>3</sub> and T<sub>2</sub> respectively.

Maternal thyroid hormones exert important developmental effects on the fetal brain<sup>21</sup> and protect the human fetus from adverse effects of

fetal thyroid hormone deficiency.<sup>22</sup> Maternal thyroxine plays a crucial role in the development of the fetal brain in early pregnancy. This has implications for fetal development in iodine deficient areas and underlies limitations to effectiveness of screening programs in preventing adverse neurological sequelae in every case even with early thyroxine substitution.

### Adrenal

During the second month adrenal cortical tissue differentiates into peripheral neocortex and active inner fetal zone. Rapid fetal zone hyperplasia and hypertrophy occurs<sup>23</sup> to comprise 85% of total adrenal size and is the major site of dehydroepiandrosterone sulfate (DHAS) and 16-hydroxy DHAS production. As there is little fetal zone 3beta-hydroxysteroid dehydrogenase (3betaOHD) activity, these compounds are produced in large quantities (equal to cortisol production) and placentally aromatized to estrogen, especially estriol. Fetal cortisol synthesis is maintained from placental progesterone and, possibly under the influence of progesterone, increased fetal zone 11beta-hydroxylase and 21-hydroxylase activity leads to considerable cortisol production. Progesterone and PRL, as well as estrogens, are implicated in fetal 3betaOHD inhibition and thus fetal zone maintenance.

A high rate of DHAS secretion is an intrinsic property of human adrenocortical cells and ACTH is the only hormone required for its synthesis. In tissue culture, even fetal zone cells increase 3betaOHD activity in response to ACTH to levels of definitive zone cells and distinction between zonae fasciculata and reticularis is lost. ACTH stimulation increases intra-adrenal blood flow leading to enhanced zonae fasciculata and reticularis activity but has no effect on zona glomerulosa function. Zonal differences in blood flow may therefore have important consequences on zonal function – adrenarche (see p. 480) may be a by-product of the need of the inner cells of the fetal adrenal to respond to the hormonal milieu of pregnancy by developing an androgen (i.e. estrogen precursor) synthesizing zone.

It is speculated that fetal adrenal steroidogenic patterns, which could reflect placental and fetal growth (see below), might provide a link with the development of adult hypertension.<sup>24</sup>

Within a few days of birth the fetal zone rapidly begins to atrophy. By 3 months the adrenal weight has halved and the weight at birth is not regained until puberty.

### Gonads

Primitive gonads appear in the fourth week as a longitudinal ridge of proliferating celomic epithelium and underlying mesenchyme between mesonephros and dorsal mesentery. Primordial germ cells appear in the yolk sac wall by 3 weeks and migrate towards and enter the ridges by 6 weeks until when male and female human fetal gonads are morphologically identical. Primitive, undifferentiated gonads will develop in a female manner unless directed towards male differentiation by the presence of the sex-determining region of the Y chromosome – SRY (see below).

In females, proliferating epithelial cords surround primordial germ cells in the mesenchyme. These cords subsequently degenerate and are replaced by others which remain near the surface of the gland whilst the surface epithelium thickens. Germ cells develop into oogonia surrounded by follicular cells derived from surface epithelium.

From the third month, oogonia undergo meiosis to form primary oocytes which, by birth, have completed prophase of the first meiotic division and entered a resting stage. At sexual maturity, they complete the first meiotic division to form secondary oocytes which are extruded into the Fallopian tube at ovulation. Primary oocytes are surrounded by a layer of flat epithelial cells, later to form the granulosa cells – the complex is known as the primordial follicle. This is surrounded by a basal lamina and, externally, a layer of thecal cells. In the maturing follicle there is oocyte enlargement, granulosa cell proliferation and thecal differentiation into inner vascular and outer fibrous layers. Some 6–7 million oogonia are present by 6 months post conception but only 2–4 million primordial follicles at birth and less than half a million by

menarche. Most follicles degenerate – only a few are lost by ovulation during reproductive life.

In males, in the presence of a Y chromosome carrying a testis determining gene – sex-determining region of the Y chromosome (SRY) – on its short arm and cell membrane histocompatibility (H-Y) antigen, normally the primitive sex cords proliferate and differentiate to form testis cords. These become separated from surface epithelium by a layer of dense fibrous connective tissue (tunica albuginea) which, with the degeneration of the surface epithelium, forms the testis outer surface (capsule).

The testis cords differentiate to form the rete testis and straight and convoluted tubules. They remain solid until puberty when they develop a lumen and form seminiferous tubules. In the fetus they comprise primitive germ cells surrounded by supporting cells which will eventually develop into Sertoli (sustentacular) cells. Leydig (interstitial) cells develop from mesenchyme.

The major hormonal stimulus for fetal Leydig cells is testosterone, and for primitive seminiferous tubule, germ cell and Sertoli cell formation it is placentally derived human chorionic gonadotrophin (HCG). At this stage, there is little pituitary GT secretion – anencephalic male genital tract development is normal.

Before gonadal differentiation, Wolffian ducts have already developed (by 4 weeks). Müllerian ducts appear at about 7 weeks. In males, in the presence of a testis, degeneration of Müllerian structures occurs by 9 weeks under the influence of anti-Müllerian hormone (AMH), a high molecular weight glycoprotein secreted by the Sertoli cells.<sup>25</sup> AMH is a member of the transforming growth factor beta (TGFbeta) family (like the inhibins and activins). The human AMH gene has been cloned and mapped to the short arm of chromosome 19. There is a critical period during which Müllerian tissue is sensitive to inhibition by AMH – although AMH is now known to be produced by Sertoli cells until puberty, no postnatal physiological effects have been identified. In women, AMH is produced by the granulosa cells of preantral and small antral follicles and may be a useful marker of ovarian aging and follicular reserve.<sup>26</sup>

Leydig cell testosterone secretion is responsible for persistence of the Wolffian ducts and their differentiation into epididymis, vas deferens, seminal vesicles and ejaculatory ducts. Male external genitalia are sensitive to dihydrotestosterone (DHT) rather than testosterone and the enzyme which converts the latter to the former, 5alpha-reductase, is present in high concentrations in these tissues. DHT is responsible for fusion of labia, growth of the phallus and formation of the scrotum.

In females, in the absence of Leydig cell testosterone secretion, Wolffian ducts virtually completely disappear. The Müllerian system, in the absence of Sertoli cell AMH secretion, differentiates into upper vagina, uterus and Fallopian tubes.

In humans, it now seems that testis development depends on a regulated genetic hierarchy initiated by the Y-linked SRY gene. Several components of the testis determining pathway have been identified and it seems that early gonadal development is the result of a network of interactions instead of the outcome of a linear cascade.<sup>27</sup>

Development of a fetus into a phenotypic male thus depends, first, on testis formation and second, on hormone production by the fetal testis. Disorders of testicular hormone production or action can lead in severe cases to phenotypic abnormalities or can predispose towards impaired reproductive health. There is evidence, of variable quality, for deteriorating human male reproductive health, including an increase in testicular cancer and falling sperm counts. It seems likely that sperm production in adulthood is susceptible to 'hormonal' disruption in fetus and neonate, perhaps in relation to estrogenic and (especially) anti-androgenic environmental chemicals.<sup>28</sup>

### Parathyroid

The fetus accumulates calcium rapidly. Maternal PTH and 1,25-dihydroxy cholecalciferol (1,25-DHCC) levels are high during pregnancy and there is active calcium (and phosphate) transfer to the fetus. 25-HCC crosses the placenta and preterm infants have lower levels than

term infants, by when levels are comparable to those in the mother. PTH and 1,25-DHCC levels are low at birth but calcitonin levels are high. Calcitonin reduces fetal bone resorption; low PTH levels aid bone calcification.

### Pancreas

Insulin is present in fetal pancreas by 8 weeks and plasma by 12 weeks and is an important anabolic factor in response to maternal glucose concentrations with major, particularly last trimester, influence on somatic size and growth. Fetal hyperinsulinemia causes adiposity and has little effect on lean body mass but there is a permissive effect on protein synthesis and hepatic glycogen deposition. Insulin does not cross the placenta in physiologically significant amounts. In normal pregnancy, fetal plasma glucose levels are modulated by maternal homeostatic mechanisms. The fetus of a poorly controlled diabetic mother has greatly increased adipose tissue stores, organomegaly and increased birth size. Other disorders associated with hyperinsulinism [e.g. persistent hyperinsulinemic hypoglycemia of infancy (HI) and Beckwith–Wiedemann syndrome] are associated with fetal overgrowth. Monogenic diseases that impair glucose sensing, lower insulin secretion or increase insulin resistance are associated with impaired fetal growth.<sup>29</sup> Insulin appears to have no direct action on release of IGF from human fetal connective tissue or hepatocytes in tissue culture and may act through stimulation of nutrient uptake and utilization (see below).

Glucagon is present in human fetal pancreatic tissue from 10 weeks and cannot cross the placenta. Its fetal metabolic role is still largely unknown but there is a high overall circulating insulin:glucagon ratio in the fetus favoring anabolism.<sup>30</sup>

Human pancreatic polypeptide (HPP) secreting cells are present in the pancreatic head by 18 weeks but sparse in the adult organ. HPP may have a role in liver glycogenolysis. The physiological role of pancreatic D (somatostatin secreting) cells, present from 10 weeks, is unknown.

### Growth factors

By the second trimester, insulin-like growth factors are present in many fetal tissues including liver, kidneys, gut, lung, cardiac and skeletal muscle, fetal zone adrenal, hemopoietic cells and dermis. They are regulated independently of GH and are important for fetal growth regulation. IGF-1 is particularly important in muscle fibre, ovarian granulosa cells (causing LH receptor and sex steroid accumulation) and brain astrocyte differentiation. IGF-2, like IGF-1, has metabolic, mitogenic and differentiative actions in a wide range of fetal tissues, is highly expressed in growth plate germinal and proliferative zones and increases extracellular connective tissue matrix synthesis, especially in chondrocytes. It synergizes with nerve growth factor in promoting neurite outgrowth from sensory and sympathetic ganglia.

Epidermal growth factor (EGF) and its probable fetal form, transforming growth factor-alpha (TGF-alpha), influences the growth, differentiation and function of epithelial cells, including lung and gut. It modulates trophoblast differentiation and function in tissue culture with release of human placental lactogen (HPL) and human chorionic gonadotrophin (HCG) via placental receptors and may be important in fetal growth retardation.

Overall late gestational fetal growth is primarily determined by the functional status of the pathways by which nutrients are transferred from the mother across the placenta and taken up by fetal tissues. Both maternal and fetal endocrine systems can influence this pathway at several levels, including regulation of placental metabolism.<sup>31</sup>

### LONG TERM IMPLICATIONS OF FETAL GROWTH

Most small for gestational age (SGA) babies are appropriately grown for their small parents, and maternal size in particular is an important determinant of birth weight. Some babies seem small because the expected date of delivery is incorrect. However, at any gestational age, babies can also be born small either because of (1) underlying pathology in the fetus (chromosomal or other genetic factors) or (2) intrauterine starvation due

to abnormal placental function causing intrauterine growth retardation (IUGR). This uteroplacental insufficiency may relate to reduced maternal and placental perfusion and is associated with low  $PO_2$ , low pH and raised lactate levels in the fetus and neonate and redistribution of fetal blood flow from the thoracic aorta to the middle cerebral artery to protect, as far as possible, the growing and maturing fetal brain.

IUGR is now thought to be important not just in the short (e.g. neonatal hypoglycemia) or medium term (e.g. difficult feeding in infancy and poor growth) but because of possible long term (adulthood) consequences. Epidemiological evidence suggests that small fetuses are more likely in adulthood to develop premature adrenarche,<sup>32</sup> hypertension and other cardiovascular diseases and type 2 diabetes mellitus<sup>33</sup> and, in girls, ovarian hyperandrogenism and polycystic ovarian syndrome.<sup>32</sup> Babies most at risk of subsequent hypertension are those born small with large placentae<sup>34</sup> and it is not yet clear how this relates to a pathophysiological classification of small babies nor whether, for example, 'normal' birth weight babies lighter than they should have been for their tall parents (and thus also starved in utero) are at risk.

Early nutrition is undoubtedly important for long term outcomes, i.e. it has biological as well as nutritional effects, and fetal malnutrition is likely to result in life-long metabolic dysregulation.<sup>33</sup> Preterm appropriate for gestational age babies could also be at risk of later insulin resistance.<sup>35</sup>

A suggested explanation for the association between low birth weight and hypertension, coronary artery disease, and insulin resistance and type 2 diabetes is thus intrauterine programming in response to maternal malnutrition. Such infants could have been exposed to excessive cortisol in utero due to relative placental 11beta-OHSD deficiency<sup>36</sup>. However it is possible that the link could be genetically determined insulin resistance resulting in impaired insulin-mediated growth in the fetus associated with insulin resistance in adult life.<sup>29</sup>

## PLACENTAL HORMONE SECRETION

The placenta is the source of a hormone structurally similar to pituitary GH (differing by 13 amino acids) coded by a variant GH gene (human growth hormone V) inactive in the pituitary. Placental GH appears to be secreted into the maternal circulation in large amounts towards full term but has disappeared within 1 h of delivery.<sup>37</sup> Thus during pregnancy, pituitary GH (hGH-N) expression in the mother is suppressed and hGH-V, the GH variant expressed by the placenta, becomes the predominant GH in the mother.

The placenta also secretes HCG (structurally similar to thyrotrophin but with significant thyroid stimulating activity) which is more likely than fetal pituitary derived LH to be the important stimulus to fetal Leydig cell testosterone production.

## MATERNAL DISEASE AND ENDOCRINE FUNCTION

Maternal thyrotoxicosis occurs in about 1 in 2000 pregnancies but hyperthyroid women seldom become pregnant unless treated, and miscarriage commonly occurs. After the first trimester there is relative independence of fetal and maternal pituitary – thyroid axes. Iodine, antithyroid drugs and human thyroid stimulating immunoglobulins (TSI) cross the placenta from mother to fetus. Neonatal thyrotoxicosis occurs in about 1.5% of infants born to mothers with Graves' disease (see later). The risk relates more to the presence of TSI than to disease activity and the disease may have been inactive for many years.

Hypocalcemia used to occur in full-term infants fed with high phosphate load cows' milk preparations. The same problem occurring in some babies on low phosphate milks suggests that maternal factors such as osteomalacia due to vitamin D deficiency (or rarer conditions such as pseudohypoparathyroidism with maternal hypocalcemia) may be important.

Fetal effects from poor maternal diabetic glycaemic control are described above. Fetal hyperinsulinism causing neonatal hypoglycemia is seen there and in hyperinsulinemic hypoglycemia of infancy (HI, formerly labeled nesidioblastosis).

## MATERNAL DRUGS AND ENDOCRINE FUNCTION

In second and third trimesters, substances of MW  $\leq 600$  cross the placenta including most drugs which are often more toxic to fetus than mother. Examples of drugs affecting endocrine function include iodides (cough mixtures, radiographic contrast media) which cause hypothyroidism with neonatal goiter, carbimazole and thiouracil (similar effects), and glucocorticoids.

## NEONATAL ENDOCRINOLOGY

By late gestation, the fetus has developed significant endocrinological autonomy. Nevertheless, profound hormonal changes occur during and shortly after birth. This has implications for newborn screening: transient abnormalities may be misinterpreted as permanent, or vice versa.

Important endocrine disorders may present in the newborn. In this section, clinical and biochemical clues and general principles are discussed.

## HYPOGLYCEMIA

Hypoglycemia is a common finding in the neonate although the definition of clinically significant hypoglycemia remains controversial. Pragmatic recommendations for blood glucose levels at which clinical interventions should be considered are given by Cornblath et al.<sup>38</sup> Fetal metabolism is essentially anabolic: enzymes concerned with formation of glycogen, fat and protein are increasingly active with advancing gestation in mammalian liver – glycogenolytic and gluconeogenic enzymes appear relatively inactive before birth. At delivery, transplacental glucose ceases. Full-term infants experience falls in blood glucose during the early hours after birth to about 2.5 mmol/L. Normal feeding is important for the subsequent rise in blood glucose levels as are hormonal changes stimulating liver glycogenolysis and gluconeogenesis and lipolysis. Glucagon levels rise, GH levels are high and there is a surge in TSH, T3 and T4 secretion.

Birth asphyxia is an important cause of neonatal hypoglycemia causing rapid depletion of glycogen stores. Glucose is the most important substrate for brain metabolism. The large neonatal brain:body mass ratio largely explains the increased susceptibility to hypoglycemia – prolonged or recurrent hypoglycemia is a preventable cause of long term neurological damage and mental retardation.

Neonatal hypoglycemia may be an important clue to endocrine disorders such as HI or insulinoma, congenital hypopituitarism (panhypopituitarism or isolated ACTH or GH deficiency) and adrenal disease causing glucocorticoid deficiency (e.g. congenital adrenal hypoplasia, hyperplasia or following bilateral adrenal hemorrhage).

Hypoglycemia, at any age, is not a diagnosis in itself (see p. 503).

## MICROPENIS

Small penis and under-developed genitalia without hypospadias are characteristic findings in a male infant with pituitary disease – generalized, GT deficiency or GH deficiency – or rudimentary testes. The association with hypoglycemia is characteristic of hypothalamo-pituitary disorders; hypotonia and feeding difficulties suggest Prader–Willi syndrome. Other congenital abnormalities may suggest other syndromes in which hypogonadism is a feature.

## AMBIGUOUS GENITALIA

The cause of ambiguity, and sex of the infant, cannot be identified by clinical examination alone (see Fig. 15.52) – an urgent karyotype must be obtained. If both gonads are palpable in the labioscrotal folds the baby is likely to be a male with XY karyotype in whom there is a defect in testosterone biosynthesis or tissue insensitivity to androgen. If no gonads are palpable the most likely diagnosis is congenital adrenal hyperplasia (CAH) – watch for possible salt loss in the commonest type (21-hydroxylase deficiency). Rarely hypertension will develop (11beta-hydroxylase deficiency).

Fetal androgen deficiency in a male may result in appearances anywhere between severe hypospadias and a 'normal female'. Exposure of a female fetus to androgen may result in appearances between clitoromegaly and 'normal male'. It is important, therefore, to try to classify disorders etiologically rather than descriptively.

Gender depends on a number of features which are normally self-consistent in any one individual: genetic sex – XX or XY; gonadal sex – presence of ovaries or testes; phenotypic sex – internal and external genital structures.

### PROLONGED JAUNDICE

Primary hypothyroidism was a common cause of prolonged jaundice in the UK. Even now, no screening program is problem free; check TSH levels again if there is clinical suspicion.

### SALT WASTING

Vomiting, diarrhea and dehydration in the early days or weeks of life is seldom due to endocrine disease; sodium and water loss in the stool from gastroenteritis or vomiting associated with pyloric stenosis are much more common. Sodium loss in the urine is due to renal or adrenal disease. Aldosterone levels will be high in renal disease but are generally low in adrenal disease (usually CAH). In pseudohypoaldosteronism, aldosterone levels will be very high. If appropriate and prompt treatment is not given, symptoms can rapidly progress to vascular collapse with severe hyperkalemia and hyponatremia, hypoglycemia, metabolic acidosis, coma and death.

### HYPOTHERMIA

Preterm babies are at particular risk of hypothermia. The SGA infant is also at increased risk because of high surface area and lack of subcutaneous fat. Suspect hypothalamo-pituitary disease with persisting hypothermia, particularly in association with hypoglycemia or micropenis.

### THE SMALL-FOR-GESTATIONAL-AGE (SGA, LOW BIRTH LENGTH) BABY

Some SGA babies have grown slowly for much of pregnancy while others only more recently. These situations can be distinguished by serial ultrasound measurements of biparietal diameter and lower thoracic circumference. The prognosis for growth and development varies with the time of onset of poor growth. Babies who have grown slowly before ~35 weeks are increasingly likely to be not only light- but also short-for-gestational age at birth and to have a low head circumference. They characteristically feed extremely poorly in infancy and later may show characteristic dysmorphic features: body asymmetry, clinodactyly, triangular 'elfin' facies – the Silver-Russell syndrome – and present in childhood with short stature (see p. 439).

Some SGA babies have specific reasons for slow intrauterine growth, e.g. congenital rubella, chromosome disorders or major congenital abnormalities. Suspect Turner syndrome in a SGA female baby with peripheral edema.

### UNDESCENDED TESTES

Cryptorchidism, in the context of otherwise normal external male genitalia, is much less common than normally retractile testes. Normal testes have usually descended by 36 weeks' gestation due to GT-induced testosterone. They will not do so if there is GT deficiency, defective testicular testosterone production or anatomical impediment in the line of descent (much more commonly a unilateral problem). Even in cases of unilateral cryptorchidism, the contralateral (descended) testis is now known to be frequently abnormal and cryptorchidism to be usually due to an endocrine abnormality at pituitary or testicular level or both. Karyotype and endocrine investigation should be undertaken, and hormonal treatment and, if necessary, orchidopexy during the early months of life are

now thought to be essential to optimize fertility<sup>39</sup>. Environmental and genetic causes for the increasing frequency of the problem are a current area of scientific interest.

### SCREENING

Few infants show diagnostic features of hypothyroidism at birth and screening programs in the USA and Europe have suggested an incidence of about 1 in 4000, double that expected from results of retrospective surveys.

Congenital hypothyroidism is an excellent disease for which to screen – it is common, unreliably diagnosed clinically until too late, detectable with simple and cheap biochemical tests on small amounts of easily stored blood, and prompt and adequate treatment usually prevents significant neurodevelopmental deficit. It is generally thought that adequate treatment within 4 weeks leads to normal overall development; subtle perceptual and hearing/speech deficits may remain.<sup>40</sup>

There are two alternative strategies for the screening program. If T4 alone is used, there is too much overlap between normal and hypothyroid values at the end of the first week. TSH must be measured in addition in those babies where the T4 is 'low'. In many countries (including the UK) TSH is measured as the primary test – there is no overlap between normal and high levels, high levels are easier to interpret as abnormal (a level twice normal is less likely to fall within the 'normal range' – see Fig. 15.7, p. 414) and are easier to measure reliably. Hypothyroidism due to pituitary or hypothalamic disease is missed (TSH levels are low) but these babies usually have clinical features associated with other pituitary hormone deficiencies (e.g. micropenis, hypoglycemia) and thyroid function is usually sufficiently preserved to prevent neurological and intellectual problems even with later diagnosis.

Screening has shown transient abnormalities, previously unrecognized, to be almost as common in many countries. In particular, preterm infants may have temporary functional abnormalities and clear-cut diagnosis may be difficult. Any abnormal screening result must be confirmed by definitive tests before diagnosis and commitment to long term therapy but the results should not be awaited before treatment is started. Generally good results (normal mental and psychomotor development) are achieved in congenital hypothyroidism following prompt detection (by newborn screening) and early postnatal thyroxine treatment in adequate dosage.

It is possible to screen newborn babies for 21-hydroxylase deficiency for raised 17OH progesterone levels using the 'Guthrie' test filter paper. The incidence is between 1 in 5000 and 1 in 23 000 (gene frequency in Europe and USA ~ 1 in 100). Boys do not have significant abnormalities at birth and there may be significant morbidity or even mortality if they present without warning with salt wasting. The non-salt losing boy (around 50% in the UK) presents late with pseudoprecocious puberty, rapid growth and tall stature but a short final height prognosis. Despite significant morbidity from late diagnosis and many newborn screening programs worldwide, in the UK it is generally considered unnecessary or 'uneconomical' to screen even though this would only add a small additional unit cost in the screening laboratory already measuring TSH and phenylalanine.

### DISORDERS OF SEX DIFFERENTIATION (DSD)

Normal fetal sexual differentiation is described earlier. Currently, further insights are being developed into the control of testis maturation in man using a primate (marmoset) rather than a rodent model.<sup>41</sup> It is increasingly possible to determine underlying molecular genetic and pathophysiological processes that have led to inappropriate virilization or its inappropriate lack and a novel human sex-determining gene has been recently linked to Xp11.21–11.23.<sup>2</sup> Nevertheless descriptive terms are sometimes of value (if they are not used simply to hide ignorance).

Abnormal external genitalia may be found in many dysmorphic syndromes and an international consensus statement on the nomenclature and management of disorders of sex differentiation has been published.<sup>42</sup> Specific disorders of fetal sex differentiation have been

descriptively categorized on the basis of gonadal (dys)morphology into the following three groups:

**46XX DSD** (formerly known as female pseudohermaphroditism)

There is virilization of *external* genitalia with XX karyotype and normal ovaries and Müllerian structures. Important causes are summarized in [Table 15.3](#). Virilization may be due to excessive fetal androgen production or exposure to increased transplacental androgen (maternal or iatrogenic). Some remain idiopathic.

Preterm female infants have underdeveloped labia mimicking ‘clitoromegaly’. Clitoromegaly is found in some rare dysmorphic syndromes (e.g. Beckwith, Seckel and Zellweger).

**Virilization by fetal androgens**  
*Virilizing congenital adrenal hyperplasia*

See p. 480.

**21-hydroxylase (P450c21) deficiency**

This is the commonest cause of virilization in the genotypic female. The degree of intrauterine virilization may depend on the completeness of the block, but the degree of salt loss, when present, correlates poorly with the degree of virilization.

Some females have relatively normal looking genitalia at birth but in the majority there is clitoromegaly and variable labial fusion. There may be a urogenital sinus with common opening for urethra and vagina. In severely affected cases, appearances are ‘normal male’ with a ‘penile’ urethra but with no testes in the ‘scrotum’. Ovarian and Müllerian development (upper vagina, cervix, uterus and Fallopian tubes) is normal. Most males appear normal at birth – the scrotum may occasionally appear pigmented and the penis large.

**11beta-hydroxylase (P450c11) deficiency**

Virilization is variable but may be severe enough for females to be brought up as males. It is much less common than 21-hydroxylase deficiency but relatively common in the Middle East. Hypertension, which occurs in some, takes time to develop. Males appear normal at birth.

**3beta-hydroxysteroid dehydrogenase deficiency**

Ambiguous genitalia occur in either sex. Males are incompletely virilized (see below). Females are virilized by excessive production of the (weak) adrenal androgen dehydroepiandrosterone (DHA). There is usually severe associated salt wasting in early infancy.

Other causes of fetal androgen overproduction, for example adrenal adenoma or congenital nodular adrenal hyperplasia, seem excessively rare.

**Transplacental virilization**

*Maternal androgens*

Variable fetal virilization from maternal ovarian and adrenal tumors has been described.<sup>43</sup>

**Iatrogenic**

During the 1950s recurrent spontaneous abortion was treated with natural (progesterone, 17OH progesterone) and synthetic (medroxy-

**Table 15.3** Causes of female pseudohermaphroditism

Virilization by:
1. Fetal androgens – congenital adrenal hyperplasia (21-hydroxylase, 11beta-hydroxylase, 3beta-hydroxysteroid dehydrogenase deficiencies)
2. Maternal androgen-secreting tumor
3. Iatrogenic (progestational abortifacients)
4. Miscellaneous (see text)
5. Idiopathic

progesterone, norethynodrel) progestogens with androgenic properties resulting in significant virilization of female fetuses. Such treatment is now almost never used.

**46XY DSD** (formerly known as male pseudohermaphroditism)

Incomplete virilization of the *external* genitalia, XY karyotype and normally differentiated testes occurs for one of three reasons (see [Table 15.4](#)): abnormality of AMH secretion or action, deficient fetal testosterone synthesis due to Leydig cell hypoplasia or an inborn metabolic error, or impaired peripheral androgen metabolism. There is an association with other abnormalities in rare dysmorphic syndromes (e.g. Meckel, Opitz and Smith–Lemli–Opitz). The genetics of undermasculinization is reviewed by Ahmed and Hughes.<sup>44</sup>

**Persistent Müllerian structures**

This is a rare familial condition in which Müllerian structures (Fallopian tubes and uterus) may be found in males whose genitalia may generally look normal apart from cryptorchidism.

**Deficient fetal testosterone biosynthesis**

*Leydig cell hypoplasia*

This is another rare disorder, probably autosomal recessive (but obviously male limited) with defective Leydig cell differentiation and testosterone response to HCG. The phenotype is female but Müllerian structures are absent because of normal Sertoli cell AMH production.

**Inborn errors of testosterone biosynthesis** (see [Fig. 15.8](#))

These result in defective virilization of the male’s internal and external genitalia. Adrenocortical steroid biosynthesis is affected when the defect is at an early stage in the pathway so that hypoglycemia and salt loss may occur. AMH synthesis is unaffected; Müllerian structures are absent.

**Cholesterol desmolase deficiency [(P450scc) cholesterol side chain cleavage deficiency, lipid adrenal hyperplasia]**

This is due to deficiency of any of the microsomal enzymes 20alpha-hydroxylase, 20,22-desmolase (the rate limiting step) or 22alpha-hydroxylase converting cholesterol to pregnenolone, causing defective androgen, glucocorticoid (GC) and mineralocorticoid (MC) biosynthesis with cholesterol accumulation in the gland. The P450scc gene is located in the q23 to q24 region of chromosome 15. In surviving cases, genitalia appear female and there is severe salt loss and hypoglycemia, often with fatal outcome; prompt treatment may be life saving.

**3beta-hydroxysteroid dehydrogenase deficiency (3beta-HSD)**

Two genes encode for 3beta-HSD: type I (placental) and type II (adrenal and gonadal). Patients with classical 3beta-HSD deficiency have type

**Table 15.4** Causes of male pseudohermaphroditism

Impaired Leydig cell activity
Leydig cell hypoplasia
Inborn errors of testosterone biosynthesis (see <a href="#">Fig. 15.8</a> )
Impaired peripheral tissue androgen metabolism
5alpha-reductase deficiency
Receptor defects
Testicular feminization (complete)
Testicular feminization (incomplete)
Reifenstein syndrome
Infertile male syndrome
Postreceptor defects
Abnormal secretion or action of AMH (persistent Müllerian duct syndrome)
Associated with dysmorphic syndromes (e.g. Opitz, Smith–Lemli–Opitz)

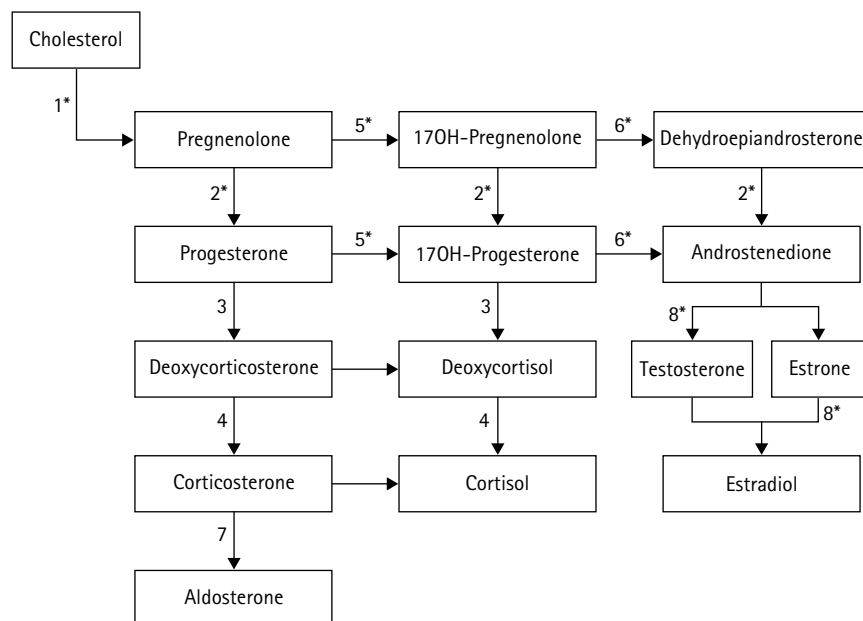

Fig. 15.8 Inborn errors of testosterone biosynthesis – marked with an asterisk (compare with Fig. 15.50). 1\* – cholesterol side chain cleaving system (20 $\alpha$ -hydroxylase, 20,22-desmolase, 22 $\alpha$ -hydroxylase); 2\* – 3 $\beta$ -hydroxysteroid dehydrogenase; 3 – 21-hydroxylase; 4 – 11 $\beta$ -hydroxylase; 5\* – 17 $\alpha$ -hydroxylase; 6\* – 17,20-lyase (desmolase); 7 – 18-hydroxylase and 18-hydroxysteroid dehydrogenase; 8\* – 17 $\beta$ -hydroxysteroid dehydrogenase.

II gene point mutations. Genotypic males are incompletely (variably) virilized. Wolffian structures are normal. Salt loss and hypoglycemia are generally severe with high mortality.<sup>45</sup>

### 17 $\alpha$ -hydroxylase deficiency (P450c17)

This results in GC and androgen deficiency (hypoglycemia and complete lack of virilization) plus mineralocorticoid excess due to ACTH drive (Fig. 15.8) resulting in hypokalemic alkalosis and hypertension. At puberty there may be virilization with gynecomastia.

### 17,20-desmolase (P450c17 17,20-lyase deficiency)

This is characterized by inadequate virilization and excessive urinary pregnanetriolone excretion. Gluco- and mineralocorticoid pathways are intact. Nevertheless, a single gene encoding cytochrome P450c17 controls both 17 $\alpha$ -hydroxylase and 17,20-desmolase activities – combined defects have been reported regardless of phenotype.

### 17 $\beta$ -hydroxysteroid dehydrogenase deficiency

There is defective conversion of androstenedione to testosterone and estrone to estradiol.<sup>46</sup> Adrenal steroidogenesis is normal. In most cases, male infants are sufficiently poorly virilized to be reared as females but there is significant virilization at puberty.

### Impaired peripheral androgen metabolism

There are three types, collectively constituting the commonest group of male pseudohermaphrodite patients:

1. 5 $\alpha$ -reductase deficiency;
2. X-linked abnormalities of the androgen receptor (including complete or incomplete androgen insensitivity, Reifenstein and the infertile male syndromes);
3. postreceptor (receptor-positive) resistance (a similar clinical spectrum to 2 but normal receptor function).

### 5 $\alpha$ -reductase deficiency

Virilization of external genitalia in the male fetus requires testosterone and dihydrotestosterone (DHT). DHT is formed from testosterone by the action of 5 $\alpha$ -reductase type 2 (5 $\alpha$ R-2). Two human cDNA clones for 5 $\alpha$ -reductase have been isolated and the 5 $\alpha$ -reductase 2 gene mapped to band 23 of the short arm of chromosome 2 (2p23).

Mediation of androgenic effects requires a functional androgen receptor (AR) located in the cytoplasmic compartment of target cells. Any event which impairs DHT formation (mutation within the 5 $\alpha$ R-2 gene or 5 $\alpha$ R-2 inhibitors) or normal function of the AR (mutation in the AR gene, anti-androgens) may result in insufficient androgen action in the male fetus and in subsequent undervirilization in the newborn.<sup>47</sup>

5 $\alpha$ -reductase deficiency is an autosomal recessive defect. The biochemical defect is in the conversion of testosterone to dihydrotestosterone (DHT) in the androgen target cell characterized by a high plasma testosterone:DHT ratio (after HCG stimulation in prepuberty). Definitive diagnosis is by finding diminished 5 $\alpha$ -reductase activity in genital skin fibroblast cultures. Newborn external genitalia appear female (fetal DHT deficiency produces a very small phallus and perineal hypospadias) but the testosterone-dependent internal (Wolffian) genital structures develop normally with testes capable of spermatogenesis.

At puberty considerable, but incomplete, virilization occurs spontaneously with male body habitus, psychosexual orientation and gender conversion. External genitalia remain small but large testosterone doses may produce cosmetic improvement. DHT therapy has proved disappointing.

### Androgen receptor defects

These may result either from major structural abnormalities of the androgen receptor (AR) gene or point mutations altering either AR messenger RNA or single amino acids causing a spectrum of appearance from 'female' (complete and incomplete testicular feminization) to 'male' (Reifenstein syndrome and infertile male syndrome). The AR gene has been cloned and is located on Xq11–12. Mutations in exon 2 and 3 code for the DNA region have been identified in patients with 'receptor positive' androgen insensitivity. However most mutations are in exons 4–8 which code for the steroid binding domain – 'receptor negative' androgen insensitivity.

As well as natural mutations in the 5 $\alpha$ R-2 gene and AR gene, recent attention is being focused on environmental endocrine disruptors that are able to mimic steroid 5 $\alpha$ -reductase deficiency or partial androgen insensitivity syndrome. Any event which impairs DHT formation (mutation within the 5 $\alpha$ R-2 gene or 5 $\alpha$ R-2 inhibitors) or normal function of the AR (mutation in the AR gene, anti-androgens) may result in insufficient androgen action in the male fetus

and in subsequent undervirilization in the newborn. Hypospadias may be due to a defect in androgen action due to mutation of the 5 $\alpha$ R-2 or of the AR gene and mutation of unidentified genes may underlie displacement of the urethral meatus from the tip to the ventral side of the phallus. An etiological role for environmental industrial and agricultural chemical products has also been postulated, since ethnic as well as geographical differences in the incidence of hypospadias have been noted.<sup>48</sup> Thus cryptorchidism and micropenis may represent a distinct phenotype, even if they are isolated, and etiological factors include 5 $\alpha$ -reductase 2 gene, AR gene mutation or environmental hormonal disruptors (chemicals or phytoestrogens).<sup>28</sup> The hypothesis of the testicular dysgenesis syndrome (TDS) proposes that several disorders of the male reproductive system such as infertility, hypospadias, cryptorchidism and testicular cancer are all manifestations of TDS, which is most likely initiated during early fetal development and may be provoked by external factors such as endocrine disruptors in addition to genetic predisposition.<sup>49</sup>

*Complete testicular feminization:* patients generally present after puberty with primary amenorrhea but normal breast development, scanty pubic and axillary hair, and female body habitus and psychosexual orientation. There is a short blind-ending vagina as Müllerian structures have regressed. Gonads show Leydig cell hyperplasia with defective spermatogenesis and may undergo malignant change if they are not removed. In *incomplete testicular feminization* there is more virilization with prepubertal clitoromegaly and variable labial fusion. There may be a mixture of virilization and feminization at puberty.

In *Reifenstein syndrome* appearance is generally male but with severe (perineal) hypospadias. Virilization at puberty may be significant but still inadequate and associated with gynecomastia. There is male psychosexual orientation and infertility. In the *infertile male syndrome* there is a normal prepubertal male appearance although penis and testes may be rather small. Gynecomastia develops at puberty and there is oligospermia and infertility.

## ABNORMAL GONADAL DIFFERENTIATION

This is a clinically heterogeneous group, including true hermaphroditism and syndromes of dysgenetic gonadal development. In most there is ambiguity of external genitalia in the newborn.

*True gonadal disorder ('true hermaphroditism')* usually presents with abnormal external genitalia (e.g. phallus with urogenital sinus at the base). Testicular and ovarian tissue are present, more commonly as ovotestes than as separate gonads. The commonest karyotype is 46XX (58%), 10% are XY and the remainder mosaics, of which the commonest is 46XX/46XY (13%). If the diagnosis is made neonatally, testicular tissue should be removed, and gender assignment should be female – there is good feminization at puberty with menstruation and fertility is possible.

XX *males* usually present with hypogonadism as adults but genital ambiguity may occur.

*Klinefelter syndrome* may be suspected in a neonate with hypospadias, small testes and extension of the scrotal skin onto the shaft of a small penis or found by serendipity at antenatal screening but is seldom diagnosed before the time of puberty (see p. 459).

*Mixed gonadal dysgenesis:* generally there is a testis with Wolffian (and absent Müllerian) structures on one side, with streak gonad and Müllerian (but poorly developed Wolffian) development on the other. Karyotype is generally 46XY or 45XO/46XY mosaic – the latter associated with clinical features and the growth pattern of Turner syndrome. Bilaterally dysgenetic testes are less common. In both groups there is a high risk of malignant change in the gonads.

*Turner syndrome.* See pp. 455–6.

*Pure gonadal dysgenesis* seldom presents before puberty. There are normal female external genitalia but the karyotype may be 46XX or 46XY. Gonadal malignant change is common.

*Agonadism* presents in a variety of clinical guises depending on the timing of testicular involution. There may be normal female appearances

with absent Müllerian and Wolffian structures, micropenis with rudimentary testes or anorchia in an otherwise normal male.

## CLINICAL MANAGEMENT

### Initial assessment

Uncertainty as to the sex of their newborn baby is extremely distressing to parents. Emphasize that their baby's sex will be swiftly determined, the baby is either male or female (and not 'somewhere in between') and that the cause of the problem will be discovered. Birth should not be registered until sex of rearing is decided. Appearance of external genitalia is important in this decision – an adequately functional phallus cannot be created out of very little tissue – but is unhelpful in reaching an etiological diagnosis.

Check the family history and for any hormone treatment during the pregnancy. Look for associated abnormalities or dysmorphic features. The most important aspect of clinical examination is for the presence of gonads – a clinical classification, based on the number of abnormalities or dysmorphic features, is useful for planning immediately relevant investigations<sup>50</sup>:

In *all* patients, an urgent karyotype is indicated for diagnostic purposes

If *no* gonads are palpable: the most likely diagnosis is the 21-hydroxylase deficiency in a genotypic female – salt loss may occur. Measurement of plasma 17OH progesterone will confirm the diagnosis; urinary pregnanetriol levels are high. 11-Deoxycortisol levels are high in 11 $\beta$ -hydroxylase deficiency. Male pseudohermaphroditism with intra-abdominal testes is much less common and true hermaphroditism very rare.

If *one* gonad is palpable, mixed gonadal dysgenesis (usually with XO/XY karyotype) is least uncommon. Pelvic ultrasound and genitogram, HCG test, gonadal biopsy and exploratory laparotomy may be necessary.

If *two* gonads are palpable, male pseudohermaphroditism is likely. An HCG test measuring testosterone, DHT, DHA and androstenedione will help distinguish 5 $\alpha$ -reductase deficiency, testosterone biosynthetic disorders and androgen receptor or postreceptor defects. In vitro androgen binding studies and measurement of 5 $\alpha$ -reductase activity in genital skin fibroblast cultures may be necessary. A genitogram may be helpful in imaging internal genitalia and lower urinary tract.

## MANAGEMENT: CHOICE OF GENDER/GENDER IDENTITY

Choice should normally be based on appearance of external genitalia and functional possibilities in the context of information (cytogenetic, biochemical and radiological) about the nature of the underlying defect and implications for pubertal development. The decision should be made jointly by parents (whose ethnic background may be important in determining their views), pediatric endocrinologist and surgeon. The karyotype is not always of fundamental importance in this context. In cases where the phallus seems inadequate but there are pressures for male gender assignment, information about likely growth of the phallus in response to androgen can be predicted with depot testosterone (50 mg once monthly i.m. for 3 months).

It used to be thought that psychosexual orientation was dependent on sex of rearing but some of this work has been discredited<sup>51</sup> (for a journalistic but interesting account see Colapinto<sup>52</sup>) and from observations in the 'natural history' of patients with 5 $\alpha$ -reductase deficiency<sup>53</sup> and those with 17 $\beta$ -hydroxysteroid dehydrogenase deficiency,<sup>54</sup> it seems that the role of the fetal testis and androgens in 'imprinting' male gender identity is crucially important.

Nevertheless, ideally, sex of rearing should be decided as early as possible. Conventionally, surgery has been carried out so as to achieve cosmetically acceptable external genitalia by 2 years. However parent/patient organizations (such as the Disorders of sex differentiation Society of North America) have been outspoken in their view that surgery should be carried

out only if and when the person with a DSD requests it, and then only after she/he has been fully informed of the risks and likely outcomes.

Sometimes, because of late presentation or late diagnosis in the older child, or if there is spontaneous 'inappropriate' feminization or virilization at puberty, gender reassignment is indicated. With expert psychiatric support and counseling this can be satisfactorily achieved but cultural considerations may again be important.

The status of the empirical evidence for the development of gender and sexuality in 46XX persons with classical CAH and its implications for clinical practice has been reviewed by Meyer-Bahlburg<sup>55</sup> and outcomes reviewed by Warne et al.<sup>56</sup>

### Incidence of tumors in DSD

Patients with a Y chromosome but androgen insensitivity or a disorder of gonadal differentiation are at increased risk of neoplasia in an intra-abdominal gonad by adolescence or early adulthood. The risk with scrotal gonads is probably much less, particularly with regular clinical and ultrasound follow-up.

Carcinoma in situ, benign hamartomas and seminomas are reported in complete gonadal dysgenesis patients. In them, therefore, testes should be removed, but some argue that this should be done after spontaneous feminization has taken place at puberty. [In contrast, virilization at puberty will occur in incomplete testicular feminization (incomplete androgen insensitivity) or an androgen biosynthetic defect and the testes should be removed in childhood.]

Tumors are common in dysgenetic gonads. Benign gonadoblastomas may be endocrinologically functional, and malignant seminomas, dysgerminomas, choriocarcinomas or yolk sac tumors are reported. Unless there can be careful observation of scrotal gonads through childhood and puberty (with subsequent removal), they are best removed in childhood.

## PHYSICAL GROWTH AND DEVELOPMENT

### ASSESSMENT

#### Historical aspects

Within the last century it has been appreciated that assessment of a child's growth is the best marker of their well-being. The repeated measurement of groups of children from particular populations over the course of time has made it possible to pass comment about the influence of social changes on the health of children as this is reflected directly in growth of stature and the timing of sexual maturation. The average height of populations in resource rich countries is increasing generation upon generation but in resource limited countries inadequate nutrition with its intermittent supply still has a profound adverse effect on physical growth and on the health of children. Growth velocity remains one of the most useful indices of public health and economic well-being in both resource limited and socially heterogeneous resource rich countries<sup>57</sup> and the importance of this has inspired the World Health Organization to a new venture with the production in 2006 of the first set of international standards reflecting how children should grow in optimal conditions ([www.who.int/childgrowth/en/](http://www.who.int/childgrowth/en/) and see below).

#### The normal pattern of growth

The normal pattern of expected growth is traditionally displayed on a growth chart. Growth charts show the range of growth of a reference population and consequently do not describe exactly the growth curve of any individual child. Nevertheless they are important tools, but it must be remembered that each child has their own individual pattern of growth and timing of the events of puberty. This is called their 'tempo' of growth.

#### Which growth chart?

Two types of growth chart produced from United Kingdom data, each with a different form of construction, are currently available. The UK 1990 standards<sup>58</sup> are recommended for general use.<sup>59</sup> These are cross-

sectional charts based largely on single measurements of many thousands of children at different ages, and the LMS statistical method<sup>60</sup> is employed to produce the mean and multiples of the standard deviation at each age and thus the smooth curves found on the growth charts (Figs 15.9–15.12). The nine centile bands are equally spread, interval 0.67 standard deviations (SD), and range between  $-2$  SD (2nd centile) and  $+2$  SD (98th centile). In an attempt to quantify extremes of variation, two further centile lines (0.4th and 99.6th which is  $\pm 2.67$  SD) are provided with shaded areas above and below respectively. The measurements of 1 in 250 normal children lie above and below these lines but the chances of finding a pathological cause for abnormal growth in a child is greater outwith these boundaries. The Buckler–Tanner charts are of the tempo-conditional type; they are constructed with a greater influence from longitudinal data, i.e. serial measurements from the same child, and the shape of the curve reflects the growth pattern of an individual child more closely.<sup>61</sup> These charts are only recommended for height measurements beyond the age of 2 years, weight standards already being outmoded for the UK population. Consequently they are best reserved for the longitudinal follow-up of the growth in height of an individual child. The variations in growth particularly at puberty can be followed more easily, and the additional colored lines assist in determining whether the growth of an adolescent with onset of puberty not at the 50th centile is normal or otherwise (Figs 15.13, 15.14).

### Racial, ethnic and national factors

UK growth charts have mainly been constructed from measurements from the indigenous white population, whereas today's population is multiracial. There are differences in body proportions between the main three human races. People of African origin have longer legs, with the opposite being true for those of Mongolian racial origin. The pattern and tempo of growth is similar across mankind, however. Although African origin and Mongolian origin children start puberty and mature earlier than Caucasian children, individual differences do not fall outside of expected norms. Even if standards particular to each racial group were available, with so much social integration they would be little use in practice. Consequently UK 1990 charts are valid both before and during puberty for all children irrespective of ethnic background. It is the calculation of a child's target height which needs to be considered in determining whether the child is of abnormal stature, not their ethnic background per se. The WHO has considered this issue in considerable detail and commissioned the WHO Multicentre Growth Reference Study. Longitudinal growth data were collected prospectively in 8440 children from birth to 5 years, breast-fed and reared in optimal circumstances, from six countries worldwide (India, Norway, USA, Ghana, Oman and Brazil). The resulting standards are intended to represent ideal growth in healthy children irrespective of racial or ethnic origin. The charts are available in either standard deviation or centile format and can be downloaded for use from the WHO website [www.who.int/childgrowth/en/](http://www.who.int/childgrowth/en/).

### Decimal ages and decimal charts

The year time scale on a growth chart may be divided according to weeks or months, or can have a decimal scale (i.e. thousandths of a year, usually rounded to 2 decimal places). For routine use the standard weekly or monthly subdivisions are preferable as this helps with accurate plotting. Decimal ages are advantageous when the calculation of height velocity is required and when more precise plotting of the growth chart is necessary, for example in long term follow-up. Decimal ages are calculated according to the following example (see Table 15.5 for decimal age conversion):

a.	Date of examination:	12th May 2007	Decimal date from table: 2007.359
b.	Date of birth:	23rd September 1998	Decimal date 1998.726
	Subtracting b from a:		Decimal age: 8.633 year

Height velocity can be calculated as the height increment (cm) divided by interval between measurements in decimal years:

Fig. 15.9 UK1990 standard centile chart for height, weight and pubertal staging in boys (© Child Growth Foundation).

- c. Decimal age at examination: 8.633 years
- d. Decimal age at previous examination: 7.876 years
- Height increment over interval c-d 0.757 years: 4.2 cm
- Height velocity (annualized, see below): 5.5 cm/year

**Plotting growth charts**

Mis-plotting is a common error even by experienced personnel, so care should be taken and the plot reviewed with reference to previous plots when available. A precise dot, uncircled, provides maximum clarity on the chart as this will not overlap with previous or subsequent points. Plots of weight in very obese children sometimes stray onto the height centile spread, so these points should be clearly indicated as being weight not height.

**Screening for growth disorders in the community (growth monitoring)**

Screening for growth and other disorders by height and weight measurement assists in the diagnosis of problems which would otherwise be missed or come to light at a later stage when the outcome of treatment may be less favorable. Growth monitoring is important in the early detection of disease in children and of particular value in detecting a wide variety of endocrine abnormalities in which poor growth may be the earliest, or only, sign of a problem. After considerable debate as to the prac-

ticality and economics of measuring all children, it has recently been demonstrated to be a very cost-effective intervention.<sup>62</sup> Currently in the UK growth is assessed at primary school entry and close to exit (ages 4 and 10 years) as a minimum, but any changes in policy need to be evidence based. Measurements should be conducted by trained staff using reliable and calibrated equipment. Regular updates on training are required.

**Which measurement?**

Standard measurements include supine length and weight with head circumference up until 2 years of age. Beyond that, height and weight are the norm. The British Society for Paediatric Endocrinology and Diabetes recommends that recording and plotting of a child's height and weight at every encounter is an example of best clinical practice. Body mass index charts (weight in kg/height in meters squared) are now available and can be used to assess a child's body composition and follow any changes (Figs 15.11, 15.12). However as an approximation, a child's weight centile should not be more than 2 centile bands above or below their height centile. This approximates to the 98th and 2nd centiles for body mass index (BMI) respectively, i.e. the determinants of obesity and underweight. Skinfold thickness may be assessed to determine the degree and pattern of obesity and to calculate body composition (percentage body fat). Skinfold thickness can also be measured

Fig. 15.10 UK1990 standard centile chart for height, weight and pubertal staging in girls (© Child Growth Foundation).

serially on a child to monitor response to a treatment or intervention but current standards are outdated and should not be used. Mid-arm circumference may be a useful simple measure of the degree of nutrition in young children, particularly in resource limited countries (see Ch. 16).

Sitting height and subschial leg length (which is height - sitting height) are useful measures to investigate body disproportion, e.g. in skeletal dysplasia, or following interventions which affect spinal growth. A sitting height stadiometer and training in measurement technique are required (see below and Fig. 15.15c). Crown-rump measurement is the equivalent to sitting height in children less than 2 years. Arm span is usually similar to standing height and therefore is a useful measure in the investigation of disproportion and also in the follow-up of children who are developing deformity, e.g. from a scoliosis, and when height measurement is not possible, e.g. in spastic diplegia. Useful reference manuals of normal physical measurements and characteristics are Buckler<sup>63</sup> and Hall et al.<sup>64</sup>

Knemometry is the technique of choice for studying short term growth as it allows precise, reproducible, non-invasive measurements of lower leg length in growing children. Such that daily (or even within-day) and weekly fluctuations in leg length can be documented, e.g. during intercurrent illness or when daily<sup>65</sup> or alternate day<sup>66</sup> steroids are administered therapeutically. Knemometry ignores spinal growth and may be influenced by the hydration of soft tissues overlying bone. As a research technique it has provided valuable insights into the factors inhibiting growth.

### Which equipment?

The most accurate height measuring equipment is the Harpenden Stadiometer, which reads to 0.1 cm (Fig. 15.15a). This is precision equipment but is not robust and the counter breaks easily with careless use. The Raven Magnimeter is the most suitable for routine clinic use. Portable equipment such as the Leicester Height Measure or the Minimeter is suitable for community or field measurements. The latter needs to be recalibrated on each occasion.

Weight is best measured on accurate electronic scales (e.g. Seca) but regularly calibrated and checked balance scales may also be appropriate in certain circumstances (e.g. when electrical power is not available). Head circumference is best measured using specially constructed tape (Lasso-o, Child Growth Foundation, Fig. 15.15d) but a disposable paper tape folded or cut in half lengthways to reduce its breadth to reduce the inaccuracy can be used.

### How to measure

The following simple steps can insure accurate and reproducible measurements.

#### Height

Remove the child's shoes and position them with the heels and back touching the backboard. Instruct the child to stand erect. Position the child in the 'Frankfurt position' so that the lower border of the

**Referral guidelines**

Consider referral for any boy whose BMI falls above the 99.6th centile/below the 0.4th centile as significantly over/underweight even on the basis of a single measurement. It is possible that a boy whose BMI falls in the tinted areas should also be referred. However, during infancy large but transient changes in centile may occur due to the shape of the charts, and these changes are normal. It should be remembered that the earlier the age of the second rise, the greater the risk of future obesity. Remember also that while BMI has a high correlation with relative fatness or leanness it is actually assessing the weight-to-height relationship: **this may give misleading results in boys who are very stocky and muscular who might appear obese on the BMI alone.**

orbit is in the same horizontal plane as the external auditory meatus (Fig. 15.15a). The horizontal moveable part of the equipment is then lowered onto the child's head and the reading taken to the nearest 0.1 cm. Some observers prefer to stretch the child gently under the mastoid processes while the child takes a breath in and then exhales, noting the maximum measurement. Others prefer not to stretch the child, but whichever technique is employed, consistency is required. Children with unequal leg length should be measured on the longest leg and this fact entered into their record. Diurnal variation in

height may show as much as a 2 cm drop from rising in the morning to the afternoon. Where accurate determination of height velocity is required, the child should be measured at the same time of the day, preferably in the afternoon, and by the same observer where possible.

**Supine length**

Infants and children under 2 years, or those with a handicap can be measured supine. This technique requires at least two people, one being the child's parent if available (Fig. 15.15b). One person should hold the child's

**Referral guidelines**

Consider referral for any girl whose BMI falls above the 99.6th centile/below the 0.4th centile as significantly over/underweight even on the basis of a single measurement. It is possible that a girl whose BMI falls in the tinted areas should also be referred. However, during infancy large but transient changes in centile may occur due to the shape of the charts, and these changes are normal. It should be remembered that the earlier the age of the second rise, the greater the risk of future obesity. head against the headboard in the Frankfurt plane as above, while the other straightens the legs and moves the footboard up against both heels firmly. The measurement can then be taken. Children with unequal leg length should be measured on the longest leg, but the frequent practice of measuring one leg only can give inaccurate readings because of pelvic tilt.

**Sitting height**

The child is positioned on the sitting height table as upright as possible with the legs fully in contact with the table (Fig. 15.15c). Back and

foot supports are adjusted to support the child. Head positioning and measurement technique is the same as for height (see above). Sitting height may also be measured by placing a flat-topped stool of known height below the stadiometer and subtracting this amount from a measurement of the child sitting on the stool.

**Weight**

Infants should be weighed naked. Older children can be weighed in light underclothes and with shoes removed. Uncooperative toddlers

can be weighed with an adult, subtracting the adult's weight measured separately (the buddy-weighing technique).

### Head circumference

This measurement is the maximum occipitofrontal circumference with the reading taken on three occasions (Fig. 15.15d). A thin specially constructed tape measure is required (see above).

### Height velocity

Much has been written on the use of height velocity as part of the assessment of the growth of a child. Appreciation of the total amount grown at each age for any child is important as part of their assessment. However the individual pattern of growth of any child can show daily, weekly and seasonal variations. Height velocity is usually assessed over periods of not less than one year to avoid seasonal effects and to minimize the effect of measurement error, but increments of less than one year can be 'annualized' for comparative purposes and this is often sufficient to recognize growth problems quickly. (For the method of calculation of height velocity see decimal ages, above.) Even so, annual height velocity tends to oscillate with the periodicity of approximately 2 years<sup>67</sup> and this needs to be taken into consideration during interpretation of growth patterns (Fig. 15.16). Rhythms of growth have been reviewed by Wales and Gibson.<sup>68</sup> Measurement of height velocity is an accurate, cheap and non-invasive contribution to assessing the need for and adjustment of endocrine replacement therapy. This can be assisted by the regular assessment of skeletal maturation (bone age) where appropriate.

### Biochemical markers of growth

In certain circumstances, carefully chosen biochemical markers of growth may overcome some of these disadvantages. Biochemical markers are free from observer bias and their precision is independent of frequency of sampling. Bone alkaline phosphatase (BALP) is found in hypertrophic chondrocytes of the epiphyseal growth plate, in matrix vesicles associated with bone mineralization and in mature osteoblasts. There is a close quantitative relationship between serial measurements of BALP and height velocity in short normal children undergoing GH treatment.<sup>69,70</sup>

### Mid parental height

In the assessment of a child's growth potential, calculation of mid parental (or target) height is essential. The difference between the male and female 50th centile heights in the UK is 14 cm. For a boy, mid parental height is calculated as the simple average of parents' height + 7 cm, for a girl average of parents' height - 7 cm. The mid parental height (MPH) can be plotted on the growth chart (Fig. 15.9) and 90% of children will achieve an adult height within + or - 10 cm of that value (the target centile range). Caution needs to be exercised when predicting adult height if one parent is of extreme stature. A chart to help assess whether a child's short stature is of familial origin or not is also available.<sup>71</sup>

### Standard deviation scores

Standard deviation scores (SDS or Z-scores) have traditionally been used to monitor individual and group variations in height or any other growth parameter over time, as the function of age is excluded, and this makes statistical analysis possible. Height measurements are normally distributed and SDS can be estimated from the UK 1990 charts, each centile band being equally spaced 0.67 SD apart. For more accurate calculation and for measures such as weight and body mass index which are in a positively skewed distribution, the methodology of Cole<sup>60</sup> should be used.

## VARIATIONS IN GROWTH

### Postnatal adjustment

Weight at birth generally reflects the intrauterine environment and nutrition, and most if not all infants will show a degree of tracking, i.e. a shift across centiles for height weight and head circumference within the first 6 months after birth. The challenge here is to differentiate between a normal growth variant and failure to thrive or another pathological process. However normal variation, i.e. adjustment to the genetic growth pattern, will show a shift upwards

or downwards by as much as 2 centile bands, followed by stabilization of growth and subsequent following of the child's genetically determined centile band. Abnormal growth patterns will continue to show centile shift beyond the first 6 months, and further investigation should take place. Weight gain is more susceptible to the influence of feeding problems and intercurrent illnesses. The regular and accurate assessment of supine length in an infant will help distinguish between normal variation and true failure to thrive and as in the normal situation will demonstrate less fluctuation than weight.

### Intrauterine growth retardation and catch-up growth

Low birth weight (defined as below 2nd centile or  $-2$  SD for gestational age) may originate as a result of poor fetal growth throughout pregnancy or just in the last trimester. Both are of different causality and produce a different outcome. The latter arises as a result of maternal factors such as placental failure or pre-eclampsia. An otherwise normal fetus is starved of nutrients and fails to gain weight but grows in length near-normally, so-called asymmetrical growth retardation. After birth, these infants almost always show complete catch-up growth with rapid weight gain within the first 6–12 months. Research based on midwifery record archives suggests that this rapid gain in weight might be associated with a higher predisposition to diseases such as coronary artery disease, hypertension and type 2 diabetes later in life – the metabolic syndrome or syndrome-X.<sup>33</sup>

Symmetrical growth retardation is shown by those fetuses which grow poorly throughout all three trimesters and who are born at low birth weight and with reduced length and head circumference. The etiology is fetal rather than maternal and although this is likely to be multifactorial, endocrine factors such as insulin and glucocorticoid resistance have been implicated, and the phenomenon of genetic imprinting may also be responsible. Imprinting of certain paternal growth genes appears to be required for normal growth. Deletions and uniparental disomy can account for the growth retardation in about 10% of infants with Russell–Silver syndrome (see p. 439 and Fig. 15.24). Most infants with this form of growth retardation either catch up either very slowly (3 years or more) or never catch up fully.

### Growth during the prepubertal years and referral criteria

Once set on a particular trajectory, a child's growth in height will deviate little from its centile band until the onset of puberty. So predictable is this pattern that concern should be raised if height drifts up or down by as little as one height centile band, even within the designated normal range (i.e. 2nd to 98th centiles), and an explanation sought. This is the basis of the advice given to those conducting community growth screening programs.

### Syndrome specific charts

The pattern of growth is so reproducible in certain conditions that specific growth charts are available, e.g. for Down<sup>72</sup> and Turner<sup>73</sup> syndromes. They serve a very useful purpose in allowing correct judgments to be made about the growth of children with these conditions, and whether other external factors such as poor nutrition or ill health are affecting a child's growth adversely. In addition they assist with the prediction of adult height and in quantifying the effect of any treatments, such as the use of growth hormone in Turner syndrome.

### Medical conditions which affect growth

Previously, chronic ill health from conditions such as cystic fibrosis, diabetes mellitus, inflammatory bowel disease, chronic renal failure and asthma could be associated with poor growth and weight gain and a delay in the onset of puberty, although with modern treatment regimens and much more careful attention to nutrition this is rarely seen. However, poor growth can still be associated with severe forms of inflammatory bowel disease, juvenile chronic arthritis, chronic renal failure and congenital adrenal

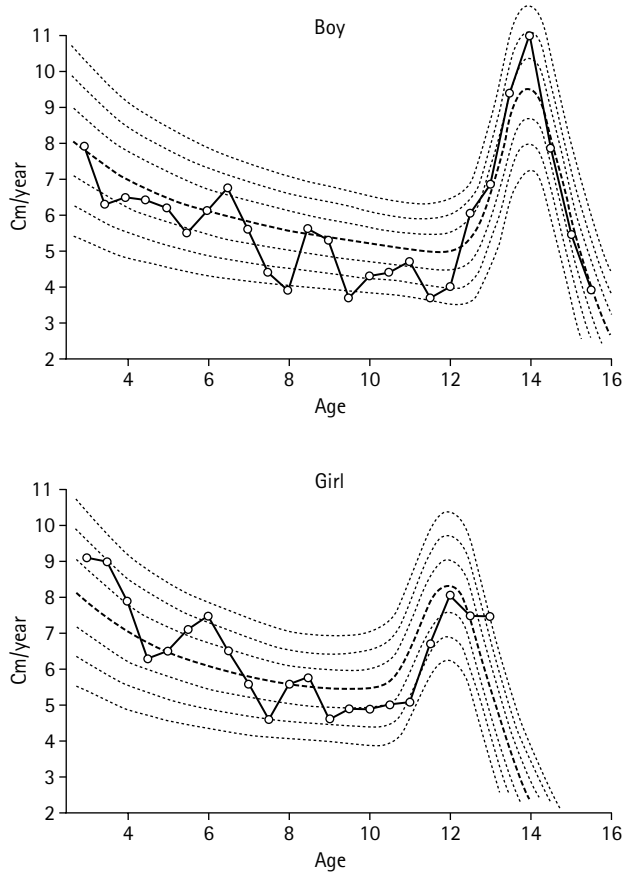

Fig. 15.16 Height velocity standards for boys and girls (redrawn from Tanner 1976) showing a height velocity curve for a typical normal boy and girl, both demonstrating the cyclical nature of growth. (From Butler et al 1990<sup>67</sup>)

hyperplasia, even when the associated glucocorticoid therapy is reduced to a minimum. The most frequently seen cause of iatrogenic growth failure is in the survivors of childhood malignancy. Treatment regimens including cranial and total body irradiation and high dose chemotherapy, often with stem cell rescue or bone marrow transplant, usually cause growth and thyroid hormone deficiencies, and steroidogenesis from the adrenals and gonads is frequently impaired. Hormone replacement may restore growth, but the success of treatment depends on how much primary damage is caused to the tissues of the body by the oncological regimens.

## BONE AGE

The bone age is a useful guide to an individual child's growth potential but the value of this investigation as a diagnostic tool is frequently overestimated, its main place being in adult height prediction. A bone age radiograph when scored according to current techniques gives a value (the 'bone age') which represents the 50th centile for a child of that age with that degree of skeletal maturation. This result can be interpreted in the same way as any measurement plotted on a reference chart. The 3rd and 97th centiles of skeletal maturity correspond to approximately 2 years either side of the child's chronological age, but whether a bone age is 'advanced' or 'delayed' its main value is estimating completed, and hence residual growth.

Conventionally X-rays of the left wrist are used because there is a large aggregation of long and round bones in this single area which can be imaged at minimal radiation dose. The Greulich and Pyle system<sup>74</sup> provides pictorial standards for direct comparison with the individual child's X-ray and the best fit determines the bone age. The Tanner-Whitehouse system (currently TW3<sup>75</sup>) requires the scoring of epiphyseal maturation of 13 individual bones (radius, ulna, 1st, 3rd and 5th

metacarpals and phalanges) and is more accurate and more suitable for longitudinal follow-up of the individual child. Bone ages can be performed serially, especially when monitoring response to treatment or an intervention, but as the rating system imposes artificial stages on a continuous biological process, it is not recommended to perform the investigation at less than 6 monthly intervals.

Epiphyseal fusion and growth cessation are now known to be related to estrogen secretion in both sexes. Thus estrogen deficiency due to mutations in the aromatase gene (CYP19) and estrogen resistance due to disruptive mutations in the estrogen receptor gene have no effect on normal male sexual maturation in puberty. However, these mutations result in an absent pubertal growth spurt, delayed bone maturation, unfused epiphyses, continued growth into adulthood and very tall adult stature in both sexes.<sup>76</sup>

## PREDICTION OF ADULT HEIGHT

It is helpful to plot the child's height for bone age on the height chart, and following the bone age/height centile through to maturity can give a reasonable approximation of the child's projected adult height. Figure 15.17 gives examples of height for chronological age and height for bone age plots in two boys, one early maturing and one late maturing, both however achieving 50th centile adult height. Although adult height prediction can be used for children with parents within the population norms it is far less reliable in extremes of stature and where pathology exists or treatment is given. Predicted adult height can be estimated based on the two principal bone age rating systems (TW3<sup>75</sup> and Greulich and Pyle<sup>74</sup>) with a margin of error in normal sized children of approximately + or - 4 cm. Reference should be made to the accuracy of height prediction from methods of bone age estimation in different disease states as margins of error vary greatly.

Mathematical description of growth and growth curves has frequently been undertaken, but the Infant-Childhood-Puberty model of Karlberg et al<sup>77</sup> provides the best description of growth during the three postnatal phases: infantile - principally under nutritional influence; childhood - growth being predominantly controlled by growth hormone secretion; and puberty - where both sex steroids and growth hormone drive growth. More recently, mathematical models have been derived to predict the response to an intervention, e.g. growth hormone treatment.

Fig. 15.17 Examples of the use of mid-parental height and bone age in the prediction of adult height in an early maturing (A) and a late maturing (B) boy. For details see text. Circle = height plot for chronological age, square = height plot for bone age, F = father's height, M = mother's adjusted height, T = target height.

## ASSESSMENT OF PUBERTY

The adolescent years are manifested by fundamental changes to the physical and psychological functioning of a person. To a pediatrician the process of puberty may influence the pathological process or management of some conditions and conversely a number of chronic conditions influence, usually adversely, the process of puberty, either in consonant way (the normal pattern of development but accelerated or delayed in time) or in a dissonant way (disruption of the normal pubertal process). Consequently an assessment of pubertal staging should be part of the clinical examination of any adolescent patient. The universally accepted method of pubertal staging is according to Tanner.<sup>6</sup>

### Clinical staging of puberty

#### Boys

In the male, ratings are expressed as stages of genital (penis) development, pubic hair development and testicular volume. Knowledge of these standards is extremely important when assessing growth in adolescents. They are shown in Figures 15.19–15.21 and are described below.

#### Genitalia (penis) development stages (Fig. 15.18)

**Stage G1:** Preadolescent. Testes, scrotum and penis are about same size and shape as in early childhood.

**Stage G2:** Scrotum slightly enlarged, with reddening of the skin and changes in the texture. Little or no enlargement of the penis at this stage.

**Stage G3:** Penis slightly enlarged, at first mainly in length. Scrotum further enlarged than in stage G2.

**Stage G4:** Penis further enlarged, with growth in breadth and development of glans. Further enlargement of scrotum and darkening of scrotal skin.

**Stage G5:** Genitalia adult in size and shape.

**Testicular volume.** Testicular volumes are assessed by palpation in comparison with a string of plastic models of testicular shape known as the

Prader orchidometer (Fig. 15.19). Although this principally measures spermatic tubular growth, testicular volume correlates closely with testosterone secretion. The models are marked according to their volumes in milliliters.

1–2 ml are prepubertal;

3–4 ml mark the beginning of puberty;

8–10 ml are associated with the beginning of height acceleration in mid-pubertal boys, usually at stage G3;

12–15 ml coincide with the maximum growth velocity, usually at stage G4;

20 ml (usually at stage G5) signifies that most boys have passed the peak of their growth spurt and are beginning to fuse their epiphyses on account of higher levels of testosterone secretion.

The majority of adult males reach volumes of 15–25 ml. Testicular volumes of less than 12 ml in adulthood may be associated with reduced fertility.

#### Pubic hair stages for boys and girls (Fig. 15.20)

**Stage PH1:** Preadolescent. The vellus over the pubes is not further developed than that over the abdominal wall, i.e. no pubic hair.

**Stage PH2:** Sparse growth of long, slightly pigmented downy hair, straight or slightly curled, chiefly at the base of the penis or along labia.

**Stage PH3:** Considerably darker, coarser and more curled. The hair spreads sparsely over the junction of the pubes.

**Stage PH4:** Hair now adult in type, but area covered is still considerably smaller than in adults. No spread to medial surface of thighs.

**Stage PH5:** Adult in quantity and type with distribution of the horizontal (or classically 'feminine') pattern. Spread to medial surface of thighs, but not up the linea alba.

**Stage PH6:** Spread upwards along the linea alba (the typical male escutcheon).

Fig. 15.18 Standards for genital (penis) development. (From Tanner 1962<sup>6</sup> with permission)

Fig. 15.19 The Prader orchidometer for the assessment of testicular volume.

### Girls

In girls it is the development of the breast which provides the best marker as to girls' progress through puberty (Fig. 15.21).

#### Breast development

**Stage B1:** Preadolescent: elevation of papilla only.

**Stage B2:** Breast bud stage: elevation of breast and papilla as small mound. Areolar diameter enlarged over stage B1.

**Stage B3:** Breast and areola both enlarged and elevated more than in stage B2, but with no separation of their contours.

**Stage B4:** The areola and papilla form a secondary mound projecting above the contour of the breast.

**Stage B5:** Mature stage: papilla only projects, with the areola recessed to the general contour of the breast.

#### The timing of puberty

In almost all children the pattern of progress through puberty is constant but the timing of attainment of each stage can be considerably variable. Centile bands for boys and girls at each stage of puberty are found beneath the weight curves on standard growth charts (see Figs

Fig. 15.20 Standards for pubic hair development in boys and girls. (From Tanner 1962<sup>8</sup> with permission)

Fig. 15.21 Standards for breast development. (From Tanner 1962<sup>6</sup> with permission)

15.9 and 15.10). The onset of puberty G2 in boys occurs at the mean age of 12.0 years (range 98th centile 9.8 years to 2nd centile 14.2 years), and in girls the mean age at B2 is 11.0 years (range 98th centile 8.2 years to 2nd centile 13.8 years). The mean age at menarche is 13.0 years (range 98th centile 11.0 years to 2nd centile 15.0 years). The duration of puberty (stage G/B2 to stage G/B5) may unusually take less than 2 years and more than 5 years, but on average is 3.0 years (2.3 years B2 – menarche in girls). A very rapid, delayed or halted passage through puberty especially with an attenuated adolescent growth spurt should be of major concern and a search for systemic or intracranial pathology should be conducted.

### Other markers of puberty

Often it is not possible to perform a formal Tanner pubertal staging due to inappropriate circumstances or refusal. Adolescents may be prepared to self-rate themselves if provided with line diagrams and simple descriptions or an orchidometer for boys. Axillary hair begins to appear 2 years after pubic hair. Facial hair grows initially above the upper lip (moustache area) at about G4. By the time sideburns begin to appear, a boy will have reached G5. The voice begins to break at G3–4. The timing of the first conscious ejaculation is very variable, but occurs in 90% boys by age 14 years. Sperm can be detected in early morning urine samples as early as 12 years of age and in early puberty (G2) before any other clinical features

are apparent. Menarche occurs by the time 90% of girls have reached B4 and PH4.

### GROWTH DURING PUBERTY

Prior to the onset of puberty height velocity gradually declines to between 4 and 6 cm/year (the prepubertal growth lag) and this is much more marked in boys than girls, especially when the onset of puberty is delayed (constitutional or maturation delay). The endocrinology of puberty gives a different tempo in boys compared with girls (Fig. 15.22). As soon as puberty begins with breast development in girls, height acceleration occurs and body shape changes become apparent. Maximal growth (peak height velocity) is achieved one year after the onset of puberty (mean 8 cm/year, range 6–10 cm/year) but the intensity of the spurt, i.e. maximal velocity achieved, is greater in early maturers and lower in later maturers. Menarche occurs 2.3 years (mean) subsequently when growth is on its decline. Girls gain on average 20–25 cm during puberty and average growth post menarche is 6 cm.

In boys peak height velocity is attained usually 2 years after the onset of puberty with maximum strength spurt following this. Peak height velocity is on average 9 cm/year ranging from 6 to 13 cm, the later maturers growing less intensely. Boys grow on average between

Fig. 15.22 Diagram of sequence of events in normal male and female puberty. Numbers indicate age ranges of each landmark stage. (From Marshall & Tanner 1970<sup>78</sup> with permission of the BMJ Publishing Group)

25 and 30 cm although the total growth during puberty is unpredictable and is the principal source of error of height prediction methods.

### COMMON ERRORS IN PUBERTAL ASSESSMENT

The method of construction of the UK 1990 growth charts reflects average population growth in children of average age at puberty (see above) so it is normal to see crossing of centile lines during the teenage years. This should not cause alarm and can be interpreted by knowing the adolescent's pubertal stage. The onset of puberty in boys is frequently missed as early scrotal and testicular changes are subtle and require careful inspection. Accurate documentation of pubertal stages is important, as 'false starts' can be common. Testicular volume is often overestimated, the orchidometer representing testicular size only, and not accessory structures such as the epididymis and scrotal skin.

### PUBERTAL VARIATIONS

#### Precocious adrenarche

Adrenarche, the awakening of the adrenal cortex to produce adrenal androgens, commences from around the age of 6 years and can be more pronounced in some children causing the appearance of pubic and axillary hair, greasiness of the skin and adult body odor. This proceeds only very slowly and in general is felt to be a variant of normal although links have been made in girls with hyperinsulinism and polycystic ovarian syndrome later on in life. For more detail see adrenarche, p. 480.<sup>32</sup>

#### Isolated menarche

Rarely an apparently prepubertal girl may present with a vaginal bleed of a few days' duration which sometimes can be repeated at monthly intervals. Exclusion of intrapelvic pathology is necessary by pelvic ultrasound and measurement of estradiol and gonadotrophins, after which this feature can be regarded as a variant of normal. A thin endometrial echo may be seen on the pelvic ultrasound scan. A single isolated vaginal withdrawal bleed (dark blood) in an otherwise prepubertal girl may be due to involution of a dominant follicular ovarian cyst. (See pseudopuberty, p. 451.)

#### Adolescent gynecomastia

Gynecomastia, either unilateral or bilateral, occurs in 40% of normal boys as a result of a testosterone/estrogen imbalance. The commonest time of onset is between Tanner stages G3 and G4, and it usually disappears 1–2 years later when testosterone levels rise (Tanner stage G4 to G5). In most situations no treatment, only reassurance, is required. Persistent discs of breast tissue may require surgical removal for cosmetic reasons. (See gynecomastia, p. 459.)

## GROWTH REGULATION AND DISORDERS OF GROWTH

### THE GROWTH HORMONE (GH) AXIS AND GROWTH

GH, a 191 amino acid anterior pituitary polypeptide, is secreted episodically throughout 24 h, but predominantly at night during slow wave sleep during which there are usually three to five discrete pulses, and is of cardinal importance in the control of growth. Release is mediated by the two hypothalamic peptides: GH releasing hormone (GHRH) – stimulatory, and somatostatin (SRIH) – inhibitory.

The hypothalamic release of GHRH and SRIH is regulated by a complex network of brain neurotransmitters and neuropeptides. Dopaminergic, serotonergic and noradrenergic pathways impinge on the GH regulatory neurone system, but cholinergic neurotransmitter pathways seem particularly important in controlling GHRH and somatostatin release. Hippocampal impulses, perhaps sleep-related, are stimulatory whilst impulses from the amygdala may be either stimulatory or inhibitory. Somatostatin secretion is mediated via the hypothalamic ventromedial nucleus.

A number of drugs induce changes in GH secretion via specific neurotransmitter pathways: clonidine is stimulatory via alpha-adrenergic and diazepam via GABA pathways; bromocriptine, propranolol and cholinergic agents probably inhibit somatostatin release. This is relevant in understanding pharmacological stimulation tests and, potentially, for therapy to stimulate GH secretion.

GH releasing hormone (GHRH) was first identified from the pancreas of a woman with Turner syndrome who developed acromegaly which failed to resolve after transsphenoidal pituitary surgery. Full bioactivity resides in its first 29 amino acids. Recently, a long-recognized family of potent small synthetic GH-releasing peptides, GH releasing hexapeptide (GHRP) and its analogues, have become important for their potential future therapeutic roles. GHRPs are active given by intravenous, subcutaneous, intranasal and oral routes, releasing GH via a specific, non-opiate, non-GHRH pituitary receptor – GHRPs do not interact with GHRH and somatostatin (SRIH) receptors. An additional, hypothalamic, site of action is possible as they require intact GHRH secretion to be effective. Continuous GHRP administration leads to pulsatile GH release.

Analogues such as GHRP6 (hexarelin) and GHRP2 have been under investigation as are nonpeptide orally active mimetics such as L-692,429. At equivalent (near-maximal) intravenous doses, hexarelin is a more potent GH secretagogue than GHRH. Intranasal hexarelin is also a potent GH secretagogue in prepubertal children with constitutional short stature. GHRPs given intravenously and orally are currently under investigation in a variety of groups of short stature children. Their potent ability to stimulate GH synthesis and release plus their effectiveness when given orally make them potentially useful, both as diagnostic agents in the evaluation of pituitary disorders and as oral GH secretagogues in 'short normal' children and those in whom 'GH deficiency' is

largely hypothalamic rather than pituitary in origin (e.g. post radiotherapy). They are ineffective in children with organic pituitary disease. For a review see Gigho and Broglio.<sup>79</sup>

Ghrelin, a 28 amino acid peptide, has been identified as the natural ligand of the GH secretagogue receptor in the hypothalamus and pituitary.<sup>80</sup> In humans, the serum GH response to intravenous ghrelin is greater than that observed with GHRH, and when ghrelin and GHRH are co-administered, the response is augmented. Ghrelin has been isolated from the arcuate nucleus, but the gastrointestinal tract, and particularly the stomach, appears to be a major site of production. Plasma ghrelin-like immunoreactivity is increased by fasting, reduced by feeding and correlates negatively with BMI.<sup>81</sup> Pharmacological studies suggest that ghrelin is involved in integrating hormonal and metabolic responses to fasting, producing an increase in GH secretion, increased drive to eat, inhibition of insulin secretion and activation of mechanisms directed at maintaining blood glucose levels.<sup>82</sup> Abnormalities of the growth hormone secretagogue receptor may be a cause of short stature in man.<sup>83</sup>

The effective therapeutic use of GHRH itself, potentially a physiological way of treating GH deficiency when the pituitary is intact, has been hampered by the lack of a depot preparation. However subcutaneous GHRH (given twice daily) has been shown to be effective at stimulating growth, e.g. in children treated with cranial irradiation-induced GH deficiency.<sup>84</sup>

Yet other peptides are also important in the regulation of GH secretion: endorphins, neurotensin and vasoactive intestinal peptide (VIP) are stimulatory whilst substance P and central TRH pathways are inhibitory. VIP may have an important role in the release of GH and prolactin in health and disease (e.g. obesity, anorexia nervosa).

GH regulates its own secretion by feedback directly or via effects mediated by the insulin-like growth factors (IGFs) and (probably) metabolic factors such as free fatty acids, insulin and glucose. This results in the characteristic pattern of episodic pulsatile secretion with amplification during the early hours of sleep. New techniques are beginning to reveal the complex functional organization of GH-secreting cells in effecting coordinated pulsatile GH secretion.<sup>85</sup> Disruption of such a coordinated network may explain such slowly developing GH deficiency states as 'neurosecretory dysfunction' or GH insufficiency following traumatic brain injury<sup>86,87</sup> or cranial irradiation.

GH is unusual in being species specific. Two forms are present in man and it is secreted as a heterogeneous molecular species. The predominant, and presumably more bioactive, form is of MW 22000 (22K). An approximately 20K form is present in smaller amounts. Structurally abnormal GH variants with varying bioactivity could be important in the etiology of growth failure in certain rare conditions but are unlikely to be common reasons for poor growth in the population as a whole.

GH is not inhibited by feedback from peripheral endocrine glands although thyroxine and glucocorticoids influence its secretion. Regulation is by GH itself (at hypothalamic and pituitary levels), peripheral GH-dependent growth factors (e.g. IGF-1), GHRH and somatostatin and metabolic factors such as free fatty acids and glucose. The physiological role of GHRPs is still unclear. The integration of this control with physiological states – sleep, exercise, appetite and nutrition – is via the monoaminergic and peptide systems described above.

The plasma half-life of exogenously administered GH is 20–25 min; that of endogenous GH is thought to be similar or shorter although this remains controversial. GH affects linear growth directly by stimulating early epiphyseal growth plate precursor cell differentiation but and it is probable that it has anabolic effects independent of IGF-1. Paracrine IGF-1, produced locally in proliferating chondrocytes of the growth plate, is more important than liver-derived circulating IGF-1 in stimulating epiphyseal cartilage growth. Receptors for many hormones, including estrogen, glucocorticoids and GH, are present in the growth plate which suggests that they directly influence local growth plate processes together with IGF-1 and other growth factors such as Indian hedgehog (Ihh), parathyroid hormone-related peptide (PTHrP), fibroblast growth

Fig. 15.23 The growth hormone receptor.

factors, bone morphogenic proteins and vascular endothelial growth factor.<sup>88</sup>

In the interaction between GH and tissue growth, the GH receptor is of crucial importance. The GH receptor was cloned from rabbit liver based on amino acid sequence data and from human liver by cross hybridization and consists of a 620 amino acid (AA) peptide situated astride the target cell membrane with a single transmembrane domain. The extracellular hormone-binding domain consists of approximately 245 AAs and there is a cytoplasmic region of 350 residues (Fig. 15.23).

Laron dwarfism<sup>89</sup> is the classical form of GHIS resulting from molecular defects in the GH receptor caused by gene deletions or point mutations. Evidence<sup>90</sup> that heterozygous expression of GH receptor mutations may be associated with growth failure raises questions not only as to whether heterozygous expression of Laron dwarfism results in a clinically important phenotype but also whether a significant minority of children with 'idiopathic short stature' could be heterozygous for mutations of the GH receptor<sup>91</sup> with abnormal receptor signaling.<sup>92</sup> This also has implications for investigation and diagnosis of short stature and GH 'deficiency'.

Current GH signal transduction models<sup>93</sup> involve activation by GH of a GH receptor-associated tyrosine kinase (GHRTK), an important early (and perhaps initiating) step in signal transduction. GHRTK is stimulated within less than 30 seconds of GH binding to the receptor by very low GH concentrations and is likely to stimulate a variety of cellular responses including kinase activity and gene expression. In particular, GH stimulates tyrosyl phosphorylation and kinase activity of a GH dependent GH receptor-associated kinase JAK 2 (one of a family of Janus kinases). JAK 2 probably serves as a signaling molecule for multiple members of a cytokine/hematopoietin family which includes GH, PRL, erythropoietin, interleukin-3, etc. GHRTK functions both to activate other proteins by phosphorylation and to phosphorylate tyrosyl residues in itself and the GH receptor. These phosphorylated tyrosines may serve as docking sites for proteins in other signaling pathways. Such studies should lead to the identification of new cellular actions for GH.

To be biologically active, GH must bind to a transmembrane receptor, which must dimerize and activate an intracellular signal transduction pathway causing IGF-1 synthesis and secretion. However, IGF-1 which, in blood, is itself bound to members of a family of binding proteins (IGFBPs), must bind to the IGF-1 receptor, in turn activating its own signal transduction pathways producing mitogenic and anabolic responses and tissue growth. Thus GH effects its action on target tissues by binding to specific receptors expressed both in the liver and other target tissues throughout the body. This activates genes which include those which code for IGF-1 which stimulates tissue growth by endocrine and (largely) paracrine and autocrine activity. The complexity of these pathways (together with the vagaries of GH assays and the pulsatile nature of GH release) helps to explain the difficulties in measuring 'GH secretory ability' or 'GH sensitivity' in many short stature children.

The clinical phenotypes of GH insensitivity reflect the effects of postnatal IGF deficiency and are broadly identical to the phenotype of complete congenital GH deficiency. This phenotype differs somewhat from that of defects of the IGF-1 gene<sup>94,95</sup> indicating that prenatal IGF-1 production is largely independent of GH and that IGF-1 (and not GH) is a major factor in intrauterine growth regulation.

## GROWTH REGULATION

The determination of the somatotroph cell line is dependent on various transcription factors: Prop-1, Pit-1, HesX-1, Lhx-3, Lhx-4. Mutations in all of these have now been identified in patients with hypopituitarism. Defective Prop-1 function causes combined pituitary hormone deficiencies. Hypogonadism represents the major difference between the Pit-1 and Prop-1 hormone phenotype. HesX-1 is necessary for the normal development of the forebrain, eyes, olfactory placodes and anterior pituitary. Mutations result in variable hypopituitarism ranging from isolated GH deficiency to panhypopituitarism.<sup>96</sup> Sox3 mutations in humans may also account for some sporadic forms of GH deficiency.<sup>97</sup> Pit-1 also plays a role in the activation and regulation of the somatotroph gene product, GH. Additional factors such as CREB and the GHRH receptor may be important for somatotroph determination, while Zn-15 and Pitx2 are thought to be involved in GH gene activation.<sup>11</sup>

A gene thought to be critical for normal growth, the 'short stature homeobox-containing gene' (SHOX), has been identified on the pseudo-autosomal region of the sex chromosomes (a region of the X chromosome which normally escapes X inactivation). SHOX may have a general role in determining chondrocyte function (and perhaps differentiation in particular) in the growth plate, and is expressed there from 12 weeks' gestation until epiphyseal fusion in late adolescence.<sup>98</sup>

SHOX mutations have been occasionally found in children with idiopathic short stature, more commonly in Leri-Weill dyschondrosteosis – an autosomal dominant form of mesomelic dysplasia which has a number of features in common with Turner syndrome (e.g. wide carrying angle, scoliosis and palatal abnormalities) implicated in both the short stature and skeletal dysplastic abnormalities of Turner syndrome. Phenotypes associated with SHOX deficiency are reviewed by Ross et al<sup>99</sup> and the genetic background to cellular expression of the hormonal control of growth regulation by Mullis.<sup>100</sup>

Mechanisms by which physiological states, GH regulation and genetic determination of growth potential are integrated to achieve appropriate stature are largely unknown. Tanner has proposed<sup>101</sup> that the CNS contains a 'sizostat' – the rate of synthesis or release of a specific molecule could decrease as maturity increases and another molecule could be synthesized in proportion to the amount of growth. A 'mismatch' would be sensed by the sizostat and growth adjusted accordingly. This concept, and 'catch-up'<sup>102</sup> and 'catch-down' growth questions whether exogenous hormone therapy in some categories of short children would necessarily increase final height significantly – predictions that do seem to be the case in various pathological conditions and so-called 'idiopathic short stature' (see below).

'Catch-up' growth, rather than CNS-dependent, is more likely intrinsic to the growth plate as suggested in a number of elegant laboratory animal experiments by Baron et al.<sup>103</sup>

The 'infancy-childhood-puberty' model of growth suggests that the infancy component (which is a continuation of fetal growth) is primarily determined by nutritional factors, the childhood component by GH and the puberty component by sex steroids. The infancy component is initially rapid but decelerates as the influence of GH appears by the end of the first year. The effect of GH is sustained but in the absence of adequate sex steroid secretion the pubertal growth spurt is blunted or absent. The combined input of the three components results in the normal pattern of growth to final height. Although simplistic, such a model enables effects of different insults which may affect growth and different treatment modalities to be studied more effectively. Thus epiphyseal fusion is thought to be estrogen mediated (in both sexes) and growth stimulating estrogen effects (in early puberty) to be mediated largely via GH. Estrogen also has direct effects on bone cross-sectional development mainly by suppressing bone resorption at the endocortical surface.<sup>104</sup>

Tall children secrete more GH than their short peers, and GH secretory pulse amplitude correlates with growth velocity although not very strongly.

'Growing pains' appear to be a frequent form of pain in otherwise healthy schoolchildren. However, they probably have little to do with growth. The pain or ache is usually bilateral, commonly situated in the

front of the thighs, in the calves and behind the knees, and never situated at or near any joints. There is never any limp, tenderness, redness or swelling. The groin is sometimes affected. Discomfort may come on suddenly or gradually and does not usually occur every day; it usually occurs late in the day and in the evening. When the child wakes in the morning, the pain has usually disappeared. It was once said that emotional growth can be painful but physical growth is not. Perhaps it is simply best to admit ignorance about the cause(s) of 'growing pains' and recognize that they are harmless and self-limiting. They may also be part of the migraine/periodic syndrome spectrum (see migraine in Ch. 22).

## THE SHORT OR SLOWLY GROWING CHILD

The 'normality' of a child's height is determined by reference to growth charts showing population norms. Ideally each country and ethnic group should have its own growth standards. In practice, UK charts serve well even in resource limited countries and for ethnic minorities within the UK as differences in final stature reflect minor differences in growth velocity over the whole growing period. Introduction in the UK of nine centile growth charts, based on seven largely cross-sectional local growth surveys between 1978 and 1990,<sup>58</sup> should help to facilitate the appropriate referral of children with growth disorders following community height *screening* (see above). The lowest centile is the 0.4 line – only one normal child in 250 will fall below that line, which is a clear indicator for referral. The interval between each provided pair of centile lines is the same – two thirds of a standard deviation. Two percent of the normal population will have a height below the second centile. It is recommended that any child between the 2nd and 0.4 centiles be monitored to see whether their growth is normal. Versions are available for community and hospital use.

The WHO Multicentre Growth Reference Study (MGRS) is described on page 422. The new growth curves are expected to provide a single international standard that represents the best description of physiological growth for all children from birth to 5 years of age and, importantly, to establish the breast-fed infant as the normative model for growth and development.<sup>105</sup>

Revised charts based on the Tanner-Whitehouse growth standards (determined in a longitudinal study of South of England children in the 1960s) have been produced – the Buckler-Tanner 1995 longitudinal standards.<sup>61</sup> Height revision is adjusted to take account of the recent cross-sectional studies and of Buckler's longitudinal study of adolescent growth.<sup>106</sup> For *monitoring* the growth pattern in an individual child such charts are preferable. Three percent of normal children will, by definition, be below the third centile on a distance (height for age) chart yet a child with a growth disorder of recent onset will be of normal stature. Only serial measurements and calculation of growth velocity will distinguish normality from abnormality.

Parental genetic contributions reduce the population standard deviation of height by about 30%. Ninety-five percent of the children of given parents will have a height prognosis within  $\pm 8.5$  cm of the mid parental *centile*. Children also 'inherit' an environment from their parents. A child's shortness, whilst 'appropriate' for his short parents, may reflect poor nutrition or emotional deprivation continuing down the generations with no family member achieving their true genetic height potential.<sup>57</sup>

The possibility of an unrecognized and untreated growth disorder in an unusually short parent must be excluded before attributing a child's shortness to constitutional reasons – pathology, e.g. GH deficiency, a skeletal dysplasia or pseudohypoparathyroidism, may also be genetically transmitted.

Growth retardation affects about one third of children younger than 5 years of age in resource limited countries and is associated with poor cognitive, neurodevelopmental and educational outcomes.

The differential diagnosis of short stature or slow growth is summarized in Table 15.6. Whatever their ultimate height prognosis, many short children may suffer emotionally and underachieve. 'Western' society views tallness as a positive attribute and the social consequences of short stature are not dependent on the presence of underlying pathol-

Table 15.6 Differential diagnosis of short stature and slow growth

<p><b>Short with currently normal growth velocity</b>  <i>Constitutional short stature, short normal parent(s)</i></p> <p><i>Previous problem affecting growth, now cured or no longer operative</i>                  Prolonged intrauterine growth retardation – light for gestational age, low birth length and head circumference, difficult feeders in infancy, including Silver–Russell syndrome – triangular facies, clinodactyly, facial and limb length asymmetry                  Congenital heart disease</p> <p><i>Physiological growth delay (delayed bone age, normal height prognosis)</i></p> <p><b>Growing slowly (whether already short or still of normal stature)</b>  <i>With increased skinfold thicknesses</i>                  Endocrine disease (e.g. panhypopituitarism, severe growth hormone insufficiency – idiopathic or secondary to tumor or irradiation, hypothyroidism, pseudohypoparathyroidism, Cushing syndrome)</p> <p><i>Disproportionate</i>                  Short limbs for spine (the dyschondroplasias, e.g. achondroplasia, hypochondroplasia, multiple epiphyseal dysplasia)                  Short limbs and spine (spine relatively shorter, e.g. mucopolysaccharidoses, metatropic dwarfism)</p> <p><i>Often without other obvious signs of disease (see text)</i>                  Chromosomal abnormalities (e.g. Turner syndrome – other signs variable)                  Unrecognized asthma (may be misdiagnosed)                  Malabsorption due to celiac disease, ulcerative colitis, Crohn's disease (bowel habit may be normal)                  Psychosocial deprivation                  Malnutrition                  Cardiovascular or renal disease</p>
---

(a)

(b)

Fig. 15.24 A child with prolonged intrauterine growth retardation (Silver–Russell syndrome) presenting with short stature. Note the triangular facies, low-set ears, asymmetry (a) and clinodactyly (b).

ogy, which must be sought if growth velocity is inadequate. Without diagnostic clues from history or examination, the screening test for a child presenting with short stature is calculation of growth velocity.

A small child who is growing normally may have small parents (constitutional short stature, but see above), growth (and likely maturational) delay, a previous period of poor growth (for example due to prolonged IUGR, e.g. Silver–Russell syndrome, see Fig. 15.24) or a combination of these factors.

There are currently many children who are short without a recognized cause. These so-called ‘idiopathic short stature’ (ISS) children can be considered either as part of the continuum between complete growth hormone deficiency (GHD) and normality, or as short stature in the absence of a demonstrable abnormality of the GH–IGF-1 axis. Synonyms of the condition have included normal short stature, primary or constitutional short stature, normal-variant short stature, constitutional delay of growth and adolescence (CDGA) and familial short stature (FSS).

The definition of ISS cannot be refined until we have an adequate definition of GHD. An agreed current working definition is that ISS is a heterogeneous state that encompasses individuals of short stature, including those with FSS, for which there is no currently recognized cause.

Many children referred to as having ISS will undoubtedly have some undiagnosed underlying pathology within the GH–IGF-1 axis, and increasing understanding of the pathophysiology of growth disorders will reduce the number of children categorized as having ISS. Licensing arrangements within the UK and EU refer to ‘non-GHD short stature’ rather than ‘ISS’.

The relatively poor sensitivity and specificity of GH stimulation tests means that many patients currently labeled as having idiopathic GHD would probably be better categorized as having ISS. Many of these ‘misdiagnosed’ patients are currently responding well to GH therapy. Significant increases in final height have been reported after treatment of ISS with GH although many of the studies have involved small

numbers of patients and have suffered from significant methodological faults. A recent randomized double-blind, placebo-controlled study has now been reported<sup>107</sup> in which despite a suboptimal treatment regimen and late age for starting treatment, a mean increase of (only) 3.7 cm was found. Another recent study<sup>108</sup> has also shown small but dose-related increases in final height.

However the clinical significance of the reported increases is doubtful and, in any case, final height is not a validated proxy for quality of life. Whilst some patients with ISS may show psychological stress, they do not appear to have clinically significant behavioral or emotional problems, and it needs to be established whether being taller produces measurable psychological benefit. There is no strong evidence that GH therapy improves psychological adaptation in children with ISS and from a socioeconomic perspective, more evidence of the effectiveness of GH therapy in individual patients with ISS is required before the use of

pooled funds can be justified. However, any treatment recommendations based on socioeconomic considerations should be tempered by the fact that it is still not possible to discriminate clearly between partial GHD, subtle abnormalities of the GH-IGF-1 axis and many cases of ISS.

The differential diagnosis of causes of slow growth, whatever the current height, is wide (see Table 15.6).

## Endocrine causes

### Impaired GH secretion

A few children lack the gene for making GH, demonstrate prenatal GH deficiency, respond to GH therapy with the major antibody response expected to a foreign protein and cannot be treated with any form of GH. Otherwise there is a wide spectrum of GH and IGF-1 secretory ability, which, within the normal population, is likely to be largely genetically determined (see above). At one end of the spectrum are children, perhaps 1 in 4000, with severe GH insufficiency ('GH deficiency'). They grow slowly (Fig. 15.25), demonstrate characteristic clinical features – truncal obesity with characteristic fat 'marbling' (Fig. 15.26), crowding of mid-facial features with immature appearance and small genitalia with micropenis in boys – and show an inadequate (<7 mU/L) response to a pharmacological stimulus to GH secretion.

There is a continuum from lack of the GH gene at one end of the spectrum through ISS (see above), moderate GH insufficiency (so-called 'partial' GH deficiency), short normal children, those of average height, tall normal individuals, to those with gigantism (Fig. 15.27). Some short, slowly growing children have what is considered to be an abnormal pattern of GH pulsatile release but normal GH responses to stimulation – 'neurosecretory dysfunction'. It is possible that genetic polymorphism for the GH or IGF-1 receptor, IGF-1 or IGFBP3, could also underlie the spectrum of height seen in a normal population, and heterozygosity for classical autosomal recessive disorders could explain growth abnormalities in many children with 'idiopathic' short stature.

Severe GH insufficiency may be congenital, acquired, isolated or associated with other pituitary hormone deficiencies. Many children with 'idiopathic isolated GH deficiency' have a hypothalamic disorder of GHRH release responding to a GHRH bolus by secreting GH normally

Fig. 15.25 A boy with severe GH insufficiency (right) who is shorter than his 2 years younger brother. Triceps and subscapular skinfold measurements were 97th centile.

Fig. 15.26 Characteristic 'marbling' of fat in severe GH insufficiency.

Fig. 15.27 The spectrum of growth hormone secretory ability.

(see below). In others, high resolution CT or MR scanning demonstrates abnormalities ranging from absent septum pellucidum associated with other midline defects (septo-optic dysplasia) to pituitary hypoplasia.

Acquired GH 'deficiency' may result from intracranial tumor (e.g. craniopharyngioma) or from cranial irradiation for medulloblastoma or acute lymphoblastic leukemia. The effects of chemotherapy on growth (and endocrine function) are increasingly recognized. Temporary GH deficiency is seen in children with psychosocial deprivation (see below) and occurs physiologically in late prepuberty and early male puberty. GH biosynthesis and release is also impaired in other conditions (e.g. primary hypothyroidism or coeliac disease) – secretion normalizes with treatment of the underlying disorder.

### Hypothyroidism

Acquired primary hypothyroidism is usually autoimmune (Hashimoto thyroiditis) and poor growth velocity and school performance often precede the well-known symptoms and signs by many months.

### Steroids (see also below)

Growth failure from glucocorticoids is usually iatrogenic (excessive medication) rather than due to pituitary dependent Cushing disease (excess ACTH secretion), adrenal tumor (benign or malignant) or ectopic tumor ACTH production which are all rare in children. Alternate day steroid regimens seem less growth suppressing.

### Disproportionate short stature

Most constitutional disorders of bone involve long bones and spine to a different extent leading to disproportionate short stature. This may be obvious clinically when there is gross disproportion but may need to be specifically identified from sitting height measurements (subischial leg length equals standing height minus sitting height) and reference to standard charts.

The most important group of skeletal dysplasias affecting cartilage and/or bone growth and development are the osteochondrodysplasias (see Ch. 29).

It is important to recognize disproportionate short stature so that accurate diagnosis can be made without unnecessary investigation. In general, biochemical investigation is unhelpful other than when a mucopolysaccharidosis or disorder of calcium metabolism is suspected and bone biopsy is rarely diagnostic. A full or selective skeletal survey with expert radiological interpretation generally yields most helpful diagnostic information although in the main only in older children.

In general specific therapy is unavailable (although there can be a short term response to GH therapy) and accurate diagnosis is necessary for genetic counseling and accurate prognosis. Limb lengthening orthopedic procedures are reviewed by Saleh et al.<sup>109</sup>

### Chromosomal abnormalities

Many chromosomal disorders are associated with poor growth and short stature, particularly absence, partial deletion or translocations of the X chromosome (Turner syndrome and its mosaic forms – Fig. 15.28) (see below). Turner syndrome girls with tall parents may not become conspicuously short until puberty fails to start. Growth charts for Turner syndrome<sup>73</sup> and Down syndrome<sup>110</sup> are available.

Inheritance of two maternal alleles from the same parent (uniparental disomy), in this case on chromosome 7, may be a feature in around 10% patients with severe IUGR (Silver–Russell syndrome or ‘primordial dwarfism’). There are several potentially relevant genes which map to the long arm of chromosome 7, e.g. those for IGFBP1, IGFBP3 and

Fig. 15.28 Two unrelated girls with Turner syndrome.

the EGF receptor. Whether any are influenced by the disomy, and thus involved in the pathogenesis of Silver–Russell syndrome, remains to be determined. In addition the chromosome 11p15 region contains a cluster of imprinted genes important for fetal growth, including IGF-2, and partial loss of paternal methylation at various loci has been found to decrease IGF-2 expression and result in clinically typical Silver–Russell syndrome.<sup>111</sup> Some children with postnatal short stature following IUGR appear to have alterations in IGF-1 receptor (IGF-1R) binding<sup>112</sup> and associations have been found between IGF-1 polymorphisms and pre- and postnatal growth in small-for-gestational-age populations.<sup>113</sup>

### Chronic disease

Differential diagnosis of the short but not fat child covers virtually the whole field of chronic disorders. Some may be suspected from history or clinical findings but poor growth is often the major diagnostic clue to psychosocial deprivation (see below), unrecognized or undertreated asthma, renal tubular acidosis and malabsorption syndromes such as celiac disease, Crohn disease or ulcerative colitis. Worldwide, protein/calorie deprivation is the commonest cause of growth failure; GH levels are high but peripheral growth factor synthesis and IGF-1 levels are low. Similar effects have also been associated with renal, cardiac and neurological diseases and with hemoglobinopathies.

Whereas it can be difficult to disentangle the relative contributions to impaired growth from the disease process itself and drugs, such as glucocorticoids (GC), data from an in vitro organ culture mouse model suggest that IGF-1 stimulation of chondrocyte hypertrophy (rather than proliferation) may result in reversibility of GC-induced growth retardation.<sup>114</sup> In clinical terms GH therapy may reverse GC-induced growth failure but will have little effect if the chronic disease process remains active.

### Psychosocial deprivation

Psychosocial deprivation often causes poor growth, may mimic idiopathic hypopituitarism in terms of GH responses to conventional stimuli and abnormal overnight GH secretory profiles may return to normal rapidly following admission to hospital. Any child growing poorly at home who thrives in hospital or when fostered (Fig. 15.29) should be suspected of being emotionally deprived (see Ch. 5).

### Laron syndrome<sup>89</sup>

Laron syndrome is an autosomal recessively inherited syndrome associated with molecular defects in the GH receptor caused by gene deletions or point mutations. These children, whose GH is active in in vitro GH receptor assays, characteristically demonstrate severe postnatal growth failure, secrete abundant GH (with normal or elevated serum levels) but have markedly reduced serum concentrations of IGF-1 and IGFBP3 and do not respond to GH therapy. Some respond well to IGF-1 therapy, and pharmacokinetic studies of recombinant human IGF-1/recombinant IGFBP3 complex are encouraging.<sup>115</sup> Such therapy has potential application in acquired (and much commoner) GH resistance states such as severe catabolism.

Early cases demonstrated low serum GHBP concentrations indicating abnormalities of the extracellular domain of the GH receptor, i.e. circulating GHBP. Many may have deletions or point mutations of the GH receptor gene [nine coding regions (exons) occupying an 87 kilobase segment of chromosome 5] coding for the GH-binding domain. However, it now seems that a minority of the several hundred cases identified worldwide have normal circulating GHBP levels suggesting a degree of heterozygosity and defects in either the portion of the extracellular domain of the GH receptor molecule needed for dimerization or intracellular defects affecting signal transduction. There is now debate as to whether heterozygotic expression of Laron dwarfism results in a clinically important phenotype.

### INVESTIGATION OF POOR GROWTH

This is summarized in Table 15.7. Random determination of serum GH levels is unhelpful – pulsatile release and short serum half-life often

Fig. 15.29 An emotionally abused child (note the characteristic expression of 'frozen watchfulness'), photographed on the day of admission to hospital. In the ward environment she showed remarkable 'catch-up' growth and growth hormone secretion normalized. She has since been successfully adopted.

result in low levels in normal children. Establishing a reasonable assessment of GH secretory ability or a firm diagnosis of GH deficiency can be difficult because of the pulsatile, and predominantly nocturnal, nature of GH secretion, variability of GH assays (monoclonal, polyclonal, RIA, IRMA which recognize different circulating forms of GH to varying

extents) and the complexity of the control of GH secretion and the GH-IGF-1 growth metabolic pathways.

All GH provocation tests may give false negative or positive responses. Screening tests are difficult to standardize and response is variable. The insulin hypoglycemia (tolerance) test (ITT) remains the standard for confirming a diagnosis of severe GH insufficiency. Adequate (symptomatic) hypoglycemia must be obtained if results are to be meaningful (blood glucose  $< 2.2$  mmol/L). Following adequate hypoglycemia, 85% of 'normal' children will produce a serum GH level of over  $\sim 15$  mU/L (usually after 30–60 min, but this cut-off is arbitrary and test stimulus and assay-dependent). In conjunction with an ITT, the GH response to GHRH is useful for determining whether 'GH insufficiency' is due to a pituitary defect or hypothalamic disorder of GHRH synthesis or release. In the latter case the GH response to GHRH will be normal indicating that pituitary somatotrophs are functional, e.g. in many children with 'isolated GH insufficiency' or 'GH insufficiency' secondary to cranial irradiation.

Tests of GH secretion must be performed only when indicated (and when other possible causes of poor growth have been considered). An ITT is potentially dangerous and requires supervision by competent and experienced junior pediatric staff working from clear and understood protocols and guidelines. These should ensure that glucose and hydrocortisone are drawn up in readiness, there is checking of insulin and glucose dosages, continual presence of a dedicated and experienced member of nursing staff present throughout for monitoring of blood glucose and conscious level, adequate and secure venous access established before insulin is administered and detailed instruction for management of hypoglycemia. It should only be undertaken in specialist endocrine units experienced with its performance.

Spontaneous nocturnal pulsatile GH release measurement provides greater insight into secretory control mechanisms, although their relevance to short stature assessment or as a predictor of response to therapy remains controversial, and this test is impracticable for 'screening' large numbers of children.

Table 15.7 Investigation of poor growth

Full medical and social history
Accurate measurement of the child and his parents
Thorough clinical examination (including measurement of blood pressure, fundi, visual fields)
Bone age
Karyotype (girls)
Specific investigation (when indicated)
Hematological (e.g. Hb, FBC, ESR)
Biochemical (e.g. Ca, $PO_4$ , alkaline phosphatase, urea and electrolytes)
Cardiac
Respiratory
Renal
Gastrointestinal including jejunal biopsy
Endocrine (e.g. T4, prolactin, GnRH, TRH tests, growth hormone provocation test*)
Skeletal (e.g. radiograph of pituitary fossa, skeletal survey)

\*Growth hormone 'provocation' tests (see text):

post-exercise	} 'screening'
3–4 h postprandial	
1 h after sleep onset	
clonidine	} 'pharmacological'
ITT	
arginine	
glucagon	
physiological sleep studies	
urinary GH.	

Urinary GH levels vary considerably day by day, are approximately 1000-fold lower than in plasma, and accuracy and reproducibility are poor.

Measurement of serum IGF-1 may be a useful screening test for identifying short children who need more complex investigations of GH secretory ability, and theoretical algorithms for the biochemical diagnosis of GH deficiency and insensitivity disorders have been proposed (e.g. Ranke<sup>116</sup>).

## TREATMENT OF POOR GROWTH

Treatment aims to correct the underlying problem where possible (e.g. gluten-free diet in celiac disease, thyroxine in hypothyroidism) and can only maximize remaining growth potential. The sooner poor growth is recognized and its cause diagnosed and treated, the better the height prognosis.

### Growth hormone

#### Preparations

From 1958 to 1985, pituitary derived GH was available in limited quantities for children with GH 'deficiency'. These preparations were withdrawn because some batches could have been contaminated with Creutzfeldt–Jacob disease (CJD) 'prion' and current purity could not be guaranteed. Biosynthetic GH, *E. coli* synthesized and produced by recombinant DNA technology, became available in the UK by late 1985. This was initially with an additional amino-terminal methionine (192 amino acids). Since December 1988, natural sequence 191 amino acid biosynthetic GH has been prescribable in the UK. This is physicochemically identical to natural human hormone. No brain tissue is involved in its production and its administration cannot transmit CJD.

#### Indications for use

Children with severe GH insufficiency (GH 'deficiency') and moderate GH insufficiency should be treated with GH provided other causes of impaired GH secretion have been excluded. Treatment with a physiological replacement dose of 15–21 units (5–7 mg)/m<sup>2</sup>/wk in daily s.c. doses will result in >90% achieving an adult height within their genetic target height range.<sup>117</sup> Larger (pharmacological – 30 U/m<sup>2</sup>/wk, 10 mg/m<sup>2</sup>/wk) doses are appropriate in Turner syndrome and chronic renal failure.<sup>118</sup> It is inappropriate to prescribe GH indiscriminately to short children, and GH therapy is of proven benefit in fewer situations than had been predicted when biosynthetic GH first became available.<sup>119</sup> The improved psychological state resulting from knowledge that treatment is being given could itself have a growth-stimulating effect via hypothalamic pathways – children with psychosocial deprivation secrete more GH and grow better when in a normal emotional environment. Postponing puberty in children with GH deficiency is not generally appropriate.<sup>120</sup>

Although a social class-related and socially desirable attribute in 'developed' societies, tall stature does not confer innate biological advantage in all societies. In disadvantaged environments (e.g. the Peruvian Andes), small mothers have more surviving offspring;<sup>121</sup> in an agricultural peasant economy, a small man is more efficient than a tall one, requiring to do less work to feed himself.<sup>122,123</sup> Even if GH therapy increases the height of a normally growing short child, will taller stature in itself contribute to academic or material success or psychological contentment? Leaving aside methodological problems in assessing possible psychological disadvantage from short stature in childhood, it seems probable that there are genuine cultural differences in the psychological effects of short stature even between 'developed' countries (e.g. USA and UK).<sup>124,125</sup>

GH therapy seems to be of particular benefit to children with Turner syndrome and could also benefit those with prolonged IUGR (who often remain short despite normal postnatal growth). The variable outcomes of studies of GH in IUGR probably reflect their heterogeneity of etiology of growth retardation. There is controversy over whether catch-up growth in SGA children has adverse metabolic consequences (e.g. insu-

lin resistance), particularly if high GH doses are used.<sup>126</sup> There is encouraging growth improvement in children with chronic renal failure treated with GH.<sup>118</sup> Infants with chronic renal failure have also been found to benefit in the short and longer term.<sup>127</sup>

GH has been evaluated in the treatment of some skeletal dysplasias but outcomes are generally disappointing and in these groups, surgical limb lengthening may be indicated once the postpubertal patient is able to decide whether they wish to undergo these major and prolonged procedures.<sup>109</sup>

Due to the shortage of available pituitary GH over many years, the dose used in severe GH insufficiency was the most 'cost effective' (in terms of increase in growth velocity achieved per unit GH given) rather than that which would maximally stimulate growth so that, even now, the optimal treatment regimen is not clearly established. A GH dose of 6–8 mg (18–24 units)/m<sup>2</sup>/week divided into daily (bedtime) subcutaneous injections may be most effective. Higher (pharmacological) doses [~10 mg (30 units)/m<sup>2</sup>/week] are more effective in chronic renal disease, Turner syndrome<sup>128</sup> and IUGR. Optimal regimens during puberty have not been established although there is some evidence that mimicking the increase in endogenous GH secretion at the pubertal growth spurt produces a better height outcome.<sup>129</sup> The role of short bursts of GH therapy in a variety of situations remains to be evaluated.

GH antibodies could result in severe growth restriction in a previously normal child but antibodies of sufficient specificity and binding capacity to produce growth attenuation are rare. Potential metabolic side-effects include glucose intolerance, hyperinsulinism, hyperlipidemia and hypertension. Reports of an increased risk of type 2 diabetes<sup>130</sup> are controversial. Benign intracranial hypertension<sup>131</sup> and slipped capital femoral epiphysis are associations but the latter is found in GH deficient children prior to GH treatment. Leukemia may be more common in GH deficient children treated with GH but there is no evidence causally linking GH treatment with leukemia. GH is best avoided in syndromes with chromosomal fragility such as Fanconi syndrome. Psychological harm could result if treatment expectations are not fulfilled.

As with most other drugs, there is wide variation in the treatment efficacy and side-effects profile of GH therapy in individual patients and pharmacogenomic studies are now underway in pediatric endocrinology, particularly in evaluating responsiveness to GH therapy.

GHRH therapy may be appropriate in many 'GH insufficient' children when the problem is at hypothalamic, rather than pituitary, level but optimal treatment regimens are unclear. Although it is possible that future growth promoting treatment modalities could include intranasal GH, intranasal GHRH, depot (intramuscular) GHRH, and IGF-1 in particular circumstances, with several of these preparations bioavailability, practical production difficulties and costs or possible side-effects remain problematic. The most promising developments in the therapeutic application of growth stimulating compounds seem currently to be in the use of depot GH preparations and GH releasing peptides which may impinge significantly on the management of certain types of growth disorder in the future.

### Anabolic steroids

Synthetic steroids with enhanced anabolic but little androgenic activity are valuable in growth delay, increasing (normal) slow growth in early male puberty and in Turner syndrome (see pp. 45–6). As with GH therapy, the decision to use these preparations should generally be the province of the specialist in growth disorders.

### Emotional support

Emotional support is particularly important for short stature children and their families. Specific treatment may not be available, may be of unproven benefit or may start too late to achieve adequate stature. Any child physically different from his or her peers will attract attention: a short child has to cope with an identity which is determined primarily (and seen by others) in terms of their size. Growth related changes in body shape and size are important determinants of perceived age and adult care-giving responses. Short children must be treated appropriately

for their chronological age, emotionally, intellectually and practically. Teasing, bullying and expectations based on physical size rather than on intrinsic abilities will cause immature behavior, underperformance at school and may impair growth further. They are likely to be aggressive to siblings and peers and more anxious and depressed than controls. Poor exam results cause the small school-leaver to have particular difficulties finding employment.

Children treated with GH should not routinely stay on GH therapy once they reach adulthood. Nevertheless, there is evidence that untreated GH deficiency in adulthood is associated with reduced muscle strength and increased fatigue, a high fat to muscle ratio, reduced bone mineral content with increased risk of osteoporosis and fractures, and adverse cardiovascular risk factors (dyslipidemia and increased fibrinogen levels). All children who have received GH replacement therapy should have their GH status reassessed in young adulthood. A consensus statement is now available with a suggested algorithm for the investigation and treatment of the GH 'insufficient' child at final height at the end of puberty.<sup>132</sup> Patients with clear structural lesions of the hypothalamus/pituitary (organic GHD secondary to a mass lesion, pituitary surgery or radiotherapy) are likely to remain GH deficient and should be considered for GH treatment in adulthood,<sup>133</sup> but others (e.g. with 'idiopathic isolated' GH deficiency) frequently have a normal GH secretory capacity on retesting. Untreated adolescents with reconfirmed 'partial' GH deficiency have altered body composition<sup>134</sup> but it is not known whether this worsens with age or is specifically associated with increased cardiovascular risk.

IGF-1 has important cardioprotective actions through stimulating nitric oxide production in endothelium and vascular smooth muscle and improving cardiac muscle cell survival and function.<sup>135</sup> However it is also mitogenic and antiapoptotic, important actions for tumor genesis, and this has led to concerns (also fueled by overinterpretation in some epidemiological studies) that if GH therapy results in persistently 'high' circulating IGF-1 levels there is an increased risk of developing some cancers in later life. However those at risk epidemiologically have high IGF-1 and low IGFBP3 levels whereas GH therapy results in increases in both. In addition, circulating IGF-1 levels do not reflect tissue IGF-1 (secreted in an autocrine and paracrine manner). A meta-analysis of high quality studies has concluded that, whilst circulating concentrations of IGF-1 and IGFBP3 are associated with modest and variable increased risks for prostate and premenopausal breast cancer, the 3–4-fold increases in cancer risk quoted by narrative reviews are exaggerated.<sup>136</sup>

### THE TALL OR RAPIDLY GROWING CHILD (Table 15.8)

Tall stature presents less often than short: syndromes causing tallness are rare whereas poor growth is a common result of childhood disease, and childhood tallness, unless extreme, is socially advantageous. Nevertheless, a tall child is often taken for older and expectations may be greater than can be met. Clumsiness and gangliness may result from neurological immaturity for size.

Advanced skeletal maturation may be associated with tallness in childhood (and a normal growth velocity) but this rarely results in problems or medical help being sought (cf. growth delay).

Constitutional tall stature infrequently presents but tall mothers sometimes worry about their normal daughters' heights. In this situation, drug treatment – attempting to limit GH secretion whilst allowing normal sex steroid mediated skeletal maturation [e.g. with bromocriptine somatostatin analogue (octreotide) or anticholinergic drugs such as pirenzepine or rapidly advancing skeletal maturation (using sex steroids)] – is generally unsatisfactory. Estrogen therapy causes an initial increase in growth velocity, and potential side-effects from the high doses necessary, both short term (headaches and nausea) and long term (diabetes mellitus, hyperlipidemia, hypertension, endometrial carcinoma), limit its usefulness particularly as there has never been a randomized controlled trial to determine its efficacy. It cannot be used much earlier than normal pubertal onset and treatment after the growth spurt

**Table 15.8** Differential diagnosis of tall stature or rapid growth

<b>Tall with currently normal growth velocity</b>
Constitutional tall stature (tall normal parent(s))
Previous rapid growth (usually due to overeating)
Physiological growth advance
<b>Currently rapid growth (whether already tall or still of 'normal' stature)</b>
<i>Associated with precocious puberty</i>
Idiopathic (physiological)
Pathological
Intracranial space-occupying lesions
Gonadal tumors
Ectopic gonadotropin-producing tumor (e.g. hepatoblastoma)
Adrenal
Congenital adrenal hyperplasia (21-hydroxylase deficiency, 11beta-hydroxylase deficiency)
Cushing syndrome
Neoplasia
Estrogen ingestion (e.g. mother's oral contraceptives)
Primary hypothyroidism
Undefined mechanisms
Birth asphyxia
Mental retardation, including tuberous sclerosis
Neurofibromatosis, McCune–Albright syndrome
<i>Not associated with signs of puberty</i>
Hyperthyroidism
Growth hormone excess (gigantism)
<i>With obesity: currently excessive food intake</i>
<b>With dysmorphic features or disproportion</b>
Marfan syndrome
Long, narrow limbs (dolichostenomelia)
Arachnodactyly
Scoliosis
Aortic incompetence – dissecting aneurysm
Myopia, retinal detachment, upward lens dislocation
Autosomal dominant (often new mutation)
Homocystinuria
Marfanoid body habitus
Mental retardation
Stiff joints with knock knee
Downward lens subluxation
Urine positive for homocystine
Autosomal recessive
Congenital contractural arachnodactyly
Kyphoscoliosis
Joint contractures
No ocular or CNS problems
Autosomal dominant
Sotos syndrome (cerebral gigantism)
Large size at birth
Hypertelorism, downslanting palpebral fissures, prominent forehead
Large hands and feet
Large male external genitalia
Mental retardation ± hypotonia, ataxia
Klinefelter syndrome
Disproportionately long legs
Small firm testes
Hypogonadism, infertility, with or without gynecomastia

is underway (early in female puberty) would have only a small effect on reducing final height. Recent data suggest that there are additional deleterious effects on fertility.<sup>137</sup>

When height prognosis remains unacceptably high to child and family, surgical epiphysiodesis, an established procedure for reducing

moderate leg length discrepancy<sup>138</sup> may be indicated. Surgical management of tall stature is reviewed by Macnicol.<sup>139</sup>

### Tall stature syndromes

These are outlined in Table 15.8. Gigantism due to excessive GH secretion is extremely rare in pediatric practice (cf. acromegaly after epiphyseal closure).

### Tallness and obesity

Tallness in childhood is commonly associated with food intake that is, or has been, excessive for growth and energy requirements. In wealthy societies, eating is a social as well as nutritional activity and moderate fatness in a baby may be seen as proof of mother love. Fat babies tend to be placid and little trouble. Once a child is overweight, calorie intake need not be excessive to maintain the situation. Continuing overeating causes rapid growth, skeletal maturational advance, earlier puberty and early epiphyseal closure – adult height is not increased. If overeating stops but calorie reduction is insufficient to lose weight, growth velocity is normal but the child is tall and bone age remains advanced.

### Rapid growth and precocious puberty

If nutrition has been normal, rapid growth is most commonly due to precocious puberty (see p. 451). Final height may be significantly short (depending on etiology and duration) due to early epiphyseal closure in pathological precocious puberty but in children with constitutional advance of growth and puberty their genetic adult height potential will be reached.

### Endocrine causes of rapid growth

These are either uncommon (thyrotoxicosis) or rare (gigantism, excess androgen secretion from an adrenal tumor).

## OBESITY AND THINNESS

Malnutrition leading to obesity or thinness is discussed in Chapter 16. Discussion here is limited to some general comments and consideration of endocrine disorders which may be associated with each nutritional state.

Mechanisms of body mass regulation include genetic, environmental and behavioral factors. Genetic studies in obese mice have revealed the *ob* gene, its products leptin and the leptin receptor to be important factors in the regulation of both appetite and energy expenditure. In rodents as well as in humans, homozygous mutations in genes encoding leptin or the leptin receptor cause early-onset morbid obesity, hyperphagia and reduced energy expenditure.<sup>140</sup>

Leptin concentrations correlate with adipose tissue mass and are regulated by feeding and fasting, insulin, glucocorticoids and other factors. Leptin acts via the CNS to reduce food intake and increase energy expenditure. Overweight children generally have leptin concentrations raised in proportion to their fat mass, and leptin deficiency or insensitivity is an extremely rare cause of obesity.

Leptin is thought to play a role as an endocrine mediator in sexual development and reproduction (see below). In addition, SGA children have both low cord blood and plasma leptin levels with a predisposition to adverse metabolic outcomes in later life. Some gut hormones have been shown to be important in influencing food intake and body weight. For a review see Druce et al.<sup>141</sup>

Weight in itself is a poor guide to nutrition – the interpretation of a high weight for a child's height as 'obesity' may be seriously misleading at times when growth and fatness are varying in opposite directions: a normal early pubertal boy is growing slowly but increasing body fat rapidly. Poor weight gain in a baby may be normal if the mother is tall and the father short as the maternal environment (in addition to genetic factors) is important in determining birth weight. In infancy weight gain largely reflects fluid flux; in the older child differences between normal and abnormal rates of weight gain are

smaller than the reproducibility of weight measurements obtained some months apart even on sophisticated (and well-maintained and balanced) weighing scales.

The use of body mass index (BMI) – weight (kg)/height (m)<sup>2</sup> – provides a practical clinical tool for identification of adults with different degrees of obesity which carry particular adverse risks, for example hypertension, hypercholesterolemia and type 2 diabetes. However use of a stable height as a basis for calculation, inapplicable to growing children, had limited its usefulness in pediatric practice. BMI changes substantially in children, rising steeply in infancy, falling during pre-school years (from around 2 years of age) and rising again (between 5 and 8 years – the 'adiposity rebound') and into adulthood.<sup>60</sup>

Children accumulate fat free mass as they grow and muscle is denser than fat. Thus BMI underestimates the percentage of lean body mass by taking no account of variations in muscularity: particularly fit and muscular individuals will have a relatively high BMI.

In normal and underweight individuals between one quarter and one half of total body fat is subcutaneous – most excess fat in the obese is deposited there. Thus the adequacy, inadequacy or overadequacy of nutrition is effectively assessed from skinfold measurements using calipers comparing results with available standards for age.<sup>142</sup> Measurement of limb circumference assesses muscle and bone as well as fat. Measurements of triceps and subscapular skinfolds are representative of total body fat<sup>143</sup> and show least between observer error.<sup>144</sup>

Care must be taken in interpretation: standards will depend on racial, maturational and genetic factors<sup>145</sup> as well as age, and change as nutritional recommendations and feeding policies vary. British children were fatter in 1975<sup>142</sup> than 1962 and there is evidence that this trend is continuing.<sup>146</sup> Standards reflect what is present in the 'normal' population, not necessarily what is optimally physiological. Despite this, skinfold measurements provide quick, easy and reproducible estimates of nutritional state and are particularly useful in longitudinal assessment of an individual child.

Mesenteric fat thickness (assessed by ultrasound) is an important determinant of metabolic syndrome<sup>147</sup> and, despite concerns about its reproducibility, waist circumference measurement (in addition to BMI) significantly increases information about the obesity-related health risks in children and adolescents.<sup>148</sup>

## OBESITY

### In 'normal' children

A standard definition of 'overweight' and 'obesity' in children and young people is desirable. In adults, cut-off points for overweight and obesity are based on morbidity and mortality associated with excessive weight. In the absence of such data in children, the International Obesity Task Force defined the cut-offs for young people by back-extrapolating from the BMI centile corresponding to values of > 25 kg/m<sup>2</sup> (overweight) and 30 kg/m<sup>2</sup> (obese) at age 18.<sup>71</sup> Simply defining overweight as > 85th BMI centile and obesity as > 95th centile means that as standards are updated the nature of any secular trend to increasing obesity is obscured (15% and 5% will always be overweight or obese respectively) and international comparisons are obscured.<sup>149</sup>

The prevalence of overweight and obesity amongst children has trebled in 20 years<sup>150</sup> and is now a global epidemic.<sup>151</sup> The increase is not only in industrialized but also in resource limited countries. Overeating and increases in sedentary behavior are the commonest causes of childhood obesity. Energy intake surplus to requirements for growth, thermogenesis, basal metabolism and activity results in fat deposition (Fig. 15.30). It is likely that some, but not all, obese individuals eat, or have been eating, excessively. Nevertheless, observed variation between individuals in energy intake necessary to achieve normal fat deposition is likely to reflect genetic factors as well as differences in energy expenditure. Relative contributions of environmental and genetic factors remain poorly understood and certainly differ between different obese individuals.

Fig. 15.30 Gross obesity in a toddler due to excessive food intake.

The first year of life is not critical for determining adipocyte numbers, which are related to the degree and duration of obesity rather than age at onset. Nevertheless, fat infants are 2–3 times likelier to become obese children than their normal peers.<sup>152</sup> A childhood BMI > 85th centile, an obese parent and an early recurrence of the adiposity rebound (at about 5 years) may predict adult obesity,<sup>153</sup> and overweight and obesity in adolescents lead to a significant and (in health terms) meaningful increase in obesity and mortality in mid-adulthood.<sup>154</sup>

There are three groups of children who are at particular risk of obesity in later life: (1) low birth weight (mainly SGA but also probably some pre-term) infants with rapid early infancy catch-up growth; (2) normal birth weight infants with an early adiposity rebound; and (3) infants with increased body weight and faster growth during infancy.<sup>155</sup> Metabolic complications seem more common in the first two groups.

Although mild overweight seems unlikely to be associated with short or long term ill health, childhood obesity may affect educational attainment and interpersonal relationships adversely,<sup>156</sup> especially in boys, will probably persist into adulthood and is associated with an increased risk of hypertension, stroke, myocardial infarction or type 2 diabetes mellitus, osteoarthritis, breast and bowel cancers, skin disorders and asthma and other respiratory problems.<sup>157</sup>

The most important treatment goal is sustainable healthy eating (rather than 'dieting') and habitual reasonable levels of physical activity (e.g. walking and cycling). Young obese children should aim to maintain their weight (which they will 'grow into') rather than lose weight. Interventions involving parents and behavior modification may be effective.<sup>158</sup> Advice is only likely to be successful if the child and whole family are involved and motivated. Evidence-based management of childhood obesity is summarized by Edmunds et al.<sup>159</sup>

Sibutramine, which inhibits the reuptake of noradrenaline and serotonin in the CNS, results in reduced energy intake and increased thermogenesis and appears safe and effective in producing short term weight loss in obese adolescents.<sup>160</sup> However, pharmacological treatment of obese adolescents remains experimental as is bariatric surgery (stomach stapling or gastric banding) which has been little studied in

children. Despite the risks, surgery for extremely obese children (BMI > 40) may have to be considered.

### Secondary endocrine effects

'Simple' obesity (due to large appetite and excessive food intake) is associated with a number of minor (secondary) endocrine abnormalities. Increased adrenal androgen secretion for chronological (but not for bone) age could be a factor influencing the early onset of puberty in such children<sup>161</sup> but increased GC metabolite excretion may reflect increased liver cortisol metabolism. There is frequently hyperinsulinemia, more marked in girls, older children and long-standing obesity, and unrelated to adipocyte size.<sup>162</sup> It is thought to be related to both insulin resistance (with a fall in the concentration of adipocyte insulin receptors) and excessive carbohydrate intake.<sup>163</sup> A low sex hormone binding protein level for age is a useful biochemical marker for insulin resistance. A low calorie diet results in a rapid fall in insulin levels (before there are changes in weight, body fat mass or adipocyte size) with a rapid rise once dieting ceases, again preceding these other changes.<sup>164</sup>

The risk of developing overt type 2 diabetes mellitus increases with age and degree of obesity but is still an uncommon complication in children, although now less so in adolescents in the UK and particularly ethnic minority groups.<sup>165</sup> Impaired glucose tolerance is certainly common amongst obese adolescents but changes in insulin secretion and sensitivity that precede its development are still poorly understood. There is evidence that altered fat partitioning in abdominal adipose tissue and skeletal muscle is an early metabolic change in obese adolescents progressing to impaired glucose tolerance.<sup>166</sup>

### As Part of genetic/endocrine disorders

Obesity can be genetic or endocrine in origin. Height measurement is an important screening test. Overeating in normal children causes an increase in growth velocity and these children are generally tall for age with bone age advance. There is early epiphyseal closure and usually no final height increase. Some adolescent boys, in particular, may present with obesity, below average height and delayed puberty. Acceleration of height velocity is seen with rapid weight gain, and strict dieting is associated with slowing of linear growth. Thus if overeating stops but there is insufficient reduction in calorie intake to lose weight, growth velocity may be normal but the child is tall and bone age remains advanced.

In contrast, virtually all endocrine and hypothalamic causes of obesity are associated with poor linear growth, short stature and bone age delay. Endocrine causes include excessive corticosteroid administration, GH insufficiency, hypopituitarism, hyper- or hypogonadotrophic hypogonadism, hypothyroidism, pseudohypoparathyroidism and craniopharyngioma. Cushing syndrome may initially cause rapid growth. Obesity also occurs with hyperinsulinism.

Hypothalamic damage from tumors, meningitis, encephalitis, radiotherapy or trauma may cause obesity. Possible mechanisms underlying the obesity include endocrine factors (hyperinsulinism – but this could be cause or effect, hyperprolactinemia, GH deficiency – but suppressed GH secretion may also be due to obesity) and nutritional and psychological factors.

Hypothalamic syndromes associated with mental retardation and obesity include Laurence–Moon–Biedl, Bardet–Biedl and Prader–Willi. Craniopharyngioma may be associated with obesity after surgery or radiotherapy even if vision and activity are normal, food intake is appropriate and endocrine replacement therapy optimal. It seems likely that 'Fröhlich syndrome' (one case of blindness, short stature, obesity and pubertal failure with a cyst in the region of the sella turcica) was due to craniopharyngioma.

The obesity of Down and other mental handicap syndromes may relate both to underlying genetic or metabolic abnormalities and physical inactivity – the latter is a major cause of obesity in physically handicapped children (e.g. spina bifida, muscular dystrophy).

Diagnosis of Prader–Willi syndrome (PWS) is based on the characteristic history and clinical features (see Ch. 14) Diagnosis may often be made at birth from the association of characteristic facial features with history of poor fetal movements, hypotonia and poor feeding.

Endocrine features include hypogonadism (micropenis, hypoplastic scrotum and bilateral cryptorchidism in males), normal or increased

GH secretion, poor secondary sexual development and delayed menarche, insulin resistance and diabetes mellitus and growth failure. Energy requirements are abnormally low and appetite insatiable. Growth may be particularly poor when appetite is most successfully controlled and during adolescence. Scoliosis may impair spinal growth and, with gross obesity, predisposes to respiratory failure and death. There is a suggestion (largely from uncontrolled cohort studies) that GH therapy is effective in stimulating growth if started in the young child and can result in a height within the parent-based target range within 3 years of treatment. However the main benefit is metabolic (body composition, fat utilization) and in improving muscle tone and power. Current studies are focusing on GH treatment in younger patients, including infancy, tempered by anecdotal reports of sudden death during GH therapy, the pathogenesis of which remains unclear.<sup>167,168</sup>

There have been recent advances in the molecular genetics of obesity risk including the suggestion that GAD2 on chromosome 10p12 is a candidate gene for human obesity and that genetic variation in GABA metabolism may influence obesity risk.<sup>169</sup> Further obesity candidate genes include loci on 6q.<sup>170</sup>

## THINNESS

Skinfold measurements and BMI, not weight, are best guides to thinness and undernutrition. A healthy child who is offered appetizing food in adequate amounts and variety in an emotionally supportive environment will eat enough to enable him to grow normally. This may be much less than mother (or granny) feels should be eaten. A thin child who is growing normally and not getting thinner should not be investigated or treated; one who is growing slowly or getting thinner needs investigation, diagnosis and treatment.

The battle to get a healthy child to eat more than necessary is one that parents are likely to lose and can produce emotional problems in both child and parents then or later. Reassurance that a thin child is healthy and growing normally will often, in itself, defuse an emotionally strained family situation. In other circumstances, treatment of the underlying cause of the thinness is necessary but may be easier with organic than emotional disorders.

Recognizable syndromes (e.g. lipodystrophy, Marfan syndrome) and malignancies are rare, but unrecognized organic disease (e.g. asthma, malabsorption due to celiac disease, ulcerative colitis or Crohn's disease) may present with few overt signs and commonly causes poor growth and thinness. Calories may be too few (worldwide the most important cause of poor growth and thinness, particularly in association with recurrent infection) but some children are on inadequate diets for ethnic or cultural reasons and some mothers are so concerned to prevent obesity that calorie intake is deficient. In the UK, emotional problems are common causes of thinness and poor growth. Anorexia nervosa may be life threatening in an adolescent.

Acute malnutrition causes loss of fat and muscle; chronic malnutrition causes stunting but thinness may be masked by fat deposition.<sup>171</sup> Secondary endocrine responses to malnutrition result from the need to conserve the limited energy intake available. Cortisol, TSH, T3, GH and IGF-1 levels are low.

IGF-1 is controlled to a major extent by nutrition. In kwashiorkor and marasmus growth slows because of end-organ unresponsiveness to the action of GH; GH levels are high<sup>172</sup> and IGF-1 levels low.<sup>173</sup>

Acute fasting in the human is associated with a reduction in GH receptor numbers and receptor loss can be prevented with GH infusion, suggesting that resistance is at the post-receptor level. Zinc deficiency is associated with reduced IGF-1 levels and supplementation may stimulate catch-up growth.<sup>174</sup>

Anorexia nervosa patients have normal cortisol production but decreased clearance rates<sup>175</sup> due to low liver 11betaOHSD activity. 5alpha-reductase levels are also reduced<sup>176</sup> – this enzyme is also present in the liver. The secretory pattern of LH is immature and pubertal development either does not begin, halts (and may regress) or there is amenorrhea, depending on age at onset of anorexia and its degree. Estrogen deficiency is likely to reduce GH pulsatile release and this may be an additional

mechanism by which growth slows. Multicystic ovaries (a normal phase in ovarian maturation) are seen during recovery, and vomiting, hypotension and cachexia may suggest Addison disease but are generally much more severe in anorexia nervosa – hirsutism may also occur in both.

## ENDOCRINOLOGICAL ASPECTS OF PUBERTY AND ADOLESCENCE

### THE GONADS

Ovaries and testes have two main functions: development and maintenance of secondary sexual characteristics, and reproductive capability. Sex steroidogenic pathways in adrenals and gonads are identical – relative differences in types and quantities of individual androgens and estrogens reflect different enzymic activities.

### Physiology

#### *The ovary*

Endocrine functions reside in ovarian follicles. Luteinizing hormone (LH) binds to theca cells to stimulate androstenedione and testosterone biosynthesis from cholesterol. These diffuse into granulosa cells which convert them to estrone (E1) and estradiol (E2) respectively (aromatization) under the influence of follicle stimulating hormone (FSH). E1 and E2 interconversion also takes place in the granulosa cells. E1 is largely albumin bound; E2 is also bound to a specific globulin which also binds testosterone.

Estrogens stimulate secondary sex character development and, in the sexually mature, estrogens and progestogens ensure fertility by releasing ova and regulating the menstrual cycle. Estrogens are responsible for growth of vagina, uterus and Fallopian tubes, and have a major role in the normal pubertal growth spurt and fusion of epiphyses at the end of puberty. They are metabolized in liver and excreted in urine.

The mechanism by which the dominant follicle suppresses others in both ovaries is unclear. 'Inhibin' is found in follicular fluid, is thought to be secreted by granulosa cells and may have local effects as well as affecting feedback inhibition of FSH.

#### *The testis*

Both LH and FSH are required for spermatogenesis. FSH is necessary for initial establishment of mature germinal epithelium and initiation of spermatogenesis. LH effects are mediated through Leydig cell testosterone secretion. Spermatogenesis duration is approximately 74 days. Thus testosterone has both endocrine (secondary sexual characteristics and libido development) and paracrine effects (a permissive effect on spermatogenesis in the presence of FSH).

Two percent of testosterone in the mature male is in free active form, one third is bound to a specific beta-globulin – sex hormone binding globulin (SHBG) – and the remainder to albumin. In the target organs which require dihydrotestosterone (DHT) (scrotum, phallus, prostate), testosterone is converted to DHT by 5alpha-reductase; in other tissues (e.g. bone, muscle, internal genitalia) testosterone acts directly.

Testosterone exerts negative feedback on LH secretion mainly at hypothalamic level but has little effect on FSH. However FSH levels are high in the castrate. There is also a family of gonadal peptides which have inhibitory ('inhibin') and stimulatory ('activin') feedback effects at pituitary level and important gonadal (paracrine) effects. Modulation of FSH secretion at pituitary level is by mechanisms distinct from the GnRH receptor on the pituitary gonadotroph. Inhibins are now known to be secreted in a variety of forms from the testis (Sertoli cells), placenta and ovary (granulosa cells).

The inhibins may be important in normal puberty (see below).

The adrenals produce quantitatively more androgens than testes and these are of importance in childhood in physiological and pathological situations. In puberty and subsequently, the role of the testes is qualitatively paramount because testosterone is much more potent than androstenedione or dehydroepiandrosterone (DHA) – testicular failure causes hypogonadism despite normal adrenal function. Small quantities of estrogen are produced by normal testes by Sertoli cell aromatization of androgen. Testosterone is also metabolized to estrogen in some

peripheral tissues (notably adipose cells) and the liver prior to urinary excretion.

### ENDOCRINE BACKGROUND TO NORMAL PUBERTY

Individual secondary sexual characteristics result from different hormonal events and must be assessed independently. Over the last century, children have tended to become taller and reach physical and sexual maturity earlier but whether this process is continuing is more contentious.<sup>177</sup>

Reports of, and recommendations based on, data which purport to show that African-American and White American girls are showing secondary sexual development respectively 2 years and 1 year earlier than was the case a generation ago<sup>178,179</sup> may well be the result of methodological (selection and observer) bias. Early breast development may be mimicked superficially by obesity which will bias self-reported data.

Although an increasing prevalence of obesity in the population might be an explanation for a genuine advance in the timing of puberty onset, the age of menarche (a much more robust maturational marker) does not seem to be lowering comparably further in industrialized nations.<sup>180</sup> This implies either significant methodological flaws in the study of Herman-Giddens et al<sup>178</sup> [and in unpublished UK data from the Avon Longitudinal Study of Parents and Children (ALSPAC)] or that the tempo of pubertal progression is slower than was previously the case (for which there is no evidence or obvious physiological explanation at a population, as opposed to individual, level).<sup>177</sup>

Accurate national registry population-based data from Denmark have estimated that 0.2% of Danish girls and 0.05% of Danish boys had some form of precocious pubertal development and, importantly, that the incidence was unchanged over the 9 years of the study (1993–2001).<sup>181</sup> In this context, the claim that similar differences in the timing of male puberty (onset of genital and pubic hair growth) have been occurring<sup>182</sup> must be treated with caution.

Although puberty timing and duration are very variable between normal individuals, pubertal development is a harmonious process: marked discrepancies from the normal sequence of events (loss of consonance) should lead to suspicion of pathology. In contrast, adolescence is sometimes far from harmonious – social pressures may be particularly marked in many who are sexually mature but still growing emotionally and intellectually, and emotional problems seen in those with the timing of puberty at either end of the normal spectrum.

### CHANGES IN FETUS, INFANT AND CHILD AND THEIR RELEVANCE TO PUBERTY INITIATION

Fetal GT production occurs from the fifth week, rising until 20 weeks. Levels are higher in females, perhaps because of feedback inhibition by fetal testosterone in males. Placental human chorionic gonadotrophin (HCG) is secreted from implantation onwards and is the major stimulus for fetal Leydig cell testosterone; it seems unlikely that the fetal hypothalamo-pituitary-gonadal axis is fully functional by postpubertal standards. After delivery, a rise in GT levels persists for several months in both sexes. Total testosterone levels are high in males partly due to high SHBG levels. During the first year, the axis becomes quiescent. There is little evidence for the existence of specific inhibitory hormones (see pineal, p. 464) although CNS inhibitory influences could be important – precocious puberty is common following cranial irradiation for acute lymphoblastic leukemia (ALL).

Pulsatile gonadotrophin releasing hormone (GnRH) secretion is of paramount importance in primate sexual maturation although there is increasing biochemical and ultrasound evidence for activity well before the onset of clinical gonadarche. During childhood, there is gradual amplification of GnRH signals with pulses of low frequency and amplitude, and from well before the clinical onset of puberty, around adrenarche, nocturnal pulsatile GnRH secretion is detectable with increasing pulse frequency<sup>183</sup> associated with multicystic prepubertal ovaries on ultra-

Fig. 15.31 The multicystic appearance of late prepubertal ovaries.

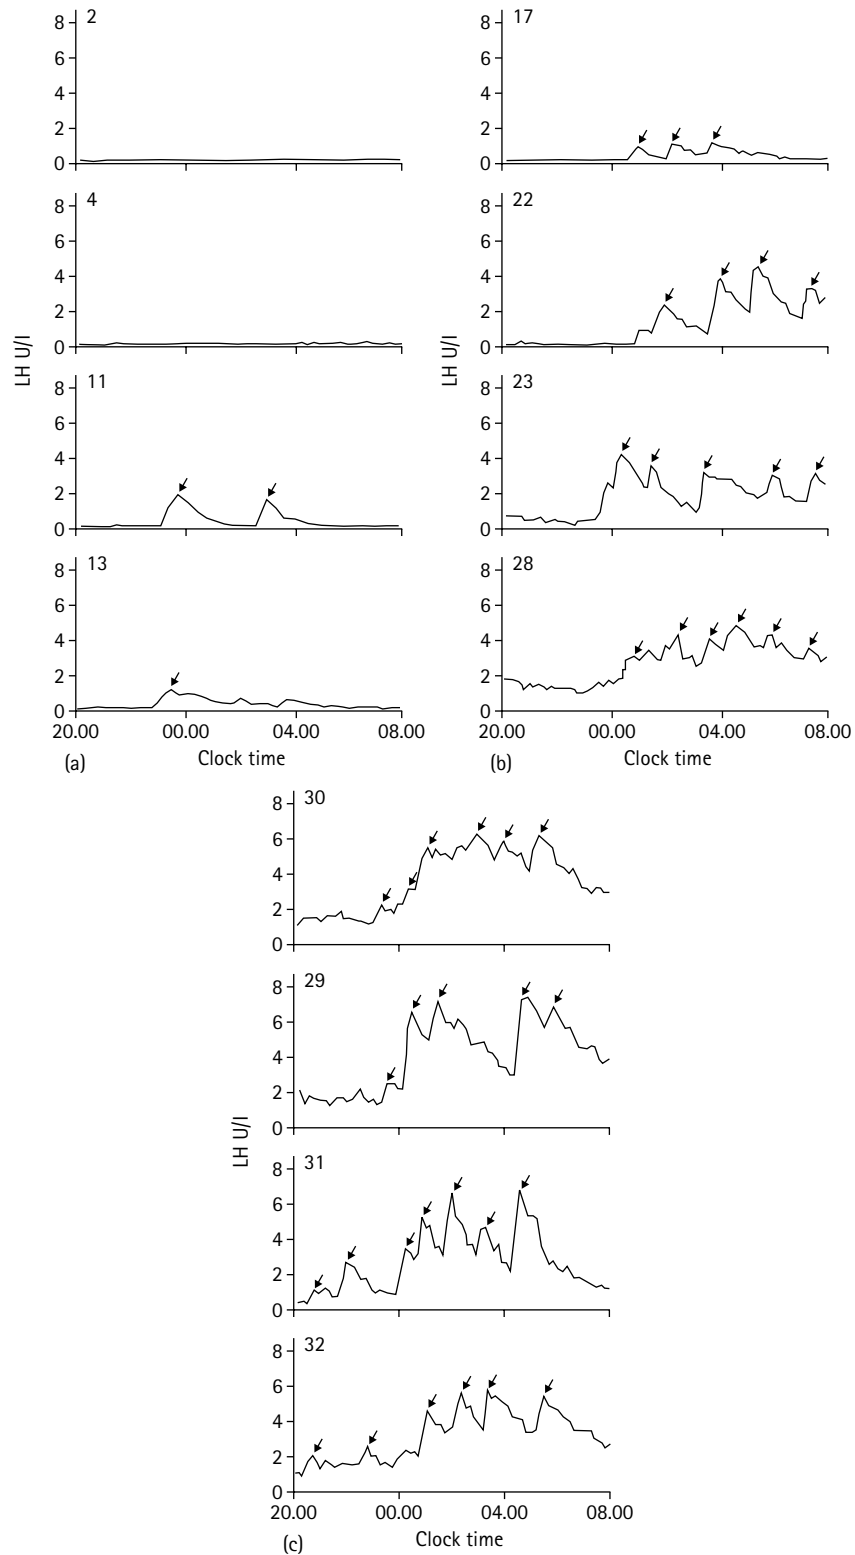

sound (Fig. 15.31). This normal stage of development (characterized by the presence of > 6 follicles of diameter > 4 mm) is associated with activation of the axis resulting in nocturnal pulsatile GnRH secretion without (as yet) estrogen-mediated positive feedback. For normal ranges of ovarian and uterine size during childhood see Neu.<sup>184</sup>

Modulation of pituitary LH secretion resulting from increased GnRH pulse frequency is an important characteristic of transition between juvenile and peripubertal stages in man (Fig. 15.32). A crucial condition for normal pubertal development may involve organization of neuronal circuits which not only maintain synchronized pulsatile GnRH release but enable their incorporation into the daily sleep – wake rhythm.<sup>186</sup> It is likely that continuing pubertal transition to adult pituitary – gonadal function involves gradual further recruitment, organization and synchronization of GnRH neuronal discharge over an increasing proportion of the evening/night and resetting of gonadal negative feedback. Clinically, an early morning testosterone measurement is a useful predictor of the imminence of puberty.<sup>187</sup>

Sensitive and specific assays to distinguish different inhibin forms have shown that in normal boys testicular production of inhibin B increases as puberty progresses and that the initiation of puberty is accompanied by a dramatic switch from a positive to a negative relationship between inhibin B and FSH.<sup>188</sup> Inhibin B may also be a more sensitive predictor than testosterone of clinical pubertal onset. The two peaks of inhibin B (during infancy and early puberty) appear to reflect the two periods of Sertoli cell proliferation in normal human males. During mid-childhood a relatively constant amount of inhibin B is secreted. The early FSH-independent increase in inhibin B that precedes clinical puberty and continues to stage G2<sup>6</sup> may be stimulated by testosterone or other Leydig cell factors. The inverse relationship between inhibin B and FSH that develops from mid-puberty onwards is consistent with the establishment of the negative feedback loop at this stage.<sup>189</sup>

Although median levels of inhibins A and B remain low until after age 10 years in girls, there is evidence, from sporadically increased levels in normal prepubertal girls and their positive correlation with FSH levels, of sporadic FSH-dependent follicular development in infancy and childhood.<sup>189</sup> In puberty, the increase in inhibins A and B and their lack of positive correlation with FSH from stage B3<sup>6</sup> onwards, suggests that follicular growth is dependent more on the duration of FSH elevation above a critical threshold than the levels per se.<sup>189</sup>

As puberty progresses, GnRH (and thus GT) pulse frequency remains at about 2 h but with increasing amplitude and daytime as well as nocturnal pulses (Fig. 15.33).<sup>185</sup> Twenty-four hour pulsatile release is necessary for full pubertal development, menarche and ovulation. In the follicular phase of the menstrual cycle, GnRH pulse frequency increases to approximately hourly and falls to 3 hourly in the luteal

**Fig. 15.32** Evolution of GT secretory profiles (1). Profiles of plasma LH between 20.00 and 08.00 h in (a) four young prepubertal subjects (G1 PH1 testicular volume = 2 ml); arrowheads indicate a significant LH pulse; none of these patients progressed into puberty during the following 12 months; (b) four prepubertal subjects: two with G1 PH1 testicular volume = 2 ml at time of study, but progression into puberty with testicular volume = 4 ml within 12 months (subjects 15 and 13); two in earlier puberty at study (G1 PH1–2 testicular volume 3–4 ml); (c) four pubertal subjects (G2–3 PH1–3 testicular volume 6–10 ml). (From Wu et al 1990<sup>185</sup>)

Fig. 15.33 Evolution of GT secretory profiles (2) and response to exogenous GnRH at different stages of pubertal development. (Data by courtesy of Dr FCW Wu<sup>185</sup>)

phase. Increasing sex steroid secretion resulting from increasing pulsatile GnRH secretion produces the physical changes of puberty and all pubertal events can be induced by pulsatile administration of exogenous GnRH, even if this is a cumbersome way to do so in clinical practice.

## ADRENARCHE AND GONADARCHE

See p. 480.

## CHANGES OF BODY COMPOSITION AND METABOLIC SIGNALS FOR PUBERTY ONSET

Although in pathological situations (e.g. anorexia nervosa, excessive exercise) nutritional factors are important for pubertal development and menarche, evidence for the hypothesis that menarche depends on attainment of a critical weight for height is poor. For a given body weight, the proportion of girls reaching menarche increases with age and the relative weight (weight as a percentage of standard weight) at 11 years explains less than 5% of variation in the age of menarche.<sup>190</sup> It is likely that in normally nourished populations genetic factors are of paramount importance for the timing of menarche – this is probably true of pubertal onset and events in general.

This does not mean that metabolic factors and signals are unimportant for pubertal development although circumstantial evidence in man suggests that it is brain (rather than pituitary) maturation which is of primary importance for puberty onset. Are there simply genetically determined biological clocks which, in the absence of pathological modulators, trigger puberty or could there be metabolic or other cues which signal into the CNS? In anorexia nervosa or severe malnutrition there are low GT levels, menstruation ceases and puberty regresses as a way of conserving energy – the likely outcome of maintenance of reproductive capacity in such circumstances would be disastrous for mother and fetus. Although anorexics who regain ~75% of ideal body weight resume menstrual cycling with normal pituitary responsiveness to GnRH,<sup>191</sup> leanness alone cannot account for the reproductive disturbances: sustained exercise (in female distance runners) affects GnRH pulse amplitude and amenorrhoeic ballet dancers who stop training resume normal menstruation within a few months without

detectable changes in body weight or composition suggesting that metabolic signals are important in controlling reproductive function in these situations and, speculatively, in the control of normal pubertal development.

The discovery of leptin, the ob gene product, has now provided a molecular basis for the lipostatic theory of the regulation of energy balance. By modulating the hypothalamo – pituitary – gonadal axis both directly and indirectly, leptin may serve as an important signal from fat to the brain about the adequacy of fat stores for pubertal development and reproduction. Normal leptin secretion is necessary for normal reproductive function to proceed and leptin may be a signal allowing for the point of initiation of and progression toward puberty.<sup>192</sup>

## ABNORMAL PUBERTY

As with other normally distributed characteristics (e.g. height or IQ) there is no absolute age at which pubertal timing becomes abnormal. Pubertal onset at an 'average' time does not necessarily exclude a pubertal disorder. The mean UK age of onset is such that 3% of boys or girls will have started puberty by 9 and 8 years and only 3% will have no pubertal signs by 13.8 and 13.4 years, respectively. A useful clinical rule is that puberty should be investigated if there is an abnormal sequence of pubertal changes (i.e. loss of consonance), any abnormal sign or symptom of underlying pathology and if signs have or have not (respectively) appeared outwith the above age limits. Studies purporting to show that the age of onset of secondary sexual development is lowering further are likely to be methodologically flawed [see above (p. 448) and Viner<sup>177</sup>].

Children with precocious puberty may simply have early onset of normal (central) mechanisms (which may be idiopathic or secondary to underlying pathology) or may have an abnormal mechanism causing development (pseudopuberty). Children with no signs by 14 years may have delay in maturation (on a background of constitutional growth delay – see p. 451) but may permanently lack ability to develop spontaneously. Investigations, potential outcomes and management are different in each situation and depend on not only presence or absence of underlying pathology but also emotional and psychological consequences. A clinical classification of disorders of puberty or its timing is given in Table 15.9.

Table 15.9 A simplified classification of disorders of puberty (see text)

<b>Precocious puberty DMUD</b>
Consonance:
Idiopathic central precocious puberty
Central precocious puberty due to, e.g.
Intracranial tumors
Cranial irradiation
Raised intracranial pressure
Gonadotrophin-independent precocious puberty (GIPP, testotoxicosis)
Loss of consonance (pseudopuberty)
Isolated premature thelarche
Thelarche variant
Adrenal causes
Premature pubarche
Congenital adrenal hyperplasia
Cushing syndrome
Adrenocortical tumors
Gonadal causes
Ovarian cysts
Ovarian or testicular tumors
Ingestion of sex steroid (accident or child abuse)
Primary hypothyroidism
McCune–Albright syndrome
Extrapituitary tumors (e.g. hepatoblastoma)
<b>Delayed puberty</b>
Consonance
Constitutional delay of growth and puberty
Chronic systemic disease
Idiopathic hypogonadotropic hypogonadism
Hypogonadotropic hypogonadism due to, e.g.
Kallmann syndrome
Craniopharyngioma
Cranial irradiation
Panhypopituitarism
Primary hypothyroidism
Loss of consonance
Turner syndrome
Ovarian agenesis with normal karyotype
Polycystic ovaries
Anorchia (primary or secondary to testicular irradiation)

## PRECOCIOUS SEXUAL MATURATION

It was conventionally considered that there were only two distinct conditions resulting in premature sexual maturation from a gonadal axis etiology: central precocious puberty and isolated premature thelarche, of which the latter is a benign condition not requiring treatment. However, there is no pathognomonic endocrinological distinction between these two conditions; LH and FSH secretion represent a complete spectrum with girls with isolated premature thelarche (see below) having predominant FSH secretion and those with central precocious puberty predominant LH secretion.<sup>193</sup>

The concept of loss of consonance is particularly useful in the differential diagnosis of precocious puberty<sup>194</sup> but initiation of normal pubertal events can be due to underlying pathology and gonadotrophin-independent precocious puberty (GIPP, an important cause of precocious puberty in boys) may be clinically identical to 'consonant' precocious puberty.

### Pseudopuberty (loss of consonance)

#### *Isolated premature thelarche*

This consists of breast development in the absence of any other pubertal signs although vaginal bleeding may occur. Onset is usually in the first year and uncommon after 2 years. There is usually cyclical waxing and waning of mild breast development (stage < B3)

which may have persisted from postnatal breast enlargement (potentially in both sexes) due to placental maternal estrogen transfer. In contrast to true precocious puberty, pubic and axillary hair does not develop, growth velocity is normal for age and skeletal maturation is not advanced.

There is evidence for increased estrogen production, high basal and GnRH-stimulated FSH levels, pulsatile nocturnal GT, predominantly FSH, secretion and increased ovarian follicular activity. Ultrasound may show several ovarian cysts whose size changes with breast size and moderate uterine enlargement.

A primary abnormality in GnRH pulse generation resulting predominantly in FSH secretion is unlikely as there is no response to GnRH analogues (see p. 453). The activin/inhibin system may be important for pathogenesis – inhibin B as well as FSH levels are high<sup>195</sup> – potentially exerting effects both at pituitary level, on FSH independently of the gonadotroph GnRH receptor, and at gonadal level by paracrine regulation.

There is waxing and waning of breast enlargement with gradual disappearance over months or years. Puberty generally takes place normally at appropriate age. Treatment consists of explanation and reassurance. Pelvic ultrasound and measurement of GTs basally and following a low dose (0.25 mcg/kg i.v.) GnRH test may be helpful in doubtful cases. Occasionally, particularly in girls presenting after 2 years, there may be confusion with early true precocious puberty and a 'non-classical' variant<sup>196</sup> has a high incidence of progression to central precocious puberty.

The variation in gonadotrophin secretion in this situation represents a spectrum of disorders of gonadal maturation which have received different names depending on the countries in which they were reported: unsustained central sexual precocity, slowly progressive precocious puberty, thelarche variant and exaggerated thelarche. It is probable that all four conditions are identical. There is a normal height prognosis and no response to gonadotrophin releasing hormone analogue treatment.<sup>197</sup>

#### *Adrenal causes*

The normal rise in adrenal androgens in mid-childhood (adrenarche, see p. 480) sometimes manifests with appearance of pubic (and less commonly axillary) hair – 'premature' pubarche' – without breast development but with increased height velocity. Such children are particularly sensitive to adrenal androgens or at the upper end of a secretory spectrum. The timing of true pubertal onset is generally unaffected. In occasional children with true precocious puberty, pubic hair development may be the first sign. Other causes of adrenal androgen secretion must be considered in the differential diagnosis and excluded.

*Congenital adrenal hyperplasia (CAH)*, specifically non-salt-losing 21-hydroxylase deficiency in boys, is the commonest cause of precocious pseudopuberty. There is virilization in early childhood but testes classically remain prepubertal – adrenals are the androgen source. Occasionally ACTH-responsive adrenal rests will cause some testicular growth but significant enlargement signifies secondary central precocious puberty (Fig. 15.34) – a common consequence of GC therapy on the pre-existing advanced skeletal maturation. Mild or late-onset forms of 21-hydroxylase or 3beta-hydroxysteroid dehydrogenase deficiencies may present with pubic hair growth in girls mimicking premature pubarche.

#### *Cushing syndrome and adrenocortical tumors*

See p. 484.

#### *Gonadal causes* (see also Ch. 24)

*Testicular tumors* are uncommon in children and (usually benign) Leydig cell androgen-secreting lesions are rare. Clinically, presentation may be with normal pubertal development but the affected testis is enlarged and the contralateral small and atrophic from suppression of the hypothalamo-pituitary-gonadal axis. Enlargement may be uniform or with a palpable nodule, causing confusion with enlargement due to ACTH-responsive adrenal rests in CAH. Rapid onset of true pubertal onset may follow surgical removal.

Fig. 15.34 True precocious puberty following glucocorticoid treatment of congenital adrenal hyperplasia. Note the testicular enlargement (same child as Fig. 15.53).

*Ovarian tumors*, usually benign in childhood, are also rare causes of precocious pseudopuberty, accounting for only around 1%. Least uncommon is the granulosa-theca cell tumor. Presentation is rarely before 4 years. Distinguishing features include early (in context of other pubertal signs) irregular vaginal bleeding or regular anovulatory cycles, marked areolar pigmentation and abdominal pain. A pelvic or abdominal mass is usually palpable.

*Ovarian cysts* are found in normal and precocious puberty. Multicystic appearances of late prepubertal and early pubertal ovaries are described above. Isolated follicular cysts may cause breast development, can be a feature of isolated premature thelarche and may regress spontaneously with conservative management.<sup>198</sup> Chronic estrogen secretion and large size may necessitate surgical removal. Polycystic ovaries may be common in puberty and late prepuberty and can be associated with pubertal delay.

#### **Ingestion of sex steroid**

Most commonly there is accidental ingestion of mother's contraceptive pills. Estrogen will cause slight breast enlargement and, often, an estrogen withdrawal bleed.

#### **Child abuse**

Sex steroids may be administered deliberately and chronically as a form of child abuse.<sup>199</sup> Sexual abuse (and pelvic neoplasia) must be excluded when vaginal bleeding is the presenting feature of precocious pseudopuberty. Factitious vaginal bleeding may be caused by presentation of mother's menstrual blood as though it came from the child. The laboratory can determine its origin.

#### **Thyroid disease**

Primary hypothyroidism may be associated both with delayed and precocious puberty. Unusually (in the context of precocity) growth velocity will not have been rapid, stature may be short and bone age is characteristically delayed. It is usually seen in girls (in whom autoimmune hypothyroidism is commoner). Breast development is the main feature (sometimes with galactorrhea) but there is usually little (androgen dependent) pubic or axillary hair development. In boys enlarged testes consist of seminiferous tubules without Leydig cells, consistent with the postulated mechanisms (p. 416). Pulsatile FSH release is common in primary hypothyroidism but only results in precocious pseudopuberty

in a few. Follicular cysts are seen on ovarian ultrasound in association with FSH predominance and suppressed GH pulsatility during overnight sampling. The latter may contribute to slower height velocity.

The child may be clinically euthyroid at presentation in puberty with normally maintained TSH and thyroid hormone levels. The pituitary fossa may be enlarged (Fig. 15.35) due to pituitary hyperplasia – the pituitary gland shrinks rapidly on thyroxine therapy. Ultimately, secondary pituitary failure may result, with an empty but still enlarged fossa on CT or MRI scan. Menarche may occur early while growth is still accelerating (cf. normal puberty and central precocious puberty). Treatment is with thyroxine.

#### **McCune–Albright syndrome**

The original descriptions were of hyperpigmented macules, precocious sexual development and thinning and sclerosis of bone with fractures in young children without systemic disease. Macular brown skin hyperpigmentation with characteristic ragged edges may not be present, and areas of rarefaction, commonly in long bones and elsewhere (polyostotic fibrous dysplasia; Fig. 15.36), may not develop until later childhood.

Fig. 15.35 Enlarged pituitary fossa due to pituitary (thyrotroph) hyperplasia in a child with primary hypothyroidism presenting with precocious puberty.

Fig. 15.36 Polyostotic fibrous dysplasia of bone in the McCune–Albright syndrome.

Multiple endocrinopathies with glandular hyperfunction (thyrotoxicosis with goiter, GH hypersecretion, Cushing syndrome, hyperprolactinemia, hyperparathyroidism and hyperphosphaturic rickets) may develop subsequently.

Endocrine hyperfunction is autonomous and not secondary to central trophic hormone stimulation. The syndrome is due to activating missense mutations in *GNAS1*, the Gs protein involved in G-protein-coupled receptor signaling, that stimulates cyclic AMP formation.<sup>200,201</sup> The mutation is variably expressed in different tissues consistent with a mosaic distribution of aberrant cells from a somatic cell mutation.<sup>201</sup>

Precocious puberty is the usual presentation, sometimes with early vaginal bleeding (cf. central precocious puberty). Bone lesions may not develop for many years and the skin pigmentation is inconstant. In girls, ovaries may be asymmetrically enlarged<sup>202</sup> by isolated follicular cysts. The GT response to exogenous GnRH is 'prepubertal' with absent GT pulsatility. As would be expected, suppression of puberty with GnRH agonists is ineffective. Cyproterone acetate or medroxyprogesterone are drugs of choice.

### Extrapituitary tumors

These may cause precocious puberty as a result of the ectopic secretion of GT-like substances. Least uncommon are hepatoblastomas in boys and ovarian chorionepitheliomas and teratomas in girls; extrapituitary intracranial malignant teratoma and pineal choriocarcinoma have been reported. In boys testicular enlargement is rapid, and vaginal bleeding often occurs early in girls.

### Central precocious puberty

Normal activation of the hypothalamo-pituitary-gonadal axis may occur abnormally early secondary to an underlying disorder or idiopathically. The pattern of secondary sexual characteristic development and endocrine findings are as in puberty developing at a more average time ('consonance') except that growth acceleration may occur relatively early in boys. This, plus more rapid epiphyseal maturation in boys in early puberty, may compromise final height more than expected in boys even with early presentation. In general, early age at onset and short parents imply a worse height prognosis but accurate individual prediction is difficult – predictive equations are most accurate for children of 'average' height developing normally at an average' time – and will tend to underestimate adult height in this context.<sup>203</sup>

Mechanisms initiating normal pubertal development are still not clearly understood, perturbations in timing even less so. Central precocious puberty presents much more frequently in girls (female:male ratio of about 10:1) and in the majority (> 80%) of girls no sinister underlying cause is found. With high resolution neuroradiological scanning, hypothalamo-pituitary hamartomas have been reported<sup>204</sup> but their incidence in the normal population at equivalent age is unclear. In boys, however, there is a high incidence of intracranial pathology, especially tumors such as teratomas, astrocytomas or gliomas causing pineal destruction – neuroradiological investigation is necessary even without abnormal signs. The sex difference in incidence of idiopathic precocious puberty may relate to lower GT release thresholds to endogenous pulsatile GnRH in girls. GIPP (see below) may account for precocious puberty in a significant number of boys in whom normal central mechanisms had previously been implicated.

In girls, investigation is necessary to confirm the mechanism and to exclude an underlying cause. Ovarian ultrasound, which will show characteristic multicystic appearances, and low dose (0.25 mcg/kg i.v.) GnRH test (more practical than overnight GT profiling)<sup>205</sup> will confirm central precocious puberty and exclude primary ovarian pathology. Neuroradiological investigation may be necessary (mandatory in boys). In addition to tumors, important central pathologies include CNS infection, raised intracranial pressure, trauma (during birth or childhood head injury) and previous cranial irradiation

### Silver–Russell syndrome

Abnormalities of sexual development, including precocious puberty, can be associated with this prolonged IUGR syndrome.<sup>206</sup>

### Gonadotrophin-independent precocious puberty (GIPP, testotoxicosis)<sup>207</sup>

Incidence, importance and classification are controversial – characteristically there are normal somatic consequences (consonance) from abnormal mechanisms (pseudopuberty). Patients have accelerated growth, early development of secondary sexual characteristics and usually reduced adult height. Diagnostic criteria are absent GT spontaneous pulsatility, poor but variable GT response to GnRH, no clinical response to GnRH analogue therapy and cyclical steroidogenesis. In reported studies there is a strong family history of precocious puberty but the etiology is unknown. Nearly all cases have been boys – girls may have the McCune–Albright syndrome. Maturation of testicular steroidogenesis and spermatogenesis is normal but GnRH/GT-independent. Testotoxicosis is caused by an activating mutation of the luteinizing hormone (LH) receptor, leading to increased levels of sex steroids in the context of low LH. Therapy has traditionally targeted steroidogenesis but drugs used have had significant side-effects. Combinations of oral antiandrogens and aromatase inhibitors seem more promising.<sup>208</sup>

### Investigation and diagnosis

In summary it is reasonable to investigate any girl < 8 and boy < 9 years with secondary sexual characteristics. Where a girl's development is harmonious and proceeds at a normal tempo (consonance) and clinical examination is normal, invasive investigation to exclude pathology is unnecessary but basal TSH, estradiol and PRL measurement with skull X-ray, low dose GnRH test and pelvic ultrasound will give valuable information about the mechanism and underlying pathology. Overnight profiling of GT secretion is essentially a research tool. If no underlying cause is found which itself requires treatment, the need to suppress GT secretion and further development is considered below. Adrenal or intracranial pathology must be actively sought in boys by steroid profiling and neuroradiological (CT or MRI) investigation.

### Clinical consequences and management

Management of precocious pseudopuberty is of the underlying cause. In central precocious puberty, an underlying cause requires treatment and pubertal suppression may be necessary also. In idiopathic cases, suppression may be indicated on social and psychological (rather than medical) grounds (see below).

Treatment of central precocious puberty was traditionally with progestogen-like drugs such as cyproterone acetate and medroxyprogesterone. Cyproterone was widely used in the UK for many years and is generally effective and free from significant side-effects in a dose of 75–100 mg/m<sup>2</sup>/day given twice daily. It has progestational, antiandrogenic, antigonadotrophic and adrenal suppressive activities – the precise mechanism by which GT secretion is suppressed is unclear.

Problems with cyproterone relate to adrenal suppression. Treated children must carry a steroid 'card' or talisman and need steroid cover during major stress, illness or surgery. Cortisol deficiency in other situations is uncommon unless high doses are used. Adults treated with cyproterone (for prostatic carcinoma) have altered lipid metabolism<sup>209</sup> which may be of concern if childhood treatment is prolonged. Taking the natural history of central precocious puberty into account, there is no evidence for improvement in height prognosis. Although still widely used, cyproterone has been replaced as treatment of choice by GnRH analogues (see below). It remains important for treatment of GIPP and may be used to cover the initial (stimulatory) phase of GnRH analogue therapy (see below).

GnRH analogues are specific and effective in suppressing central precocious puberty and are the treatment of choice. Some analogues are now available in the UK as depot preparations which are administered about every 10–12 weeks.<sup>210</sup>

Although they act by desensitizing the pituitary to GnRH and inhibiting pulsatile GnRH secretion, analogues have an initial stimulatory effect (lasting several weeks) on sex steroid secretion. This is of most practical relevance in a girl sufficiently advanced for a menstrual bleed to occur. In this situation, particularly, additional treatment with cyproterone for the first 4 weeks of analogue therapy is appropriate. Height velocity may initially increase further due to the effect of sex steroids on spinal growth. Sometimes GnRHa therapy decreases height velocity to below normal rates and this may be due to a prior acceleration of growth plate senescence secondary to the prior exposure to unphysiologically high estrogen levels.<sup>211</sup>

Effectiveness of therapy is best assessed by serial pelvic ultrasound in girls (assessing ovarian morphology and volume, uterine cross-sectional area and endometrial thickness), by clinical assessment of testicular volume in boys, plasma estradiol and testosterone measurements (respectively) and (if necessary) GT responsiveness to GnRH (0.25 mcg/kg i.v.). There is no effect on the adrenal axis (cf. cyproterone) but (as with cyproterone) probably no effect also on improving height prognosis.<sup>203</sup> Slowing of epiphyseal maturation on treatment is mirrored by a slowing of height velocity (perhaps due to reduced GH pulsatile secretion secondary to sex steroid suppression).

In the absence of underlying pathology, there is no *prima facie* reason why those who, for genetic or constitutional reasons, are destined to reach adult height earlier than average should fail to reach their genetically determined adult height. There are also methodological reasons for being cautious about the conclusions from many studies which purport to show that interventions with GnRHa increase adult height. Many studies include patients in the 'precocious puberty' group who probably have the larche variant.<sup>203</sup> In addition, most studies fail to recognize that in comparing adult height achieved with predicted adult height (PAH) at the start of treatment, skeletal maturational (bone age) estimations on the same individual repeated through puberty do not show increments of 1 'year' bone age (BA) per year chronological age (CA) because BA accelerates and deviates from a cross-sectional-based centile in a way similar to that for height. BA standards are based on those with puberty at an average age, thus in those entering puberty at an age younger than average, a rapid acceleration and progressive advancement of BA occurs – at peak height velocity BA velocity can be up to 2.5 'years' per year.<sup>106</sup> As a result, predicted adult height at the start of treatment is misleadingly low and any treatment effect on adult height (e.g. from GnRHa treatment) will be overestimated.<sup>203</sup>

It is on this theoretical background that specific growth stimulation using GH therapy in addition to pubertal suppression is being assessed but it is best reserved for those in whom final height is particularly reduced due to underlying pathological causes of precocious puberty.<sup>203</sup>

Whatever the therapy, secondary sexual development will seldom diminish significantly and families must be warned not to expect dramatic cosmetic improvement. GnRH analogues may allow further long-term progression of pubic and axillary hair. There is evidence in girls for reversibility of inhibition<sup>212</sup> and for recovery of hypothalamo-pituitary-gonadal function and ovarian activity occurring from the pre-treatment stage of puberty.<sup>213,214</sup> There is little experience of long-term outcomes of GnRH analogue therapy in boys – observed effects on inhibition of seminiferous tubule activity could impair subsequent fertility if irreversible.

Emotional problems are often considerable in these children who are already tall for age. They appear clumsy and, in association with precocious puberty, may be more aggressive with undesirable social consequences. They feel different both because of size and precocious development and are often ill equipped to cope with psychological aspects of adolescence, particularly if parents and teachers are uncomprehending or embarrassed. Ultimate short stature may be particularly emotionally disabling against this background. However the indication for suppressing puberty with gonadotrophin releasing hormone analogues is for psychological or psychosocial reasons and not to achieve an improvement in final stature.<sup>203</sup>

The decision to treat idiopathic central precocious puberty thus depends on age at onset, rate of progression, level of emotional support provided by parents and other social and psychological factors. Menarche in primary school can cause additional psychological problems. In every case emotional support must be given.

## DELAYED SEXUAL MATURATION

Late puberty, particularly when accompanied by short stature and delayed skeletal maturation, is the commonest reason for referral to a pediatric endocrinologist. This 'constitutional delay of growth and puberty' (CDGP) is seen more commonly in boys, who are also more stressed by it as growth deceleration continues until puberty is well advanced. Pathological causes of late puberty are much more common in girls (e.g. Turner syndrome); central causes are equally common in both sexes. A karyotype is an important early investigation in any slowly growing girl and mandatory if puberty is delayed even without any syndromic 'stigmata'. Virtually any chronic systemic disease may be associated with both growth retardation and pubertal delay.

### Constitutional delay of growth and puberty (CDGP)

This is the likely diagnosis in a healthy adolescent short for the family but not for pubertal stage and skeletal maturation, giving a normal height prognosis. There is often a family history of CDGP in parents or siblings but its presence does not make the diagnosis and absence does not exclude it. CDGP is more common and often more stressful in boys. Emotional, psychological and social consequences may be severe despite absence of underlying pathology. Aspects of treatment which require consideration are puberty induction, growth stimulation and emotional support. Individual treatment modalities interact with each other in terms of their psychological and physical effects.

### Chronic systemic disease

Chronic systemic disease may cause slowing of growth which may or may not be reversible (see Ch. 34) and is often associated with subsequent maturational delay or pubertal failure. Anorexia nervosa results in secondary endocrine disturbances (see thinness, p. 455) whilst pubertal delay causes secondary psychological disturbances. A sympathetic clinical psychologist or child psychiatrist is helpful in providing evidence of underlying emotional disturbance and managing primary or secondary emotional problems.

Causes of growth and maturational delay or failure in these conditions may be explicable in nutritional, secondary hormonal, metabolic or therapeutic (e.g. glucocorticoid treatment) terms. However in many conditions the etiology is both multifactorial and poorly understood.

### Malnutrition and weight loss

Undernutrition is the commonest worldwide cause of growth failure and pubertal delay and may occur in resource rich countries, for example with inappropriate 'fadish' diets or emotional deprivation. Whatever the specific relevance of metabolic signals for the onset of puberty, it is likely that growth retardation and pubertal delay or failure are a secondary adaptation to the need to conserve energy and to prevent reproduction in suboptimal circumstances.

### Exercise

Intensive training (e.g. in female gymnasts) can lead to delayed sexual maturation, and amenorrhea occurs in female distance runners. Amenorrheic ballet dancers who stop training resume normal menstruation within a few months without detectable changes in body weight or composition.

### Hypothalamo-pituitary disorders

Puberty is initiated when GnRH begins to be secreted by the hypothalamus but many of the genetic factors involved with the onset of puberty remain to be determined. Hypogonadotropic hypogonadism may cause pubertal delay, arrest or infertility depending on age at onset and severity. The cause is usually a hypothalamic disturbance in GnRH pulsatile release.

Several genes have been identified as causes of 'idiopathic' hypogonadotropic hypogonadism (IHH) in the human accounting for 10–20%

of cases described: KAL, the gene for X-linked Kallmann syndrome (IHH and anosmia), DAX1, the gene for X-linked adrenal hypoplasia congenita (IHH and adrenal insufficiency), GnRHR (the GnRH receptor), and PC1 (the gene for prohormone convertase 1, causing a syndrome of IHH and defects in prohormone processing).<sup>215</sup>

Mutations in GPR54, which encodes a novel G-protein receptor activated by the ligand KiSS-1, can cause autosomal recessive IHH and the KiSS-1/GPR54 system is now thought to be an important system for the regulation of puberty and reproduction.<sup>216</sup> Mutations in GPR54 affect receptor signaling and probably regulate the reproductive axis at hypothalamic level by direct stimulation of GnRH release via G-protein-coupled receptor 54.<sup>217</sup> Galanin-like peptide (GALP) may mediate the effects of leptin on the reproductive system.<sup>218</sup> It seems increasingly likely that the KiSS-1/GPR54 system could, in the future, be a target for therapies in children with disorders of sexual development.

Primary GT deficiency is usually associated with pituitary tumors (e.g. craniopharyngioma) and other pituitary hormone deficiencies. Cranial irradiation is associated with (hypothalamic) GT deficiency. Prolactinomas are rarely associated with delayed puberty – moderately elevated PRL levels are due to stress.

In contrast to CDGP, a child with hypogonadotropic hypogonadism is generally normal or tall for the family and bone age is arrested at around 13 'years' in the older child. A family history of delay with hypogonadism (cryptorchidism or micropenis) and anosmia suggests *Kallmann syndrome* – inherited as an autosomal dominant with relative male limitation. Features may include color blindness, other midline craniofacial abnormalities, nerve deafness, mental retardation and renal anomalies. Differentiation from CDGP is generally possible at presentation and molecular genetic abnormalities (in the KAL gene) have been described.<sup>215</sup>

Mental retardation syndromes associated with GT deficiency and obesity include Laurence–Moon–Biedl (with polydactyly and retinitis pigmentosa) and Prader–Willi.

## Hypothyroidism

Acquired hypothyroidism is often associated with pubertal delay but may cause precocious puberty.

## Gonadal

### *Disorders of ovarian function*

These may relate to defective estrogen secretion or action (hypogonadism), androgen overproduction (hirsutism, amenorrhea or virilization), ovulatory failure (infertility) or menstrual abnormalities (amenorrhea and infertility). **Turner syndrome (TS).** Primary gonadal dysgenesis is much more common in girls because of the high incidence of Turner syndrome. Although diagnosis is usually possible well before the age when puberty should occur, even in those with no dysmorphic features, few children are now measured regularly and accurately by primary carers so that presentation with delayed puberty is common. There is a poor correlation between physical manifestations (Figs 15.37, 15.38) – neonatal lymphedema, broad ('shield') chest with widely spaced nipples, webbed neck, high arched palate, low posterior hair line, wide carrying angle, short fourth metacarpals and hypoplastic or malformed (spoon-shaped) nails (Fig. 15.39), cardiac and renal abnormalities – and the precise genetic abnormality.

One to two percent of all conceptuses have TS but rates of early spontaneous miscarriage are very high so the birth prevalence is about 1 in 2500. About half have a single X chromosome and the remainder have one normal X and one abnormal because of partial deletions, ring formation or

Fig. 15.37 Turner syndrome diagnosed at birth – note the peripheral edema in a small-for-gestational-age infant.

Fig. 15.38 Turner syndrome presenting with pubertal delay in a 14-year-old girl.

short or long arm isochromosomes. At least 10% have mosaicism (different proportions of abnormal cells in different tissues) and molecular analysis suggests that the proportion is much higher. In children with mixed karyotypes, there is an equal abnormal genetic contribution from mother and father whereas in the 45X karyotype the missing chromosome is paternal in origin. The presence of Y chromosomal material can also be detected by karyotype and molecular genetic techniques. If it is found, gonads should be removed to prevent possible malignant change (e.g. gonadoblastoma).

Short stature homeobox-containing (SHOX) gene mutations have been implicated in both the short stature and skeletal dysplastic abnormalities of Turner syndrome. Genomic imprinting (differential expression of genetic material depending on whether it originates from father or mother) is important in several disorders (e.g. Prader–Willi/Angelman syndromes) and is relevant in determining some aspects of the TS phenotype (e.g. cardiac abnormalities, neck webbing) when the normal X chromosome is maternal in origin (see Ch. 14).

The fetal ovary forms normally and germ cell numbers are normal until the end of the second trimester. These then decline to birth and subsequently at a variable but increased rate so that a ‘menopause’

occurs before puberty in the majority. Some will enter puberty spontaneously – this is more common with ‘mosaicism’ (but see above). With partial deletions, long arm preservation may be important for ovarian function and short arm deletions are associated with the growth deficit.

There is defective end-organ responsiveness to growth factors at cartilage and collagen level and a spectrum of GH secretory insufficiency. Intrauterine growth is poor, growth velocity declines progressively after infancy and the pubertal growth spurt is absent. As the height relationship with parents is maintained, TS girls with tall parents (or, more specifically, a tall parent from whom their normal X chromosome has been inherited) may not become conspicuously small until they fail to enter puberty when their normal peers are growing rapidly. Approximately 20 cm in height is lost compared to relevant population means – the mean adult UK height is about 143.0 cm although it may be a little more in ‘mosaics’ and when short arm material is present. Thus about 20% of TS girls will achieve a spontaneous final height above the 3rd centile for the normal population. Specific growth charts for Turner syndrome are available.<sup>73</sup> Significant deviation from syndrome specific centiles necessitates a search for additional pathology (e.g. hypothyroidism or Crohn’s disease).

Mean IQ is 95 and the majority have IQs within the normal range. Many have specific difficulties with visuospatial perception and full psychometric assessment will allow specific remedial help. Autoimmune disease is more common in TS: autoimmune thyroiditis has an increasing risk with age and particularly by adolescence.<sup>219</sup> The frequency of antithyroid antibodies also increases with age as it does in the normal population – elevated antibody titers indicate the need for regular evaluation of thyroid function.

Ideally estrogen replacement must be initiated to keep the TS girl in line with her peers and increased at a physiological rate. An appropriate regimen is described below. This produces good cosmetic breast appearances and allows normal psychological maturation and bone mineralization. Oral estrogen enters the portal circulation and exposes the liver to high levels – transdermal natural estrogen patches will be preferable in the future. Estrogen replacement therapy is necessary at least until menopausal age and probably beyond.

Ultra-low dose estrogen in early childhood cannot be routinely recommended on present evidence although estrogen has an important role in bone mineral accrual prepubertally and there are data supporting its use.<sup>5</sup> GH therapy (see below) can normalize bone mineralization.<sup>220</sup> Delaying estrogen therapy much beyond 13 years may increase social isolation, stigmatization and psychological distress and reduce life-long bone mineralization, and recent data suggest that delay is unnecessary from a height point of view also.<sup>221</sup>

Growth-promoting therapy with GH with or without additional anabolic steroid (oxandrolone) has been widely assessed in TS but many studies have significant methodological flaws. Pharmacological doses of GH produce a dose-related increase in height to socially acceptable levels in many TS girls; most gain is during the first 3 years of therapy; individual responses are variable and unpredictable; combining GH with oxandrolone increases the tempo of growth, thus shortening the duration of GH therapy to final height, and may contribute extra height gain – androgenic side effects of oxandrolone are dose related whereas the growth-promoting effect is not and thus very low doses (0.0625 mg/kg daily) are optimal.

The first high quality (Canadian) trial of GH therapy in Turner syndrome has now been reported<sup>221</sup> and shows an average adult height gain (over predicted/controls) of around 7 cm. However, in view of the high dropout rate, lack of data for starting GH therapy at less than 7 years, variable individual responses and increase in some side-effects, there are still a number of unanswered questions. Height is not a validated proxy for psychological well-being or quality of life and, based on French population TS data, two thirds of the TS patients treated with GH in the Canadian study would not have considered the treatment to have been worthwhile based on these results.<sup>222</sup>

TS women are candidates for in vitro fertilization using donated ova. In future, they, and perhaps women with acquired gonadal dysgenesis who have had abdominal irradiation in childhood, will be candidates for cryopreservation and ovarian autografts, although the latter group, unlike TS women, will have compromised uterine function.

Rarely ovarian agenesis occurs with a normal female karyotype. Stature is normal and there are no dysmorphic features. The presence of an XY cell line necessitates removal of dysgenetic gonads.

Fig. 15.39 The nails in Turner syndrome (the same girl as in Fig. 15.38).

### Disorders of testicular function

These are uncommon. Anorchia is usually detected prepubertally but may be secondary to testicular irradiation in the treatment of ALL or follow suboptimal management of testicular torsion.

### Polycystic ovarian syndrome

Menstrual disturbances in many adult women presenting with polycystic ovarian syndrome (hirsutism, obesity and menstrual irregularities) had been thought to date from puberty but ultrasonic appearances (enlarged ovaries with many small circumferential cysts surrounding increased stromal tissue) may be common in prepuberty and an important pathological cause of pubertal delay. There is an association with premature pubarche and prepubertally detectable hyperinsulinemia and dyslipidemia. Birth weight SD scores have been found to be lower in premature pubarche girls than in controls, and particularly so in those with hyperinsulinemia and subsequent ovarian hyperandrogenism. This suggests that these associations may result, at least in part, from a common prenatal origin.<sup>32</sup>

### Investigation

Distinguishing physiological from pathological delay may be impossible clinically. Assessment must include physical examination (nutritional state, fundal and visual field assessment) and calculation of height velocity. Loss of 'consonance' – tall stature for the family associated with pubertal delay and delayed bone age – is incompatible with CDGP and may be due to Klinefelter syndrome, hypogonadism or GT deficiency; marked pubic or axillary hair growth in a girl with absent breast development suggests Turner syndrome. The appropriateness or otherwise of height velocity can only be determined in the context of pubertal stage, e.g. growth should be accelerating in a girl with stage 2 breast development but slow growth is normal in a boy until 8–10 ml testicular volumes. Assessment of skeletal maturity may indicate likely delay before puberty starts spontaneously (if it will do so) but seldom distinguishes pathology from physiological delay.

Children with loss of consonance should be investigated at any age, as should those with signs or symptoms attributable to an underlying pathological process. Where height and degree of skeletal maturational delay seem appropriate for the family in terms of final height prediction, delay is probably physiological. Three percent of normal boys and girls will have no signs of puberty by 13.8 and 13.4 years respectively and it is reasonable to investigate those presenting after this. Even if delay is physiological it is unkind (in emotional and psychological terms) and

inappropriate (in growth terms) to allow too much delay in relation to the child's peers, and pubertal induction may be indicated.<sup>223</sup>

Raised GT levels are diagnostic of primary gonadal failure but are not elevated before about 10 years. At any age, normal testes will respond to stimulation by LH (given as HCG) by secreting testosterone. In hypogonadotrophic hypogonadism there is a presumed lack of LH receptors in the testis, basal and stimulated GT levels will be low and the testosterone response to HCG is absent. Pubertal imminence can be assessed by measuring nocturnal GTs – pulsatile nocturnal GnRH release occurs well before clinically detectable signs – or more practically by measuring the GT response to a small (0.25 mcg/kg i.v.) dose of GnRH.<sup>205</sup> If puberty is imminent, LH responsiveness will exceed that of FSH and rise significantly. Where available, skilled ultrasound assessment is helpful in girls and non-invasive. An 8 a.m. plasma testosterone level may be a useful simple guide in boys<sup>187</sup> but inhibin B may be a more sensitive predictor than testosterone of clinical pubertal onset.<sup>224</sup>

Moderately raised basal PRL levels may be due to stress but higher levels are a sensitive indicator of reduction in its dopaminergic inhibitory control secondary to hypothalamic lesions or those causing portal compression (e.g. craniopharyngioma, radiotherapy, histiocytosis X). Hyperprolactinemia is itself a cause of delayed puberty. Prolactinomas are rare in children – PRL levels are generally very high (> 3000 mU/L). A significantly elevated PRL is thus a sensitive indicator of intracranial pathology as a cause of delayed puberty and an indication for neuro-radiological investigation which is important if an evolving endocrinopathy is suspected – hypogonadotrophic hypogonadism may be the first sign of panhypopituitarism.

There is physiological blunting of GH secretion in late prepuberty in both sexes and in early male puberty so that, if pharmacological testing of GH secretion is deemed necessary and is to be interpreted correctly, sex steroid priming is necessary. Stilbestrol was originally studied in both sexes but depot testosterone or oral estrogen are used in boys and girls respectively.

If pathology is suspected, investigations should be carried out urgently (treatment of underlying pathology may be necessary) and puberty induced at normal time and tempo. Otherwise, although much can be learnt by several months' observation of growth and for early signs of puberty, the psychological pressures on some can be considerable.<sup>223</sup> The short, undeveloped and poorly qualified 16-year-old school-leaver may find it particularly hard to obtain employment. It is inappropriate to induce puberty late to maximize prepubertal growth because continuing late prepubertal growth deceleration is leading to a lower point from which to accelerate and the magnitude of the pubertal

growth spurt in a late developer is generally smaller. It is also unkind to subject a child to unnecessary social and emotional pressures.

With optimal treatment, puberty can be started at an appropriate time and progressed at a physiological tempo. In girls, too large a starting dose and too rapid escalation of estrogen therapy will reduce the magnitude of the growth spurt, produce cosmetically unattractive 'cylindrical' breasts and potential difficulties in important emotional and psychological aspects of adolescent development. A boy may have 2 years or more from early testicular enlargement until he notices height acceleration. Meanwhile his more average peers are both more developed and growing 3–4-fold faster. Stimulation of growth during early male puberty is thus of considerable potential psychological benefit. Possible therapies (anabolic steroid, androgen or GH) are reviewed by Kelnar.<sup>223</sup>

### Clinical consequences and management

Emotional and psychological consequences of delay are not dependent on the presence of underlying pathology: the most common group, boys with CDGP, may suffer considerably yet are entirely normal. Where an underlying non-endocrine condition is responsible, diagnosis and optimal management may facilitate spontaneous development. When pubertal induction is necessary, it should mimic closely normal pubertal progression to optimize growth, cosmetic appearances and psychological maturation. Too rapid induction is disadvantageous and is unnecessary if induction is not unduly delayed.

### Puberty induction

Induction in girls is with estrogen whatever the precise nature of pubertal failure. An appropriate starting regimen is ethinylestradiol 1–2 mcg orally daily, increasing to 10 mcg over 18–24 months. At that dose, or before if breakthrough bleeding occurs, a progestogen (e.g. norethisterone 350 mcg) should be added for 5 days every 4 weeks. Unopposed estrogenic endometrial stimulation otherwise increases risks of endometrial or breast carcinoma. Full secondary sexual development will generally occur with ethinylestradiol 20–30 mcg – a low estrogen combined contraceptive pill may then be conveniently substituted. If hypogonadism is permanent, estrogen/progestogen therapy must be maintained to enable sexual intercourse to be enjoyed without discomfort and prevent osteoporosis and, perhaps, early atherosclerosis. Transdermal natural estrogen, when available in low enough dosage for pubertal induction, will be preferable.

Many different regimens are used for hormone replacement therapy in young women, and it is likely that optimal HRT in young women (in terms of bone strength, cardiovascular protection, feminization, etc.) is different from that appropriate for older women who are 'conventionally' postmenopausal.

In boys, physiological sex steroid replacement is even more difficult. Conventionally, depot preparations of testosterone esters (e.g. Sustanon 50–100 mg i.m. once every 6 weeks increasing gradually over 2 years to 250 mg i.m. twice weekly) are used. Oral testosterone (undecanoate, TU) was considered too variably and excessively absorbed for pubertal induction but experience suggests that resulting high total testosterone levels reflect changes in SHBG on treatment, and that appropriate free (active) testosterone levels for pubertal induction are achievable with TU 40 mg alternate daily – TU may be the treatment of choice for the short, sexually immature adolescent boy where explanation and reassurance alone are not enough.<sup>223</sup> Long term androgen replacement will probably be best given using testosterone implants or transdermally – patches are now available in the UK and suitably low dose regimens for pubertal induction need evaluation.

In future, recombinant human chorionic gonadotrophin (rHCG) therapy may be a suitable alternative in boys with hypogonadotropic hypogonadism; in girls HCG may cause abdominal pain, ascites and hemorrhagic rupture of ovarian cysts. Spermatogenesis would be induced by recombinant FSH (rFSH). Optimal fertility in both sexes requires eventual low dose pulsatile GnRH therapy.

The physician will need to assess carefully individual underlying psychological and social pressure before deciding on the optimal management of CDGP, which might comprise anabolic steroid (oxandrolone) or testosterone therapy.<sup>223</sup> The role of aromatase inhibitors in increasing adult height in adolescent boys by inhibition of estrogen action is under evaluation.<sup>225</sup>

Emotional support is always important whatever other treatment modalities are used but the morale boost from an increase in growth velocity in early male puberty is often dramatic with improvement in school attendance and performance.

## OTHER DISORDERS RELATED TO FEMALE AND MALE REPRODUCTION

### AMENORRHEA

Amenorrhea may be secondary (absent menstruation with previously normal menstrual history) – causes include pregnancy, anorexia nervosa, intense training or chronic underlying disease – or primary (menstrual bleeding has never occurred). Primary amenorrhea may be a consequence of abnormal GnRH pulsatile secretion or release – a middle stage between GnRH deficiency causing delayed or arrested puberty or infertility due to anovulatory cycles. Other important causes include primary ovarian failure (often in TS), gonadal dysgenesis with absent uterus (e.g. the XY girl) or imperforate hymen. Hypertension suggests 17alpha-hydroxylase deficiency.

### NOONAN SYNDROME

In this syndrome, which is thought to have an incidence of 1 in 1000 to 1 in 2500 live births, there is frequently variable hypogonadism associated with characteristic features such as pulmonary valvular stenosis, a broad forehead with hypertelorism, epicanthic folds, ptosis and downward slanting palpebral fissures, abnormal or low-set ears, neck webbing, low posterior hair line, shield chest or kyphoscoliosis, deafness, visual problems, clotting disorders and short stature (Fig. 15.40). However, as in TS, all these are inconstant and diagnosis has been clinical, with the typical facial features and at least two other features as key elements. The phenotype changes with age.

Cryptorchidism is found in about two thirds of boys; sexual development generally occurs spontaneously but is delayed. Infertility is

Fig. 15.40 Noonan syndrome.

usual. In girls (whose karyotype is normal) puberty and menarche can be delayed (presentation may be with primary amenorrhea) but fertility seems common. Mean adult height is approximately 162.5 cm (males) and 153 cm (females) although standards are based on relatively small numbers and largely cross-sectional data. GH treatment improves medium term height velocity, and theoretical adverse effects on cardiac ventricular wall thickness (potentially leading to hypertrophic obstructive cardiomyopathy) have not been seen.

Noonan syndrome is associated with germline gain-of-function mutations in the PTPN11 gene which encodes the protein tyrosine phosphatase Shp2 (a protein that controls cardiac semilunar valvulogenesis) on the long arm of chromosome 12 (12q24.1)<sup>226</sup> but only in about 40–50% of those identified clinically. The presence or absence of these mutations influences responses to GH therapy.<sup>227</sup>

The recent finding of germline oncogene (KRAS) mutations in some patients with Noonan syndrome, cardio-facio-cutaneous syndrome and Costello syndrome (which have some phenotypic features in common) suggests a common underlying molecular basis and may explain the reported increased tendency to malignancy in these conditions.<sup>228</sup>

Further knowledge of the true incidence and phenotypic diversity may allow the design of appropriately controlled studies of the efficacy of GH therapy with sufficiently large numbers of subjects defined on a molecular genetic basis and followed to final height.

### KLINFELTER SYNDROME (KS) (47XXY)

There is tall stature for the family with disproportionately long legs from childhood (Fig. 15.41), small testes for apparent virilization (Fig. 15.42) and azoospermia. Presentation is usually with tall stature, hypogonadism (often with marked pubertal gynecomastia) or infertility. The incidence is about 1 in 500 to 1 in 1000 live births. Prepubertal faster than average growth relates to the extra 'dose' of the SHOX gene. Extremely tall ultimate height with increasingly disproportionately long legs relates to testosterone secretion inadequate for conversion to estrogen and epiphyseal closure at the appropriate time or for normal rapid late pubertal spinal growth – GH predominantly stimulates long bone growth. Spontaneous pulsatile GT secretion in pre- and peripubertal 47XXY boys may be normal, cf. the usual GT elevation in adults. Pubertal onset is generally not delayed. Mean IQ is below the population mean, but most are within the normal range. If the diagnosis is made sufficiently early, excessive stature can be prevented, or at least reduced, by high dose testosterone treatment (but see below) or epiphysiodesis.<sup>139</sup> There is now the potential to achieve fertility by testicular sperm extraction and intracytoplasmic sperm injection techniques, particularly in the young adult with KS.<sup>229</sup> Whilst the outcome seems less favorable in those who had high dose testosterone supplementation in puberty it is unclear as to whether this is causative or simply reflects the greater need for such supplementation in those worse affected.

### GYNECOMASTIA

Hormonal effects on breast structures are complex. In males androgens are important in inhibiting stimulatory estrogenic effects on breast tissue: breast development occurs in pubertal girls at estrogen levels comparable to those in adult males. It also occurs in androgen insensitivity syndromes, where testosterone is inactive because of androgen receptor deficiency, at normal male estradiol levels.

Thus a degree of gynecomastia occurs in < 50% of normal boys during early to mid-puberty when estrogen levels are high in relation to androgens. It is usually mild, resolving spontaneously within 12–18 months, but sometimes subareolar mastectomy is necessary if the condition is distressing and persistent. Gynecomastia is a particular feature of Klinefelter syndrome (see above). Gross pubertal gynecomastia, prepubertal gynecomastia or persistence in late puberty requires investigation.

Prepubertal gynecomastia may be unilateral, can cause discomfort and is usually benign, self-limiting and idiopathic. Exposure to exogenous estrogen or endogenous production by adrenal, testicular or other tumors

must be excluded. Drugs such as digoxin, methyl dopa, ketoconazole and cannabis and amphetamine abuse have been associated.

### UNDESCENDED TESTES

This common problem is considered elsewhere (see Ch. 37, p. 1620.). Many 'undescended' testes are simply retractile, can be manipulated into the scrotum and will descend (and stay in the scrotum) at puberty. Hypogonadotropic hypogonadism is the most common cause of cryptorchidism which is now known to be an important cause of infertility secondary to impaired hormonal priming in infancy; genetic defects have been described in minority of subjects.<sup>215</sup> In bilateral cryptorchidism fertility is likely to be severely compromised. Cryptorchidism and micropenis may represent a DSD phenotype, even if they are isolated, and a karyotype should always be checked. In unilateral cryptorchidism the undescended testis fails to establish an adequate adult stem cell pool by 2–3 months of age and similar (if less severe) changes occur in the contralateral (descended) testis. To enhance the chance of adult fertility, hormonal treatment (GnRH analogue over 4 consecutive weeks) should start by 6 months of age. If there is no response HCG should be given (500IU

Fig. 15.41 Klinefelter syndrome – note the disproportionately long legs in this 202 cm 18-year-old.

Fig. 15.42 Genitalia in Klinefelter syndrome – note the small testes for the degree of virilization (the same subject as in Fig. 15.41).

i.m. weekly for 3 consecutive weeks). If there is still no response, orchidopexy and testicular biopsy should be carried out. The biopsy will identify those with a germ cell count  $<0.2$ /tubule and/or no adult dark (Ad) spermatogonia. They should be treated with a further course of a GnRH analogue (10mcg every other day for 6 months). GnRH<sub>a</sub> has been shown to induce increased numbers of germ cells and their differentiation from gonocytes into Ad spermatogonia which improves the chance of fertility.<sup>39</sup>

Scrotal testes are necessary functionally (testosterone biosynthesis, spermatogenesis/fertility), cosmetically and because of the (difficult to quantify) risk of malignant change in functional intra-abdominal testes. A testis not in the scrotum by infancy is now thought unlikely to show adequate spermatogenesis. Functional but ectopic tissue which cannot be brought into the scrotum surgically is probably best removed unless it is easily accessible to clinical examination and follow-up can be assured. Nonfunctioning intra-abdominal testicular tissue is probably best left – it carries extremely low risk of malignant change and may be impossible to locate at laparotomy or laparoscopy.

## THE HYPOTHALAMO-PITUITARY UNIT

### CONNECTIONS/ANATOMY/PHYSIOLOGY

Ontogeny of fetal hypothalamo-pituitary hormone biosynthesis is described on p. 415. By 15 weeks' gestation the hypothalamus is anatomically mature and functionally active and by 18 weeks pituitary vascularization is complete. The hypothalamo-pituitary axis is functional by 20 weeks with development of the portal system. Functional maturity is important for normal development of thyroid (secondary to TSH secretion), external genitalia in the male (GH and GTs) and adrenal (ACTH and related peptides).

The pituitary gland is situated within the pituitary fossa, directly below and in close relationship with the hypothalamus. Laterally are

Table 15.10 Hypothalamic regulatory peptides and their properties

Regulatory peptide	Amino acids	Molecular weight
Growth hormone releasing hormone	40/44	4545/5040
Somatostatin (growth hormone release inhibiting hormone)	14	1638
Gonadotropin releasing hormone/ luteinizing hormone releasing hormone	10	1182
Thyrotropin releasing hormone	3	362
Corticotropin releasing hormone/factor	41	4758

the cavernous sinuses, the internal carotid arteries, the 3rd, 4th and 6th cranial nerves and temporal lobes. Above lie arachnoid and subarachnoid spaces and above them the optic chiasma and hypothalamus.

The hypothalamus has afferent connections with frontal cortex, thalamus, amygdala, hippocampus and anterior thalamic (autonomic) nuclei and can integrate and respond to a wide range of physiological and behavioral inputs. Efferent pathways also connect with midbrain, pons, medulla, amygdala and hippocampus and there are specific pathways to adenohypophysis via the portal system and to neurohypophysis via the supraopticohypophyseal tract.

Neuroendocrine control of hypothalamic secretion is by CNS neurotransmitters including dopamine, noradrenaline, serotonin, acetylcholine, gamma-aminobutyric acid (GABA), melatonin and histamine. Anterior pituitary hormone secretion is directly controlled by hypothalamic factors (regulatory peptides) that affect hormone synthesis and release (Table 15.10).

## ANTERIOR PITUITARY HORMONES

### Corticotrophin (ACTH)

ACTH is a single chain 39 amino acid polypeptide. The first 24 N-terminal amino acids are identical in most species and produce the biological (adrenocortical) activity. However ACTH is one of a group of related pituitary peptides which originates from a common large molecular weight (31 000) glycosylated precursor molecule, pro-opiomelanocortin (POMC). Glycosylation accounts for basophil staining of pituitary corticotrophs.

The bovine precursor protein (Fig. 15.43) consists of 265 amino acids encoding three peptides: ACTH, beta-lipotrophin (beta-LPH) and a 105 amino acid N-terminal sequence N-POMC. Human N-POMC is a 76 amino acid peptide of molecular weight 11 200. All three POMC-derived peptides are found in the same secretory granules within the cell, are released concomitantly into the circulation in equal concentrations, become undetectable after hypophysectomy and their plasma concentrations rise after adrenalectomy. Secretion is stimulated by median eminence extracts containing CRF activity and suppressed by dexamethasone. Plasma concentrations of N-POMC and ACTH correlate closely, reflecting coordinated synthesis and secretion.

The principal modulator of ACTH secretion is CRF but vasopressin also has a stimulatory effect on ACTH secretion, directly and by potentiating the actions of CRF. Neurotransmitter pathways important in ACTH secretion are alpha-adrenergic (perhaps most important), cholinergic, serotonergic and histaminergic (all excitatory) and via GABA (inhibitory).

ACTH release is circadian, resulting in the early morning peak of ACTH and cortisol in association with more frequent ACTH pulses. Factors modulating its secretion are cortisol [by negative feedback at hypothalamic (mainly) and pituitary levels via fast and slow feedback loops] and ACTH itself at pituitary level.

ACTH stimulates adrenal growth and cortisol synthesis and release. Plasma half-life is about 10 minutes. Mechanisms stimulating adrenocortical steroidogenesis are complex: ACTH binds to its adrenal cell membrane receptor, in the presence of calcium ions, to generate cyclic AMP; cyclic AMP activates, by phosphorylation, enzymes which stimulate hydrolysis of cholesterol esters (first steps in adrenal steroidogenesis). Rapid steroid production follows (p. 479 and Fig. 15.50). There is also

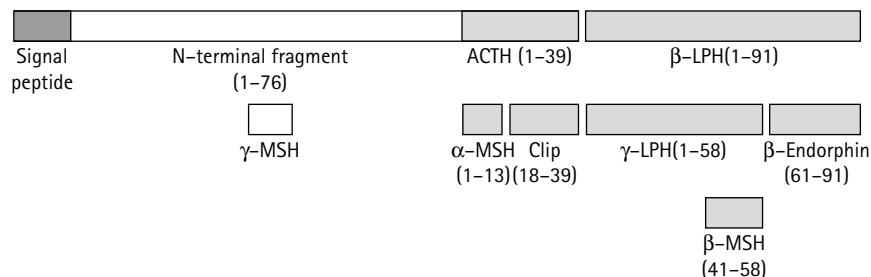

Fig. 15.43 Structure of bovine pro-opiomelanocortin (POMC). (After Nakanishi et al 1979<sup>230</sup>) (The connecting peptide N-POMC 79–109 has been omitted.)

a slower, chronic effect on protein synthesis in the cytochrome P450 dependent enzyme systems (11beta-, 17alpha- and 21-hydroxylases).

ACTH acutely stimulates aldosterone release from zona glomerulosa cells – this has important practical implications for managing of salt-losing CAH – and modulates adrenal androgen secretion. It stimulates amino acid and glucose uptake by muscle and lipolysis in adipose cells and inhibits thymic growth.

The 13 ACTH N-terminal amino acids are identical with alpha-MSH (see Fig. 15.43) and homologous with amino acids 7–13 of beta-MSH. Beta-MSH is not present in the pituitary or circulation in man and may not exist in discrete form. The etiology of skin pigmentation in pathological states is unclear – ACTH itself is probably causative in some situations.

### Somatotrophin (growth hormone)

See p. 436.

### Gonadotrophins (GTs – LH, FSH)

LH and FSH are glycoproteins (MW 30 000 and 32 000 respectively), each with identical A but different B chains and possibly stored within the same secretory granules in pituitary gonadotrophs. Release is controlled by a single hypothalamic hormone, GnRH (see Table 15.10). GnRH is released in a pulsatile manner.

In men, LH stimulates testicular Leydig cell testosterone secretion and FSH stimulates spermatogenesis. In women, LH induces ovulation, maintains the corpus luteum and stimulates it to produce progesterone and estrogens. Ovarian follicles secrete estrogens in response to FSH and endometrial gland growth and secretion result from estrogen and progesterone secretion, respectively. In men, LH secretion is under negative feedback control from testosterone and FSH secretion is regulated by inhibin B secreted by testicular Sertoli cells. In the female, estrogens exert either positive feedback at pituitary level (before ovulation) or negative feedback (at other times). For further details on the inhibins, see p. 447.

### Prolactin (PRL)

PRL (198 amino acids, MW 22 500) is strikingly homologous with GH. Its major role is in initiation and maintenance of lactation. Its role in childhood, when levels are low and constant, is unknown although it rises in response to stress. There is no evidence that slight rises during normal puberty are important in pubertal onset or control. Transiently high levels in neonates secondary to fetoplacental estrogen may cause galactorrhea ('witch's milk') from engorged breasts in either sex.

PRL is predominantly under inhibitory dopaminergic control and hyperprolactinemia is an important early nonspecific sign of neuroendocrine disturbance and intracranial pathology. A PRL inhibiting factor (PIF) has been postulated but has not been characterized. GABA may also have some inhibitory effect but TRH and VIP are stimulatory.

### Thyrotrophin (TSH)

TSH is a glycoprotein, MW 26 600. It shares a common A chain with LH and FSH. TRH stimulates TSH synthesis and release which increases thyroid vascularity and stimulates follicular cell hypertrophy. TSH stim-

ulates iodine uptake, organification, coupling of tyrosines and the synthesis and release of thyroxine (T4) and triiodothyronine (T3). Feedback inhibition is by T3, both directly and via deiodination of T4 within the pituitary. In man dopaminergic inhibition may occur at the level of the thyrotroph; the inhibitory role of somatostatin is unclear in normal physiology. Glucocorticoids inhibit TSH release at hypothalamic level.

After birth, there is a large rise in TSH release followed by a more gradual rise in circulating T4 and T3 levels. TSH levels return to normal by the end of the first week but thyroid hormone levels may be elevated for up to several weeks.

### Melanocyte-stimulating hormones (alpha- and beta-MSH)

See above under ACTH.

## POSTERIOR PITUITARY HORMONES

### Arginine vasopressin (antidiuretic hormone, AVP) and oxytocin

Vasopressin and oxytocin are 9 amino acid peptides differing from each other at two sites (amino acids 3 and 8). They are synthesized in the supraoptic (mainly vasopressin) and paraventricular (mainly oxytocin) hypothalamic neurones bound to proteins (neurophysins I and II) whose function is unknown. Both hormones reach the posterior pituitary, where they are stored in secretory granules, via the supraopticohypophyseal tract.

The principal stimulus to vasopressin (AVP) release is rising plasma osmolality, but plasma volume and blood pressure may exert independent effects. Some physiological states (e.g. pain, stress, sleep) also stimulate vasopressin release. The most important physiological action is to cause water reabsorption by renal distal tubules and collecting ducts – water is reabsorbed in excess of sodium resulting in concentrated urine. Plasma osmolality is normally kept within the range 275–290 mosmol/kg throughout life.

The principal stimulus to oxytocin release is suckling. Oxytocin stimulates the 'let-down' reflex during lactation and uterine contractility. It has weak antidiuretic activity. Except in pregnancy and the puerperium, its physiological role in man is unknown. Neither excess nor deficiency is associated with any syndrome in children (or adults).

## DISEASES OF THE HYPOTHALAMO-NEUROHYPOPHYSEAL UNIT

### Diabetes insipidus (DI)

Hypothalamic AVP deficiency leads to voiding of inappropriately large volumes of dilute urine (polyuria). If thirst sensation is normal, fluid lost is replaced and there is excessive drinking (polydipsia) to maintain normal plasma osmolality. Nocturia is invariable and may present as secondary enuresis in older children. If thirst recognition is defective (usually due to extensive hypothalamic damage to both AVP and thirst osmoreceptors) or there is no access to adequate or appropriate fluid (e.g. in neonate or infant), hypernatremic dehydration may result in fever, irritability, vomiting and failure to thrive, and polyuria may be absent.

Polyuria and polydipsia may result from renal unresponsiveness to AVP (nephrogenic DI, see Ch. 18). Sometimes primary polydipsia ('compulsive

water drinking') may develop in children (leading to secondary polyuria). Both these situations must be considered in the differential diagnosis as must other causes of polyuria (e.g. urinary tract infection, diabetes mellitus). Defects in AVP release are usually due to hypothalamic dysfunction – more than 75% of secretory capacity must be lost before symptoms develop. Removal of, or damage to, the neurohypophysis does not cause DI.

DI is rare in childhood: the incidence in Finland is 5 cases per million per year up to 14 years of age.<sup>231</sup> Causes are listed in Table 15.11.

Primary DI may be familial or sporadic, and families with dominant or X-linked inheritance have been described.

Familial AVP deficiency (DI) is of variable severity which increases with age and may not manifest itself clinically until adolescence. It is probably due to a degenerative process in the cells of the hypothalamus that produce antidiuretic hormone (AVP). As there is high redundancy of function (more than 75% of secretory capacity must be lost before symptoms develop) it is not surprising that, despite being inherited, the condition may take many years to develop.

AVP deficiency is found in 25–50% of children with Langerhans' cell histiocytosis and may precede other evidence of the disease by months or years (see Ch. 24, p. 1030). Other rare infiltrative causes include Hodgkin disease, leukemias and sarcoidosis but transient DI is common after head injury and pituitary surgery. It may complicate severe neonatal infections and may be associated with autoimmune states with AVP antibodies.

Differential diagnosis of polyuria depends on history, examination and laboratory tests. Osmotic diuresis (e.g. due to salt or glucose) is readily excluded from the history and by testing the urine for glucose. Habitual polydipsia most often develops in response to fluids being offered to pacify a demanding infant or young child. Such primary polydipsia of 'psychogenic' origin is suggested by fluctuating symptoms, evidence of psychological difficulties in the child or family, and a refusal of water (as opposed to juice) if waking thirsty at night. A morning plasma osmolality in the normal range (cf. in DI) often contrasts with a low value in the evening.

History of head injury, meningitis or encephalitis should be sought. Poor growth suggests either inadequate appetite or food intake relating to the polydipsia or an associated anterior pituitary lesion with TSH, GH, GT or ACTH deficiencies. TSH or ACTH deficiency may temporarily conceal DI until thyroxine or cortisol replacement is given. Headaches, vomiting and visual disturbances indicate raised intracranial pressure secondary to tumor.

Synchronous measurements of plasma and urinary osmolality are valuable provided accurate assays are available. If not, plasma sodium (not specific gravity) should be substituted. Inappropriately low urinary osmolality with raised plasma osmolality confirms DI – charts aiding interpretation have been produced for children.<sup>236</sup> To achieve this mismatch a water deprivation test may be necessary. Plasma AVP assays are increasingly available but their value in diagnosis of central DI in children is not established (high, diagnostic values are found in nephrogenic DI).

Water deprivation tests are potentially both dangerous and misleading if inadequately supervised and a strict protocol should be followed. Several protocols are available: Czernichow<sup>237</sup> is readily accessible. Specific additional endocrine and neuroradiological investigations may be necessary.

Provision of adequate water with free access to solute-free fluid at all times is vitally important. Treatment with AVP has been much simplified by the availability of a synthetic AVP analogue 1-desamino-

8D-arginine vasopressin (DDAVP, desmopressin) which has a longer duration of action than AVP itself. It can be administered intranasally – a reasonable starting dose is 0.25 mcg (in neonates), 0.5–1.0 mcg (infants) and 2.5 mcg (children). Therapeutic effect is seen within 1 h. The 2 or 3 times daily dose is adjusted to provide an antidiuretic effect for 8–12 h and may need increasing during rhinitis. DDAVP, like other small peptides, is orally active and can now be given orally – initially 100 mcg tds; maintenance 200–600 mcg per day in divided doses as above.

Special care must be taken with infants who do not have free access to water and children with an impaired sense of thirst (adipsic DI) who can be extremely difficult to manage. Water intoxication is a risk with overdosage or if water is given inappropriately. A talisman detailing the disease and its therapy should be carried or worn at all times.

Poor control of DI is associated with nocturia, enuresis, irritability and poor behavior and school performance. Appetite and growth velocity may be poor. Polyuria may lead to secondary enuresis. If treatment is optimal, prognosis reflects the underlying condition in secondary DI: in treated primary DI growth and development should be normal.

### DI, diabetes mellitus, optic atrophy, deafness syndrome ('DIDMOAD' syndrome, Wolfram syndrome)

See p. 503.

### Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)

Causes are listed in Table 15.12. Excessive AVP secretion results in water retention, hypo-osmolality and dilutional hyponatremia. Inhibition of aldosterone with continuing AVP secretion leads to paradoxically high urinary sodium levels and concentrated urine. AVP levels may not be supranormal but are inappropriately high for the expanded extracellular volume and hypo-osmolality.

In pediatric practice, SIADH is usually seen either in neonates following birth asphyxia, hyaline membrane disease or intraventricular hemorrhage, or in older children in association with meningitis, encephalitis or CNS tumors. It occasionally complicates pneumonia or pulmonary

Hypothalamic tumor 38% – craniopharyngioma 23% (usually postoperative); germinoma 6.5%; optic neuroma rarely
Idiopathic 23% – autoimmune factors may be important
Congenital renal 23%
Histiocytosis X 8%
Cerebral malformations 3%
Primary polydipsia 3%
Traumatic 2%

tuberculosis, vincristine or cyclophosphamide therapy, and is a common, temporary (up to several days) complication of surgery requiring general anesthesia. It may be a particular problem in burns and trauma patients. SIADH may be iatrogenic, due to inappropriate intravenous fluid therapy.

The first signs and symptoms are often masked by, or taken as manifestations of the underlying problem – anorexia, confusion, headaches, muscle weakness and cramps. Eventually, there is vomiting, convulsions or coma. There is no edema. Diagnosis depends on clinical suspicion and the above biochemical findings.

Treatment is by water restriction to between 30% and 50% maintenance and sodium replacement to compensate for secondary sodium losses. Correction should be gradual (over several days). In situations where this cannot be achieved drug therapy may be indicated. Lithium and demethylchlortetracycline have serious side-effects in children and should not be used. Furosemide (with slow infusion of hypertonic saline) may be indicated. AVP antidiuretic analogues which, it was hoped, would become the treatment of choice, have all had significant vasopressor activity.<sup>238</sup>

## DISEASES OF THE ADENOHYPHYSIS

### ACTH excess

Hypercortisolism in children usually results from excessive GC medication. Endogenous adrenocortical overactivity is rare, whether due to adrenal tumor (benign or malignant), hyperplasia, ectopic tumor ACTH production or pituitary dependent ACTH secretion (Cushing disease). Cushing syndrome includes all pathological states secondary to excessive GC production. Cushing found a basophil pituitary adenoma in only six of his original 12 patients<sup>239</sup> – it is now thought that bilateral adrenal hyperplasia secondary to excessive ACTH secretion of pituitary origin is not a single entity and may be due to a variety of hypothalamic, pituitary or even CNS (neurotransmitter) abnormalities.

Classical clinical features of hypercortisolism (hypertension, striae, truncal obesity, moon face, osteoporosis) are less obvious in children than in adults. Growth failure is usually marked but there can be temporary adrenal androgen-mediated acceleration. Investigation with

low and high dose dexamethasone suppression tests and hCRH test will identify the etiology<sup>240</sup> – Cushing disease itself is probably the commonest cause in children and adolescents.

The aim in treating Cushing disease is to control cortisol overproduction (if appropriate by removing the source of ACTH hypersecretion) whilst avoiding permanent endocrine deficiencies and dependence on replacement therapy. In practice, treatment of Cushing syndrome in children is still controversial given its poorly understood and diverse etiological basis. Options include surgery to adrenals or pituitary, pituitary irradiation (conventional or with radioactive implants), or medical management with dopaminergic agents or serotonin antagonists. Collaboration between pediatric and adult endocrinologists, an experienced neurosurgeon and a radiotherapist is essential for a successful therapeutic outcome.

### ACTH deficiency

ACTH deficiency is usually associated with other anterior pituitary hormone deficiencies which may be congenital, idiopathic, due to brain malformations or pituitary hypoplasia or to tumors such as craniopharyngioma (especially following surgery and/or radiotherapy). Hypothalamic CRF/pituitary ACTH secretion is more resistant to irradiation than the GH or GnRH axes. Secondary or tertiary adrenal insufficiency can be difficult to diagnose and assess but ACTH deficiency is rarely found in patients with a normal MRI and TSH levels.<sup>241</sup> Isolated ACTH deficiency is rare, may be congenital and can be associated with primary hypothyroidism – thyroxine therapy precipitates adrenal insufficiency by increasing cortisol clearance.

Congenital panhypopituitarism (see Fig. 15.44) is associated with severe neonatal hypoglycemia but isolated ACTH deficiency does not usually produce as severe adrenal hypofunction as in primary adrenal insufficiency. GC and adrenal androgen secretion are impaired; aldosterone secretion is normal. Collapse with salt loss may occur during severe intercurrent illness or general anesthesia. Treatment is with appropriate GC replacement.

### TSH deficiency

Congenital hypothyroidism due to decreased TSH stimulation of thyroid hormone secretion may be due to abnormalities of hypothalamic or

Fig. 15.44 Untreated panhypopituitarism (a) at age 11 years, (b) and (c) at age 71 years.

pituitary development, isolated TRH or TSH deficiency (familial or idiopathic) or panhypopituitarism. Congenital primary hypothyroidism is 15–30-fold more common.

TSH deficiency may present in later childhood, usually in association with other anterior pituitary hormone deficiencies and secondary to tumors (especially craniopharyngioma), cranial irradiation (to which the thyroid axis is relatively resistant) or meningitis. Symptoms and signs due to associated deficiencies usually predominate.

Differential diagnosis of primary, secondary (pituitary) and tertiary (hypothalamic) hypothyroidism and management is discussed below.

### Gonadotrophin (GT) deficiency

Isolated GT deficiency may occur without underlying anatomical abnormality. Usually congenital abnormalities of brain development give rise to hypothalamic GnRH deficiency, either isolated (e.g. Kallmann syndrome) or associated with other hypothalamic disturbances. GT deficiency may be associated with other pituitary hormone deficiencies in pituitary aplasia or hypoplasia, craniopharyngioma, etc.

### Hyperprolactinemia

Moderately raised PRL levels are an early nonspecific sign of neuroendocrine disturbance and particularly of suprasellar or hypothalamic space-occupying lesions. Stress also causes a moderate rise in PRL levels. Very high levels result from PRL-secreting micro- or macroadenomas but these are rare in children. They may cause delayed puberty. Raised PRL in association with raised GT (and especially FSH) levels causes precocious puberty in primary hypothyroidism.

### Intracranial space-occupying lesions

These are the second commonest neoplasms in children (after leukemia) accounting for 20% of the total. Endocrine aspects are of practical importance in a variety of ways:

#### As 'early warning' signs of intracranial pathology

1. Moderately raised PRL levels in the absence of stress (see above).
2. Slow growth or signs of precocious or delayed puberty resulting from endocrine dysfunction may precede more specific clinical manifestations by many months.

#### In pre-, peri- and postoperative management

1. Hydrocortisone cover must be adequate for the stress of surgery, irradiation or radioactive implant.
2. Transient DI is common after surgery to the pituitary area but temporary inappropriate ADH secretion may occur (management is reviewed by Albanese et al<sup>242</sup>).

#### Permanent hormone replacement therapy after surgery and/or radiotherapy

1. The need for therapy should be reassessed in terms of adeno- and neurohypophyseal function after these procedures – variable deficiencies of any or all hormones may be found.
2. Some tumors are particularly associated with endocrine dysfunction. These include craniopharyngiomas (see below), hypothalamic and optic nerve gliomas, third ventricular tumors and pituitary adenomas. Third ventricular tumors and hamartomas and other tumors of the pituitary stalk region may result in hypofunction, but may, like many pituitary adenomas, be functional. They seem to be more common in boys and precocious puberty may be the earliest sign.

### Craniopharyngioma (see Ch. 24, p. 1011)

This is the commonest tumor affecting the hypothalamo – pituitary region in childhood and accounts for 8–13% of all intracranial tumors in those under 14 years of age. The endocrine situation is never improved by surgery or radiotherapy (usually it is made worse) and endocrine disturbance alone is not an indication for either form of treatment.

Pre-, peri- and postoperative management and fluid balance must be meticulous. Pre-existing hormone deficiency should be corrected but hydrocortisone to cover the stress of the procedure must always be given even if ACTH reserve seems adequate. The need for long-term replacement therapies should be assessed several weeks postoperatively. DI may only become

obvious after cortisol replacement. Occasional damage to the thirst center causes major management problems. In many cases, GH, thyroxine, hydrocortisone (certainly to cover stress and sometimes regularly), DDAVP and pubertal induction will be necessary. Despite appropriate hormone replacement, obesity can be a major long term problem in many patients. The prognosis is improved with early diagnosis and careful initial management.<sup>243</sup>

## OTHER DISORDERS

### Septo-optic dysplasia

Septo-optic dysplasia (SOD) is a condition characterized by midline neurological abnormalities associated with pituitary and optic nerve hypoplasia. The abnormalities and their manifestations are variable but a presentation may be with disturbed hypothalamic function and resulting hypopituitarism (usually GT, GH and AVP deficiencies) in infancy with hypothermia, hypoglycemia and blindness. CT or MR scanning shows variable hypoplasia of the optic nerves, chiasma and hypothalamic infundibular region, often with an absent septum pellucidum. Similar endocrine consequences are sometimes seen in other midline developmental abnormalities such as corpus callosum agenesis.

The homeobox gene *Hesx1/HESX1* was initially implicated in pituitary development through loss-of-function studies in the mouse. Although the etiology of SOD is unknown, a homozygous missense point mutation in the gene resulting in a single amino acid substitution, Arg160Cys (R160C), is associated with a heritable form of human SOD.<sup>244</sup> Numerous other *Hesx1/HESX1* gene mutations are now described and are important in providing a genetic basis for more general midline defects associated with an undescended or ectopic posterior pituitary.

### Empty sella syndrome

Pituitary hypoplasia is associated with a small fossa. The infundibulum and pituitary stalk are normal but the chiasmatic cistern may extend into the small sella and appear empty with the stalk outlined by CSF. Enlargement of the sella and pituitary has been found in some cases of primary hypothyroidism, see [Figure 15.35](#). Decreasing pituitary size on thyroxine replacement may give the appearance of an empty sella with the small pituitary gland situated posteroinferiorly within the enlarged fossa.

### Diencephalic syndrome

This is usually due to an anteriorly growing hypothalamic glioma which presents in infancy or early childhood with excessive alertness and hyperexcitability, pallor, vomiting, gross wasting and failure to thrive. CSF protein levels are raised and tumor cells may be present. CT or MR scanning will confirm the diagnosis.

### Sotos syndrome (cerebral gigantism)<sup>245</sup>

Prenatal overgrowth occurs in several syndromes, including the Sotos and Weaver syndromes which are probably closely related. Birth weight and length are high reflecting the rapid intrauterine growth. This continues until by middle childhood growth velocity is normal. As puberty occurs early, final stature is seldom excessive. Mental retardation is common but may be mild or absent. Associated cardiac defects are common and there are increased malignancy risks. There are also similarities with another tall stature syndrome, Beckwith–Wiedemann, and excessive secretion of fetal growth factors could be etiologically important.

## THE PINEAL GLAND

The pineal, like the hypothalamus, develops from the diencephalon. Ependymal cells and vascular mesenchyme from the anterior part of the diencephalic roof plate form the choroid plexus. Caudally, the roof plate of the diencephalon thickens, evaginates by about 7 weeks and forms an ultimately cone-shaped solid organ, the pineal, attached by a peduncle to the posterior border of the third ventricle. It lies in the quadrigeminal cistern between the superior colliculi covered by the splenium of the corpus callosum and is innervated by postganglionic sympathetic superior

cervical ganglionic nerve fibers. Pinealocytes form a mosaic pattern around capillaries, astrocytes and ganglion cells.

At one time thought to be the seat of the soul, seen as guiding the cerebral hemispheres or, more mundanely, being important in the control of the onset of human puberty, the pineal role remains speculative. Pinealocytes convert tryptophan via serotonin to melatonin which is primarily produced by the pineal gland during the dark period of the light–dark cycle.

It had been conjectured that endocrine pubertal events are inhibited prepubertally by melatonin. However, there appears to be no inhibitory effect of melatonin on GT secretion: 24-hour melatonin profiles are similar in prepuberty, puberty and adulthood (low daytime levels, high nocturnal levels). Blindness, which would upset the pineal circadian clock, is associated with early menarche.

Melatonin may have a role in inhibiting gonadal development – levels decrease significantly with sexual maturation and age. There is evidence for a decline in the day to night increment of serum melatonin concentrations from infancy to childhood, that children with early puberty have lower melatonin day to night increments than age matched controls, and that those with constitutionally delayed puberty show increments comparable to those of preschool children.<sup>246</sup>

This implies a relationship between maturation and the mechanisms controlling pineal gland secretion whether or not melatonin plays any significant role in the onset of puberty. Certainly, in seasonal breeders melatonin regulates reproductive physiology and influences the age of sexual maturation in laboratory rodents. In the human, melatonin rhythms are closely related to those of reproductive hormones during infancy and reciprocally correlated during puberty. There are melatonin receptors in the brain and gonads, and sex hormone receptors in the pineal gland but functional relationships have not been demonstrated.

In pediatric practice the pineal is important in two, sometimes related, contexts: rare pineal tumors and precocious puberty. Pineal tumors comprise < 1% of all intracranial tumors, are associated with precocious, delayed or absent puberty, but classically cause precocious puberty in boys. Lesions can be multifocal. About half are radiosensitive germinomas; astrocytomas, gliomas, germ cell teratomas and carcinomas also occur. Pineal destruction is usually associated with precocious puberty. Germinomas sometimes secrete HCG and alpha-fetoprotein, and secreting pineoblastomas and pineocytomas (pinealomas) occur.

Signs of raised intracranial pressure are common due to aqueduct compression. Visual loss, paresis of upward gaze and hypothalamic dysfunction (obesity, loss of temperature control, DI) may occur. Surgery is hazardous. Most pineal tumors recur after radiotherapy but germinomas are curable.

The pineal normally calcifies to varying extent with age. It is rarely seen radiographically before 6 years, is found in 2% by 8 years and 10% by 15 years (30% on CT scan). CT or MRI is indicated if calcification is seen on skull radiographs up to about 10 years and in any boy with central precocious puberty.

## THE THYMUS

The thymus comprises cells of two origins. The epithelial component derives from 3rd and 4th pharyngeal pouches, the same embryological origin as the parathyroids. Thymic migration to the thorax from about 6 weeks is associated with parathyroid migration and branchial (pharyngeal) arch organization to form the aortic arch and other structures. Abnormal thymic stromal differentiation results in DiGeorge syndrome, where disruption of TGF-beta signaling in neural crest stem cells may be responsible for at least some of the phenotypic features.<sup>247</sup>

T-lymphocyte progenitors travel from fetal liver and, postnatally, from bone marrow and undergo maturation within the thymus to form T lymphocytes – the lymphoid component. Thymic stromal cells manufacture humoral substances, thymosin and thymopoietin, thought to be important in this maturational process. The thymus is the major site of production of immunocompetent T lymphocytes from their hematopoietic stem cells. Thymic hormones induce in situ T-cell marker differentiation, expression and functions. These polypeptide hormones localize in the reticulo-epithe-

lial (RE) cells of the thymic cellular microenvironment. Thymosin derivatives have been detected as products of neoplastically transformed cells and employed in the early diagnosis of neoplasms. In clinical trials, thymic hormones strengthen the effects of immunomodulators in immunodeficiencies, autoimmune diseases and neoplastic malignancies.<sup>248</sup>

Thymus and other lymphoid tissues reach their greatest proportion of body weight at birth, and by puberty are nearly twice their size in the young adult. The decline to adult size is probably sex steroid mediated. Adrenalectomy delays involution and severe infection or stress hastens it. In addition to its central role in immune regulation, the thymus may influence non-immunological components of the body, including the neuroendocrine system.

Cellular immune deficiencies of aging correspond to decline in function of the hypothalamo-pituitary–endocrine axis. Recent studies point to important roles for the pituitary, the pineal and the autonomic nervous system as well as the thyroid, gonads and adrenals in thymus integrity and function. Thymic function at the local level requires complex cellular interactions among thymic stromal cells and developing thymocytes, involving paracrine and autocrine mediators including interleukins and interferon-gamma. An important endocrine function of the thymus is to package zinc in zinc-thymulin for delivery to the periphery.<sup>249</sup>

Thymic tumors are rare but may arise from either tissue component. There is an association with myasthenia gravis, and tumors secreting an ACTH-like substance causing Cushing syndrome are described.

## THE THYROID GLAND

### EMBRYOLOGY

The thyroid gland develops as an epithelial proliferation in the pharyngeal gut floor at 17 days between what will become the body and root of the tongue – the foramen caecum. It descends as a bilobed diverticulum in front of the pharyngeal gut, still connected to it by a canal – the thyroglossal duct. This normally disappears but cystic remnants may persist – a thyroglossal cyst. Migration continues in front of hyoid bone and laryngeal cartilages to the definitive position in front of the trachea by 7 weeks.

### PHYSIOLOGY

By 30 min post delivery, TSH levels surge, perhaps reacting to the cooler extrauterine environment. In response, within 28 h, total and free T3 and T4 levels rise – TBG levels do not change. High rT3 levels fall gradually over weeks. The importance of ‘physiological neonatal hyperthyroidism’ is not known, but animal data suggest a role in catecholamine-mediated brown fat and nonshivering thermogenesis.

Normal thyroid function is crucial in infancy and childhood because of its importance for normal somatic and brain growth and development. Thyroid hormone actions include protein synthesis, cholesterol turnover, water and ion transport and thermogenesis. There are direct and indirect (growth factor synthesis) effects on growth and CNS and skeletal development.

The thyroid concentrates iodide from blood (as do other tissues – salivary and mammary glands, placenta, uterus, stomach and small bowel) and (uniquely) combines it with tyrosine to form metabolically active derivatives. Endemic dietary iodine deficiency is the commonest cause of hypothyroidism and affects some 300 million people worldwide. This has implications for fetal CNS development<sup>250</sup> – see below.

Steps in thyroid hormone biosynthesis are summarized in [Figure 15.45](#). Inborn errors of each step are described and comprise about 10% of neonates with congenital non-endemic hypothyroidism. Transport of iodide into thyroid cells is rate limiting. Iodide oxidation (activation) is followed by peroxidase-catalyzed tyrosine iodination and iodotyrosine coupling to form T3 and T4. Thyroglobulin (TG), a high molecular weight iodinated glycoprotein, provides tyrosyl residues for iodotyrosine synthesis (any other physiological role is speculative) and reaches the circulation via thyroid lymphatics. Mono- and di-iodo tyrosines (MIT and DIT), T3 and T4 are stored as extracellular colloid. Thyroid hormone secretion involves formation of intracellular colloid droplets, fusion with lysosomes, proteolytic digestion and hydrolysis of thyroglobulin to form free

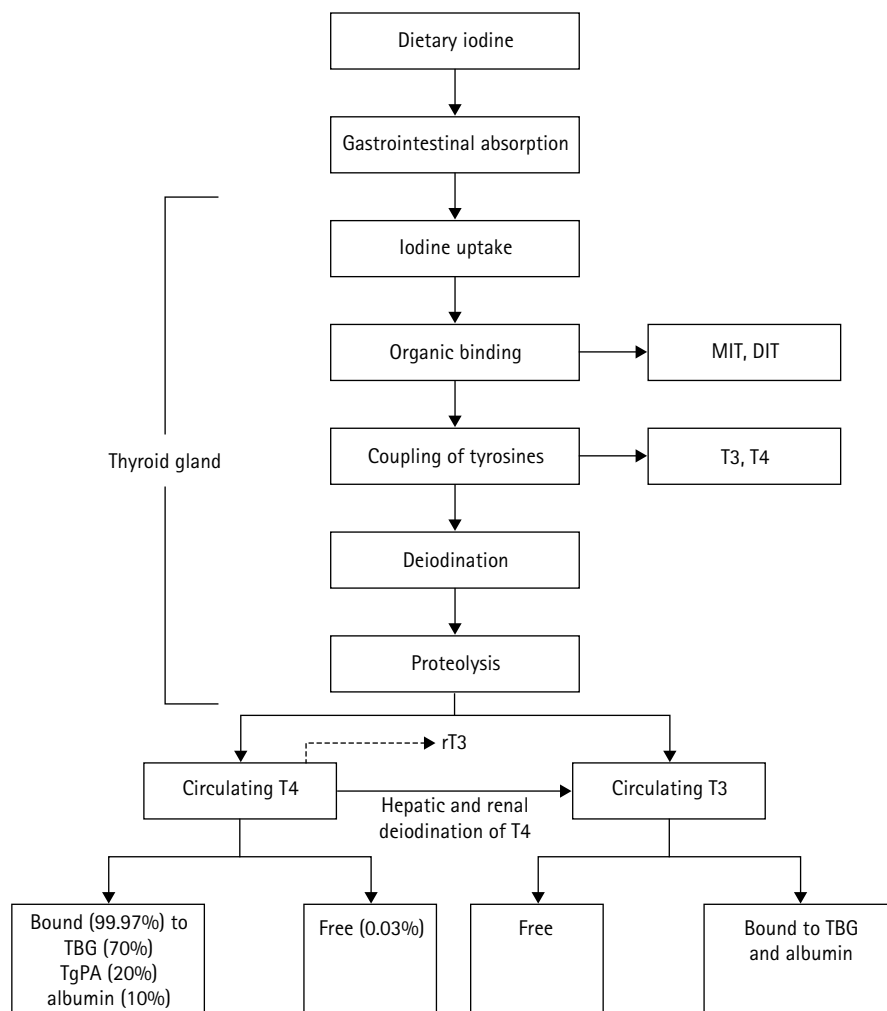

Fig. 15.45 Thyroid hormone biosynthesis. DIT, di-iodo tyrosine; MIT, mono-iodo tyrosine; TBG, thyroxine binding globulin; TgPA, thyroglobulin antibody by passive agglutination.

MIT, DIT, T3 and T4. T3 and T4 are released into the circulation; MIT and DIT are deiodinated and free iodide is reutilized for hormone synthesis.

Physiological thyroid hormone action at cellular level is by binding to a specific nuclear plasma membrane and mitochondrial receptors. T3 binding to nuclear receptors seems most important.

For many years it was believed that maternal thyroid hormones did not reach the developing embryo and fetus throughout gestation. More recent research has shown that this is not the case and that these hormones, derived from the mother, probably do exert important developmental effects on the fetal brain.

There is evidence from animal (largely rat) experiments that if the fetal thyroid gland is underactive (congenital hypothyroidism), the transfer of normal amounts of maternal thyroxine (T4) is crucial and protects the fetal brain until birth.<sup>22</sup> Most of the results from animal experiments seem relevant in man, and some, such as the transfer of maternal hormones from mother to fetus during pregnancy and their protective effects on the fetal brain of infants with congenital hypothyroidism, have also been directly demonstrated in man.<sup>21</sup>

Specifically, current evidence suggests that if fetal thyroid secretion is impaired (congenital hypothyroidism), transfer of maternal thyroid hormone (thyroxine, T4) is normally sufficient to enable the fetal brain to convert this thyroxine to triiodothyronine (T3) upon which fetal brain growth and development is dependent, and thus to avoid major subsequent neurodevelopmental problems until birth. The protective effect of normal maternal circulating T4 concentrations ends at birth and cerebral T3 deficiency in the newborn follows, which is why treatment with thyroxine must be started in the congenitally hypothyroid baby within a few weeks of birth.

In some parts of the world, severe iodine deficiency is endemic amongst the population and can result in low maternal T4 levels during early pregnancy. In that situation even prompt treatment of the congenitally hypothyroid baby with thyroxine following birth does not prevent the child from having neurological problems and cognitive and intellectual impairment. This emphasizes the crucial role of maternal thyroxine in the development of the fetal brain in early pregnancy.<sup>250</sup>

Thus the effects of congenital hypothyroidism alone on fetal brain growth and development do not result in significant or irreversible neurodevelopmental abnormalities. The central nervous system damage in congenital hypothyroidism is preventable by adequate early postnatal thyroxine treatment provided maternal thyroid status has been adequate during the pregnancy. This is also demonstrated by the generally good results (normal mental and psychomotor development) achieved in this condition following prompt detection (by newborn screening) and early postnatal thyroxine treatment in adequate dosage (see below).

## REGULATION OF FUNCTION

Plasma iodide and circulating TSH levels regulate thyroid follicular cell function. Circulating FT4 exerts negative feedback on TSH release. Seventy-five to eighty percent of circulating FT3 is produced by deiodination of T4 in peripheral tissues. The control mechanism for production of T3 in nonthyroidal tissue is poorly understood but during many disease states or fasting T4 conversion to T3 is reduced and (inactive) rT3 accumulates. T3 has 3–4 times the potency of T4 and binds to cell membrane receptor proteins with 10-fold greater affinity.

## THYROID FUNCTION TESTS (TFTs)

Normal ranges for TFTs are age related and vary between laboratories. The most sensitive single test of primary thyroid disease is plasma TSH immunoradiometric assay (IRMA). In primary hypothyroidism levels are raised; in hyperthyroidism (or overtreatment of hypothyroidism) levels are suppressed, usually to below the assay detection limit (<0.1mU/L). RIA TSH measurement will not reliably distinguish appropriate from excessive replacement.

Total T3 (TT3) and T4 (TT4) levels reflect TBG levels; free (active) hormone measurements (FT3, FT4) reflect functional thyroid status more accurately. T3 may be a more sensitive guide to developing thyrotoxicosis than T4 if TSH IRMA assays are unavailable, but diagnosis on clinical examination is seldom problematic.

Biochemical assessment strategies are reviewed by Vanderscheuren-Lodeweyckx.<sup>251</sup> It is good practice to measure TSH and FT4 simultaneously to assess the whole axis. TRH tests are no longer considered useful in assessing hypothalamo-pituitary function, and they are not of practical use either for diagnosing central hypothyroidism or discriminating between hypothalamic and pituitary disorders.<sup>252</sup>

Most specific situations where nonthyroidal illness, pregnancy or drug treatment causes abnormal TFTs (e.g. malnutrition, anorexia nervosa) are uncommon in pediatric practice provided tests are not performed during severe intercurrent illness. During the acute phase of such illnesses (e.g. severe burns or trauma, diabetic ketoacidosis, liver or renal failure), TT3, TT4 and FT3 levels are often low, FT4 may be low or normal (depending on assay methodology); TSH may also be low or normal. During recovery, thyroid hormone levels gradually normalize, but persisting low levels, even with raised TSH levels, do not necessarily indicate hypothyroidism.

Drugs affecting TFTs include estrogens, salicylates, phenytoin, carbamazepine, glucocorticoids and propranolol. Iodide (in expectorants) can cause clinical, as well as biochemical, hypothyroidism.

Apparent thyroid disorders in euthyroid patients due to abnormal carrier proteins will not cause confusion if free hormone and IRMA TSH assays are available. Children with hereditary TBG deficiency (X-linked dominant inheritance, incidence 1 in 10 000, males:females 9:1) will have low TT4 and TT3 levels; high levels of TBG, and thus of TT4 and TT3, are seen during estrogen therapy. In both situations, FT4, FT3 and TSH levels are normal and the patient is clinically euthyroid.

Raised TSH levels with normal FT4 levels in treated hypothyroidism may indicate poor compliance (other than just before a clinic visit). TFTs must always be considered in the context of growth velocity and skeletal maturation and not in isolation (see earlier). Clinical examination alone for signs of hypothyroidism or thyrotoxicosis is a very insensitive guide.

## FUNCTION IN PRETERM INFANTS

TT4 and FT4 levels increase with gestation – ~25% of preterm infants have low levels by term standards (50% at less than 30 weeks). FT4 levels are never as low as in congenital hypothyroidism. There is presumed hypothalamic immaturity: TSH levels may be normal or low; TSH and T4 levels rise normally following TRH. T4 levels correct spontaneously with maturation over 4–8 weeks, postnatal growth and development are normal and treatment is unnecessary. This has implications for screening programs and the timing of retesting of preterm babies so that cases of congenital hypothyroidism in the preterm are not missed and whether this should be postnatal age- or birth weight-related.

There are babies (term or preterm), however, with significantly reduced FT4 levels (into the congenital hypothyroidism range). This seems much more common in Europe than the USA (perhaps reflecting relative iodine availability). Prevalence in Belgium is 20% in the preterm and related to gestational length.<sup>253</sup> Cord blood T4 and TSH levels are normal for gestation. In many, thyroid function quickly normalizes; in others, recovery may take 1–2 months and treatment has been thought to be necessary (based on observational studies) in order to prevent abnormal neurodevelopmental outcomes. Although a Cochrane review<sup>254</sup> does not support the use of thyroid hormones in preterm infants to reduce neonatal mortality, improve neurodevelopmental

outcome or reduce the severity of respiratory distress syndrome, a further study with 10 year follow-up<sup>255</sup> shows benefit in those less than 28 weeks' gestation but a worse outcome at 29 weeks' gestation. The influences of many postnatal illnesses and drug usage are important in the preterm<sup>256</sup> and further large scale studies are warranted.

Transient hypothyroidism may occur in preterm infants exposed in utero to maternal iodine-containing drugs or following injection of radiographic contrast agents. Low T3 levels are commonly seen in preterm infants and may persist for 1–2 months. They are due to the lower T3 postnatal surge and reduced conversion of T4 to T3 in peripheral tissues resulting from, e.g. birth asphyxia, hypoglycemia, hypocalcemia and relative malnutrition. FT4 and TSH levels are usually normal for gestational age and no treatment is necessary.

## HYPOFUNCTION

### Congenital *Thyroid dysgenesis*

The commonest cause of congenital hypothyroidism is aplastic, hypoplastic or ectopic thyroid tissue – thyroid dysgenesis – occurring with consistent prevalence worldwide: 1 in 3500 to 4500 births. Females are twice as commonly affected but familial cases are rare – nearly all occur sporadically and idiopathically although there is increased incidence in Down syndrome babies and seasonal variation. In 50% there is some functioning thyroid tissue resulting in a spectrum of severity of hypothyroidism. There is generally no relationship with maternal thyroid function, treatment with thyroxine or thyroid autoimmune status. A role for immunoglobulins which block TSH-stimulated thyroid cell growth in vitro in pathogenesis remains speculative.

### *Dyshormonogenesis (inborn errors of thyroid hormone biosynthesis)*

Autosomal recessively inherited defects in thyroid hormone biosynthesis are the second commonest causes of congenital hypothyroidism, accounting for about 10% of those identified on screening (i.e. about 1 in 40 000 births). Presence of a goiter at birth is strongly suggestive but may not develop for months or years. There is a spectrum of hypofunction but it is generally less severe than in the dysgenetic group. Sex incidence is equal.

A defect may occur at any biosynthetic step (Fig. 15.45):

1. Decreased TSH responsiveness – very rare.
2. Decreased trapping of iodide: thyroid enlargement and reduced (or virtually absent) radioiodine (RAI) uptake by thyroid and tissues such as salivary glands and gastric mucosa.
3. Defective organification: peroxidase deficiency (defective oxidation of thyroidal iodide to reactive iodine). The association with high tone or complete nerve deafness (Pendred syndrome, 2 per 100 000 children of school age) is not due to peroxidase deficiency – the precise etiology of the thyroid biosynthetic defect (and deafness) is unknown. Together, these are the commonest dyshormonogenetic defects. In peroxidase deficiency (and most Pendred patients) there is a rapid fall in thyroid radioactivity with thiocyanate or perchlorate after radioiodine administration.
4. Defective iodotyrosine coupling or deiodination: nondeiodination of MIT and DIT leads to their leakage from the gland, urinary excretion and iodine loss.
5. Abnormal thyroglobulin synthesis, storage or release.

### *Hypothalamo-pituitary (tertiary/secondary) congenital hypothyroidism*

Congenital hypothyroidism due to TRH or TSH deficiency may be familial or sporadic, isolated or associated with other hypothalamo-pituitary deficiencies and can be associated with anatomical defects (e.g. absent pituitary or sella turcica). Prevalence is about 1 in 100 000 births. Associated hypothyroidism will be missed by TSH screening. This is not critically important – there are often associated features (dysmorphism, micropenis, hypoglycemia) drawing attention to the differential diagnosis. Hypothyroidism is generally mild and treatment can be unnecessary for some months.

### Clinical and laboratory features

During the early weeks of life, babies are usually asymptomatic and early clinical signs are nonspecific (Fig. 15.46): even in resource rich countries only about 5% are diagnosed before the positive screening result and only ~50% can be diagnosed reliably before 3 months, by when subsequent neurodevelopmental problems are much more likely. No screening program is totally reliable – there must still be clinical suspicion in certain circumstances. Important features include: umbilical hernia, wide posterior fontanelle or goiter at birth, a placid, sleepy, 'good' baby, poor feeding, constipation, hypothermia, peripheral cyanosis, edema, prolonged physiological jaundice. More specific features such as the coarse facies, large tongue, hoarse cry, dry skin and low hair line are late signs.

Biochemically, both dysgenetic and dyshormonogenetic groups have low T4 and high TSH levels after neonatal changes have settled. About 1 in 6 will have T4 levels in the lower part of the normal range.

### Screening

Although clinical detection of congenital hypothyroidism is unreliable, no screening program is 100% specific and sensitive: there may be laboratory error or communication breakdown between laboratory and clinician, and there is a minority of affected babies in whom the screening result will be normal. Up to 10% of babies with congenital hypothyroidism will not have grossly elevated screening TSH values. Where TSH is used for screening, hypothyroidism due to hypothalamic or pituitary disease will be missed; where T4 (followed by TSH for the lower range of T4 values) is used, a 10th centile or absolute T4 level of 130–140 nmol/L cut-off is used as <20% of affected babies have low normal (90–140 nmol/L) T4 levels.

All abnormal or suspicious screening results must be confirmed before the infant is committed to long term therapy but it is safer to start thyroxine whilst definitive results are awaited. If they are normal, full reassessment is necessary.

### Scanning

Thyroid scans using  $^{99m}\text{Tc}$ -pertechnetate or  $^{123}\text{I}$ -labeled sodium iodide (the latter has the advantage of shorter half-life and better concentration in the thyroid) may be helpful in the newborn for detection and anatomical localization of functioning thyroid tissue and to exclude the commonest dyshormonogenetic defect (organification). The technique is relatively invasive, time-consuming and expensive, and results can be unreliable, especially when tests are performed by inexperienced investigators. Misleading results can also result from maternal blocking immunoglobulins or perinatal iodine contamination.

Such 'functional' scans may be supplemented by 'structural' ultrasound scanning (inexpensive and rapid) which will provide complementary information in skilled hands. Ultrasound can reveal whether thyroid tissue is present in the normal position but is poor at detecting ectopic thyroid tissue. If no gland is detectable with normal T3 but low T4 levels and measurable levels of thyroglobulin, an ectopic rest of thyroid tissue is likely. From a practical management perspective, the need for scanning (either or both modalities) remains controversial.

Following  $^{123}\text{I}$ -labeled sodium iodide scanning, most dyshormonogenetic defects (other than of iodide trapping) will show high or normal isotope uptake and normal thyroid position and anatomy. In the commonest defect (peroxidase deficiency) there is discharge of 60–70% of radioactive iodide within 1 h following perchlorate. If organification is normal, less than 5–10% is discharged within 1 h. Frequencies of different possible biosynthetic defects are unknown although molecular genetic studies have revealed mutations in the thyroid peroxidase (TPO) and thyroglobulin genes in some familial cases.<sup>257</sup>

### Treatment

Once the diagnosis is suspected, treatment is urgent and should be started immediately blood has been taken for definitive testing without waiting for those results. Sodium-l-thyroxine (l-T4) is the treatment of choice as it is reliably absorbed and its peripheral endogenous conversion to T3

Fig. 15.46 Congenital hypothyroidism presenting (a) at 3 months in 1978 (prior to UK screening) and (b) at 10 days following a raised level of TSH screening (1983).

allows automatic 'fine tuning' of function. In infancy, T4 levels should be in the upper normal range and T3 levels normal. TSH levels must not be used as a guide to treatment efficacy in infancy – in > 50% the feedback set point is abnormal and TSH levels remain high in the presence of adequate replacement and normal T4.

A starting dose of l-T4 of 15 mcg/kg orally (or, conveniently, 50 mcg) once daily is appropriate and ~ 15 mcg/kg is usually appropriate throughout infancy. Recent data confirm that it is better to suppress TSH levels as quickly as possible (using higher doses than previously recommended) rather than simply normalizing free T4 levels.<sup>258,259</sup> Marginal over-replacement can generally be compensated for by endogenous deiodination but under-replacement may result in significant long term neurological impairment.

After infancy, the required daily dose is ~100 mcg/m<sup>2</sup>/24 h. Over-treatment will cause symptoms and signs of thyrotoxicosis but clinical-assessment alone only detects significant under- or over-replacement.

Growth, TFTs, bone age maturation and clinical progress (including psychomotor development) should be checked regularly during the first year. Assessment should be at 1 month and then every 3 months. It is essential that parents know the importance of giving the l-T4 regularly and do not forget or stop treatment because their baby seems normal.

By the third year of life, briefly interrupting medication will have no long term effects on brain growth and development and it is necessary to assess the need for permanent treatment. So as to minimize the time off treatment, T3 (with its shorter half-life) can be substituted for l-T4 therapy (100 mcg l-T4 is equivalent to 20 mcg T3) for 2 weeks, all treatment stopped for 7 days, thyroid function checked (and an isotope scan performed if indicated) and the previous l-T4 dose restarted immediately whilst results are awaited and assessed. Alternatively l-T4 can simply be discontinued for 2 weeks.

### Outcome

'Not the magic wand of Prospero or the brave kiss of the daughter of Hippocrates ever effected such a change as that which we are now enabled to make in these unfortunate victims, doomed heretofore to live in hopeless imbecility, an unspeakable affliction to their parents and their relatives' William Osler wrote in 1897<sup>260</sup> on the transforming effects of the then recently introduced thyroid replacement therapy. However, although gross physical manifestations of congenital hypothyroidism are abolished by treatment, significant neurodevelopmental and intellectual deficits remain unless treatment is started during the early weeks of life.

Delay beyond 3 months is particularly serious: in one study<sup>261</sup> the mean IQ with treatment before 3 months was 89, 70 if started between 3 and 6 months and 54 after 6 months. With screening programs, sufficiently early diagnosis is almost always possible and neurodevelopmental prognosis good. At 2 years, children adequately treated before 4 weeks show no differences from controls on the Bayley mental development index, and at 3, 4 and 5 years, in Stanford Binet IQ assessment in contrast to those inadequately treated.<sup>262</sup> However, there may be subtle deficiencies in hearing/speech performance scales at 1 year and practical reasoning at 18 months and 3 years and, possibly, in motor and perceptual abilities, speech, behavior and personality.<sup>258</sup>

It seems that a low T4 level (< 30–40 nmol/L) at diagnosis is associated with a deficit in mental development.<sup>263</sup> A recent comprehensive UK survey<sup>264</sup> has demonstrated a discontinuous effect of severity of congenital hypothyroidism with a risk of a 10 point IQ deficit with initial thyroxine level of < 40 nmol/L. Lower social class (perhaps also associated with poorer compliance) accounted for another 10 point IQ decrement. Up to 10% needed special education<sup>40</sup> in contrast to other studies.<sup>265</sup> Surprisingly, timing of onset of treatment did not seem important.

### Acquired

Hypothyroidism may develop, usually insidiously, at any age. Important causes are summarized in Table 15.13.

#### Endemic iodine deficiency

Worldwide, ~ 300 million people have endemic goiter. Simple iodine deficiency is generally responsible but genetic factors may predispose and environmental goitrogens (e.g. *Brassica* vegetables) potentiate the

**Table 15.13** Important causes of acquired hypothyroidism in childhood

Autoimmune thyroiditis
Thyroid dysgenesis
Endemic iodine deficiency
Exposure to goitrogens
Hypothalamo-pituitary disease (TRH/TSH deficiency)

effects. Iodine deficiency leads to deficient thyroid hormone production. TSH hypersecretion and increased iodide trapping with goiter and raised T3:T4 ratio. Such compensatory mechanisms can result in euthyroidism with goiter or varying degrees of goitrous hypothyroidism. In endemic areas < 8% of the population may be affected.

The problem is still common in some areas of Europe, Scandinavia and the Middle East including Switzerland, Finland, Austria, Germany, Italy, Spain, Greece, Lebanon and Iraq. In Switzerland and Finland iodination of salt is effectively reducing the prevalence – endemic cretinism is now uncommon.

In the context of low maternal T4 levels during early pregnancy, even prompt treatment of the baby with thyroxine following birth does not prevent the child from having neurological problems and cognitive and intellectual impairment (see above). The introduction of iodized salt in Denmark (where iodine intake was low) has resulted in a small increase in the incidence of autoimmune hypothyroidism, predominantly in young people against a background of low rates of overt hypothyroidism.<sup>266</sup>

#### Autoimmune (Hashimoto) thyroiditis

This commonest cause of acquired hypothyroidism in non-endemic areas of iodine deficiency was described by Hashimoto in 1912. Girls are much more commonly affected; a family history of thyroid disorders is found in about one third.

The gland, infiltrated by lymphocytes and plasma cells (delayed hypersensitivity) with fibrosis and degeneration, is generally irregularly enlarged and firm. There is prominence of normal architecture but usually no nodules. Acinar regeneration can occur – growth immunoglobulins and TSH may be important for this. One or more of several possible types of circulating antithyroid antibodies are found in about 95% at presentation but such antibodies also occur in up to 20% of the 'normal' population (some of whom may eventually develop thyroiditis). The commonest antibodies are against thyroglobulin and microsomes but antiperoxidase (now commonly available), TSH-receptor blocking or stimulating, colloid and thyroid growth inhibiting or stimulating antibodies may occur. Antinuclear factor (ANF) is particularly likely to be positive in children.

Presentation may be with euthyroid goiter, goiter with hypothyroidism or in the context of pre-existing autoimmune disease. In < 10%, and particularly at adolescence, presentation may be with signs of thyrotoxicosis. Usually, however, onset is with insidious hypothyroidism (Fig. 15.47) – classical myxedema may not occur for many months. School performance frequently deteriorates but can be attributed to other problems. Height velocity slows but this may not be recognized if children are not measured regularly – slow growth must be prolonged before a single measurement or simple observation detects conspicuous short stature.

In a still euthyroid child, diagnosis can be made on the basis of goiter, increased antiperoxidase, antithyroglobulin or antimicrosomal antibody titers, abnormal thyroid scan with positive perchlorate discharge test and biochemical signs of compensated hypothyroidism.

Associated multiple endocrine deficiency disease includes diabetes mellitus with or without adrenal insufficiency (Schmidt syndrome), hypoparathyroidism, candidiasis, pernicious anemia and thrombocytopenia. Fewer than 30% of children with type 1 diabetes mellitus will have detectable thyroid antibodies and 10% will have raised TSH levels. There is an association between autoimmune thyroid disease and a variety of cytogenetic disorders including Down, Turner, Klinefelter and Noonan syndromes. All children with diabetes mellitus and cytogenetic disorders should be screened regularly for thyroid disease.

Fig. 15.47 The result of insidious development of hypothyroidism over several years.

There is usually progressive thyroid atrophy and treatment, once started, is generally life-long. If there is initial hyperfunction, euthyroidism and eventual hypothyroidism will probably develop. Spontaneous remission is said to occur in < 30% of adolescents. Nodules in Hashimoto thyroiditis are due to lymphoid or thyroid hyperplasia and only rarely indicate malignancy.

Diffuse goiter in a euthyroid adolescent occurs commonly in non-endemic areas. Some have Hashimoto thyroiditis but in others aspiration biopsy shows a colloid goiter with no evidence of the characteristic lymphocytic infiltration and there may be autosomal dominant transmission. Although, in the medium term, the goiter usually regresses untreated, the common finding of thyroid-stimulating immunoglobulins (TSI) and the fact that a significant number of adults presenting with nodular goiters have a history of diffuse adolescent goiter suggest that autoimmune mechanisms are important for pathogenesis.

Ultrasound measurement of thyroid volume is preferable to palpation for grading goiters, and normative data for thyroid volume by ultrasound in iodine-sufficient school children are now available.<sup>367</sup>

### **Thyroid dysgenesis**

Most inborn errors of biosynthesis present in the newborn or by infancy. However, with mild compensated defects, goiter develops slowly and hypothyroidism may not develop until childhood. There is an increased incidence of thyroid dysgenesis in Down syndrome.

Ectopic and inadequately functional thyroid may present as an enlarging mass at the base of the tongue or along the course of the thyroglossal duct ('cryptothyroidism'). Removal of a 'thyroglossal cyst' may result in severe hypothyroidism if that is the only functional thyroid tissue present.

Thyroid destruction due to infiltration with cystine crystals may cause eventual hypothyroidism in children with cystinosis.

### **Exposure to goitrogens**

Foods interfering with thyroid hormone biosynthesis include cabbage, cassava and soybeans. Ingestion of a goitrogen in the context

of a genetically predisposed population or iodine deficiency is more likely to result in frank hypothyroidism. Drugs acting similarly include iodide (in proprietary expectorants), perchlorate and thiocyanate, lithium, amiodarone, phenylbutazone, aminoglutethimide, amino-salicylic acid and the specifically antithyroid drugs, carbimazole and propylthiouracil.

### **Hypothalamo-pituitary dependent hypothyroidism**

Slowing of linear growth due to TSH or associated GH deficiency is the usual presentation with a history of head injury, cranial irradiation for leukemia or medulloblastoma, meningitis or granulomatous disease. Craniopharyngioma must be excluded. There may be associated neurological signs, and symptoms or signs relating to underlying disease, or hypothalamo-pituitary dysfunction. Latent hypothalamo-pituitary hypothyroidism may develop in 'isolated' GH deficiency treated with GH and may prevent growth acceleration.

### **Thyroid hormone unresponsiveness**

Families with goiter and variable thyroid hormone unresponsiveness have been described with possible autosomal dominant or recessive inheritance. The defect may be at receptor or postreceptor level.

### **Presentation and diagnosis**

Slowing of height velocity is the earliest sign. Retrospectively, growth data (or holiday photographs) will help pinpoint age at onset. Skinfold measurements are usually increased and bone age delayed but both are common in many childhood endocrinopathies. Very delayed skeletal maturation (> 3 years over chronological age) is a particular feature. Muscle weakness is common on testing but is seldom a presenting complaint. Muscle atrophy, hypertrophy and dysfunction have been described. Classical signs of myxedema develop gradually with infiltration of many tissues (including skin) by mucopolysaccharides, hyaluronic acid and chondroitin sulfate (Fig. 15.47). Skin becomes yellow from high carotene levels and there may be tiredness (with poor school

Fig. 15.48 Alopecia associated with autoimmune hypothyroidism.

performance), cold intolerance and characteristically slow relaxation of tendon reflexes. Hypertrichosis with low hair line may occur, as may hair loss with alopecia (Fig. 15.48).

Classically pubertal delay occurs, but a significant minority develop precocious puberty and this may occur whilst the child is still clinically euthyroid. A failing thyroid gland causes hypothalamic release of TRH; consequent high TSH levels initially maintain euthyroidism but TRH also stimulates PRL and GT (LH and FSH) release causing ovarian estradiol secretion and breast development in girls and testicular (and sometimes penile) enlargement in boys. PRL may cause inhibition of gonadal stimulation by LH but not FSH resulting in sustained gonadal stimulation. A direct effect of TSH on the HCG receptor has also been described.<sup>268</sup> Clinically there is loss of consonance with breast development with or without galactorrhea in girls. Testicular (with or without penile) enlargement occurs in boys due to the FSH-dependent seminiferous tubule development. LH-dependent Leydig cell development does not occur and there is little (androgen-dependent) pubic or axillary hair development. There is no increase in height velocity, short stature and (pathognomonic) BA delay. The sella turcica may be enlarged. Why a minority of children with acquired hypothyroidism develop sexual precocity rather than pubertal delay is unexplained. On thyroid replacement therapy pubertal development arrests and there may be some regression until puberty recommences at a time appropriate to bone age maturity.

Clinical diagnosis of acquired hypothyroidism must be confirmed biochemically before treatment is started. Low total or free T4 or T3 levels confirm hypothyroidism, raised TSH levels that the defect is at thyroid level. A goiter necessitates thyroid and other autoantibody measurement. If there is no goiter, or no evidence of autoimmune disease, thyroid scanning to exclude dysgenesis is valuable.

Inappropriately low (i.e. low or normal) TSH levels for low T3 or T4 levels suggest hypothalamic or pituitary disease. With acquired TSH deficiency, pituitary function and neuroradiological tests are necessary to identify other pituitary hormone deficiencies and exclude a pituitary tumor.

### Treatment

The drug of choice is sodium-L-thyroxine (L-T4) – usually ~100 mcg/m<sup>2</sup>/24 h once daily but precisely adjusted individually. Catch-up growth usually follows onset of treatment and height prognosis is favorable in

comparison with most growth disorders. However, it is important to interpret height velocity on treatment in the context of accurate assessment of rate of bone age maturation. Inappropriately rapid skeletal maturation for height velocity indicates overtreatment and will result irretrievably in stunting due to early epiphyseal fusion. IRMA TSH levels are sensitive markers of over-replacement, under-replacement or noncompliance (except in hypothalamo-pituitary disease).

There is still controversy about whether to treat euthyroid patients with compensated autoimmune hypothyroidism. Treatment does not alter the natural progression of the disease and chronic oversecretion of TRH/TSH is not generally associated with problems (although there are theoretical risks in children treated with radiotherapy for brain tumors), but enlarged pituitary fossa and secondary pituitary failure have been described. Often free T4 levels are low and treatment should certainly start if so or growth velocity is slow.

### Outcome

Mental retardation does not occur in late onset hypothyroidism. School performance and growth improve on appropriate replacement therapy. Final height is normal for the family.

## HYPERFUNCTION

### Neonatal

Neonatal thyrotoxicosis is rare and usually due to transplacental passage of TSI from a mother with active or inactive Graves' disease or Hashimoto thyroiditis. High maternal antibody titers are strong predictors of neonatal disease in a clinically euthyroid mother whose disease has been inactive for many years. Only 1.5% of mothers with thyrotoxicosis due to Graves' disease will have affected babies. Thyrotoxicosis is nevertheless rare in pregnancy – autoimmune disease tends to remit during pregnancy and anovulatory cycles are common in thyrotoxic women.

Goiter may be present at birth and an irritable infant rapidly develops tachycardia, dysrhythmias, flushing, hypertension and weight loss (until cardiac failure supervenes) despite ravenous hunger. There may be associated jaundice, hepatosplenomegaly and a bleeding tendency due to thrombocytopenia and low prothrombin levels. In some, symptoms and signs are delayed for 7–10 days either because of transplacental passage of maternal antithyroid drugs or postnatal T4 to T3 conversion.

Total and free T4 and T3 levels are high and TSH suppressed within a few days – cord blood levels may be normal. The half-life of TSI is 2–3 weeks and clinical resolution of the disorder mirrors their degradation – the condition is generally self-limiting over 4–12 weeks. In severely affected babies, mortality may be as high as 25% due to cardiac arrhythmias or high output failure. Propranolol (1–2 mg/kg/24 h) with carbimazole (0.5–1 mg/kg/24 h) and Lugol's iodine (5% iodine, 10% potassium iodide, 8 mg tds) to inhibit thyroid hormone synthesis and secretion may be life saving. Satisfactory response is usually seen within 24–36 h. As thyrotoxicosis comes under control, iodine and propranolol can be gradually withdrawn and carbimazole gradually discontinued from about 6 weeks. Rarely, persisting hyperthyroidism suggests early onset Graves' disease.

### Graves' disease

In children, thyrotoxicosis is nearly always due to Graves' disease, is much rarer than hypothyroidism and rarer than in adults – only about 5% of patients with Graves' disease present in childhood or adolescence, usually in the second decade. It is 3–5-fold more common in girls. As in Hashimoto thyroiditis, there is evidence of an autoimmune disorder on a background of genetic (HLA A1, B8, DR3) predisposition and positive family history of thyroid disease in about 60%.

The thyrotoxicosis is due to thyroid follicular cell TSH receptor IgG antibodies – thyroid stimulating immunoglobulins (TSI) – which bind to the extracellular receptor domain stimulating thyroid hormone release analogously to TSH via the adenylyl cyclase cAMP system. They do not cause the eye signs although these too are immunologically mediated.

The TSH receptor is a 744 amino acid, single chain, polypeptide glycoprotein member of the guanine-nucleotide binding (G) protein-coupled receptor family and represents the primary target antigen for autoantibodies mediating the hyperthyroidism and goiter of Graves' disease. Glycosylation is necessary for receptor expression and hormone-receptor interactions.

### Clinical features

The onset may be insidious and is usually well established before presentation to a physician. As in hypothyroidism, poor school performance may be marked, but usually from poor concentration, tiredness and behavior disturbances with temper tantrums and emotional lability. There is marked weight loss despite rapid growth and enormous appetite. The gland is usually diffusely enlarged and often with a bruit. Many systemic (tachycardia, tremor and sweating) and eye (staring due to lid retraction, wide palpebral aperture and lid lag) signs reflect sympathetic overactivity. Periorbital puffiness, exophthalmos, chemosis and squint due to infiltration of the orbit, lacrimal glands and ocular muscles occur less commonly and severely than in adults, but exophthalmos in particular may persist once euthyroidism is established. Pretibial myxedema characteristic of adults is rare in children.

### Diagnosis

In children, a clinical diagnosis can usually be made confidently, but there must be biochemical confirmation and hyperthyroidism secondary to TSH hypersecretion must be excluded. Usually free and total T4 levels are high (occasionally they are normal but T3 levels are raised) and TSH is suppressed even using a sensitive (IRMA) assay. TSI are positive. Skeletal maturity is generally advanced disproportionately for the rapid growth.

### Treatment

Treatment aims to reduce excessive thyroid hormone secretion and blunt the somatic consequences (largely mediated via beta-adrenergic pathways). The former may be achieved with antithyroid drugs (e.g. carbimazole or propylthiouracil), surgery (subtotal thyroidectomy) or radioactive iodine (<sup>131</sup>I). In childhood, in most centers, antithyroid drugs are the initial treatment of choice. These inhibit diiodotyrosine and iodothyronine formation and, to some extent, tyrosine iodination. Thyroid function normalizes by 3–4 weeks. The initial dose of carbimazole in childhood is 0.5 mg/kg/24 h and of propylthiouracil 5 mg/kg/24 h, both in three divided doses.

Skin rashes occur in 2–3% on either drug but are usually transient and a change of therapy is not usually necessary, particularly if antihistamine is used symptomatically. More seriously, agranulocytosis may occur idiosyncratically, unpredicted from serial blood counts. Full recovery usually occurs on stopping treatment and the alternative generally substituted as cross-reactivity is rare. Progressive neutropenia can also occur: symptoms such as sore throat must be taken seriously and blood count checked regularly.

Once clinical and biochemical euthyroidism is achieved, it is probably beneficial (in terms of reducing both the goiter and necessity for frequent monitoring of thyroid function for developing hypothyroidism) to add l-thyroxine to an appropriate (usually half to one third of initial dose) antithyroid medication. Combination therapy has also been reported to decrease production of TSI and the frequency of thyrotoxicosis recurrence in adults.

Although antithyroid drugs do not alter the natural disease process, they do, in most children, allow maintenance of euthyroidism until spontaneous remission occurs (usually after about 2 years). Signs that this is not the case include persisting goiter and continuing presence of TSI. In any case there is a high relapse rate (50–70% within 2 years).

Beta-blockers (e.g. propranolol) are valuable during the first 2–3 weeks of treatment in providing symptomatic relief of tachycardia, nervousness and tremor and can then be discontinued as the specific antithyroid drug becomes clinically effective.

*Subtotal thyroidectomy* may be the treatment of choice in young adults in whom hyperthyroidism has returned after > 2 years of medi-

cal treatment or if compliance with treatment is poor – and, because of high relapse rates on medical treatment, is the primary treatment of choice in some centers with a surgeon experienced in thyroid surgery. Patients must be made euthyroid before surgery, in which case morbidity and mortality are comparable to other major procedures. Specific complications include laryngeal nerve palsy (transient or permanent), transient hypocalcemia (~10%) and permanent hypoparathyroidism (~1%). One year post surgery, 80% are euthyroid, 15% have permanent hypothyroidism (easily treated with thyroxine) and 5% are still thyrotoxic. Either thyrotoxicosis or hypothyroidism may develop many years after surgery in a previously euthyroid patient.

*Radioactive iodine* (<sup>131</sup>I iodide) is the treatment of choice if judged by ease of administration, efficacy, short term safety and cost.<sup>269</sup> UK use has traditionally been restricted to adults > 40 years because of fears (based on few data) that risks of congenital malformations in subsequent pregnancies are increased or, if used in younger patients, leukemia or thyroid cancer could result – radiation is indeed an important cause of thyroid cancer in children<sup>270</sup> as the short-lived radioactive fallout caused by the 1986 Chernobyl nuclear power plant accident demonstrated.<sup>271</sup> However the evidence suggests that treating young people, including pediatric patients, with radioiodine is effective and safe in the long term (> 30 years follow-up).<sup>272</sup> A lower age cut-off of 17 years is still recommended in the USA.<sup>273</sup>

Generally, use in UK pediatric practice has been restricted to poorly compliant adolescents who cannot be rendered euthyroid for surgery, but with increasing long term experience practice may change. There is a high incidence of hypothyroidism (25% in the first year, a subsequent annual rate of 24% and an incidence of 80% by 15 years post treatment).

### Hashimoto thyroiditis

About 5–10% of children with Hashimoto thyroiditis present with hyperthyroidism, particularly in adolescence. Occasionally Graves' disease and Hashimoto thyroiditis coexist: there are clinical and laboratory features of the latter with TSI antibodies present. Treatment is as for Graves' disease.

### TSH hypersecretion

This is a rare cause of thyrotoxicosis, described either with a pituitary TSH-secreting tumor or a defect in TSH feedback inhibition by T3 causing goitrous hyperthyroidism associated with high TSH levels – an indication for neuroradiological evaluation.

### Autonomous functioning nodules

These are uncommon in children and adolescents, usually occurring after ~35 years. Occasionally, single nodules of follicular adenoma (diameter > 3 mm) are found in association with thyrotoxicosis. Diagnosis is by isotope scanning. Carcinoma occurs in less than 1% of functional nodules (see below).

### NEOPLASIA (Table 15.14)

A history of head and neck irradiation was common in children presenting with thyroid neoplasia and the latter is common following

Table 15.14 Types of thyroid neoplasia

Follicular (epithelial) tumors
Follicular adenoma
Follicular carcinoma
Papillary carcinoma
Anaplastic carcinoma
Nonfollicular tumors
Medullary carcinoma
Lymphoma
Teratoma
Miscellaneous

Chernobyl<sup>271</sup> – see above. Palpable thyroid nodules must be taken seriously – the prevalence of malignancy in childhood thyroid nodules is probably less than 15–20% but still higher than in adults.

Thyroid neoplasia may arise from follicular epithelium (follicular adenoma and carcinoma, papillary carcinoma, anaplastic carcinoma) or other tissue (medullary carcinoma, lymphoma, teratoma, metastatic tumor). More than 50% of solitary thyroid nodules in childhood are cystic lesions or benign adenomas. Hyperfunctioning adenomas are rare and 90% of malignant nodules consist of well-differentiated follicular carcinomas. In this group, prognosis is better than for rarer types.

Features suggestive of malignancy include history of head and neck irradiation, a hard or rapidly enlarging nodule, lymphadenopathy, hoarseness, dysphagia or metastases. Nodules in Hashimoto thyroiditis rarely represent carcinomatous change. In other situations, radioisotope and ultrasound scanning are valuable for differential diagnosis. Ultrasound identifies cystic lesions (usually benign); if iodide is concentrated by the nodule(s), carcinoma is rare. Small needle aspiration biopsy<sup>274</sup> may aid further diagnosis of cystic lesions and distinguish benign from malignant lesions.

Treatment (where possible following needle biopsy histology) is surgical removal of the affected thyroid lobe and subsequent total thyroidectomy if frozen sections reveal malignancy. Radioiodine treatment postoperatively is reserved for metastatic disease or distant lymph node involvement. Prognosis is excellent even with metastatic well-differentiated follicular carcinoma. TSH must be fully suppressed chronically by adequate thyroxine therapy so as not to stimulate tumor growth or regrowth. Life expectancy is normal with follicular carcinoma but not with rarer carcinomas despite radical surgery, radiotherapy and chemotherapy.

An important rare thyroid carcinoma [medullary thyroid carcinoma (MTC), accounting for <10% of thyroid carcinomas] arises from parafollicular (C) cells and nearly always secretes calcitonin and sometimes other hormones (e.g. ACTH, serotonin, prostaglandins). Although often sporadic, they are associated with syndromes involving tumors of neuroectodermal origin (multiple endocrine neoplasia – MEN) inherited autosomal dominantly. MEN type 2 (MEN 2) comprises three syndromes: medullary thyroid carcinoma alone (familial MTC); MTC, pheochromocytoma and hyperparathyroidism (MEN 2A); and MTC, pheochromocytoma, ganglioneuromatosis and a Marfanoid habitus (MEN 2B). (MEN 1 comprises hyperparathyroidism, pancreatic islet cell tumors and pituitary adenomas.)

These familial endocrine neoplasia syndromes (MEN 1, MEN 2 and von Hippel–Lindau) can now be diagnosed genetically in childhood. The MEN 1 gene is on chromosome 11, the MEN 2 gene on chromosome 10, and children with a mutation and all offspring of affected subjects where the mutation is unknown should be screened on a regular basis (for protocols, see Johnston et al<sup>275</sup> and Brandi et al<sup>276</sup>).

The aggressive nature of the thyroid lesion, which may develop in childhood or adult life (usually before pheochromocytoma), has led to a search for markers of its presence whilst still microscopic. Calcitonin levels are usually normal at this stage but may rise significantly following pentagastrin infusion. Previously, annual stimulation tests provided the best monitor in affected children – rising levels with time as well as raised absolute values may be suspicious.<sup>275</sup>

In a family with MEN 2 cases, a predisposing RET proto-oncogene abnormality on chromosome 10 indicates whether a child (at 50% risk) has inherited the condition and will guide the timing of prophylactic thyroidectomy to prevent progression to thyroid carcinoma and lymph node metastases. Codon-specific timing of thyroidectomy may be indicated, with some (e.g. with codon 634 mutations) needing surgery well before 5 years of age.<sup>277</sup>

MEN 1 is caused by germline mutations of a tumor suppressor gene MEN1 at 11q13 coding a protein, menin, which is involved in the regulation of gene expression at the level of transcription and important for maintaining TGF-beta signaling.<sup>278</sup>

Prophylactic thyroidectomy may be justified – therapy (as well as diagnostic) consensus guidelines for MEN 2 (and MEN 1) are available.<sup>276</sup>

## PARATHYROID GLANDS AND CALCIUM METABOLISM

There are two pairs of parathyroid glands, superior and inferior, although two, five or six glands may be present in normal individuals. Paradoxically, the inferior pair originates (at ~5 weeks) from the 3rd pharyngeal pouch (endodermal) tissue, the superior pair from the 4th pouch. The inferior pair are pulled medially and caudally by the migrating thymus to the thyroid; the superior attach higher on its dorsal surface. There are two cell types: chief cells secreting parathyroid hormone (PTH) and oxyphil cells (function unknown).

Although the major function is contributing to calcium and phosphate homeostasis by PTH production, the role of the parathyroid in health and disease must be considered in conjunction with other hormones and metabolic factors.

## PHYSIOLOGY OF CALCIUM HOMEOSTASIS

Calcium must be accumulated by a growing child – 99% of total body calcium is present in the skeleton. Nevertheless, as well as for bone mineralization, calcium is important for normal endocrine and neuromuscular function at plasma membrane level, enzymatic reactions and blood coagulation, so that the 1% in extra- and intracellular fluids must be closely regulated within narrow concentration limits. Thus homeostatic control mechanisms are inevitably complex. Serum calcium concentration is maintained within normal limits by the interaction of vitamin D, PTH and calcitonin acting at three target tissues: bone, kidneys and gastrointestinal tract. Unlike calcium, normal serum inorganic phosphate levels are age related during childhood (declining from high levels in infancy).

Calcium is present in serum in three fractions in dynamic equilibrium: 50% ionized (metabolically active), 40% protein bound (inactive), the remainder complexed to phosphate, citrate, etc. The proportion of ionized calcium is controlled by vitamin D, PTH and calcitonin but is affected by acid–base changes (acidosis increases and alkalosis decreases ionized calcium levels as hydrogen ions compete with calcium for albumin binding sites). Vitamin D itself is biologically inactive and must be hydroxylated to active metabolites.

Total serum calcium is measured routinely – ionized levels may be measured directly using ion-selective electrodes. Indirect estimation of biologically active calcium using a formula may be misleading if serum protein concentrations are low. In hypoproteinemic states total calcium may be low but ionized calcium normal. Diet and diurnal variation will influence many indices of mineral and bone metabolism.

Although hypo- or hypercalcemia may be associated with disorders of vitamin D metabolism or parathyroid disease, non-endocrine disorders (e.g. chronic renal failure) may be etiologically important. Specific disorders of mineral and bone metabolism occur in infants, occasionally secondarily to maternal hyperparathyroidism.

Peak bone mass accumulation and mineralization occurs during puberty, continues into early adult life and is influenced by genetic (racial) factors, body mass, adequate calcium intake during growth and physical activity. A current recommendation for dietary calcium intake in children between 9 and 18 years so as to maximize peak bone mass and minimize fracture risk and osteoporosis in later life is 1300 mg per day.<sup>279</sup> Peak calcium accretion is attained at 12.5 years in girls and 14 years in boys. Only around 10% of adolescent girls in the USA achieve the recommended intake but separate supplementation has been reported to lower the age of menarche<sup>280</sup> which may have an adverse effect on bone mineral accretion overall.

Reduced peak bone mass occurs in GH deficiency, GT deficiency, male hypogonadism, Turner syndrome and delayed puberty. Bone mass is also reduced by malnutrition, chronic illness and anorexia nervosa. Appropriate management of these conditions will reduce risks of clinically significant osteoporosis from middle age.

## CALCIUM REGULATION IN THE FETUS AND NEONATE

Normal fetal bone mineralization requires considerable net calcium and phosphorus transfer from mother to fetus. There is active placental transport of calcium and some 80% of the total accumulates in the third trimester. Fetal blood total and ionized calcium levels exceed those in the mother by about 0.5 and 0.25 mmol/L respectively and absolute values have doubled from mid-gestation to a mean of 2.75 mmol/L at term.

PTH and calcitonin do not cross the placenta but it is not clear whether active vitamin D metabolites do. Both fetal kidney and placenta can synthesize the active metabolite 1,25-dihydroxy vitamin D. Although their importance compared with that of the maternal kidney is uncertain, it seems likely that fetal 1,25-dihydroxy D is the major stimulus to placental calcium transfer, perhaps analogously to its effect on intestinal calcium absorption.

To accommodate fetal transfer, there is increased maternal intestinal calcium absorption – calcium loss to the fetus stimulates maternal PTH secretion and maternal 1,25-dihydroxy vitamin D levels are raised. In the fetus, conversely, PTH levels are suppressed and calcitonin levels high encouraging bone mineralization.

At birth, cessation of transplacental calcium and these hormonal changes cause significant lowering of serum calcium. Lowest levels are reached, in the term neonate, between 24 and 48 h after birth; by 5 days rising PTH and falling calcitonin levels have established 'normal' serum calcium levels. Intestinal absorption of calcium and phosphate (very low in the fetus) is, suddenly, the sole mechanism and source – 1,25-dihydroxy vitamin D<sub>3</sub> secretion increases sharply.

As with other physiological changes from fetal to extrauterine life (e.g. circulatory, respiratory, bilirubin metabolism), these complex adaptations lead potentially to a variety of neonatal disorders, especially in the preterm.

### Vitamin D

Vitamin D (calciferol) is a collective term for two steroid-related, cholesterol-derived naturally occurring compounds, vitamin D<sub>2</sub> (ergocalciferol) – derived from the plant sterol ergosterol, and vitamin D<sub>3</sub> (cholecalciferol) – produced in skin by the effect of ultraviolet irradiation on a precursor (7-dehydrocholesterol) in the epidermal Malpighian layer (Fig. 15.49). In man D<sub>2</sub> and D<sub>3</sub> are equally active biologically. Serum D<sub>3</sub> levels are higher in summer than winter (reflecting differences in sunlight exposure). Pigmented skin synthesizes it less efficiently.

Plant and animal foods (e.g. fish, eggs, butter and margarine) are important sources of D<sub>2</sub> and D<sub>3</sub> respectively. Absorption is via upper small intestine and lymphatic system in chylomicrons. Normal bile salt secretion is necessary – absorption is impaired by steatorrhea. In blood, ~98% is bound to a high MW liver-derived protein which also transports and binds active vitamin D metabolites and acts as a buffer against vitamin D toxicity.

The first step in vitamin D activation (Fig. 15.49) is 25-hydroxylation in liver microsomes but bowel and kidney may contribute. 25-Hydroxy D is the major circulating metabolite but is metabolically inactive and converted in mitochondria of the proximal renal tubule to two major metabolites, proportions depending on physiological requirements: active 1,25-dihydroxy D and 24,25-dihydroxy D (some, but much less, biological activity). Other metabolites of uncertain pathophysiological significance and with varying biological activities can be formed. Placenta and bone can also hydroxylate at C1.

1,25-dihydroxy D has major effects on intestinal villus and crypt cells, osteoblasts and osteoclasts and distal renal tubular cells. The net effect is to increase serum calcium and phosphate by stimulating intestinal absorption and mobilization from bone, and reducing renal excretion. Calcium mobilization from bone is also PTH dependent.

Average total serum concentrations of 1,25-dihydroxy D are 1000-fold lower than those of 25-hydroxy D but there is only a 10-fold difference in relative concentrations of the free (metabolically active in the case of 1,25-dihydroxy D) components.

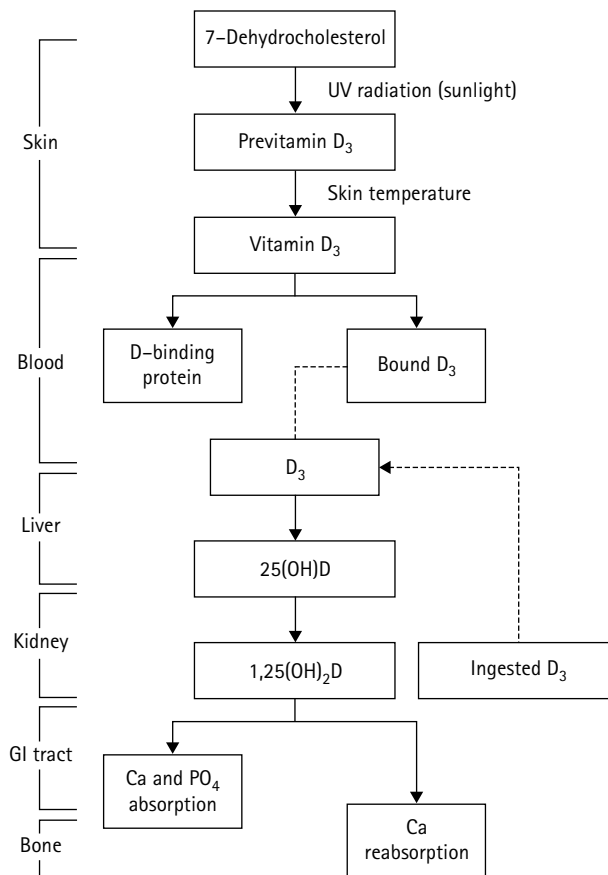

Fig. 15.49 Vitamin D metabolism and its regulation.

### Parathyroid hormone (PTH)

PTH is an 84 amino acid peptide, MW 9500; 34 amino acids at the amino- (N-) terminal are essential for receptor binding and activation and thus biological activity. The PTH gene is close to the insulin gene on the short arm of chromosome 11. PTH is synthesized by parathyroid chief cells and cleaved from higher molecular weight biologically inactive precursors which are not released into the circulation. Both intact PTH and carboxy- (C-) terminal fragments are released into the circulation and the proportion of the latter is increased in primary hyperparathyroidism. Intact PTH is metabolized by liver (predominantly) and kidney and fragments returned to the circulation. Intact PTH and N-terminal fragments are cleared rapidly (<10 min); C-terminal fragments (mainly metabolized by kidney) are cleared more slowly (2 h). Thus circulating PTH is a heterogeneous mixture of intact hormone together with N-, C-terminal and intermediate fragments.

Serum calcium concentration is the major regulator of PTH synthesis and release. There is a greater response to evolving hypocalcemia than to falling levels within the normal range. Hypercalcemia suppresses PTH secretion. Catecholamines, vitamin D metabolites and cortisol increase PTH secretion but their physiological function is doubtful.

The major role of PTH is prevention of hypocalcemia by three main mechanisms: calcium resorption from bone, renal calcium reabsorption and, indirectly, increasing intestinal calcium absorption by stimulating renal 1,25-dihydroxy D synthesis.

In bone, PTH regulates the movement of calcium between lacunar osteocytes and extracellular fluid, and influences remodeling. Osteoblasts (not osteoclasts) have PTH receptors and it is presumably release of an osteoblast factor which promotes osteoclast activation. A factor of MW 500–1000 has been postulated. PTH has several effects on renal tubules, acting distally to promote calcium and inhibit phosphate and bicarbonate reabsorption and proximally to stimulate hydroxylation at C1 to form 1,25-dihydroxy D.

Heterogeneity of circulating PTH forms makes measurement difficult. There is cross reactivity of RIAs against the intact molecule, the N- and C-terminal and the intermediate region. Because serum half-lives of intact PTH and N-terminal fragments are shorter than those of the C-terminal or intermediate fragments, the latter account for 80% of immunoreactive material measured and better reflect PTH secretion rates. Except in chronic renal failure (where C-terminal and intermediate fragments accumulate because of impaired glomerular filtration), assays specific for C-terminal or intermediate fragment PTH provide better discrimination between normal and raised PTH levels. Some PTH RIAs (and bioassays) are too insensitive to distinguish between normality and hyposecretion.

There is diurnal circadian variation in serum PTH secretion with higher values in early morning. For correct interpretation, simultaneous serum calcium and phosphate concentrations should be measured. Renal phosphate reabsorption and urinary cyclic adenosine monophosphate (cAMP) may need assessment. The ratio of tubular maximal rate of phosphate reabsorption to glomerular filtration rate is calculated from simultaneous fasting serum and urinary phosphate and creatinine concentrations and reference to nomograms – ratios are high in hypoparathyroidism and low in hyperparathyroidism. cAMP is important in PTH release into the circulation in response to hypocalcemia; measurement is useful for indirectly assessing circulating active PTH, evaluating the renal response to exogenous PTH and distinguishing pseudohypo- from hypoparathyroidism.

### Calcitonin

Calcitonin is synthesized in and secreted by thyroid parafollicular (C) cells of neuroectodermal origin. It is discussed here because of its importance in calcium metabolism.

As for insulin and PTH, the gene encoding calcitonin is on the short arm of chromosome 11. Calcitonin is a 32 amino acid peptide, MW 3500, derived from a polypeptide precursor by loss of N- and C-terminal fragments. Species differences derive from mid-molecule amino acid sequences. The entire sequence is required for biological activity. Calcitonin-like bioactive material has been identified in thymus, lung, adrenal medulla, brain and parathyroid glands but none are major sources of circulating calcitonin.

As with PTH, serum calcium concentration is the major regulator of calcitonin secretion but with opposite effect: hypercalcemia stimulates and hypocalcemia suppresses calcitonin secretion. Gastrointestinal hormones such as gastrin, glucagon and cholecystokinin stimulate calcitonin secretion as do estrogens, beta-adrenergic agonists and 1,25-dihydroxy D, but none seem physiologically important. Pentagastrin (a synthetic gastrin derivative) is used to stimulate calcitonin secretion in the diagnosis of medullary thyroid carcinoma.

More sensitive assays are helping to define calcitonin changes with age and deficiency states. In children, monomeric calcitonin (the major active circulating form) is present in very low concentrations – levels are higher in infancy.

Like PTH, calcitonin influences serum calcium levels by action on bone, kidneys and bowel. It inhibits bone resorption by reducing osteoclast cytoplasmic motility. In kidney it binds to specific receptors to increase calcium, phosphate, magnesium, sodium and potassium excretion and stimulates 1-hydroxylation in the proximal tubule to produce 1,25-dihydroxy D. This promotes intestinal calcium reabsorption indirectly but it may also have a direct, but inhibitory, effect.

The importance of calcitonin for physiological calcium metabolism regulation remains uncertain. Neither thyroidectomy nor calcitonin hypersecretion from medullary thyroid carcinoma affects serum calcium levels. Its major inhibitory effect on bone resorption is directly antagonistic to PTH and 1,25-dihydroxy D and its role in that context may be prevention of excessive resorption. It is secreted in response to eating calcium-rich food secondarily to secretion of various gastrointestinal and pancreatic hormones which itself inhibits. The net effect is delayed calcium absorption which may be important in preventing postprandial hypercalcemia and hypercalciuria.

A major physiological role may be in situations (fetal life, infancy, pregnancy and lactation) with extra needs for calcium and when calcitonin and 1,25-dihydroxy D levels are high – calcitonin may prevent unwanted bone resorption whilst allowing the stimulatory effect of vitamin D on intestinal calcium absorption.

### DISORDERS OF CALCIUM AND BONE METABOLISM

Metabolic and hormonal interactions in many of these disorders are complex.

Advances in understanding the molecular pathogenesis of disorders of calcium, vitamin D and bone, including the roles of the extracellular calcium sensor, the vitamin D receptor, and new factors for bone cell embryogenesis and function, are reviewed by Langman.<sup>281</sup>

Significant diagnostic pointers can be obtained from a full history (including family history) and specific abnormalities found on examination. To minimize effects of food and diurnal changes, blood is ideally taken in the fasting state in the morning and, when possible, without compression of the arm (venous stasis also influences calcium levels).

The important basic laboratory measurements are of serum calcium (Ca), phosphate (P) and alkaline phosphatase (ALP) which should be interpreted in the context of simultaneously estimated serum total protein and albumin, electrolytes, creatinine, magnesium and pH. Urine measurements (early morning or 24 h collections) of calcium, phosphate, creatinine and hydroxyproline (a measure of bone turnover) may be valuable. If significant abnormalities are found, more complex investigations can be instigated assessing aspects of parathyroid function, vitamin D metabolism and bone turnover as indicated.

### INFANCY

See also Ch. 12.

1. Hypocalcemia: early and late neonatal hypocalcemia
2. Hypercalcemia
  - a. Idiopathic infantile hypercalcemia (see below)
  - b. Familial hypocalciuric hypercalcemia (see below)
  - c. Neonatal primary hyperparathyroidism
  - d. Hypervitaminosis D (see below)
  - e. Other associations: fat necrosis; phosphate deficiency
3. Metabolic bone disease in the preterm infant.

### ABNORMAL 1,25-DIHYDROXY VITAMIN D SECRETION OR ACTION

#### Increased intake (hypervitaminosis D)

Vitamin D intoxication usually results from excessive treatment of hypoparathyroidism, rickets, renal osteodystrophy, etc. with concentrated preparations – it is available in proprietary multivitamin preparations without prescription in many countries and may also be prescribed inappropriately. ‘Stoss therapy’ – administration of 600 000 units for the prevention of rickets – is not now used but was formerly a cause. Toxicity may persist for many weeks because of adipose tissue storage. Despite its potency, an advantage of the synthetic analogue of 1,25-dihydroxy D (1 $\alpha$ -hydroxy D) is its short half-life with more rapid return to normocalcemia after inadvertent overdose.

Clinical signs reflect hypercalcemia from excessive intestinal calcium absorption and bone resorption. Initially, there is nausea and vomiting with anorexia, constipation and polyuria. Infants fail to thrive and become irritable. Ultimately, there may be nephrocalcinosis with renal insufficiency and ectopic calcification. Investigation confirms hypercalcemia with hypercalciuria; serum PTH will be suppressed – normal or elevated PTH with hypercalcemia indicates hyperparathyroidism.

Treatment is by withdrawing the vitamin D preparation and calcium supplements (if any), saline infusion and furosemide (to increase urinary calcium loss) and glucocorticoids (e.g. hydrocortisone 4 mg/kg/24 h 6 hourly) which gradually reduces intestinal calcium absorption.

*Idiopathic hypercalcemia of infancy* was thought to be due to excessive vitamin D administration. This is unlikely to be the case, although it remains a heterogeneous and poorly understood condition. The fall in incidence of the mild form observed in the UK preceded the reduction in vitamin D supplementation of artificial infant feeds. Incidence of the severe form often associated with mental retardation, cardiovascular abnormalities (supraaortic aortic stenosis or peripheral pulmonary stenosis) and facial and other dysmorphic features has not changed. The mild form is now rarely seen. The severe form (Williams syndrome – see Ch.14, p. 390) may be due to a defect in calcitonin synthesis or release resulting from a neural crest developmental anomaly affecting face, heart and thyroid C-cell (calcitonin-producing) precursors which would explain the variable relationship between somatic developmental abnormalities and degree of calcium homeostatic disturbance (calcium levels may be normal). The molecular genetic defect in Williams syndrome is a deletion of the elastin gene and other contiguous genes at 7q11.23.

### Increased synthesis

Hypercalcemia from raised 1,25-dihydroxy D levels (with suppressed PTH) is seen in granulomatous disease (sarcoidosis, tuberculosis, etc.) due to conversion of 25-hydroxy D into the active metabolite by 1-hydroxylation in granulomatous cells. Similar findings in some patients with lymphoma are unusual – most patients with hypercalcemia due to malignant disease have low 1,25-dihydroxy D levels and reduced intestinal calcium absorption, and other mechanisms are presumably involved.

### Increased secretion and/or responsiveness (absorptive hypercalciuria)

This specific type of 'idiopathic' hypercalciuria is thought to be due to a primary abnormality of secretion of, or responsiveness to, 1,25-dihydroxy D. It may be transmitted autosomal dominantly and cause renal stones or hematuria. A form secondary to a renal tubular defect is also found (see renal hypercalciuria below) and may share a common pathogenesis.

### Decreased formation or action (calciopenic rickets)

Rickets (Table 15.15) is caused by defective growth plate mineralization and may be due to decreased calcium and phosphate availability in extracellular fluid at those sites (deficiency or malabsorption of vitamin D, defective formation or action of 1,25-dihydroxy D – calciopenic rickets; increased renal phosphate excretion or decreased intake – phosphopenic rickets). Phosphopenic rickets is usually due to renal phosphate loss (see below) but hypophosphatemia, commonly seen in low birth weight preterm infants, is due to inadequate phosphate intake – see also Chapters 12, 16 and 18.

**Table 15.15** Classification of rickets

'Classical': lack of sunshine, diet deficient in vitamin D	Immigrants (pigmented skin); during rapid growth (infancy/puberty)
Malabsorption	Celiac disease; giardiasis; hepatobiliary disease (biliary atresia/fistula; cirrhosis; neonatal hepatitis)
Hereditary renal (mainly tubular)	Hypophosphatemic; vitamin D dependency; fibrous dysplasia/neurofibromatosis (with hypophosphatemia); Fanconi syndrome (including cystinosis, tyrosinemia, Lowe syndrome, Wilson disease); distal renal tubular acidosis
Acquired renal (mainly tubular)	Chronic renal failure (glomerular); hypophosphatemia; hypercalciuria

## ABNORMAL PTH SECRETION OR ACTION

### Increased secretion (primary hyperparathyroidism)

Increased PTH secretion may be a normal physiological compensatory response to hypocalcemia (secondary hyperparathyroidism). Primary hyperparathyroidism is due to abnormally increased secretion of PTH, is rare in childhood and uncommon even by adolescence with an overall prevalence of 25 per 100 000.

The etiology is unknown but cases may be sporadic (nearly always associated with a solitary adenoma, rarely with carcinoma) or familial (usually due to hyperplasia of all four glands). Familial cases may be isolated (autosomal dominant and recessive forms are reported), but may be associated with autosomal dominant multiple endocrine neoplasia syndromes: MEN 1 (see below) in association with pancreatic tumors or gastrinoma and pituitary adenomas; and MEN 2 with medullary thyroid carcinoma and pheochromocytoma, see p. 473. There is also an association with autosomal dominant hypocalciuric hypercalcemia syndrome where there is defective renal calcium excretion (see below).

Heterozygous germline mutations of the tumor suppressor gene MEN1 (on chromosome 11) are responsible for multiple endocrine neoplasia type 1 (MEN 1), a dominantly inherited familial cancer syndrome characterized by the combined occurrence of pituitary, parathyroid and enteropancreatic tumors.<sup>282</sup> It typically presents with clinical signs or symptoms in the middle decades of adult life but intractable peptic ulceration (Zollinger–Ellison syndrome due to a gastrin secreting pancreatic tumor) is reported by adolescence and raised gastrin and calcium levels may be found in asymptomatic family members by then. Hypercalcemia occurs in about 97% and the serial fasting serum calcium measurement is a valuable screening test. For a screening protocol see Johnston et al.<sup>275</sup>

The clinical spectrum of primary hyperparathyroidism ranges from asymptomatic to lethal. There may be fatigue, anorexia, constipation, polyuria, polydipsia, renal stones, bone pain and pathological fractures. Diagnosis depends on demonstration of inappropriately high PTH levels for hypercalcemia on three separate occasions. This is found otherwise only in familial hypocalciuric hypercalcemia (see below) where urinary calcium excretion is low for the hypercalcemia. Antibody against the C-terminal or intermediate PTH fragments is more sensitive to high PTH levels. Radiographically, there is usually generalized bone demineralization, osteolysis and subperiosteal bone resorption, especially of the phalanges and, occasionally, cysts.

Once diagnosis is secure, surgical parathyroid exploration by an experienced surgeon is necessary. Preoperative localization of the responsible gland is unreliable (although ultrasound may detect enlargement < 1 cm) – hyperplasia of all four is common. In this situation total parathyroidectomy with autotransplantation of tissue into the forearm is the treatment of choice. Other family members should be screened for hypercalcemia.

### Decreased secretion (hypoparathyroidism – HP)

HP is much more common than hypersecretion but less common than decreased peripheral hormone action ['end-organ resistance' due to receptor or postreceptor abnormalities – pseudohypoparathyroidism (PHP)].

Cases may be sporadic or familial. Presentation can be in the neonate and may be transient, permanent (autosomal dominant, recessive, sex-linked recessive and sporadic forms have all been described) or part of DiGeorge syndrome – see Chapter 14, p. 390. Postneonatal onset may be idiopathic or occur secondarily to neck surgery, irradiation, hemosiderosis, hypomagnesemia, etc.

A familial (autosomal recessive) form may be associated with autoimmune disease affecting other endocrine glands (especially Addison disease) and mucocutaneous candidiasis [polyglandular autoimmune disease (PGAD) type 1] or autoimmune polyendocrinopathy – candidiasis – ectodermal dystrophy (APECED). Presentation is with severe candidiasis (due to a defect in cellular immunity) followed, successively, by HP and Addison disease (rarely before mid-childhood). Other autoimmune

manifestations include alopecia, vitiligo, thyroiditis, chronic hepatitis and pernicious anemia. Parathyroid antibodies cause glandular destruction.

APECED results from loss-of-function mutations in the Aire gene which controls expression of self antigen in thymic epithelial cells and thus prevents autoimmunity.<sup>283</sup> Growth failure may result as the growth plate (particularly in early life) may be an additional target.

Clinical signs and symptoms of HP are from hypocalcemia due to decreased renal calcium reabsorption, bone resorption and, indirectly, decreased intestinal calcium absorption. Manifestations depend on age, severity and speed of onset and relate to the neuromuscular system (latent tetany – positive Chvostek and Trousseau signs; overt tetany – paresthesiae, muscle cramps, carpopedal spasm), brain (focal or grand mal convulsions, papilledema, basal ganglia calcification, eventual mental retardation), heart (prolonged QT interval), eyes (lenticular cataracts) and ectodermal changes (dry skin, coarse hair, brittle nails, tooth enamel hypoplasia).

Treatment aims to correct hypocalcemia and prevent recurrence (treatment of associated problems may also be indicated). A vitamin D preparation is currently the long term treatment of choice – PTH is expensive and must be given parenterally daily.

Acute hypocalcemia is treated with 10% calcium gluconate (9.4% calcium by weight) 1–2 ml/kg by slow i.v. injection repeated, as necessary, 6 hourly, or carefully and slowly infused (in dilute form). Oral calcium supplements (e.g. calcium gluconate) and a vitamin D analogue (e.g. 1alpha-hydroxy D 25–50 ng/kg/24 h) should be started and serum and urinary calcium levels checked 3 monthly. Vitamin D will not correct renal calcium loss – although there is reduced urinary calcium excretion, there is relative hypercalciuria due to deficient (PTH mediated) renal tubular calcium reabsorption and thus serum calcium levels should be maintained in low normal range to avoid nephrocalcinosis and renal stones. Treatment with a thiazide diuretic and sodium restriction may be necessary.

### Decreased peripheral action (pseudohypoparathyroidism – PHP)

Uncommon causes of PTH-resistant HP include severe hypomagnesaemia (which causes resistance to and decreased secretion of PTH) and calciopenic rickets (due to low 1,25-dihydroxy D levels). Receptor or postreceptor defects of response to PTH at the target organ (especially the renal tubule) are more common, first described by Albright – pseudohypoparathyroidism.<sup>284</sup> This heterogeneous condition has been divided into several types:

#### *Type 1 (originally described by Albright)*

There is often symptomatic hypocalcemia in mid-childhood on a background of variable mental retardation and characteristic (but inconstant) somatic features ('Albright's hereditary osteodystrophy', AHO) including short stature, obesity, round face, short neck (Fig. 15.4) and marked metacarpal and metatarsal shortening (especially 4th and 5th – see Fig. 15.6). There is no phosphaturic response to PTH administration and a blunted urinary cyclic AMP increase in comparison with both normals and patients with HP. This type has been further subdivided on the basis of decreased (type 1a) or normal (type 1b) amounts of a protein membrane component that couples the PTH receptor to the catalytic unit of the adenylate.

#### *Type 2*

In this rarer form,<sup>285</sup> the defect is thought to be due to an intracellular defect beyond cyclic AMP generation – cyclic AMP responses to PTH are normal but the phosphaturic response is defective.

These differences do not entirely explain the very variable clinical manifestations (see below). Some patients with somatic features show no renal resistance to PTH – pseudopseudohypoparathyroidism (pPHP). In some families, PHP type 1 and pPHP coexist and individuals may fluctuate between normo- and hypocalcemia.

PTH activates the adenylate cyclase system via the Gs alpha member of the 'G' protein family, a heterotrimeric guanine nucleotide binding protein. The gene encoding Gs alpha is GNAS1. The Gs alpha protein

membrane component is deficient in PHP type 1a/pPHP.<sup>286</sup> Numerous GNAS1 mutations have been identified in PHP-1a and pPHP.<sup>287</sup> Patients with either disorder show skeletal and developmental defects (AHO). Owing to paternal imprinting with inactivation of the paternal allele, which may be tissue- or cell-specific, resistance toward PTH and, often, other hormones is only observed in patients with PHP-1a, i.e. the variable and tissue-specific hormone resistance observed in PHP 1a may result from tissue-specific imprinting of the GNAS1 gene.<sup>1</sup> Patients with PHP-1b show PTH-resistant hypocalcemia and hyperphosphatemia but no AHO. The abnormal regulation of mineral ion homeostasis, such as in PHP-1a/pPHP kindreds, is paternally imprinted. Recent linkage studies have mapped the genetic defect responsible for PHP-1b to chromosome 20q13.3, making it likely that mutations in distinct regions of the GNAS1 gene are the cause of at least three different forms of PHP.<sup>288</sup>

The G protein family mediates numerous transmembrane hormone and sensory transduction processes in eukaryotic cells including LH, GH and TSH synthesis and release.<sup>1</sup> Unsurprisingly, therefore, abnormalities of other peptide hormones, particularly thyroid and GT, have been described in these patients. It is likely that abnormalities of GH secretion also occur – the GRF/receptor complex on the somatotroph activates a similar coupling ('G') protein to stimulate adenylate cyclase and hence GH synthesis and release. Thus in PHP there could be a defect in GRF binding and/or activation of its regulatory protein similar to that postulated for the defect in PTH regulatory protein.

Although these individuals are a heterogeneous group, some grow better on GH treatment. Indeed GH deficiency as a consequence of GHRH resistance in the context of PHP-1a is consistent with Gs-alpha imprinting in the human pituitary.<sup>289</sup> Treatment of hypocalcemia in PHP is analogous to treatment in HP (see above).

## ABNORMAL CALCITONIN SECRETION

### Increased

Hypocalcemia is almost never a feature of calcitonin excess. High calcitonin levels are seen in *medullary thyroid carcinoma* (sporadic or in MEN 2, see p. 473) and a variety of nonthyroid tumors in adults but have not been described in children. Levels are high in the rare autosomal recessive condition pyknodysostosis and may be raised in pancreatitis. High levels, presumably due to a normal physiological response, are described in hypercalcemic states and renal insufficiency.

### Decreased

A number of congenital and acquired hypocalcitoninemic conditions are described, including primary hypothyroidism or post-thyroidectomy, anticonvulsant treatment (phenytoin or primidone) and Williams syndrome (see Chapter 14, p. 390).

## ABNORMALITIES OF PHOSPHATE EXCRETION

### Increased

*Phosphopenic rickets* results from excessive urinary phosphate excretion with resulting hypophosphatemia (Table 15.15) and only rarely from inadequate intake (other than in the preterm infant – see above and Ch. 12). Familial forms of primary hypophosphatemia secondary to renal phosphate loss have been described including X-linked (dominant) hypophosphatemic rickets (Albright's vitamin D resistant rickets) and autosomal dominant and recessive forms. Phosphopenic rickets is a feature of Fanconi syndrome (sporadic or familial, idiopathic or secondary to a number of inborn metabolic errors); it has been described in rare (usually benign mesenchymal) tumors and is a feature of distal renal tubular acidosis (sporadic and familial).

### Decreased

Decreased renal phosphate excretion is important in the pathogenesis of *renal osteodystrophy* – other factors such as altered vitamin D metabolism become increasingly important as renal failure worsens (see Ch. 18). *Tumor calcinosis* (deposition of calcium phosphate around large

joints due to increased phosphate reabsorption) is rarely seen outside Africa and may be familial or sporadic.

## ABNORMALITIES OF CALCIUM EXCRETION

### Increased

Hypercalciuria may be associated with hypercalcemia (e.g. vitamin D intoxication, primary hyperparathyroidism), normocalcemia (e.g. distal renal tubular acidosis, following corticosteroid, furosemide or immobilization) or may be 'idiopathic'. Absorptive (see above) and renal forms (renal hypercalciuria) of this last group occur but may share a common pathogenesis.

### Decreased (familial hypocalciuric 'benign' hypercalcemia)

There are inappropriately raised (normal or high) PTH levels with hypercalcemia (see above). Inheritance is autosomal dominant. Hypercalcemia results from increased tubular calcium reabsorption, but there are no consequent symptoms of chronic hypercalcemia. There is a presumed abnormal set point for calcium mediated PTH suppression but no abnormalities of vitamin D metabolism, calcitonin secretion or parathyroid histology have been found. Parathyroid surgery is ineffective and contraindicated.

## PRACTICAL DIFFERENTIAL DIAGNOSIS

### Rickets

Initial clinical assessment, characteristic radiographic changes and raised ALP, decreased P and normal (especially in phosphopenic rickets) or decreased Ca in serum usually make diagnosis straightforward. It is important to determine etiology (Table 15.15) and further tests will usually be necessary.

Normal PTH and cyclic AMP levels are characteristic of phosphopenic rickets (usually familial X-linked hypophosphatemic, but associated hypercalciuria suggests the rarer autosomal recessive type unless there is inadequate phosphate intake in, for example, the preterm infant). Tumor rickets should be considered in sporadic cases presenting in late childhood or adolescence. Renal function must be assessed to exclude primary renal causes such as chronic renal failure and Fanconi syndrome (which may be secondary to other inborn metabolic errors) and is characterized by glycosuria and aminoaciduria.

Secondary hyperparathyroidism (i.e. secondary to calcium malabsorption) with raised PTH levels suggests calciopenic rickets, usually due to lack of vitamin D or impaired synthesis or action of the active metabolite 1,25-dihydroxy D. Further differential diagnosis necessitates measurement of individual vitamin D metabolites: low levels of 25-hydroxy D are found in all acquired forms (nutritional, liver disease, malabsorption, anticonvulsants). If 25-hydroxy D levels are normal, low 1,25-dihydroxy D levels indicate vitamin D deficient rickets type 1 and high levels indicate end-organ resistance to its action (type 2).

### Hypocalcemia

In the presence of normal total protein, albumin and magnesium levels and renal function, repeated fasting early morning hypocalcemia is interpreted in the context of serum phosphate levels. If these are high, HP or PHP is likely and can be differentiated on the basis of PTH and cyclic AMP measurements: in PHP, PTH levels are high and, in type 1 – the common form – there is blunted cyclic AMP response to PTH infusion; in HP, PTH levels are low and the cyclic AMP response is normal.

Low or normal serum phosphate levels suggest calciopenic rickets; elevated ALP and PTH levels will confirm the diagnosis, which should be further elucidated as above.

### Hypercalcemia

Confirmed raised fasting early morning hypercalcemia on at least three occasions with normal renal function and serum protein and albumin levels is uncommon in childhood. Raised or even detectable PTH levels

in the presence of hypercalcemia are inappropriate and indicate primary hyperparathyroidism. MEN syndromes (see p. 478) should be excluded and family members screened for hypercalcemia. Detectable PTH levels with hypercalcemia but hypocalciuria are characteristic of familial hypocalciuric hypercalcemia.

Suppressed PTH levels suggest vitamin D intoxication (most commonly), idiopathic infantile hypercalcemia, malignancy, sarcoidosis or Addison disease.

### HP from PHP

Hypomagnesemia, because of its dual effect on PTH secretion and resistance to PTH action, may produce features of both HP and PHP – serum magnesium must be checked in hypocalcemia. Somatic features of Albright hereditary osteodystrophy (see above) and radiographic changes of hyperparathyroidism indicate PHP. In HP, PTH levels are inappropriately low for hypocalcemia; PTH levels are high in PHP. Deficient cyclic AMP generation after PTH infusion is characteristic of PHP. Measurement of plasma cyclic AMP has replaced the older tests which measured urinary cyclic AMP excretion.

## OTHER THERAPIES – BISPHOSPHONATES

Bisphosphonates are synthetic analogues of inorganic pyrophosphate and have been used in adults to treat osteoporosis (mainly), but also Paget's disease, metastatic breast carcinoma and hypercalcemia. They are being used more extensively in pediatric practice, particularly for the treatment of osteogenesis imperfecta (reducing fracture risk), juvenile or glucocorticoid-induced osteoporosis and fibrous dysplasia despite a variable (and sometimes minimal) evidence base for their efficacy and concerns regarding their safety.<sup>290,291</sup> More data are needed before their role in these conditions can be established (see also Chapter 29).

## THE ADRENAL GLANDS

The adrenal glands are formed from mesodermal and ectodermal components which form cortex and medulla respectively. During the fifth week, mesothelial cells migrate and proliferate to form large acidophilic cells which comprise the fetal cortex. These become surrounded by smaller cells which later make up the definitive cortex. Meanwhile, sympathetic neural crest neuroblasts invade the medial aspect of the fetal cortex forming the adrenal medulla rather than nerve processes and known as chromaffin cells.

For ontogeny of fetal adrenal steroidogenesis see p. 415. The neonatal adrenals are comparable in size to the kidneys. After birth, there is rapid atrophy of the fetal zone of the cortex and adrenal weight at birth is only regained by late puberty. The definitive cortex secretes glucocorticoids (GC) affecting carbohydrate metabolism, mineralocorticoids (MC) affecting electrolyte balance, and androgens (which are also estrogen precursors). The medulla secretes catecholamines (adrenaline and noradrenaline).

## THE ADRENAL CORTEX

### Morphology and steroidogenesis

The cortex comprises three histologically distinct zones but cells appear to migrate through them changing function as they do so. This has important implications for control of steroidogenesis. The outer (subcapsular) zone, the zona glomerulosa, consists of balls of small cells and overlies the radially arranged cord-like bundles of larger cells of the zona fasciculata. The innermost area, the zona reticularis, consists of a network of short cords with capillaries. It only gradually becomes a distinct zone from ~6 years and largely accounts for the pubertal adrenal size and weight spurt. In contrast, there is relatively little change in postnatal morphological glomerulosa and fasciculata appearances.

In tissue culture, fasciculata and reticularis cells differ functionally as well as histologically, preferentially synthesizing GC (cortisol) and

androgens respectively. Dehydroepiandrosterone (DHA) is a marker of zona reticularis function. Increasing production of androgens by reticularis from about 5 or 6 years and peaking around 12 or 13 years – ‘adrenarche’ – is synchronous with morphological and functional reticularis development. Aldosterone, the main MC, is produced in the zona glomerulosa (but also in other organs including the CNS).<sup>292</sup>

Plasma measurements reflect one moment in time, but many steroids are released episodically in relation to circadian rhythms and to environmental stimuli, often in sudden bursts at intervals.

Cortisol is secreted intermittently in response to pulsatile ACTH release. Most secretory activity occurs during sleep but there are, on average, about nine episodes of cortisol secretion through a 24 h period in adults under basal conditions. The circadian diurnal cortisol rhythm results from maximal duration and number of ACTH secretory episodes between 3 a.m. and 8 a.m. Circadian cortisol rhythm is present by ~6 months and is abolished in Cushing syndrome.

ACTH binds to receptors on the adrenal cell membrane, activating adenylate cyclase (a calcium dependent step); cyclic AMP activates enzymes (mainly intracellular protein kinases) which stimulate hydrolysis of cholesterol esters. Steroidogenesis is initiated in mitochondria by cholesterol binding to a C27 side chain cleavage enzyme which starts its stepwise conversion to pregnenolone, a necessary step in biosynthesis of all three groups of adrenal cortical hormones.

There are acute and chronic responses to ACTH in terms of GC biosynthesis. In contrast, the glomerulosa only seems to produce aldosterone acutely – chronic ACTH stimulation is not generally associated with sustained hyperaldosteronism. ACTH is probably the most, and perhaps only, important adrenal androgen modulator. It is likely that changes in adrenal androgen production with age (cf. unchanging cortisol levels for surface area) result from ACTH-mediated intrinsic local vascular and morphological changes, and children with familial glucocorticoid deficiency demonstrate diminished adrenal androgen secretion implicating a significant role for ACTH, rather than a specific, unidentified, pituitary adrenal androgen stimulating hormone, in the induction of adrenarche.

Physiological ACTH levels regulate acute aldosterone fluctuations – ACTH is important in the pathogenesis of GC-suppressible hyperaldosteronism.<sup>293,294</sup> Although the primary control mechanism is the renin–angiotensin system, this ACTH role is important in managing salt losing CAH (p. 483).

GCs such as cortisol and corticosterone are fast feedback antagonists of ACTH secretion; other steroids [e.g. deoxycorticosterone (DOC), deoxycortisol (S) and synthetic GCs] show delayed feedback inhibition. The relative importance of these responses in normal physiological control of ACTH is unclear.

Simplified steroidogenic pathways are summarized in Figure 15.50. For the clinician, working knowledge of the pathways will aid understanding of physical and biochemical consequences of various types of congenital hyperplasia.

Approximately 70% of circulating cortisol is bound to a 52000 molecular weight alpha-2 globulin, transcortin (corticosteroid binding globulin – CBG) and ~20% albumin bound. Aldosterone, other GCs and precursors are less strongly bound to CBG and synthetic steroids only weakly. CBG is synthesized in liver; levels are increased by estrogen and decreased in cirrhosis. Binding sites are saturated when total plasma cortisol levels exceed about 600 nmol/L; at normal concentrations very little free cortisol is in plasma or excreted in urine. Urinary free cortisol is thus a sensitive screening test for Cushing syndrome (p. 484). Cortisol plasma half-life is 60–90 min; that of aldosterone is only ~20 min because proportionately much less is protein bound. Important adrenal androgens include DHA and its sulfated form (DHAS) which is also synthesized by the gland. DHAS half-life is 10–20 h; DHA secretion is episodic and concurrent with cortisol. Aldosterone levels show marked circadian changes which follow cortisol but are significantly influenced by posture.

Normal values for individual steroids and urinary metabolites in infancy, childhood and puberty are available<sup>295</sup> based on cross-sectional and mixed longitudinal studies.

Urine sampling is atraumatic and 24 h collections are more likely than isolated plasma samples to reflect accurately overall steroid

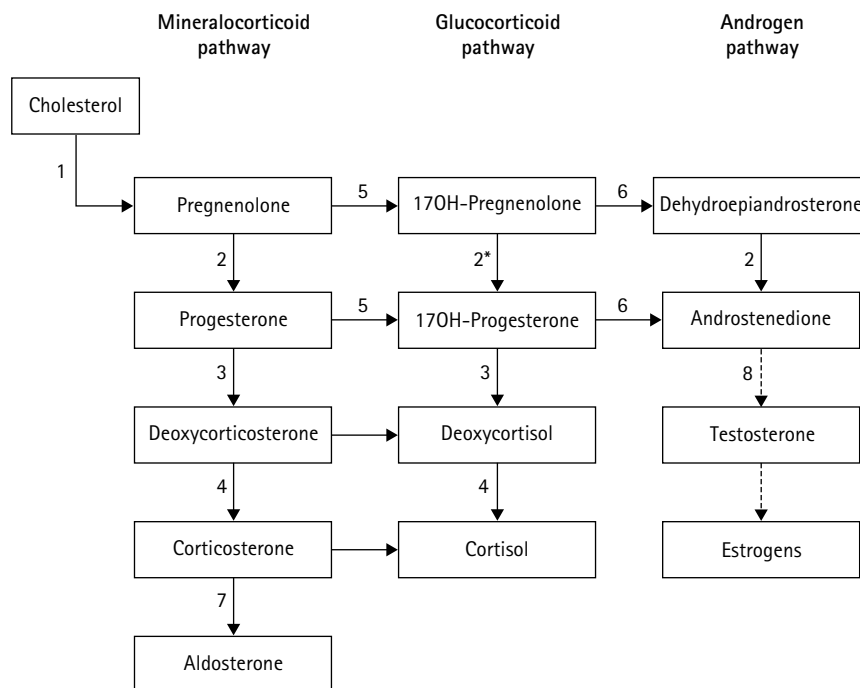

Fig. 15.50 Pathways of adrenal biosynthesis. 1 – cholesterol side chain cleaving system (20α-hydroxylase, 20,22-desmolase, 22α-hydroxylase); 2 – 3β-hydroxysteroid dehydrogenase; 3 – 21-hydroxylase; 4 – 11β-hydroxylase; 5 – 17α-hydroxylase; 6 – 17,20-lyase; 7 – 18-hydroxylase and 18-hydroxysteroid dehydrogenase; 8 – 17β-hydroxysteroid dehydrogenase.

production. However, such collections may be difficult and unreliable in infants and young children. In general steroids are present in urine in about 1000 times their plasma concentrations. However, because of the complexity of metabolic pathways via which adrenal (and gonadal) steroids are excreted (and influences of disease or drugs) there can be uncertainty about clinical significance, relationship to gland of origin or even specific steroid from which they derive. Nevertheless, steroid profiles obtained by gas chromatography are valuable in complementing plasma steroid assays, e.g. studying normal children longitudinally to determine changes with age and the mechanism of adrenarche, detecting abnormal metabolites (e.g. secreted by tumors), metabolite ratios (e.g. in 5 $\alpha$ -reductase deficiency), differential diagnosis of rarer or less clear-cut forms of CAH and differential diagnosis of salt losing states in infancy due to aldosterone biosynthetic defects.

## Adrenarche

Adrenarche, the awakening of the adrenal cortex to produce adrenal androgens, commences from around the age of 6 years. During the early months of life the fetal zone rapidly atrophies so that high fetal and neonatal DHAS levels [reflecting low 3 $\beta$ -hydroxysteroid dehydrogenase (3 $\beta$  OHSD) fetal zone activity] fall and remain low for ~6 years. During mid-childhood adrenal androgen secretion rises steeply ('adrenarche') (Fig. 15.51) – coincident with zona reticularis development.

Adrenarche is important because of (1) its role in precocious sexual (pubic and axillary) hair development in mid-childhood; (2) possible relevance to triggering normal puberty, although underlying mechanisms and relationship to subsequent rises in GT and gonadal steroids at clinical puberty onset ('gonadarche') are controversial; (3) the association between premature adrenarche and subsequent functional ovarian hyperandrogenism, polycystic ovarian syndrome, and insulin resistance in later life ('syndrome X') but which may present by childhood or adolescence, and an association with previous intrauterine growth retardation; (4) potential etiological relevance to concomitant steep rise in normal blood pressure (BP) centiles and the mid-childhood growth spurt.

The adrenal androgen rise is not accompanied by significant increases in intermediate metabolites in cortisol or corticosterone biosynthesis for body surface area.

In some children, predominantly girls, the rise manifests as appearance of pubic, and sometimes axillary, hair ('premature pubarche'). These children probably represent one end of a spectrum of adrenal androgen secretion or perhaps of sensitivity to its action as plasma levels are not always high for age. It must be distinguished from nonclassical, late onset or missed CAH and (rare) adrenal tumors (in which, in contrast, androgens are not dexamethasone suppressible) as well as from true precocious puberty. In one clinic, a 30% incidence of nonclassical 21-hydroxylase deficiency was found

Fig. 15.51 Urinary excretion of dehydroepiandrosterone sulfate (DHAS) in childhood. (From Kelnar 1985<sup>296</sup>)

in those presenting with premature pubarche.<sup>297</sup> Although premature pubarche per se is probably physiological and has no adverse effect on the onset and progression of gonadarche and final height (puberty timing is normal or slightly early), hirsutism or polycystic ovarian disease may develop at puberty. Thus 'exaggerated' adrenarche can be a forerunner of syndrome X in some children (see above – Ibanez et al<sup>32</sup>). The association of these endocrine – metabolic abnormalities with reduced fetal growth and their genetic basis remain to be elucidated.<sup>32</sup>

The role of adrenarche in man remains controversial – it is difficult to extrapolate from pathological situations to normal gonadarche control. Adrenarche may be delayed in children with CDGP and isolated GH deficiency but not in hypergonadotrophic hypogonadism (e.g. Turner syndrome). Children with Addison disease enter puberty normally and in diabetic adolescents gonadarche may proceed normally despite delayed adrenarche. Children with congenital adrenal hypoplasia all have hypogonadotrophic hypogonadism and do not enter puberty normally.

Adrenarche is coincident with the preadolescent fat spurt and with the (disputed) mid-childhood growth spurt. The latter could reflect a bone and muscle response to adrenal androgens, directly or indirectly by influencing GH secretion.

Adrenarche could simply be a by-product of the need of inner fetal adrenal cells to respond to the hormonal milieu of pregnancy by developing an androgen (i.e. estrogen-precursor) synthesizing zone. Other than man, only the chimpanzee has adrenarche, which therefore occurs in two species which have the most prolonged interval between birth and puberty. Adrenarche may merely be revealed by such an interval. However, the more complex the organism the greater the advantage in prolonging the period between birth and reproductive activity to allow brain growth and childhood learning. If during that period androgens are required for continuing skeletal and muscular growth, this could be achieved by transferring androgen biosynthesis from gonad to adrenal – adrenarche.

## Congenital adrenal hyperplasia (CAH)

CAH describes collectively a group of autosomal recessively inherited disorders of adrenal corticosteroid biosynthesis due to deficiency of one of five enzymes in the cholesterol to cortisol biosynthetic pathway – 21-hydroxylase (21OH, P450c21), 11 $\beta$ -hydroxylase (11 $\beta$ OH, P450c11), 3 $\beta$ -hydroxysteroid dehydrogenase (3 $\beta$ OHSD), 17 $\alpha$ -hydroxylase (17 $\alpha$ OH, P450c17) and cholesterol desmolase (P450scc) (see Fig. 15.50). Deficiencies of other enzymes such as 17,20-desmolase (P450c17 17,20-lyase), 17 $\beta$ -hydroxysteroid dehydrogenase (17 $\beta$ OHSD) and 5 $\alpha$ -reductase have effects limited to the adrenal androgen (and gonadal) biosynthetic pathway.

The steroidogenic block due to a specific enzyme deficiency will have potential clinical effects by two types of mechanism: (1) distal hormone deficiency and (2) the effect of ACTH drive, a compensatory response in CRF – ACTH release secondary to the defect in cortisol biosynthesis and reduced feedback inhibition of ACTH, leading to (a) proximal metabolite accumulation and (b) abnormal production of steroids whose biosynthesis is unaffected by the primary enzyme deficiency (Table 15.16).

Thus in the commonest form of CAH (21OH deficiency, P450c21 deficiency) there is, potentially, cortisol deficiency (in practice unstressed cortisol levels are normal as the enzyme deficiency is seldom complete), aldosterone deficiency and salt loss (when the defect is also present in the zona glomerulosa); plasma 17-hydroxyprogesterone (17OHP), and its principal urinary metabolite, pregnanetriol, levels are raised (and conveniently measured to confirm the diagnosis) and ACTH hypersecretion results in excess adrenal androgen and virilization (by birth in females, during early childhood in undiagnosed males).

Inappropriately raised plasma ACTH levels for plasma cortisol are pathognomonic of CAH – measuring cortisol alone is useless for diagnosis. Although the clinical picture may suggest the specific underlying enzyme defect, definitive diagnosis is dependent on detecting raised plasma levels of precursors in plasma by RIA or IRMA and

characteristic urinary metabolites. Occasionally, measurement following ACTH stimulation may be necessary if the situation is not clear-cut. Pointers to the possibility of CAH include ambiguous genitalia in the newborn, vomiting with dehydration and urinary salt wasting during early days or weeks of life, collapse during stress (e.g. severe intercurrent illness or general anesthesia) at any age, hypertension, hirsutism or inappropriate virilization, primary amenorrhea, unexplained previous neonatal death (particularly if parents are consanguineous) and a family history of CAH.

### 21-Hydroxylase (21OH, P-450c21) deficiency

This is by far the commonest form of CAH worldwide although there are considerable ethnic differences. The frequency of the homozygous state varies from 1 in 5000 (Europe) to 1 in 23 000 and is particularly common in Alaskan Eskimos (1 in 700). Nonclassical 21OH deficiency (see below) seems more common and may affect 1 in 30 Jews of Eastern European (Ashkenazi) origin and 1 in 100 other whites.<sup>298</sup>

#### Genetics

Molecular genetic techniques have localized two genes encoding the 21OH enzyme, CYP21B (active) and CYP21A (inactive), to the short arm of chromosome 6 either side of the genes for the fourth component of complement – there is close linkage with the HLA complex. Deletion of CYP21B is associated with severe, salt-wasting disease and the HLA B47, DR7 haplotype; deletion of CYP21A seems not to cause any hormonal abnormality.<sup>299</sup> Most affected individuals are compound heterozygotes. HLA associations with nonclassical 21OH deficiency vary between ethnic groups.

Obligate heterozygote parents of salt-losing and simple virilizing patients show identical sodium, aldosterone and renin responses to a low sodium diet, and some infants with aldosterone biosynthetic defects subsequently develop normal glomerulosa 21OH activity suggesting that other (non-HLA linked) mechanisms are involved in enzyme expression.

The importance of these molecular genetic developments lies in the practical ability to confirm (pre- or postnatally) whether family members are affected or unaffected and in advancing understanding of pathogenesis.

Prenatal diagnosis of 21OH deficiency was first reported in 1965<sup>300</sup> on the basis of elevated 17-ketosteroids and pregnanetriol levels in amniotic fluid (i.e. dilute fetal urine) of an affected fetus. Raised 17OHP and androstenedione levels have since been found in many studies and HLA genotyping of amniotic cells was used in addition. Chorionic villosus sampling, and molecular typing for restriction fragment length polymorphisms of the chromosome 6 loci, 21-hydroxylase gene and HLA, is now possible by 8–11 weeks' gestation and has replaced HLA genotyping of amniotic cells. Rapid early prenatal diagnosis by direct assay of specific mutations using DNA amplification by polymerase chain reaction (PCR) is feasible.

#### Antenatal diagnosis (AND) and treatment

Where there has been a previously affected female child, the possibility of prenatal treatment to reduce or prevent significant neonatal virilization in a second affected female fetus and obviate the need for surgery in infancy and beyond is potentially attractive. Dexamethasone (which crosses the placenta) is used in a dose not exceeding 20 mcg/kg/day of the prepregnancy weight in 2–3 divided doses to suppress the excessive ACTH/androgen induced virilization. Fetuses in whom therapy would be appropriate are affected females – a one in eight possibility with each pregnancy. However dexamethasone must be started very early in pregnancy because sexual differentiation starts at 6 weeks' gestation, and significantly before antenatal diagnosis is possible. Thus 7 out of 8 infants will have treatment unnecessarily for a number of weeks. In affected female infants treatment is continued to term.

Although data from uncontrolled studies are available concerning prenatal diagnosis and dexamethasone therapy, the degree of benefit (reduced virilization) compared to potentially significant maternal side-

effects is unclear – possible long term childhood side-effects have not been studied. Substantial adverse effects on neuromotor and cognitive function at school age have been found after postnatal dexamethasone therapy for lung disease of prematurity<sup>301</sup> and transient variations in glucocorticoid status may have profound and long term programming effects in later life<sup>302</sup> by influencing the number and morphology of corticotrophs as well as the hypothalamo-pituitary-adrenal axis.<sup>303</sup>

At present, therefore, there seems insufficient evidence regarding the safety of mother and fetus to recommend general dexamethasone use outwith controlled scientific studies.

#### Heterozygote detection and neonatal screening

Stimulated 17OHP levels after ACTH will distinguish classical 21OH deficiency patients from heterozygotes for classical or nonclassical disease and from HLA-typed normal family members but HLA typing cannot be used on a population basis to detect heterozygosity (e.g. in the spouse of a potential carrier).

Newborn screening is probably desirable. Male infants (with normal genitalia) may give no warning of a salt-losing crisis with higher morbidity and mortality.<sup>304</sup> Females may be sufficiently virilized to be thought normal males leading to later gender reassignment or hysterectomy and sterility. Non-salt-losing males may be late diagnosed, by when secondary true precocious puberty and ultimate short stature may be inevitable. In a retrospective study covering the last 30 years in five middle European countries there was a 4-fold higher mortality amongst siblings and salt-wasting males in the first year of life compared with the general population. It was calculated that 2–2.5 salt-wasting and up to 5 simple virilizing infants stay undiagnosed out of 40 expected CAH patients per year in the countries investigated. Both clinical detection and treatment of CAH patients, at least in males, were insufficient.<sup>304</sup>

Classical 21OH deficiency is more common than phenylketonuria and, in Europe, is nearly as common as congenital hypothyroidism. A reliable and cheap (in centers already providing a neonatal screening service) screening test is available<sup>305</sup> using heel-prick capillary blood samples taken onto filter paper to measure 17OHP, easily done as part of the 'Guthrie test' procedure.

Significant mortality and serious physical and emotional morbidity consequent on late diagnosis has led to many screening programs worldwide, e.g. Italy, France, Japan, Ireland, New Zealand and a number of USA States.<sup>306</sup> Experience from screening more than 1 000 000 neonates in over 13 screening programs in 6 countries confirms that screening improves detection of salt-wasting newborns whose diagnosis is otherwise delayed or missed and in whom there is significant mortality and morbidity.<sup>307</sup> Morbidity in non-salt-losing males presenting in mid-childhood is also considerable.

However, current screening programs yield a high proportion of false positive results and the future use of tandem mass-spectrometry to evaluate positives found in the initial Delfia screen may significantly improve the effectiveness of a screening program.<sup>308</sup> False negative results seem to be more common in girls.<sup>309</sup>

Genotyping may be a helpful diagnostic tool and a good complement to neonatal screening, especially in confirming or discarding the diagnosis in cases with slightly elevated 17OHP levels. It also provides information on disease severity, which reduces the risk of overtreatment of mildly affected children.<sup>310</sup>

In the UK it is generally considered unnecessary or 'uneconomical' to screen the whole newborn population even though this would add only a small additional unit cost in screening laboratories already measuring TSH and phenylalanine. There may be insufficient acknowledgment of considerable potential morbidity and concentration on mortality statistics. However, there are, to date, few published data on improvements in morbidity resulting from early detection and treatment.

#### Clinical presentation

Classical simple virilizing 21OH deficiency in a karyotypic female results in masculinization generally leading to ambiguous external genitalia recognized at birth (Fig. 15.52) but occasionally so severe that the

Fig. 15.52 Ambiguous genitalia in a 10-day-old genotypic female due to 21-hydroxylase deficiency.

infant is thought to be a normal male. Internal female structures including ovaries, Fallopian tubes and uterus are normal (there are no testes to elaborate AMH) but there is variable labioscrotal fold fusion with a urogenital sinus, genital pigmentation and clitoromegaly. Males usually appear normal at birth but present with penile enlargement, rapid growth (and tall stature) and advanced skeletal maturation (leading to eventual short stature) within a few years (Fig. 15.53). Finding small testes with clinical signs of precocious puberty suggests the adrenals as the androgen source but skeletal maturational advance can be marked so that true precocious puberty develops when treatment starts (see Fig. 15.34).

Fig. 15.53 Precocious pseudopuberty – a boy with non-salt-losing 21-hydroxylase deficiency at presentation at 5 years – testicular volume 2 ml (see also Fig. 15.34).

In the classical salt-wasting form (50–75%) there is an additional defect in mineralocorticoid biosynthesis with aldosterone deficiency due to an inability to convert progesterone to deoxycorticosterone in the glomerulosa. Presentation in both sexes is with severe renal wasting of sodium, dehydration and vomiting within a few days or weeks of birth – this should be foreseen as a possibility in a baby with ambiguous genitalia.

Nonclassical ('mild, late-onset') 21OH deficiency was suspected in women presenting with hirsutism and infertility, and family studies in classical 21OH deficiency characterized it as having different (and differing) HLA associations from classical forms but also autosomal recessive. It may present as early as 6 months or later with premature pubarche, rapid growth (and reduced height prognosis), acne, male-type baldness in the female, delayed menarche or secondary amenorrhoea. There is an association with polycystic ovarian disease – infertility may result and respond to GC therapy.

#### Laboratory diagnosis

17OHP measurement in the newborn is reliable for screening and diagnosis but false positives are reported in preterm or sick neonates. Plasma ACTH, androstenedione and urinary pregnanetriol levels will also be raised. In the salt-wasting form, there is urinary sodium loss (cf. the gut in gastroenteritis); aldosterone levels are low for the high renin levels (cf. renal disease). Clinical and laboratory features of this and the other least uncommon forms of CAH are summarized in Table 15.16. Management is discussed below.

#### 11beta-hydroxylase (11betaOH, P450c11) deficiency

This accounts for some 5% of CAH. There is no HLA association (cf. 21OH deficiency). Clinical manifestations are, as predicted from biosynthetic pathways (Fig. 15.50), identical to 21OH deficiency from the virilizing point of view – in some affected individuals there is restriction of the defect to the glucocorticoid pathway. In over 50%, however, the glomerulosa is also affected but the consequences differ from 21OH deficiency (Table 15.16) because there is accumulation of deoxycorticosterone (DOC) which has significant MC (salt-retaining) properties and, in excess, causes hypertension. DOC may not be directly responsible for hypertension in all cases as some patients with 11betaOH deficiency with raised DOC levels are normotensive and others are hypertensive with normal or only slightly raised DOC levels. Other DOC metabolites such as 18-hydroxy DOC have been implicated.

18-hydroxylation (the next step in the aldosterone biosynthetic pathway) is a function of the same mitochondrial enzyme – a defect in 18-hydroxylase is often seen with 11betaOH deficiency. Milder (late onset) forms and even salt-wasting patients have been reported – clinically 11betaOH deficiency is as heterogeneous as 21OH deficiency.

Hypertension, when present, is characteristic and may be extreme; hypokalemic alkalosis is common. Virilizing effects are as described under 21OH deficiency above. DOC and deoxycortisol (S) levels are raised, as are their respective urinary tetrahydro (TH) metabolites (THDOC and THS), and rise further following ACTH, but their proportional elevations vary between subjects. Prenatal diagnosis has been carried out using a combination of amniotic fluid studies and maternal urinary THS measurement. Management is discussed below.

#### 3beta-hydroxysteroid dehydrogenase (3betaOHD) deficiency

This is also associated with ambiguous genitalia in newborns but the site of the block (Fig. 15.50) results in potential ambiguity both in genotypic males and females (Table 15.16): high levels of DHA and its peripheral conversion to potent androgens result in variable clitoromegaly in females but are insufficient to fully masculinize a male infant, resulting in variable hypospadias (often the severe perineo-scrotal form) with palpable testes. The defect in MC biosynthesis usually causes severe salt wasting. Mild defects are important causes of hirsutism presenting in young adult women so that, as in 21OH deficiency, mild, late onset

Table 15.16 Clinical and laboratory features in the commonest forms of congenital adrenal hyperplasia

Enzyme deficiency	Sexual ambiguity in newborn	Salt-wasting	Hypertension	Blood	Urine
21-hydroxylase (simple virilizing)	Female	–	–	17OHP ++ An ++ DHA n/+ Renin n/+	PT ++ Aldo n
21-hydroxylase (salt-wasting)	Female	+	–	17OHP ++ An ++ DHA n/+ Renin ++	PT ++ Aldo –
11beta-hydroxylase	Female	–	+	17OHP + An ++ DHA + Renin –	PT + THS ++ Aldo –
3beta-hydroxysteroid dehydrogenase	Male and female	+	–	17OHP n/+ An ++ DHA +++ Renin +	PT n/+ Aldo –

17OHP = 17alpha-hydroxyprogesterone, An = delta-4-androstenedione, DHA = dehydroepiandrosterone, THS = tetrahydrodeoxycortisol, Aldo = aldosterone, PT = pregnanetriol. +++ = very high, ++ = high, + = moderately high, n = normal, – = low, – – = very low.

forms are apparently more common than the classical severe type. There is no HLA association and neither ethnic nor geographical clustering. Prenatal diagnosis is impossible because of low 3betaOHSd fetal zone activity.

### 17alpha-hydroxylase (17OH, P450c17) deficiency

Mineralocorticoid biosynthesis is intact (Fig. 15.50) and ACTH drive may result in neonatal hypertension and hypokalemic alkalosis. Deficient adrenal (and gonadal) sex steroid secretion means that karyotypic females usually present with failure of puberty and primary amenorrhea; males have ambiguous genitalia or virilize inadequately at puberty with gynecomastia. Recently described CYP17 mutations correlate poorly with phenotypic features (degree of virilization, blood pressure, etc.).<sup>311</sup>

### P450 oxido-reductase deficiency (POR)<sup>312</sup>

Formerly known as ‘apparent combined P450c17 and P450c21 deficiency’ this newly characterized variant of CAH is associated with cranio- and radiofemoral synostosis and mid-facial hypoplasia (and is distinct from other craniosynostosis syndromes caused by FGFR mutations).

### Cholesterol desmolase deficiency (P450scc, cholesterol side chain cleavage deficiency, lipoid adrenal hyperplasia)<sup>313</sup>

This was originally described as lipoid adrenal hyperplasia because of adrenal accumulation of cholesterol. Pregnenolone is the precursor of all MCs, GCs and androgens (Fig. 15.50) and complete deficiency is presumably incompatible with life. In contrast to congenital adrenal hypoplasia (see below), gonadal steroids are also deficient. The P450scc gene has been located in the q23 to q24 region of chromosome 15.

### Management of CAH

The basic defect (in cortisol biosynthesis) has wide repercussions including survival itself, sexual differentiation, growth, pubertal development and adult sexual functioning. Management potentially involves sex assignment, hormone therapy, surgery and psychological and emotional support with attention to growth and puberty and not merely adrenal steroid levels.

*Hormone replacement* is aimed at appropriately suppressing excessive ACTH drive rather than simply replacing cortisol; cortisol levels are often normal in the unstressed situation. In a baby with salt loss, titration of the appropriate GC replacement dose (against ACTH, adrenal androgen or 17OHP levels) is misleading until there is sodium balance (evidenced by normal plasma renin and plasma and urinary sodium). In the older child also, raised ACTH levels may be due to inadequate MC replacement.

The normal cortisol production rate is lower than previously thought: approximately 6–7 mg/m<sup>2</sup>/day. Appropriate GC replacement will allow normal growth, skeletal maturation and puberty – hydrocortisone (HC) 12–15 mg/m<sup>2</sup>/day in 2–3 divided doses is usually appropriate. However, larger doses (<20–25 mg/m<sup>2</sup>/day) may be necessary to suppress androgen levels and a combination regimen of physiological GC replacement with antiandrogens or aromatase inhibitors<sup>225</sup> has been suggested<sup>314</sup> as has carbenoxolone as an 11betaOHSd inhibitor<sup>315</sup> – or bilateral laparoscopic adrenalectomy for difficult to control cases.<sup>316</sup>

To mimic normal diurnal rhythms, approximately two thirds of the total HC dose is usually given first thing in the morning and the last dose at bedtime. In some it is necessary to give a longer acting steroid (e.g. prednisone or dexamethasone) at bedtime if early morning ACTH and 17OHP levels are not to be too high – once-daily dexamethasone may be appropriate for adolescents and adults and may also improve ovarian function in women.

The correct GC dose must be determined for each individual. Too low a dose will allow androgen-mediated excessively rapid growth, disproportionate bone age advance and eventual stunting. Too much will cause slowing of linear growth and delay (but not comparable delay) in bone maturation, also resulting ultimately in short stature. Swinging from one extreme to the other causes cumulative deficits in height prognosis.

Monitoring is by accurate growth and bone age assessment supplemented by home finger-prick blood spot 17OHP profiles four times daily approximately monthly. Abnormally rapid growth and bone age maturation is associated with nonsuppressed 17OHP levels (>40 nmol/L), whereas GC over-replacement, evidenced by pathologically slow growth, is associated with levels <10 nmol/L.

GC therapy must be increased 2–3-fold during stress such as significant infection or general anesthesia which could otherwise precipitate hypoglycemia and collapse. The family should be provided with, and instructed in the use of, home blood glucose monitoring strips, and injectable hydrocortisone in case the child is vomiting or becomes

rapidly ill at home. A Medicalert bracelet or talisman should be worn, as with other patients on steroid medication.

Mineralocorticoid (MC) replacement is necessary in salt-losing forms of CAH, given as the synthetic analogue 9 $\alpha$ -fluorocortisol (fludrocortisone) 0.1–0.15 mg/m<sup>2</sup>/day in one or two daily doses. However the salt-losing crisis cannot be treated with fludrocortisone (nor with hydrocortisone which has limited MC activity) – emergency treatment with sodium replacement and i.v. normal or even hypertonic saline will be necessary as the total body sodium deficit is considerable. Once sodium balance is restored, fludrocortisone is introduced (and GC dose titration can begin) but oral sodium supplements (initially 2 mmol/kg/day) may also be required during infancy. Regular BP and urinary electrolyte measurements are sufficient to check that MC replacement is appropriate. Renin and aldosterone clinic measurements may not be very meaningful. After infancy, children can adjust their salt intake and theoretically do not require long term MC replacement. In practice, health and growth seem better if MC therapy is continued. The hypertension found in some forms of 11 $\beta$ OH and 17OH deficiencies responds to GC suppression of ACTH/MC overproduction.

Sex assignment seldom poses problems but for a review of the development of gender and sexuality in 46XX persons with classical CAH and its implications for clinical practice see Meyer-Bahlburg.<sup>55</sup> In 21OH and 11 $\beta$ OH deficiencies karyotypic females with ambiguous genitalia should normally be reared as girls – internal sexual organs are normal female and with appropriate therapy there is a significant chance of fertility. Clitoral reduction is sometimes appropriate for cosmetic reasons (see below). Assignment in rarer forms (3 $\beta$ OHSD, 17OH and cholesterol desmolase deficiencies) where males may be very poorly virilized depends on functional possibilities after potential reconstructive procedures.

In severely virilized females, clitoral reduction is widely felt to be best undertaken before 6 months. The vascular and neural supply to the glands is maintained to aid later sexual functioning and pleasure. Labial separation, if necessary, may be carried out simultaneously. Vaginal reconstruction has been thought best delayed until after puberty – often simple stretching will allow estrogen-mediated development at puberty obviating the need for major surgery, and early reconstruction has been more commonly associated with discomfort at intercourse. However, there are contrary views in favor of early one stage reconstructive surgery.<sup>317</sup> Fertility prospects are generally good in males, but abnormal sonogram findings of testicular adrenal rests are more frequent in the salt-wasting form and are associated with a higher risk for infertility.<sup>318</sup> Fertility is reduced in affected women.<sup>319</sup>

Emotional support is necessary for families of children with ambiguous genitalia particularly in the neonatal period and adolescence. Reports of high rates of homosexuality in female CAH patients may reflect inadequate vaginoplasty and difficult heterosexual relationships but effects of high androgen levels on the female fetal cerebral cortex could be important. Psychosexual outcomes in individuals treated prenatally will help to resolve the question but are not yet available.

Because standard and indeed 'optimal' GC therapy may result in Cushingoid side-effects and suboptimal growth and height prognosis, several supplementary approaches including GnRH analogues, aromatase inhibitors and antiandrogens have been proposed in order to reduce the GC dose. However, as compliance (concordance) with prescribed medication(s) is generally the biggest cause of suboptimal treatment outcomes, it is doubtful whether the need to take additional tablets will improve control. Similarly, bilateral adrenalectomy has been tried in patients with CYP21 null mutations or difficulty in achieving good control on conventional therapy<sup>320</sup> and found (in a small cohort) to be safe and effective. The advantages of easier therapeutic management (no hyperandrogenism) must be balanced against an increased risk of adrenal crises and Nelson syndrome. All such treatments remain experimental.

### Hyperadrenocorticism

Adrenal hypercorticism is commonly secondary to trophic hormone stimulation causing adrenal hyperplasia and hypersecretion and rarely primary (usually due to adrenal tumor). Clinical features are mimicked

**Table 15.17** Important causes of adrenocortical hyperfunction

Glucocorticoids	Iatrogenic (glucocorticoid therapy); Cushing syndrome; carcinoma/adenoma; bilateral hyperplasia (Cushing disease/pituitary tumor/ectopic ACTH-secreting tumor)
Mineralocorticoids	Primary hyperaldosteronism; Conn syndrome (adenoma); Bartter syndrome; congenital adrenal hyperplasia (17 $\alpha$ -hydroxylase and 11 $\beta$ -hydroxylase deficiencies); deoxycorticosterone- (DOC) or corticosterone-secreting tumors
Sex steroids	<i>Androgens</i> Congenital adrenal hyperplasia (21-hydroxylase and 11 $\beta$ -hydroxylase deficiencies); 'premature' adrenarche (pubarche); virilizing carcinoma/adenoma <i>Estrogens</i> Feminizing carcinoma/adenoma

by (and in practice much more commonly due to) excessive GC administration (iatrogenic Cushing syndrome – see below). Causes are listed in [Table 15.17](#).

### Cushing syndrome

Cushing syndrome (disorders due to chronic excessive GC production) is uncommon in childhood – only 5–10% of reported cases – and rare in young children. It may be due to: (1) benign or malignant adrenal tumor; (2) pituitary ACTH hypersecretion (Cushing disease); (3) ACTH or CRF hypersecretion from malignant extrapituitary tumors (ectopic ACTH syndrome); (4) supraphysiological parenteral, oral, nasal or topical GC or ACTH therapy for other medical conditions – most frequently.

Clinical features are due to cortisol excess resulting in protein catabolism, increased carbohydrate production, fat accumulation and potassium wasting. In children, classical signs and symptoms (hypertension, truncal obesity, moon face, striae, proximal muscle weakness, osteoporosis, psychiatric symptoms) are usually less clear-cut than in adults, and combined growth effects of hypercortisolism and excess adrenal androgen secretion may cause growth failure or temporarily rapid growth. The former is more common, however, and hirsutism, progressive truncal obesity and growth failure (cf. obesity due to overeating), make up the most common presenting triad. Hypertension is usually only moderate and of multifactorial pathogenesis.

Iatrogenic disease must be specifically sought. ACTH is used to treat hypsarrhythmia and oral GC is used for a variety of chronic renal and connective tissue disorders (now less commonly for asthma). Large doses of inhaled steroids can be associated with significant adrenal suppression and growth failure as can nasal drops and topical steroids, depending on the extent of surface treated, frequency of application, potency of drug, use of occlusion and the age of the child. Infants, treated for seborrheic dermatitis/eczema, and adolescents are relatively sensitive to topical steroid side-effects – an infant's (wet and occluded) napkin area has relative absorption 42-fold higher than the forearm; adolescents' increasing fat deposits and muscle mass inducing dermal remodeling makes them particularly susceptible to striae particularly around breasts and buttocks. If the hypothalamo-pituitary-adrenal axis is suppressed, treatment must be withdrawn gradually if acute adrenal insufficiency (see below) is not to be precipitated.

No single screening test is reliable in detecting Cushing syndrome at an early stage or in differentiating it from exogenous obesity. A normal plasma cortisol diurnal rhythm, with normal urinary free cortisol levels and a normal short (overnight) dexamethasone suppression test (0.3 mg/m<sup>2</sup> orally at midnight measuring 8 a.m. plasma cortisol) will reasonably exclude the diagnosis. A 2-day low dose (6 mg/kg every 6 h)

dexamethasone suppression test measuring plasma cortisol at 48 h, or urinary free cortisol corrected for creatinine, is necessary if results are equivocal.

Once the diagnosis is established, further differential diagnosis of the cause may also be difficult. Rapidly evolving symptoms, palpable abdominal mass and virilization at any age make adrenal carcinoma most likely and this is relatively common in infancy, but generally diagnosis depends on imaging techniques (e.g. adrenal ultrasound, pituitary and adrenal CT scanning, adrenal iodocholesterol scintigraphy) and further dynamic hormone tests (e.g. response to metyrapone, high dose dexamethasone, CRF). Petrosal sinus sampling seems not to be a reliable test for lateralization of a pituitary adenoma.<sup>321</sup> Diagnostic algorithms are available<sup>240</sup> – investigation should be carried out in specialist centers.

Treatment depends on the cause and may be medical, surgical (to pituitary or adrenals), radiotherapy or radioactive implants. Medical treatment (e.g. with drugs blocking cortisol biosynthesis or GC antagonists) is of value in many patients prior to surgery, if inoperable lesions are found and in Cushing disease. In virtually all situations, however, treatment is urgent because of the progressive and severe natural course if untreated.

### Hyperaldosteronism

Primary MC hypersecretion is very rare in childhood and usually due to a zona glomerulosa adenoma (Conn syndrome) or bilateral hyperplasia. There is sodium retention and hypertension with hypokalemia, renin suppression and hyperaldosteronism which fails to suppress with dexamethasone. In addition to hypertension, there may be muscle weakness, polyuria and impaired growth. Treatment is medical (long term spironolactone) in hyperplasia and surgical in adenoma.

### Familial forms of hyperaldosteronism

Dexamethasone-suppressible hyperaldosteronism is clinically and biochemically indistinguishable from primary hyperaldosteronism but aldosterone levels suppress rapidly on dexamethasone. Hypertension can be controlled by GC therapy. Autosomal dominant inheritance (not HLA linked) has been proposed. *Bartter syndrome* is discussed in Chapter 18, p. 551. *Apparent mineralocorticoid excess (AME) syndrome* is often familial – aldosterone levels are low and there is no evidence for overproduction of other MCs. The pathogenesis is now known to be primary *11beta-hydroxysteroid dehydrogenase (11betaOHSD) deficiency* resulting in defective cortisol metabolism to cortisone. The resulting prolongation of cortisol half-life and bioactivity may result in sufficient MC activity to cause hypertension. Diagnosis depends on the finding of a raised (>1) ratio of the main urinary metabolite of cortisol (tetrahydrocortisol, THF) to that of cortisone (THE) on gas chromatography, in association with low renin hypertension and normal or low aldosterone levels.

11betaOHSD is a widely distributed enzyme which exists in two types – type II is found in the placenta and distal renal nephron, is NAD dependent and converts the (active) glucocorticoid cortisol (F) to (inactive) cortisone (E) (Fig. 15.54). The mineralocorticoid receptor (MR) has little affinity for E whereas aldosterone cannot be inactivated in this way and retains full access to the MR.<sup>322</sup> Increased availability and binding of cortisol at the MR at the renal distal tubule is the currently accepted pathophysiological mechanism underlying AME.

Fig. 15.54 Cortisol–cortisone interconversion (see text).

11betaOHSD may be of wider importance than simply in the etiology of AME. It is plentiful in the placenta and could be important in protecting the fetus from maternal cortisol. It is speculated that the growth-retarded human fetus has been exposed to excessive cortisol in utero due to relative placental 11betaOHSD deficiency which could reflect placental and fetal growth and that this has long-lasting effects (e.g. adult hypertension) by imprinting via brain receptor or neurochemical mechanisms.<sup>36</sup>

*Secondary hyperaldosteronism* may be due to various causes, most importantly renin-secreting tumors either of the juxtaglomerular apparatus or from ectopic sites such as pancreatic adenocarcinoma. Renin levels are very high.

*Pseudohypoaldosteronism* due to end-organ resistance to aldosterone is characterized by high levels of urinary aldosterone metabolites which distinguish it from 18-hydroxylase and dehydrogenase deficiencies. Clinical presentation is identical and it is discussed under sodium-losing states (see below).

### Insufficiency

Adrenocortical hypofunction may result from primary adrenal disorders or may be secondary to hypothalamo–pituitary disorders. Hypofunction may be complete or affect specific functions – GC, MC or androgen biosynthesis. Chronic conditions may present with dramatic symptoms relating to acute adrenal insufficiency (‘Addisonian crisis’) but may remain asymptomatic and diagnosis may be long delayed. Causes are listed in Table 15.18.

### Congenital adrenal hypoplasia

After CAH, this is the commonest neonatal cause of adrenal hypofunction. Sporadic cases are associated with anencephaly or other congenital (e.g. renal and cardiac) malformations and maternal pre-eclampsia. Familial forms are sex-linked or autosomal recessive. Adrenocortical failure presents with adrenal hypoplasia or atrophy – combined adrenal autopsy weight <1 g or <1% of total body weight

Table 15.18 Important causes of adrenocortical hypofunction

Primary complete (glucocorticoids/mineralocorticoids/androgens)
Congenital adrenal hypoplasia
Lipoid adrenal hyperplasia (cholesterol desmolase deficiency)
Addison disease
Adrenal apoplexy (Waterhouse–Friderichsen syndrome)
Adrenal hemorrhage/cysts
Adrenoleukodystrophy
Autoimmune multiple endocrinopathy syndromes
Primary selective – glucocorticoids
Congenital adrenal hyperplasia (21-hydroxylase, 17alpha-hydroxylase and 11beta-hydroxylase deficiencies)
Iatrogenic
Hereditary unresponsiveness to ACTH
Primary selective – mineralocorticoids
Pseudohypoaldosteronism
Aldosterone biosynthetic defect (18-hydroxylase and 18-dehydrogenase deficiency)
Primary selective – androgens
17,20-desmolase deficiency
Secondary
Iatrogenic (glucocorticoid therapy)
Hypothalamo–pituitary dysfunction
Panhypopituitarism
Isolated ACTH deficiency
Craniopharyngioma
Structural midline defects

is characteristic. It is a rare cause of low maternal estriol levels during pregnancy.

Histological findings are heterogeneous but of three main types: (1) primary (cytomegalic) – a rare form in males, with poorly differentiated cortex, disordered architecture and giant cells; (2) secondary (anencephalic) – the commonest in sporadic and familial cases – the fetal zone is reduced or absent but definitive cortex is well differentiated, mimicking the appearance in anencephalics; (3) miniature, comprising about one third of cases – the glands are small but normally differentiated. All three types occur sporadically.

Two hereditary forms have been characterized: (1) autosomal recessive, usually associated with the miniature histological type; (2) X-linked, usually associated with the cytomegalic form and affecting boys. The latter type is now known to be due to mutations in the DAX-1 gene – DAX-1 is a member of the orphan nuclear hormone receptor family expressed in the adrenal gland, gonads, ventromedial hypothalamus and pituitary gonadotrophs. There is an association with hypogonadotrophic hypogonadism and with X-linked glycerol kinase deficiency.

In all types and forms, clinical presentation is within the first few hours or days of life with vomiting, diarrhea, apnea, hypoglycemia with convulsions, hyponatremic dehydration, hyperkalemia and metabolic acidosis. Plasma cortisol and aldosterone levels are very low with high renin. ACTH levels are very high (cf. adrenal failure secondary to pituitary disorders but not differentiating it from CAH). In karyotypic females it is indistinguishable from cholesterol desmolase deficiency but other forms of CAH can be identified as described above. Treatment is analogous to that of salt-losing CAH. Prognosis was poor but is now much improved, particularly in those surviving the first few days.

### **Familial GC deficiency (hereditary unresponsiveness to ACTH)**

Onset is after the first year, sometimes with recurring hypoglycemia but often merely with a history of prostration during intrinsically mild intercurrent illness. There is hyperpigmentation and tall stature is common. Inheritance is probably autosomal recessive. The pathogenesis is unknown but may be degenerative – the glomerulosa is broad but fasciculata and reticularis are reduced to a fibrous band.

There is a defect in cortisol production with high ACTH levels, and also diminished adrenal androgen secretion implicating a significant role for ACTH in the control of adrenal androgen secretion. MC production is normal under basal conditions but may not remain so, making the distinction from Addison disease particularly difficult. Treatment is with GC, which must be increased during severe intercurrent illness.

### **Addison disease**

This primary chronic form of adrenal insufficiency first described in 1855 is rare in childhood affecting ~ 1 in 10 000. Hypoadrenalism much more commonly results from corticosteroid medication suppressing the pituitary–adrenal axis (see below). Variations in incidence – historically, geographically and in age of onset – probably represent changes in the epidemiology of the primary causes of adrenal damage and failure: until the 1950s, tuberculosis was overwhelmingly the commonest cause but 20 years later it accounted for only about 1 in 5 UK cases.

The commonest cause is now autoimmune (AI) adrenal disease. As with other AI diseases there is a familial incidence and female preponderance. Adrenalitis is characterized by lymphocyte infiltration and adrenal microsomal and mitochondrial autoantibodies are found. The medulla is unaffected. There are associations with other autoimmune conditions including hypoparathyroidism (in about 1 in 3 cases) and mucocutaneous candidiasis [polyglandular autoimmune disease (PGAD) type 1], thyroid disease and/or diabetes mellitus (PGAD type 2) and a range of other autoimmune endocrinopathies (PGAD type 4). Antibody titers are generally low, decrease further with age and do not correlate with the severity of the endocrinopathies. Cell-mediated (T-lymphocyte) processes are more likely to be responsible for the adrenal cortical destruction. Familial (autosomal recessive) occurrence probably

relates to the inheritance of the underlying tendency to AI disease – there is an association with HLA A1, A3 or B8.

There is GC and MC deficiency which may not develop simultaneously. In childhood, presenting features are usually hypoglycemia, progressive lassitude and muscle weakness, gastrointestinal disturbances (including constipation or diarrhea, vomiting and abdominal pain), associated with mild hyperpigmentation (classically of buccal and vaginal mucosa, nipples and palmar creases and pressure areas – axillae and groin – due to pituitary beta-lipotropin secretion). In practice, pigmentation may simply appear as excellent suntan or 'dirt' over extensor surfaces exposed to friction (e.g. knees, knuckles, elbows).

Major symptoms result from cortisol deficiency and consequent high plasma ACTH elevation. Glycogen stores are low – severe hypoglycemia may occur during fasting or intercurrent stress or illness. Hyponatremia results from aldosterone deficiency and reduced plasma volume induced vasopressin secretion causing water retention.

Characteristic laboratory findings are hyponatremia, hyperkalemia, raised urea, fasting hypoglycemia and anemia. Basal cortisol, aldosterone and adrenal androgen levels are commonly normal but with raised ACTH levels. Cortisol levels do not rise 60 or 120 minutes after a 'short' ACTH test (i.v. 1,24-ACTH 500 ng/1.73 m<sup>2</sup>) – although the sensitivity of this test is still debatable – or after i.m. ACTH 25 mg/m<sup>2</sup> (8 hourly for 3 days). Low T4 with raised TSH levels may be found but often correct rapidly with GC treatment without thyroxine. Adrenal autoantibodies are characteristically present even before clinical onset and should lead to regular testing of adrenal function in patients with other AI disorders or siblings of affected individuals.

Acute 'Addisonian' crisis may occur as the presenting feature in a previously unsuspected case precipitated by intercurrent illness or stress. There is hypotension (otherwise uncommon in children with Addison disease), dehydration, prostration and collapse, with hypoglycemia and the classical electrolyte disturbances described above, superimposed on symptoms and signs of the precipitating cause. Treatment with intravenous hydrocortisone and plasma or normal saline with 5 or 10% dextrose is urgent. Intravenous or intramuscular hydrocortisone must be continued whilst oral GC replacement is started. With adequate sodium replacement, MC treatment is not usually necessary acutely.

GC therapy must be increased 2–3-fold during stress such as significant infection or general anesthesia which could otherwise precipitate hypoglycemia and collapse. Instruction should be given in the use of home blood glucose monitoring strips and injectable hydrocortisone provided for home use in case the child is vomiting or becomes rapidly ill at home. A Medicalert bracelet or talisman should be worn.

Long term treatment is with oral hydrocortisone, usually 10–15 mg/m<sup>2</sup>/24 h – the dose individually adjusted based on disappearance of symptoms, normal growth and skeletal maturation and normal diurnal ACTH levels. MC dosage (fludrocortisone 0.1–0.15 mg/m<sup>2</sup>/24 h) is less critical provided it is adequate and assessed as in salt-losing CAH. Treatment must be life-long. Adrenal androgen therapy is unnecessary in childhood but a mild androgenic preparation may improve libido and pubic hair growth in adolescent and adult women. It is usually considered that puberty is normal in timing and progression (cf. congenital adrenal hypoplasia). Prognosis is normal in terms of health and life span presupposing optimal prevention and treatment of acute crises.

### **Sodium-losing states**

These may be due to renal disease (e.g. dysplasia, tubular disease, Bartter syndrome – see Ch. 18, p. 551) or adrenal insufficiency. Adrenal urinary sodium wasting is characterized by hyperkalemia and due to defective aldosterone biosynthesis (congenital adrenal hypoplasia, salt-wasting forms of CAH – see above – or isolated aldosterone biosynthetic defects) or impaired action at the renal tubule (pseudohypoaldosteronism – see below and Ch. 18, p. 552).

Isolated defects of aldosterone biosynthesis may result from defective 18-hydroxylation or 18-dehydrogenation in conversion of corticosterone to aldosterone (see Fig. 15.50). Both are due to deficiency of corticosterone methyl oxidase (CMO) which converts corticosterone to

18-hydroxycorticosterone – defective hydroxylation is known as CMO I, defective dehydrogenation as CMO II.

Inheritance is autosomal recessive. Presentation is with marked salt wasting, hyperkalemia and failure to thrive usually in early infancy. GC and androgen function are normal. Although, as in 21OH deficiency, there can be self-regulation of salt intake and proximal renal tubular maturation, the salt-wasting tendency is life-long and MC replacement should be for life.

*Pseudohypoaldosteronism* is due to a primary renal tubular sodium/potassium ATPase defect. The effects of aldosterone are mediated largely through activation of the epithelial sodium channel, and inactivating mutations of this channel lead to pseudohypoaldosteronism with signs of mineralocorticoid deficiency. Clinical presentation is identical to the 18-oxidation (CMO) defects (see above) but aldosterone is markedly elevated and MC therapy ineffective as the proximal renal tubule is unresponsive to its action. Treatment is with sodium supplements. Transient pseudohypoaldosteronism has been reported with the renal tubular resistance to aldosterone secondary to renal disease (see also Ch. 18).

### **Adrenoleukodystrophy (ALD)**

Various uncommon associations between chronic adrenal insufficiency and progressive brain demyelination are described with differing inheritance but have in common the abnormal accumulation of saturated unbranched or monosaturated very long chain fatty acids due to a defect in their catabolism. The ALD gene maps to the long arm of the X chromosome (Xq28) and adrenal insufficiency is secondary to cortical destruction – treatment is with GC and MC. The neurological disorder is progressive – these and related conditions (e.g. Zellweger syndrome) are further discussed in Chapter 26, p. 1114.

Other causes of acute adrenal insufficiency include adrenal destruction, e.g. hemorrhage due to birth trauma and Waterhouse–Friderichsen syndrome (sepsis and collapse, often associated with meningococemia).

### **Steroid withdrawal**

Most commonly, adrenal crisis results from abrupt withdrawal of GC medication when the axis is suppressed from chronic GC administration (oral, inhaled, intranasal or topical) or failure to increase GC during severe intercurrent illness or stress (see above). Alternate day GC causes less hypothalamo – pituitary – adrenal axis suppression and appears more growth sparing. ACTH treatment is associated with more rapid current growth than is high dose GC, but this probably results from additional secondary adrenal androgen secretion and, if bone age advances disproportionately rapidly, ultimate stature may be just as impaired.

### **Tumors**

Adrenal cortical tumors are rare in children. Virilizing tumors<sup>323</sup> are relatively more common than feminizing or nonsecreting tumors and are usually carcinomas rather than adenomas although their malignancy can be difficult to determine. They are histologically identical to those causing Cushing syndrome but differ in secretory pattern and thus clinical manifestations. Predominantly androgen hypersecretion produces pseudoprecocious puberty – tall stature with growth acceleration and precocious pubic and axillary hair; in boys growth of the penis with prepubertal size testes, in girls clitoromegaly and labial enlargement. Adrenocortical carcinomas are aggressive and tumor size relates poorly to malignancy. Treatment other than by surgical removal is disappointing and the prognosis often poor. Tumor morphology is a better predictor of metastatic risk than biochemical markers or immunohistochemistry.<sup>324</sup>

## **THE ADRENAL MEDULLA**

The medulla comprises cells of neuroectodermal origin which synthesize and secrete catecholamines, hormones containing a dihydroxylated

phenolic ring. The most active compounds, adrenaline and noradrenaline, are both secreted by the medulla and noradrenaline is also produced in sympathetic ganglion cells.

### **Catecholamine biosynthesis**

Catecholamines are synthesized (Fig. 15.55) from dietary tyrosine and tyrosine converted from phenylalanine by liver hydroxylation. Tyrosine is converted to dihydroxyphenylalanine (DOPA) in brain and sympathetic tissue as well as adrenal medulla. There is then conversion to dihydroxyphenylethylamine (dopamine) and to noradrenaline and, only in the adrenal medulla and the organ of Zuckerkandl at the aortic bifurcation, to adrenaline. Catabolism and excretion (Fig. 15.55) is via vanillylmandelic acid (VMA) and homovanillic acid (HVA), urinary markers for catecholamine hypersecretion. Hypoglycemia, hypoxia, hypovolemia and exercise stimulate catecholamine release. Adrenaline has alpha- and beta-adrenergic effects but noradrenaline is mainly alpha-adrenergic. Vasoconstriction is alpha receptor mediated; cardiac stimulation is via the beta receptor. Dopaminergic effects also occur.

### **Hypofunction**

Adrenomedullary hypofunction is seldom important clinically. Adrenomedullary unresponsiveness is a rare cause of hypoglycemia in children but might be found less infrequently if catecholamines were measured more often during hypoglycemia. Sweating and pallor do not occur. The disorder may be of primarily hypothalamic origin as adrenocortical responsiveness may also be impaired and there is an association with perinatal problems.

In familial dysautonomia (Riley – Day syndrome), an autosomal recessive condition most common in Ashkenazi Jews, there is disturbed autonomic function due to dopamine-beta-hydroxylase deficiency resulting in impaired noradrenaline biosynthesis. Urinary VMA is decreased and urinary levels of HVA, a dopamine metabolite, are high. There is impaired swallowing in infancy with aspiration pneumonia, excessive sweating and salivation, defective lacrimation, labile BP, indifference to pain, loss of taste buds and corneal insensitivity and ulceration. Treatment is symptomatic and the majority die in childhood.

### **Hyperfunction**

Catecholamine hypersecretion is usually associated with hypertension due to a neural crest catecholamine-secreting tumor – pheochromocytoma, neuroblastoma, ganglioblastoma or ganglioneuroma, although the mechanism of hypertension in neuroblastoma patients may be renovascular in origin – and discussed below.

## **ENDOCRINE HYPERTENSION**

### **IMPORTANCE OF HYPERTENSION IN CHILDHOOD**

The majority of children with higher than average blood pressure (BP) for age are part of a normal spectrum and those above the 95th centile will, in general, come within the category of essential hypertension although many will simply be obese.<sup>325</sup> BP tracking occurs from an early age in normal children<sup>326</sup> – there are steeper rises in normal levels from ~7 years of age. The pathogenesis of essential hypertension is poorly understood – primary endocrine abnormalities seem unlikely to be of paramount significance. Until pathogenesis is clearer, preventive measures aimed at children in the upper BP centiles will remain controversial. Mass BP screening of children is probably unjustified.<sup>327</sup> Aldosterone levels have been found to predict development of hypertension in normotensive subjects and increased aldosterone action may contribute to hypertension and cardiovascular damage in around 10% of patients with established hypertension.<sup>292</sup>

In contrast, children with sustained and very high BP are likely to have hypertension secondary to specific, and treatable, causes – overwhelmingly (~90%) renal disease (see Chapter 18). Diagnosis and treatment are urgent because, in this group, there is high morbidity and mortality from untreated hypertension. Too few ill children have BP measured. Regular measurements should be made in those

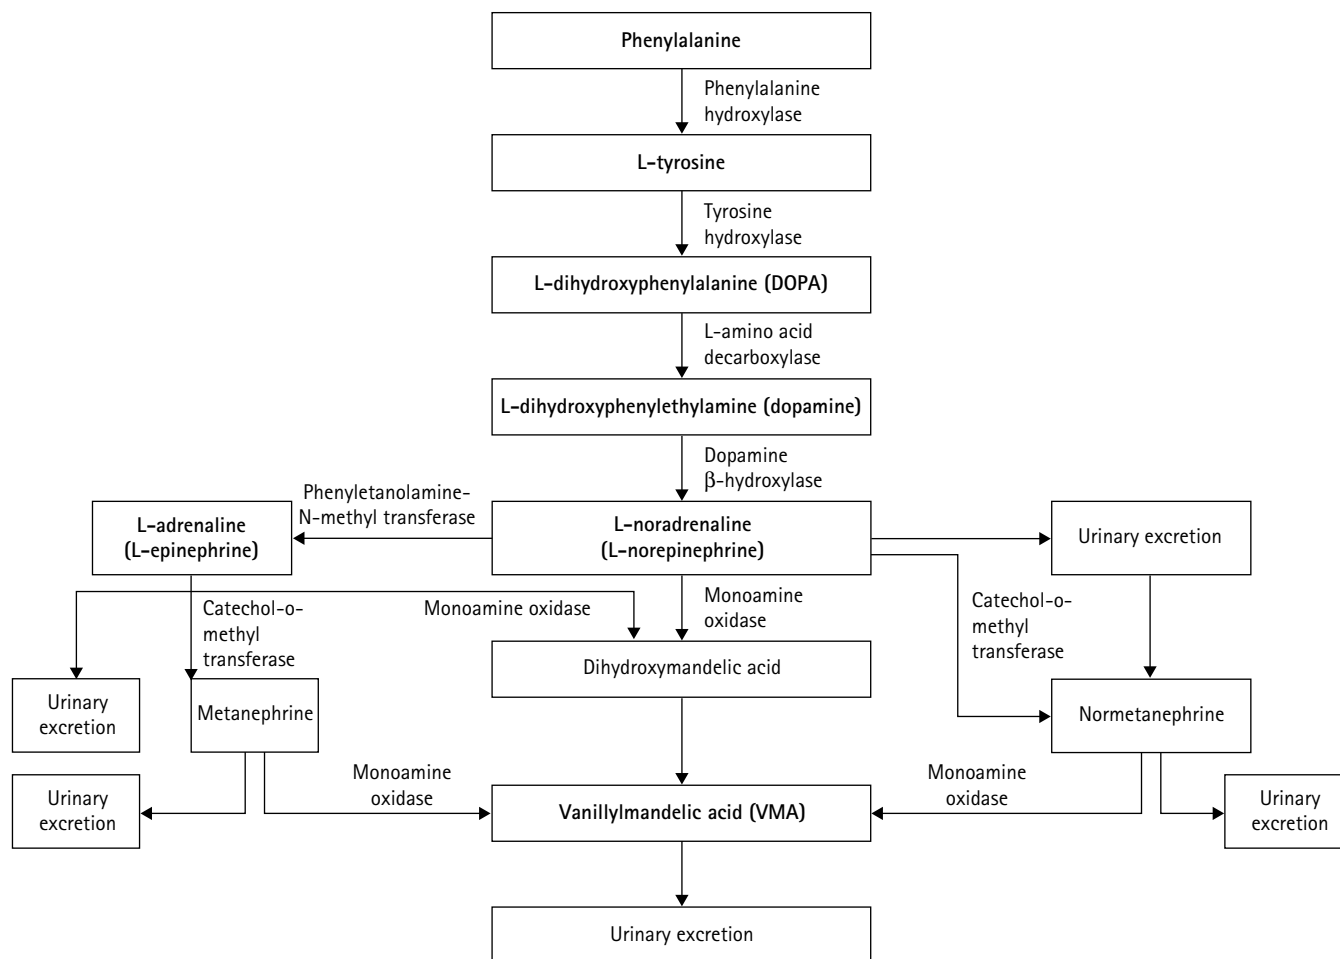

Fig. 15.55 Catecholamine biosynthesis and metabolism.

with renal disease or diabetes and if previously high BP has been found.<sup>327</sup>

Endocrine hypertension usually results from corticosteroid excess (with low renin levels, cf. renal causes) or, less commonly, from catecholamine excess.

## ENDOCRINE CAUSES OF HYPERTENSION

### Corticosteroid excess

#### *Congenital adrenal hyperplasia (CAH)*

Some patients with 11βOH deficiency and all with 17OH deficiency are hypertensive from ACTH-stimulated mineralocorticoid overproduction secondary to impaired cortisol biosynthesis. In both, excessive DOC levels are generally thought to be responsible for the hypertension (but see above). Appropriate GC treatment returns BP to normal.

#### *Primary and familial forms of hyperaldosteronism*

Although rare, their study has increased understanding of mechanisms which may have much wider significance (see above).

#### *Cushing syndrome*

Hypertension is common in children with Cushing syndrome but BP may be only moderately elevated. Its etiology is multifactorial including the significant mineralocorticoid effect of excessive cortisol secretion, increased renin substrate and, perhaps, increased vascular reactivity to vasoconstrictors (see above).

*Exogenous excessive administration of glucocorticoid* is a much commoner cause of hypertension than any of the above.

### Catecholamine excess

Pheochromocytomas are rare causes of secondary childhood hypertension. They develop from chromaffin cells. Two thirds are from the adrenal medulla but they can also arise from the sympathetic chain in the abdomen, the mediastinum or the neck. They are usually sporadic but may be familial and associated with MEN 1 and MEN 2 (p. 473) and von Hippel – Lindau syndrome (pheochromocytoma, retinal hemangioblastoma, renal cysts and carcinoma) or neurofibromatosis.<sup>275</sup> The tumors can be bilateral and multiple. In childhood, hypertension is nearly always sustained rather than paroxysmal, and headaches, sweating, nausea and vomiting are common. There may be visual disturbances, abdominal pain, polydipsia and polyuria, convulsions and acrocyanosis.

Diagnosis depends on raised plasma catecholamine levels and increased urinary excretion of catecholamines and their metabolites (metanephrines, VMA and HVA). Repeated collections and estimations may be necessary. Localization of the tumor(s) may be possible by non-invasive techniques [ultrasound, CT scan, <sup>131</sup>I- or <sup>231</sup>I-metaiodobenzylguanidine (MIBG) scintigraphy].

If invasive techniques (e.g. arteriography or vena caval catecholamine sampling) are planned there must be full alpha- and beta-sympathetic blockade, careful BP monitoring and drugs which will acutely lower BP immediately available. Blockade is necessary preoperatively to prevent severe hypertension, hypotension and dysrhythmias during definitive surgical removal. Complete surgical removal results in BP normalization and, usually, 'cure' – only 5–10% are malignant. Analogous pharmacological blockade is necessary in children with hypertension associated with neuroblastoma.

## THE ENDOCRINE CONSEQUENCES OF CURING CHILDHOOD CANCER

Long-term effects of radiotherapy (RT) and chemotherapy (CT) on growth and endocrine function have become more obvious and important as survival following childhood cancers has improved. The incidence of childhood cancer is 100–130 per 10<sup>6</sup> per annum and 1 in 600 children under the age of 15 years will develop cancer which is now curable in 65–70%. One in 1000 young adults are now childhood cancer survivors. Leukemia (predominantly lymphoblastic) makes up approximately one third of childhood cancers and brain and spinal tumors about one quarter. Treatment-induced late effects are potentially manifested in a number of areas including growth and puberty, endocrine dysfunction, infertility, cognitive dysfunction and the risk of second tumors.

The risk relates to treatment modality and the challenge remains to further improve survival rates whilst reducing the incidence and severity of treatment-induced late effects. These can be anticipated and monitored to optimize prevention and treatment – ideally through multidisciplinary follow-up involving pediatric oncologist, pediatric endocrinologist, pediatric neurologist, radiation oncologist, pediatric neurosurgeon, clinical psychologist and social worker.

Adverse effects on growth may result from radiation-induced hormone deficiencies, impaired spinal growth from spinal RT (and from CT), primary hypothyroidism from spinal RT, precocious or delayed puberty from abnormal GT secretion, gonadal failure (puberty/fertility) from RT or CT, and problems with nutrition or obesity.

At diagnosis of acute lymphoblastic leukemia (ALL), there is already low bone turnover with reduced levels of collagen formation and resorption markers (PICP, PIIINP and ICTP). In remission, there is further bone synthesis suppression (low levels of PICP and PIIINP) and growth suppression<sup>328</sup> which probably relates to glucocorticoid (prednisolone) and high dose methotrexate therapies. This suggests that there may be an increased risk of long term osteoporosis and fractures. Comparison between countries suggests that the degree of growth impairment is proportional to the intensity of the CT regimen. CT has a disproportionate effect on spinal growth impairment, perhaps because of the large numbers of spinal epiphyses. High dose cranial irradiation is associated with a significant potential height deficit because of the combined effects of precocious puberty and an impaired pubertal growth spurt (see below). Chemotherapy also causes abnormalities of growth and bone turnover in children with solid tumors.<sup>329</sup>

The hormone deficiency effects of RT will depend on the site of irradiation, total dose of irradiation, fractionation schedule and the child's age at treatment. Growth impairment will result from RT to the hypothalamo-pituitary axis (the hypothalamus is more radiosensitive than the pituitary and the GH axis the most radiosensitive followed by the gonadal axis). RT to the spine (in the treatment of medulloblastomas, ependymomas, germinomas) will result in late pubertal growth failure (the spinal growth spurt occurs towards the end of secondary sexual development) and primary hypothyroidism due to a direct effect on the thyroid gland. CT (glucocorticoids, methotrexate) will also impair growth (see above). Tumor recurrence should always be considered as a cause of growth failure in these patients.

RT doses of > 24 Gy will be associated with precocious (especially in young girls) or delayed puberty and GH deficiency within 5 years.<sup>330</sup> Very high RT doses [e.g. ~ 54 Gy (used in craniopharyngioma)] will cause GH deficiency within 2 years. Lower doses (< 24 Gy) may be associated with precocious puberty, an impaired pubertal growth spurt due to relative GH insufficiency and reduced pubertal spinal growth. Total body irradiation (TBI) used as preparation for bone marrow transplantation (~ 7.5–15.75 Gy) may also be associated with pubertal GH insufficiency, thyroid dysfunction and a radiation-induced skeletal dysplasia. In the medium term, impaired beta-cell function seems often to result from TBI resulting in degrees of insulin resistance, impaired glucose tolerance or even frank diabetes.<sup>331</sup>

The same total dose of RT given in several fractions minimizes GHD and growth impairment and fractionated TBI produces less damage to

normal tissues. Younger children (especially girls) are more likely to develop precocious puberty and a pubertal growth spurt can be mistaken for 'catch-up' growth. Obesity can normalize growth at the expense of disproportionate bone age advance and reduced height prognosis.

Clinical growth assessment should consist of the regular measurement of sitting and standing height, skinfolds, weight and calculation of BMI, and puberty staging. Laboratory assessment (baseline free thyroxine, cortisol, testosterone/estradiol, IGF-1, etc.), physiological profiles (GH, GTs, cortisol, etc.) and dynamic tests (insulin hypoglycemia, GnRH, HCG, TRH, Synacthen, etc.) will be relevant. Integrating the information as a prelude to appropriate investigation and treatment is an important role for the pediatric endocrinologist in the multidisciplinary team. Much information can be gleaned from careful anthropometry and pubertal assessment in the context of knowledge about the anticancer treatment received so as to minimize investigations in children who have already been through many unpleasant treatments and investigations.

Available treatment modalities include the use of GH for growth failure, pubertal suppression and thyroxine, glucocorticoid and sex steroids as indicated.

If a child has a good prognosis from the underlying condition 2 years from treatment, GH therapy should be given when indicated on biochemical and anthropometric grounds. There is no evidence that GH is associated with reactivation of the primary lesion.

The majority of childhood cancer survivors are fertile. There are low risks of infertility following chemotherapy for Wilms' tumor and ALL and following cranial RT < 24 Gy. Infertility or subfertility is common after CT for Hodgkin disease or RT (TBI, testicular or pelvic). Thus ovarian failure after TBI is common with the risk relating to age at treatment (younger children are at lower risk). Physiological sex steroid replacement therapy improves uterine function (blood flow, endometrial thickness) so that these women could potentially benefit from assisted reproductive technologies. However they have reduced uterine distensibility with increased risk of IUGR and miscarriage or preterm delivery.

In boys, the germinal epithelium is much more sensitive to radiation than Leydig cells – 1.2 Gy to the testis will result in azoospermia, whereas > 20 Gy (in prepuberty) or > 30 Gy (postpuberty) is necessary before Leydig cell function is damaged significantly. Thus spontaneous progression through puberty does not necessarily indicate subsequent fertility. Inhibin B is a potential marker of gonadotoxicity in prepubertal children treated for cancer.<sup>332</sup>

As part of their monitoring, childhood cancer survivors should have routine assessment of gonadal function. The majority will be fertile and the risk of infertility relates to the treatment received. In some situations hormonal manipulation may restore fertility. Counseling is necessary for young people at high risk of infertility and sperm cryopreservation is available for postpubertal boys. Ovarian cortical strip cryopreservation is one current research technique in girls. Strategies to protect the prepubertal testis from damaging effects of CT or RT are under investigation.

An evidence-based guideline for the long term follow-up of child and adult survivors of childhood cancer is available.<sup>333</sup>

## THE PANCREAS AND CARBOHYDRATE METABOLISM

### PANCREATIC MORPHOLOGY

The pancreas forms by proliferation of endodermal duodenal epithelium at the end of the fourth week of development as separate dorsal and ventral pancreatic buds. The ventral bud migrates posteriorly from a position close to the primitive liver bud and bile duct to lie in close contact with the dorsal bud. The duct systems and parenchyme subsequently fuse and the definitive (common) pancreatic duct is formed by the distal part of the dorsal and entire ventral duct. Failed fusion is a common normal variant. The pancreas is supplied by the splenic and superior mesenteric arteries and drained by the splenic and superior mesenteric veins into the portal vein. The islets of Langerhans, the pancreatic endocrine units, develop from the parenchymatous pancreatic tissue during

the third month, are scattered throughout the gland and secrete insulin by about 5 months. There is a rich blood supply to and rich sympathetic and parasympathetic (vagal) innervation in contact with the islet cells.

Exocrine pancreatic function is discussed in Chapter 19. The main endocrine secretions, insulin and glucagon, are intimately concerned in glucose homeostasis. Insulin is secreted from islet beta cells, glucagon from alpha cells. There are also delta cells (thought to secrete somatostatin and perhaps gastrin) and a fourth cell type, F cells, which secrete pancreatic polypeptide (PP). The physiological importance of PP is unclear although it is secreted in response to food. Somatostatin's role in this context is in downregulating the rate of entry of nutrients from the gut by delaying gastric emptying, decreasing duodenal motility, altering splanchnic blood flow, suppressing pancreatic exocrine and endocrine (insulin and glucagon) secretion and gastrin and secretin production from the gut. Thus integration of islet cell hormone and portal vein hormonal secretions is influenced by nutritional state, extrapancreatic hormones (especially gastrointestinal inhibitory polypeptide – GIP) and autonomic input.

## INSULIN

Insulin is formed in beta cells from a 9000 molecular weight precursor, proinsulin, itself derived from a larger polypeptide precursor, preproinsulin. Proinsulin is an 86 amino acid linear molecule with three peptide chains – A, B and (intermediate) C (Fig. 15.56). A and B peptides are joined by two disulfide bonds. C peptide is cleaved in Golgi apparatus by proteolytic enzymes leaving the covalently bonded A and B peptides (chains) – the definitive insulin molecule (MW 6000) (Fig. 15.56) – stored in cytoplasmic granules. Insulin and C peptide are thus present in granules in equimolar concentrations and expelled together into the draining capillary (emiocytosis). Circulating C peptide is a

marker for endogenous insulin secretion, disappearing at the end of the partial remission ('honeymoon') period of diabetes mellitus.

Insulin is the major metabolic hormone. Factors modulating secretion include glucose, amino acids, glucagon, secretin, gastrin and GIP. During feeding, rising blood glucose and amino acid concentrations stimulate release – there are two phases in the response, a short-lived burst as preformed insulin is released and a slower and more sustained phase of de novo synthesis.

Insulin stimulates glucose uptake by muscle and fat cells, its conversion to glycogen and triglycerides and amino acid incorporation into muscle protein. Lipolysis, glycogenolysis, gluconeogenesis and muscle breakdown are inhibited and hepatic glycogen synthesis stimulated. The net effect is a fall in blood glucose associated with low circulating levels of free fatty acids, ketone bodies and branched chain amino acids. As plasma glucose levels fall below normal (e.g. during starvation), insulin secretion diminishes and secretion of glucagon and other hormones which increase blood glucose levels (catecholamines, GH, glucocorticoids) is stimulated ('counter-regulation') leading to stabilization of blood glucose levels. Insulin is mainly degraded in liver and kidney but also in pancreas and other tissues.

## GLUCAGON

Glucagon is a single chain 29 amino acid polypeptide (MW 3485) secreted by islet alpha cells. Plasma levels increase during starvation – falling blood glucose levels are probably the major release stimulus but protein ingestion stimulates secretion through release of gut hormones such as pancreaticozym. Anxiety and exercise increase secretion via sympathetic pathways. Somatostatin suppresses secretion.

Fig. 15.56 Structure of proinsulin.

Glucagon increases glucose levels by liver glycogenolysis and gluconeogenesis and stimulates fat cell lipolysis (increasing free fatty acids and ketones) and insulin, catecholamine, GH and calcitonin release. Circulatory half-life is only about 10 min – degradation is mainly in liver and kidney.

**Integration**

Interaction between insulin, glucagon and other counter-regulatory hormones is crucial in glucose and protein homeostasis, to provide sufficient and constant supply of glucose substrate to brain and for growth and energy requirements in infancy and childhood. The liver is particularly important for glucose homeostasis – liver gluconeogenesis, glycogen synthesis and glycogenolysis are summarized in Figure 15.57.

During *starvation*, two thirds of daily glucose production is directly utilized by the brain as an energy source, insulin secretion falls and counter-regulation follows. This produces increased proteolysis, lipolysis, glycogenolysis and gluconeogenesis with reduced tissue glucose uptake resulting in increasing blood glucose levels. There are increased plasma fatty acids (used as an additional energy source), glycerol, ketone bodies and branched chain amino acids associated with high levels of glucagon, cortisol, GH and catecholamines and low or undetectable insulin levels (Fig. 15.58).

In the *fed* state, circulating glucose stimulates insulin secretion and suppresses counter-regulation. Proteolysis, lipolysis, glycogenolysis and

gluconeogenesis are suppressed, tissue glucose uptake increases and blood glucose levels fall (Fig. 15.58).

Understanding glucose homeostasis is necessary for rational differential diagnosis, investigation and treatment of hypoglycemia (see p. 490).

Surprisingly little is known about overnight blood glucose levels in normal children. Cyclical variation, periodicity 80–120 min, is described with a gradual fall until wakening with no evidence of a dawn blood glucose rise. In some children levels fall to < 3 mmol/L. Maintenance of normoglycemia seems largely mediated through free fatty acid metabolism (with significant differences between 8 p.m. and 8 a.m. beta-hydroxybutyrate levels) whereas lactate levels suggest that glycogen stores are relatively protected overnight but available for acute hypoglycemic crises.

**DIABETES MELLITUS (DM)**

DM is defined as a metabolic disorder of multiple etiology characterized by chronic hyperglycemia with disturbances of carbohydrate, protein and fat metabolism resulting from defects in insulin secretion, insulin action or both. Consensus guidelines discussing the epidemiology, classification and management details have been published by the International Society for Paediatric and Adolescent Diabetes (ISPAD)<sup>334</sup> and evidence-based guidelines, with a section on diabetes in children and young people, have been published by the Scottish Intercollegiate Guidelines Network.<sup>335</sup>

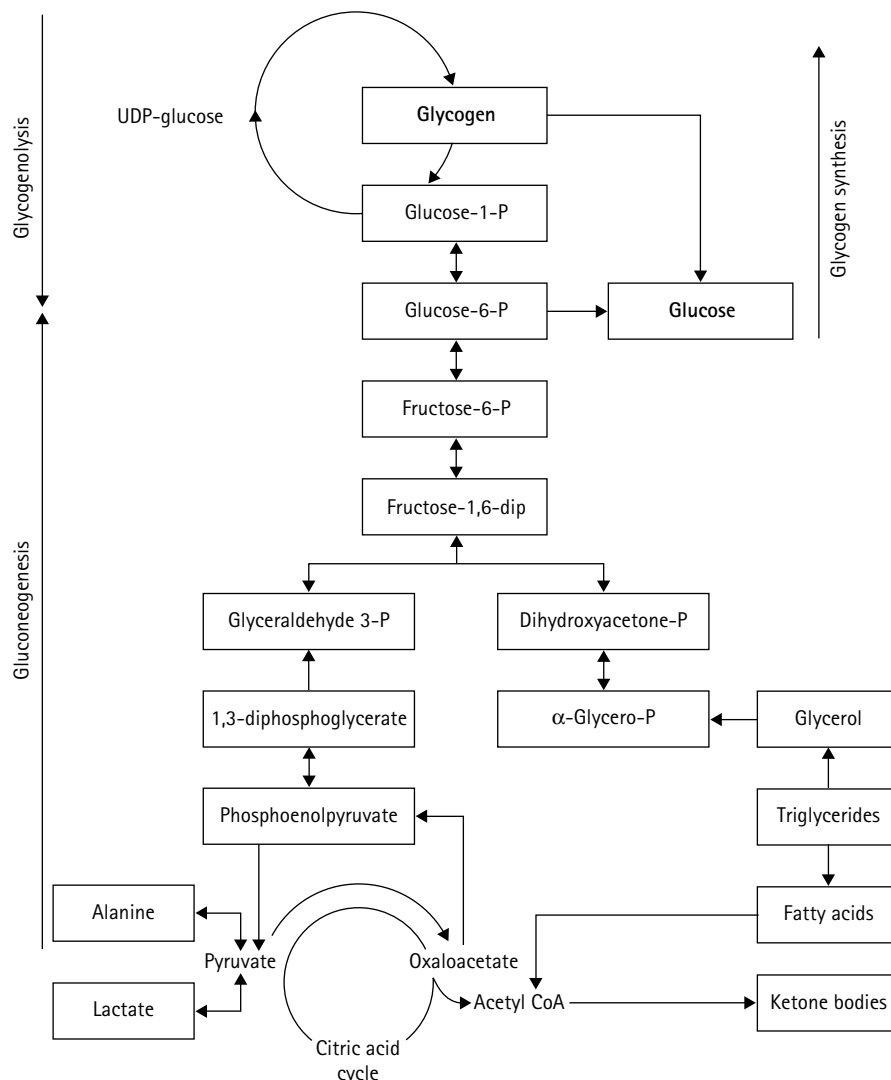

Fig. 15.57 Metabolic pathways of liver gluconeogenesis, glycogenolysis and glycogen synthesis.

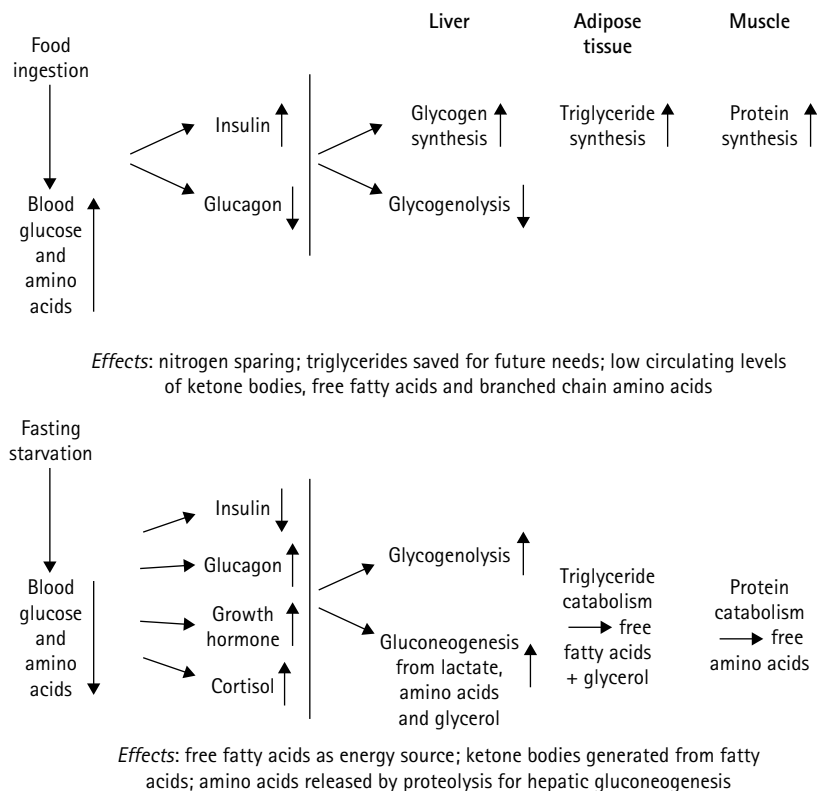

Fig. 15.58 Metabolic and endocrine characteristics of fed and fasted states.

## HISTORICAL INTRODUCTION

Diabetes mellitus (DM) was first mentioned (though not by name) in the 'Ebers' papyrus (about 1550 BC). 'Diabetes' (siphon or diuresis) was first used by the Turkish physician Aretaeos of Capadokia (AD 130–200): 'Diabetes is an awkward affection melting down the flesh and limbs into the urine patients never stop making water life is short and painful they are affected with nausea, restlessness and a burning thirst and at no distant term they expire.' (Aretaeos 1554). The sweetness of diabetic urine ('mellitus' = sweet), first mentioned in sixth century AD Indian Vedic literature was rediscovered by Thomas Willis (1674).<sup>336</sup> Matthew Dobson (1775) showed that the sweet taste was due to sugar and that serum also tasted sweet.<sup>337</sup>

For 1500 years it was thought that the kidney's inability to retain water caused diabetes. Von Mering & Minkowski<sup>338</sup> showed that total pancreatectomy in dogs resulted in diabetes mellitus and, within 10 years, islet function was becoming understood and fasting and dietary treatment introduced. The discovery of insulin by Banting and Best in 1922<sup>339</sup> led to early development of insulin for treatment of human diabetes.

## DISEASE SPECTRUM

Recognition of the spectrum of diabetes and its manifestations led to a WHO classification: primary diabetes mellitus is insulin dependent (IDDM) – type 1, or non-insulin-dependent (NIDDM) – type 2, irrespective of age of onset.

DM is the commonest metabolic or endocrine disorder in children and adolescents and was almost invariably type 1. In the past, the diagnosis (as opposed to the management) of DM in children and adolescents has not been complex. However, the current etiological diversity of DM in the young makes their differential diagnosis (suspected clinically and confirmed on a molecular genetic basis) very important for determining prognosis and appropriate treatment.<sup>340</sup>

Non-insulin-dependent DM occurs temporarily in the partial remission ('honeymoon') phase of type 1 DM and permanently in type

2 DM, genetic syndromes accompanied by DM, and 'maturity onset diabetes in the young' (MODY). The overall UK prevalence in young people of non-type 1 DM is currently around 3% of the total, with type 2 making up less than 0.5%. In a largely Caucasian population, MODY is over 10 times more common than type 2 DM. However, type 2 DM predominates in areas with large ethnic minority (e.g. Asian Indian) populations.<sup>340</sup>

Typical phenotypic features in type 1, type 2 DM and MODY are summarized in Table 15.19 – based on referrals to a specialist genetics of diabetes unit in Exeter UK,<sup>340</sup> and ISPAD.<sup>334</sup> There is no single phenotypic marker that is pathognomonic for non-type 1 DM making both individual diagnosis and epidemiological study difficult.<sup>340</sup>

## TYPE 2 DM

Type 2 DM has become very much more common in adolescents and children in association with the dramatically rising prevalence of obesity in these age groups but still has a low prevalence in childhood in the UK overall, apart from ethnic minorities who are at increased risk.<sup>165</sup> In Europe as a whole, type 2 DM and impaired glucose tolerance in children and adolescents with obesity is an increasing problem.<sup>342</sup> In contrast to the USA,<sup>343</sup> severe disorders of glucose tolerance are still uncommon even in a UK at risk population.<sup>156</sup>

Intrauterine growth retardation may increase the risk of type 2 DM<sup>33</sup> as may maternal smoking during pregnancy.<sup>344</sup> Many genes are involved in the etiology of type 2 DM, each contributing a small amount to the overall risk. Certain ethnic indigenous populations seem particularly at risk of type 2 DM (e.g. Pima Indians, Australian Aboriginals, Tonga Islanders). Among 15–19-year-old North American Indians, the prevalence of type 2 diabetes per 1000 is 50.9 for Pima Indians, 4.5 for all US American Indians. From 1967–1976 to 1987–1996, the prevalence increased 6-fold for Pima Indian adolescents. Among African Americans and whites aged 10–19 years in Ohio, type 2 diabetes accounted for 33% of all cases of DM.<sup>345</sup>

Table 15.19 Characteristics of pediatric DM patients (After Hattersley 2000<sup>340</sup>, 2001<sup>341</sup>)

	Type 1	MODY GCK	MODY HNFalpha-1	Type 2	Diabetes + syndromes
Age of diagnosis in pediatric clinic	11 (0–16)	5 (0–16) = age of testing	15 (4–16)	15 (10–16) usually postpubertal females	Variable
Severity of glycemias	Progressive 11–50 mmol/L	Mild 5.5–14 mmol/L	Variable, progressive 5–25 mmol/L	Variable 5–25 mmol/L	Variable 5–25 mmol/L
Ketosis	Ketosis prone, insulin dependent by 5 yr post diagnosis	No ketoacidosis, not insulin dependent	Ketoacidosis rare, not insulin dependent	Ketoacidosis rare, not insulin dependent	Ketosis in DIDMOAD, not in others
Optimal treatment	Insulin	Diet	Sulfonylureas	Metformin	Variable
Parents affected	0–1	1 (often not diagnosed)	1	1–2	Rarely
Obesity	+/-	+/- (5% BMI >30)	+/- (5% BMI >30)	++++	Variable + to +++
Acanthosis nigricans	—	—	—	++	Variable
Racial	Low type 2 prevalence	Low type 2 prevalence	Low type 2 prevalence	High type 2 prevalence	All
Islet antibodies	++++	—	—	—	—
Biochemical features		Small increment OGTT	Large increment OGTT, high HDL, low renal threshold	Variable	Low HDL, high TG
Genetic test specificity	+	++++	++++	—	+++

BMI, body mass index; DIDMOAD, DIDMOAD syndrome; GCK, glucokinase; HDL, high density lipoprotein; HNF, hepatic nuclear factor; MODY, maturity onset diabetes in the young; OGTT, oral glucose tolerance test; TG, thyroglobulin.

In Japanese adolescents, type 2 DM is four times more common than type 1. In the USA, young people with type 2 DM are most commonly obese girls from minority populations with insulin resistance, acanthosis nigricans and a family history of type 2 DM. This is becoming a major health problem with up to 45% of children diagnosed with DM in parts of the USA now having type 2. Currently, in the UK, type 2 DM is also becoming much more common, especially in early postpubertal obese girls. There is seldom ketosis at presentation, fasting insulin levels are raised (with low SHBG levels – a marker of insulin resistance), and there is often dyslipidemia and hypertension. Chronic microvascular complications are at least as severe and often occur earlier and more rapidly than in type 1 DM.

There can be diagnostic confusion with type 1 and MODY, but there is, in contrast with type 1, obesity and a stronger family history (an 80% chance of one or both parents having type 2 DM). The obesity and family history do not help the differential diagnosis from MODY where there is a similar family history and age of onset.

Treatment with diet, exercise and, often, metformin is indicated. Metformin is also being used in adolescents with severe insulin resistance and impaired glucose tolerance but its overall effectiveness and safety profile remains unclear.

### MATURITY ONSET DIABETES IN THE YOUNG (MODY)

MODY is a heterogeneous group of autosomal dominantly inherited, young-onset beta-cell disorders (Table 15.19). Characteristically, two or more consecutive generations are affected with individuals diagnosed before 25 years of age. MODY comprises two discrete clinical syndromes (Table 15.19): glucokinase MODY [caused by mutations in the glucokinase (GCK) gene on chromosome 7p, MODY 2] and transcription factor MODY [caused by mutations in the genes encoding hepatocyte nuclear factor (HNF)-1alpha (chromosome 12q, MODY 3 – the commonest form), HNF-1beta (MODY 5), HNF-4alpha (chromosome 20q, MODY 1) and insulin promoter factor (IPF)-1 (MODY 4)].<sup>340,341</sup>

In white UK children with non-type 1 diabetes MODY is as common as type 2 DM, and MODY should be particularly suspected if there are three consecutive generations with DM, insulin requirements persistently < 0.5 U/kg/day and no tendency to ketosis. GCK MODY is mild and nonprogressive with hyperglycemia caused by a resetting of the pancreatic glucose sensor. It is treated with diet, and complications are rare.

In contrast, transcription factor MODY results in a progressive beta-cell defect with a high incidence of diabetic complications. Sulfonylureas are the treatment of choice for patients with HNF-1alpha mutations and very good control is achievable. HNF-1beta mutations are associated with DM and renal cysts and HNF-1beta has a critical role in renal development.<sup>346</sup> Mild mutations in IPF-1 predispose to type 2 DM but most transcription factor mutations result in monogenic DM.<sup>341</sup>

### TYPE 1 DM

The remainder of this section refers to type 1 DM unless otherwise stated.

### Incidence and pathogenesis of type 1 diabetes mellitus

Prevalence (sum of patients related to total age-related population) and incidence (age-related annual manifestations) show wide variations worldwide. Incidence rates for type 1 DM show a 400-fold variation and there are intriguing findings: annual incidence rates broadly increase with distance (north and south) from the equator both within Europe (3.7 per 100 000 in France, 45 per 100 000 in Finland) and within quite small distances within countries (about 2-fold higher in Scotland than England and higher in northern Scotland than southern).<sup>347</sup> Within individual areas, incidence is higher in whites than non-whites and in boys (M:F ratio about 1.1:1) and increases with age, peaking at adolescence. In many studies in geographically disparate countries an increasing incidence of between 2 and 5% per annum is reported (a rise in 50% over 10 years).

Incidence and prevalence differences reflect the complex interaction of genetic and environmental factors (e.g. temperature, nutrition, viruses, chemical toxins) in the development of diabetes. Genetic factors are clearly important as there is an increased incidence in parents and siblings of index cases: the risk to a sibling is 15–50-fold that in the normal population and 12–15% of young people under the age of 15 years with diabetes mellitus have an affected first degree relative.<sup>348</sup> Children are three times more likely to develop diabetes if their father has diabetes rather than their mother.<sup>349</sup>

Monozygotic twins are concordant for type 1 DM five times more frequently than dizygotic twins but the rate is much lower than in type 2 diabetes and a discordance rate of nearly 50% over a 30-year

follow-up suggests the importance of environmental factors in clinical manifestation of the genetically susceptible individual.

Type 1 DM is a T cell mediated autoimmune disease involving beta cell damage from inflammatory cytokines and autoaggressive T lymphocytes. A large number of chromosomal regions have been identified as containing potential diabetes susceptibility genes although the IDDM1 locus, which encompasses the major histocompatibility (HLA) complex on chromosome 6p, is the major genetic risk factor. The HLA DQ genes are the primary susceptibility genes within this region – loci DR3 and DR4 have particularly strong associations and increase the relative risk for developing diabetes between 3-fold (DR3) and 14-fold (DR3/DR4 heterozygosity). The IDDM2 locus maps to a variable number of tandem repeats in the insulin gene region on chromosome 11.<sup>350</sup>

The HLA identical sibling of a child with type 1 diabetes has about a 90-fold increased risk of developing the disease before 15 years. The risk is hardly increased at all if the sibling is HLA non-identical. Ninety to ninety-eight percent of all type 1 diabetics express DR3, DR4 antigens or both, but fewer than 1% of healthy subjects with such markers will ever develop diabetes.

*Environmental factors* are crucial for disease expression and clinical diabetes development and may be either causative or protective. Epidemiological data indicate that such factors operate from early in life. The search for preventable environmental triggers for autoimmune destruction and acute decompensation precipitating clinical diabetes onset (by when > 90% of beta cell function is destroyed) continues.

Viruses can cause diabetes in animals, and in humans there is seasonal variation of clinical onset in association with high viral prevalence with a particular association with Coxsackie B4.<sup>351</sup> However, it is known that beta cell destruction, ultimately leading to decompensation and clinical onset of diabetes, occurs over many years prior to presentation. A virus or other 'insult' such as early exposure to cows' milk protein, chemical toxin, certain foods or cooking products, or even stressful life events have been postulated as being responsible for triggering autoimmune (AI) beta cell destruction in genetically susceptible individuals. Childhood vaccinations do not increase the risk of developing type 1 DM in childhood.<sup>352</sup> Acute decompensation, up to many years later and leading to clinical presentation, is often due to an intercurrent infection when insulin requirements rise and cannot, by then, be met.

Histopathological studies indicate that AI mechanisms are paramount in diabetes pathogenesis which has implications for its prevention or modification by immunosuppression. There is a strong association between type 1 diabetes and other AI disease (e.g. thyroid, adrenal, parathyroid).

Although a number of specific genetic, immune and metabolic markers have been identified as significant risk factors there is as yet no evidence for effective prevention.<sup>353</sup> In particular, high dose nicotinamide<sup>354</sup> and low dose oral or parenteral insulin<sup>355,356</sup> have failed to halt beta cell damage in individuals at increased risk for type 1 DM. Screening (whether in the general population or in high risk children and young people) is currently unethical and not recommendable except in the context of future randomized trials of prevention therapy strategies.

### Clinical onset and diagnosis

Although, in retrospect, parents may feel their newly diagnosed diabetic child has not been 'right' for several months with poor appetite and malaise, the clinical onset in most children is usually relatively acute: increasing polyuria (due to osmotic glucose load), secondary polydipsia, weight loss, anorexia and fatigue develop over days or weeks.<sup>334</sup> Some children present particularly acutely with rapid onset of ketoacidosis and coma. This may be more common in DR3/DR4 heterozygotes, DR3 patients presenting less. More acute onset is also reported in younger children perhaps because of lack of awareness by parents or health professionals, or pre-existing enuresis, hence the importance of testing the urine for glucose in any child with secondary enuresis.

Once suspected, diagnosis is not usually difficult, but too often there is delay because urine is not tested (for glucose and ketones) when a

child presents with nonspecific symptoms or signs – anorexia, vomiting, abdominal pain, tachypnea (assumed to be 'pneumonia'), vaginal candidiasis, fatigue or irritability or recurrent skin infections.<sup>334</sup> Finding glycosuria or hyperglycemia (random level = 11.1 mmol/L) is an emergency – the child should preferably be seen the same day and certainly within 24 h and never simply referred by letter to an outpatient clinic. If diagnosis and treatment are not prompt, further catabolism may rapidly cause increasing ketosis and acidosis (Fig. 15.59) with coma and death. There is still significant morbidity and mortality in children who present with severe ketoacidosis and dehydration, and children unconscious at presentation have a 12-fold increase in mortality compared to those not in coma.<sup>357</sup>

If the diagnosis is in doubt, criteria are the same in children as for adults<sup>358,359</sup>:

- symptoms (polyuria, polydipsia or unexplained weight loss) plus random venous plasma glucose  $\geq 11.1$  mmol/L; *or*
- fasting venous plasma glucose  $\geq 7$  mmol/L [impaired fasting glycemia (IFG) is indicated by a level  $\geq 6.1$  and  $< 7$  mmol/L]; *or*
- plasma glucose  $\geq 11.1$  mmol/L at 2 hours after a 75 g oral glucose load (impaired glucose tolerance is indicated by levels of 7.75 mmol/L up to 11.1 mmol/L).

Normal values 2 hours following the glucose load are  $< 7.75$  mmol/L.

In asymptomatic patients, the diagnosis should only be made on the basis of at least two abnormal measurements of significant hyperglycemia on separate days.

Improvements in health education (of parents and professionals) and prompt access to a specialist pediatric unit will help reduce the incidence of severe ketoacidosis.

Morbidity and mortality will be reduced if specific well-learned, well-understood and adequately supervised management guidelines are followed. An integrated care pathway (ICP) for management of diabetic ketoacidosis<sup>360</sup> (DKA) heightens awareness of optimal diabetes management, increases confidence in management by staff and reduces inappropriate treatment variation leading to improvements in clinical practice (see below). Such ICPs are also of potential benefit in other areas of diabetes management (e.g. the management of the newly diagnosed child without ketoacidosis, hypoglycemia, children undergoing emergency or elective surgery, etc.).

### Initial management of the child without ketoacidosis

Most children who have developed diabetes have only mild symptoms and are not ketoacidotic. With a network of primary carers (e.g. diabetes specialist nurses) nearly all such children can be successfully managed at home. Careful continuing assessment – frequent telephone contact and at least daily home visits – is necessary to prevent onset of ketoacidosis at home and to provide basic information.

Fig. 15.59 A newly (and 'late') diagnosed diabetic with severe ketoacidosis and dehydration.

This approach is being increasingly adopted in many UK centers and is cost-effective but may be inappropriate for socially deprived families, rural settings a long way from the hospital or, particularly, in areas where adequate community-based personnel with specialist training are unavailable. Some parents are so distressed at diagnosis that admission is desirable. A home-based program of management and education for children and their families is an appropriate alternative to a hospital-based program (Grade C recommendation<sup>335</sup>) but potential benefits of home management – greater acceptance by the family and a quick return to ‘normal’ family life – can also be achieved if the child’s hospital admission is sensitively handled. There is no evidence that either home or hospital initial management and education is superior – the appropriate choice should depend on local circumstances and resources.

Whatever strategy is adopted, several days will be necessary for unhurried education of child and family in basic diabetic care. It is a mistake to try and impart too much early information – upset, anxious, grieving or frightened parents and children are not receptive learners. Simple practical information and instruction about insulin, injection techniques and dietetic principles are important with a positive emphasis that, provided simple guidelines are followed, their child will soon be feeling better than for some weeks and will be able to take part in all the activities enjoyed. Availability of a personal diabetes handbook with written information is helpful.

### Recognition and treatment of ketoacidosis

A child with ketoacidosis and severe dehydration (Fig. 15.59) is dangerously ill and requires emergency treatment. Vomiting and abdominal pain with tenderness and guarding may mimic an acute abdomen whilst hyperventilation may be misdiagnosed as pneumonia. There may be circulatory collapse, oliguria and coma. Salicylate poisoning should be considered in the differential diagnosis.

In children known to have type 1 DM on insulin, ketoacidosis is usually precipitated by intercurrent infection (fever is not part of DKA), but may occur if too little insulin is given (perhaps because of fear of hypoglycemia), insulin is omitted altogether (e.g. by an emotionally disturbed adolescent) or with menstruation or severe emotional upset. In this group, there may not be pronounced hyperglycemia, particularly if insulin has been (correctly) continued or increased but vomiting has led to inadequate carbohydrate (CHO) intake. For this reason, urinary ketones should always be tested for by the established diabetic when there is significant hyperglycemia on home blood glucose testing as metabolic decompensation may be more severe than realized. Near patient plasma ketone testing is proving valuable in monitoring the adequacy of treatment and, for example, ‘sick day’ management at home.

DKA management is facilitated by the use of an integrated care pathway to reduce inappropriate treatment variation leading to improvement in clinical practice.<sup>360</sup> The priority is appropriate *volume repletion* – rehydration is more crucial than insulin in the early stages. Initial fluid should be isotonic (0.9%, 150 mmol/L) saline, or PPS if there is circulatory collapse or unconsciousness – 10–20 ml/kg within the first 30–60 min for initial volume expansion. A rapid history, clinical examination and blood glucose (by indicator stick) will confirm the diagnosis and a sample for true blood glucose, urea and electrolytes, plasma osmolality and arterial blood gas estimation should be obtained as the infusion is set up. Full blood count, hematocrit, platelets and an infection screen (blood culture, urine microscopy and culture, viral cultures, swabs) should be obtained and the ECG monitored.

Dehydration should be assessed clinically:

- mild (3–5%) – dry mucus membranes, reduced skin turgor;
- moderate (6–8%) – the above plus sunken eyes and poor capillary return;
- severe (≥ 9%) – shock with poor perfusion, hypotension, thready pulse, tachycardia;

and, if possible, by weighing and comparing with average weights for age or previous records. PPS should be given if there is severe dehydration and/or marked acidosis.

Whilst hypernatremia is due to severe water loss (exceeding sodium loss), hyponatremia is usually factitious – high glucose levels increase

extracellular tonicity and draw water out of cells thereby diluting the extracellular sodium content – and often associated with hyperlipidemia. Empirically derived equations have been developed to calculate the ‘true’ sodium value which results when all excess glucose is removed from the extracellular fluid: either divide the plasma [glucose] (mmol/L) by 4 and add the result to the measured plasma [Na] (mmol/L), or subtract 5 from the plasma [glucose] mmol/L, divide the result by 3 and add this figure to the plasma [Na] (mmol/L). It can be helpful to apply one or other when managing DKA with initial hyponatremia to identify the [Na] which will be reached with approaching normoglycemia a number of hours later. Plasma sodium levels should rise as ketoacidosis is corrected. If levels are > 150 mmol/L 0.45% saline should be substituted for 0.9% saline. If the plasma sodium is falling rapidly, fluid replacement should be recalculated to be given over 48 hours or longer.

Creatinine levels may be spuriously high due to assay interference by acetoacetate and hematocrit may be falsely elevated by osmotic swelling of erythrocytes in the Coulter counter.

Dehydration should generally be corrected over 24 hours or longer with 0.9% saline. The deficit (ml) is calculated as % dehydration × weight (kg) × 10. Normal fluid requirements are calculated as 100 ml/kg for the first 10 kg body weight, 50 ml/kg for the second 10 kg and 20 ml/kg for the remainder. The hourly infusion rate is then calculated as

$$\frac{\text{maintenance requirements} + \text{deficit}}{24}$$

The volume of any albumin that may have been given during resuscitation should be ignored.

Indications for correcting over 48 hours are pH < 7.1, initial plasma [Na] < 128 or > 150 or any child aged 5 years or less.

A short acting *insulin* must be used and is best given as a continuous intravenous infusion by syringe pump. Conventionally a rate of 0.1 units/kg/h is recommended but a rate of 0.03–0.05 units/kg/h (50 units of a short-acting insulin in 50 ml of 0.9% saline produces a solution containing 1 unit/ml of insulin) has proved safe and effective in our hands over many years. The aim is to decrease the blood glucose gently (by about 2–3 mmol/L/h) and the rate of insulin infusion adjusted in aliquots of 0.1 ml (= 0.1 units) / hour (0.03 units/kg/h should be the minimum infusion rate). This regimen results in a smooth and steady fall whilst being sufficient to switch off ketone production. The infusion should be changed 12 hourly.

Acidosis will almost always correct with correction of fluid balance. Correction should not be too rapid, and as pH is a log scale small changes are significant. If the acidosis is not correcting, resuscitation may have been inadequate and more PPS may need to be given.

*Bicarbonate* should be considered only with severe acidosis (pH < 7.0), impending circulatory collapse (requiring inotrope support) or respiratory depression and used only on advice of senior medical staff as a slow i.v. infusion. In less severe ketoacidosis it may increase the risk of cerebral edema (due to the large sodium load) and hypokalemia (more rapid shift of potassium into cells) with increased morbidity and mortality. It must be infused slowly intravenously (over 30–60 min) and separately. The amount needed is derived from the formula:

$$\begin{aligned} & \text{mmol bicarbonate (ml of 8.4\% NaHCO}_3\text{) required} \\ & = \text{wt (kg)} \times \text{base deficit (mmol/l)} \times 0.1 \end{aligned}$$

Once blood glucose levels are ≤ 13 mmol/L, 0.45% saline/5% dextrose is substituted for 0.9% saline. The insulin infusion rate is then adjusted to maintain blood glucose levels between 7 and 13 mmol/L. If blood glucose levels fall to 7 mmol/l or less, 10% dextrose and 0.45% saline should be substituted without decreasing the rate of insulin infusion further as adequate insulin is necessary to switch off ketosis.

*Potassium*. There is always substantial depletion of total body potassium whatever the initial plasma level, which will fall once insulin is commenced. KCl (20 mmol/500 ml saline) should be added once the child has passed urine (or in the knowledge that urine has been passed

in the previous 4 hours). Potassium replacement can be adjusted to maintain normal plasma levels. A cardiac monitor (observing for T wave changes) is important if levels are abnormal.

If no urine is passed by 4 hours, catheterization may be necessary. Inappropriate ADH secretion may develop (low urine output, high urinary and falling plasma osmolalities) necessitating fluid restriction to prevent cerebral edema. Low plasma sodium levels may be factitious (see above) – plasma osmolality is a better hydration guide. All urine passed should be tested for glucose and ketones.

Neurological observations, including Glasgow Coma Score (GCS – see Table 22.48), should be frequent and changes or development of headache reported to medical staff immediately. A nasogastric tube should be passed if there is vomiting or drowsiness (the stomach will be dilated and aspiration can be fatal), aspirated hourly, and gastric losses included in an accurate fluid balance record. Intravenous ranitidine (1 mg/kg t.i.d) should be given if the aspirate is positive for blood. Antibiotics may be necessary if infection is suspected once bacteriology specimens are obtained. Fluid balance should be calculated hourly and near patient blood glucose should be monitored hourly using a strip test read on a glucose meter. Capillary or venous blood gas measurements, plasma glucose (measured in the laboratory) and urea and electrolytes should be checked 4 hourly until the pH reaches 7.3. The aim should always be to correct metabolic abnormalities slowly – too rapid changes are thought to contribute to the risk of cerebral edema (see below) with significant morbidity and mortality.

Once the fluid deficit is corrected, maintenance requirements should be recalculated and given. The nasogastric tube is removed when bowel sounds are present. Oral fluids can be started gently as tolerated from 12 to 18 hours onwards once pH is > 7.3 and urinary ketones are moderate or less. Intravenous fluids are discontinued when the child is rehydrated, drinking, eating a light diet and ketone free. Intravenous insulin is continued until ketones are absent and just prior to a meal. If the insulin infusion is stopped prematurely, ketonuria and anorexia will take longer to resolve and acidosis may persist.

A suitable initial s.c. insulin regimen is 0.8 units/kg/day given as  $\frac{2}{3}$  daily dose pre-breakfast [of which  $\frac{1}{3}$  as short acting (soluble) insulin and  $\frac{2}{3}$  as intermediate acting (isophane) insulin], and  $\frac{1}{3}$  total daily dose split as short acting insulin pre-tea (evening meal) and  $\frac{2}{3}$  as intermediate-acting insulin pre-bed. Thirty to sixty minutes after s.c. insulin is given the i.v. insulin infusion is discontinued and the child fed. Potassium should be given orally (as KCl 1 mmol/kg/24 h) for 2 days. Children with DKA are best managed on a high dependency unit and high quality, appropriately experienced nursing care is essential. After recovery, diabetes education begins.

In many countries there are major issues with regard to the provision of skilled medical services to remote and rural communities and this is a particular issue for children with DKA.

## Cerebral edema

Cerebral edema is the main cause of morbidity and mortality and single commonest cause of death in children with diabetes. It is a feared complication of DKA, often developing several hours after starting treatment in a context of apparent biochemical and clinical improvement. Over a 3 year period in the mid to late 1990s in the UK, the calculated risk of developing cerebral edema was 6.8 per 1000 episodes of DKA. The risk is higher in new (11.9 per 1000 episodes) as opposed to established (3.8 per 1000) diabetes. Within childhood, there are no sex or age differences but children are more susceptible than adults (in whom hypoglycemia is a much commoner context for cerebral edema to develop).<sup>361</sup> Little is known of the etiology of cerebral edema in DKA – over-rapid fluid replacement and insulin infusion, hypoxemia and injudicious bicarbonate use<sup>362</sup> may increase its likelihood, but it is unlikely to be due solely to management factors – changing management practices have not been associated with a drop in the incidence – and biological patient variables may be important. There may be an association with low arterial partial pressures of carbon dioxide and high urea levels (reflecting the degree of dehydration) at presentation.<sup>362</sup>

Signs and symptoms of cerebral edema consist of headache, irritability, decreasing conscious level (falling GCS) and convulsions. Danger signs are a falling plasma sodium concentration, poor urine output, bradycardia and hypertension. Papilledema is a late sign. Hypoglycemia should be excluded. Diagnosis and treatment are urgent.<sup>361</sup> Mannitol 20% (2 g in 10 ml) 0.5 g/kg should be given i.v. over 30–60 minutes but needs to be started within a few minutes of the diagnosis of cerebral edema if it is to be effective. Mannitol may need to be repeated and there should be urgent discussion with senior medical and ITU/anaesthetic staff about the need for intubation and hyperventilation. Any child with a GCS falling below 12 should be observed carefully where there are facilities and expertise for intubation. A GCS of less than 8 will need urgent elective intubation and ventilation which may be life saving. MR scanning is helpful if available. Fluid should be restricted to  $\frac{2}{3}$  maintenance and the fluid deficit corrected over 48–72 (rather than 24) hours. Unfortunately, cerebral edema occurs even when management of DKA follows current ‘best practice’ guidelines and mortality (24%) and morbidity (35% of survivors) rates remain high.<sup>363</sup> Subclinical brain swelling may be common during even optimal treatment<sup>364</sup> and seems generally not to be of long term consequence.

Whilst most increased mortality in diabetes is related to long term complications, there is also a significantly increased mortality in young people, with a 4-fold increase in the age- and sex-specific standardized mortality rate for those diagnosed before the age of 2 years and a 2-fold increase for those diagnosed between 3 and 15 years, in many cases due to ketoacidosis (with or without presumed cerebral edema).<sup>365</sup>

## Long-term management

There is irrefutable epidemiological evidence (at least in those aged 13 years or over) from the American 10 year prospective Diabetes Control and Complications Trial<sup>366,367</sup> that if good long term glycaemic control is achieved, risks of microangiopathic complications (retinopathy, nephropathy and neuropathy) are greatly reduced. The question is therefore not ‘why’ or ‘whether’ to maintain good glycaemic control but ‘how’.

Other questions remain. Pediatricians seldom see complications silently bequeathed with their patients to adult diabetologists. What level of childhood or adolescent glycaemic control constitutes ‘sufficiently good’ or optimal control? Is prevention of complications by establishment of good control in childhood and adolescence a realistic goal? How is it to be achieved in the context of normal physical and emotional growth and normal daily activities and family lifestyle? Will it be at the expense of more hypoglycemia? If so, how frequent or severe must it be in children of different ages before it affects cognitive function long term? Does more education or new or improved skills in family or clinician necessarily produce better control?

There is now no doubt that better metabolic control is associated with fewer and delayed microvascular complications.<sup>366</sup> This applies to younger children, and suboptimal metabolic control at all ages is likely to be associated with higher risks of acute (DKA, severe hypoglycemia) and long term complications. However, in very young children, the achievement of very tight glycaemic control must be balanced against the increased risks of severe, and potentially damaging, hypoglycemia. Basal insulin analogues may be particularly helpful in this regard (see below).

Optimal control must also be achieved in the context of normal family and school life and normal physical and emotional growth. Diabetes is a largely self (child and family) managed condition and successful care models need to focus on strategies that promote and maintain improved self-care behaviors. Children, young people and their families need to be empowered to control diabetes. Specific attempts to increase the effectiveness of education in diabetes care can improve short term control. Focuses need increasingly to be on insulin regimens that are flexible and fit the demands of school and social life. New technologies [continuous subcutaneous insulin infusion (CSII), inhaled insulin, continuous glucose monitoring systems, etc.]<sup>368</sup> have the potential to allow young people with type 1 DM to take control of their diabetes.

Motivation derives from encouragement and explanation, not coercion and arbitrary rules. Diabetes must not be ignored but should not need to preoccupy the child or family. Goals need to be framed from the perspective of the person with diabetes and their family. Education (instruction) is a partnership between health care professionals and families which attempts to achieve this through increased understanding of diabetes, empowerment and self-confidence in management.<sup>369</sup> Specific management aims and decisions will reflect the child's age, the family's diverse abilities, motivation and psychosocial backgrounds and personnel and resources available in hospital and community. A consistent approach by all members of the team is vital and will do much to create an environment in which the quality of control can improve.

Normoglycemia is dependent on an appropriate balance between calorie (carbohydrate, fat and protein) intake necessary for normal growth and energy expenditure and insulin. Diverse uncontrollable or unpredictable factors affect glycemia, e.g. intercurrent infection, a birthday party, attending the clinic, exams, GH, puberty, menstruation. Living with diabetes may require support which can be derived from involvement with self-help organizations.

Achieving 'tight' glycemic control in the context of a 'normal' lifestyle remains difficult for many families – in many children control is inadequate – but is helped by the multidisciplinary approach of the pediatric diabetes clinic: doctors have specialist knowledge of pediatrics, growth and diabetes; there is a dietician present with expertise in pediatric dietetics and diabetes; a psychologist or child psychiatrist may sit in or be readily available. Family emotional problems may be precipitated by diabetes impacting on parents or other siblings; the child's and family's emotional responses to diabetes will themselves have major effects on glycemic control. Omission of insulin, simulating hypoglycemia or making up test results is common and an understandable response in many situations either to gain reward or avoid reprimand. This does not represent severe underlying psychopathology but should prompt a re-evaluation of management and a consistent parental and professional approach with proactive psychological involvement (see below).

Diabetes nurse specialists (DNS) are important assets to a clinic as key members of the multidisciplinary diabetes team linking family, home, school, community and hospital in a way that other health professionals cannot. They provide specific support in hospital and at home at diagnosis and at times of crisis, visit schools to talk to teachers, provide continuing support, advice and education, by telephone and through home and school visits, and discuss specific problems with the hospital-based team.

**Insulin regimens**

Insulin is vital for glucose transport, storage and disposal. Glucose transport into cells provides energy, conversion to glycogen provides storage in liver and muscle, excess glucose is converted into fat, and protein catabolism is inhibited. The body's insulin requirements are continually fluctuating. In normal individuals, glucose is the main stimulus to insulin release from pancreatic beta cells; insulin is secreted into the portal vein and is immediately physiologically available. Insulin levels thus rise rapidly after meals and snacks with equally rapid falls to basal secretory rates between meals and at night. The main aim in type 1 DM management is to reproduce physiological insulin secretion with the aim of optimizing glycemic control. Most currently practicable regimens do so relatively poorly, but modern molecular engineering techniques – leading to the development of extremely short acting and extended action (true basal/background) insulin analogues – together with developments in continuous subcutaneous insulin infusion (CSII) pump technology are providing opportunities for young people with type 1 DM to take more informed control of their diabetes and achieve improved glycemic control<sup>368</sup> – see below. However, improvement in metabolic control can be related to intensified education and training rather than to pump therapy itself. Patient satisfaction, and perhaps metabolic control,<sup>370,371</sup> may be better with pump therapy than with

multiple injections but it is considerably more expensive financially and in terms of time and resources needed from the diabetes team. Results of research studies may not be directly applicable to a particular clinical setting and patient population, and intensified education with appropriate psychological motivational and dietetic input may still be the most effective and cost-effective way to improve metabolic control in children and adolescents with type 1 DM.

The regimen chosen must be individualized for child and family. Traditional examples are shown in Figure 15.60. Conventional therapy for type 1 diabetes has consisted of twice daily soluble and isophane insulin regimens with support from a multidisciplinary health care team and regular diabetes and health monitoring. Such twice daily regimens are still frequently used by many children and young people and are simple but inflexible (meals need to be eaten on time and have a relatively fixed carbohydrate content). A relatively physiological split is 30% soluble (short acting)/70% isophane (long acting). The insulins can either be premixed and injected using an insulin 'pen' or mixed by the patient (necessitating use of a syringe and needle).

Alternatively, a generally more satisfactory regimen, which reduces the risk of nocturnal hypoglycemia, consists of the pre-breakfast insulin given as above (either free mixing or premixed) but the evening soluble and isophane insulins split with soluble insulin given before the evening meal (supper, Scottish 'tea') and the isophane before bed. Short acting analogue insulin can be substituted for soluble insulin in these regimens and may be valuable in managing some patients, e.g. toddlers whose appetite is unpredictable and who can be injected after the meal.<sup>372</sup> Lente insulin is far from ideal as a 'background' – it has a peak in action between 2 and 6 hours after injection and even ultra-lente has a significant peak at 8–12 hours. Basal analogue insulins are preferable.

More intensive multiple daily injection (MDI) basal-bolus regimens are also used. In one regimen, soluble insulin is given preprandially and isophane insulin at bedtime. The soluble insulin provides sufficiently

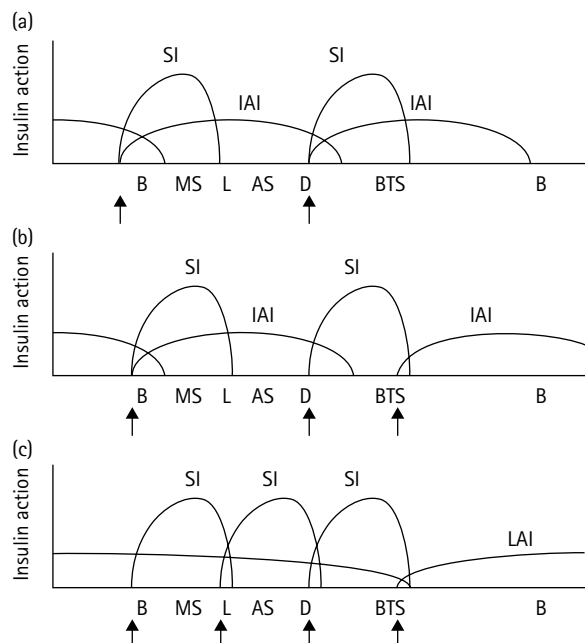

Fig. 15.60 Examples of insulin regimens: (a) two daily doses of short and intermediate acting insulins; (b) as (a) but the evening intermediate acting insulin delayed until bedtime; (c) insulin pen regimen – combination of preprandial short acting insulin with long acting insulin at bedtime. Key: B = breakfast; MS = mid-morning snack; L = lunch; AS = afternoon snack; D = dinner (Scottish tea); BTS = bedtime snack; SI = short acting insulin; IAI = intermediate acting insulin; LAI = long acting insulin; ↑ = insulin injection.

sustained action over the day to provide basal as well as bolus (meal-time) insulin availability. The main disadvantage is the need for four injections daily but this is compensated for by flexibility of lifestyle, meal sizes and times and exercise. Better, and obviating the need for snacks between meals, boluses of rapid acting insulin analogues (see below) can be given up to five times daily preprandially with a basal analogue insulin at bedtime. The bolus analogue can be given immediately before (or even during or immediately after) a meal (obviating the need to wait 20–30 minutes with soluble insulin). There is a reduced risk of nocturnal hypoglycemia and improved postprandial control with analogue<sup>373,374</sup> rather than soluble insulin<sup>367</sup> regimens with the added potential for improved glycemic control.

CSII regimens deliver insulin via an indwelling subcutaneous (usually abdominal) fine cannula, powered by microprocessor controlled pump devices which allow variable and programmable basal infusion rates between meals and overnight together with boluses of insulin when food is taken. This is undoubtedly the regimen which currently approximates most closely to physiological insulin delivery in people who do not have diabetes, with the potential for optimal glycemic control and reduced risk of hypoglycemia. Missing a meal or unexpected exercise can be adjusted for much more readily.

In contrast to the situation when insulin pump therapy was first introduced in the 1970s, current CSII and pumps seem well tolerated by children and young people because of their small size and flexible programmability which puts them in control of their diabetes – sporting activities without hypoglycemia, flexible meals in keeping with their peer group and less nocturnal hypoglycemia. However, there are still few published randomized trial data on the efficacy and safety of CSII versus MDI regimens. Evidence regarding the impact of an intensive insulin regimen (four or more injections or CSII) on long term control is derived principally from the Diabetes Control and Complications Trial (DCCT) which also involved a comprehensive patient support element (diet and exercise plans, monthly visits to the health care team, etc.).<sup>367</sup> Thus although intensive insulin therapy (MDI or CSII) significantly improved glycemic control over a sustained period compared with conventional insulin therapy (two injections per day), DCCT did not include children aged less than 13 years and, due to the study design, it is impossible to separate the benefits of intensive insulin therapy from intensive support.

In any case, intensive insulin therapy should only be delivered as part of a comprehensive support package (Grade B recommendation<sup>335</sup>). Thus CSII has resource implications – not only are insulin pumps and their consumables expensive but intensive support is necessary from diabetes teams (increased patient and family contact and support at least in the early stages, continuous blood glucose monitoring downloading and advice, etc.).

The insulin regimen should be tailored to the individual child to achieve the best possible glycemic control without disabling hypoglycemia (Grade C recommendation<sup>335</sup>). The number of daily insulin injections does not necessarily correlate with excellence of glycemic control. In a study from Sweden,<sup>375</sup> mean HbA<sub>1c</sub> levels of 7% and a low incidence of severe hypoglycemia have been reported with such an intensive regimen, but in Belgium<sup>376</sup> similar results have been reported using a twice daily insulin regimen. Other important factors for good glycemic control include continuing support from the health care team, psychosocial factors and blood glucose self-monitoring.

**Insulin Analogues.** There are currently several rapid acting insulin analogues available: insulin lispro (reversed proline and lysine at positions B29 and B30), insulin aspart (aspartate substituted for proline at B28) and insulin glulisine (lysine replacing asparagine at B3, glutamate replacing lysine at B29). Plasma insulin concentrations peak more rapidly and higher and decrease more rapidly than following soluble s.c. insulin. The peak action is approximately one hour after injection and there is no activity by 3–4 hours. A virtually peakless long acting insulin analogue (glargine insulin) has recently become available<sup>377</sup> – there is C terminal elongation of the insulin beta chain by two arginines and replacement of asparagine by glycine in position A21 – and experience

is developing in its use.<sup>378–381</sup> Hypoglycemia risks may be reduced using glargine compared to NPH (lente) insulin in adults<sup>382</sup> and similar data are now available in children and adolescents.<sup>383</sup>

A further long acting insulin analogue (insulin detemir) has now been introduced. Its pharmacokinetic profile suggests that its action may be slightly shorter than that of glargine but it too may decrease hypoglycemia risk in children with type 1 DM.<sup>384</sup> Indeed it may be superior in that regard as it has a significantly more predictable glucose-lowering effect than both NPH insulin and insulin glargine.<sup>385</sup> More studies and wider experience are necessary before the definitive role of these basal insulins in children and adolescents with type 1 DM can be determined but they are likely to increasingly replace NPH insulin and are particularly valuable in very young children.

With a combination of rapid and basal analogue insulins it is potentially possible to achieve improved ('tighter') control without problematic hypoglycemia. This reflects both the reduced variability of absorption of the basal analogue insulins and an awareness that bolus insulin analogues must be adjusted on the basis of postprandial plasma glucose increments.

### Insulin requirements

About 30–60% of children and adolescents demonstrate a partial remission ('honeymoon') phase (insulin requirements <0.5 units/kg/day) for up to 6 months (sometimes longer) after diagnosis. Subsequently average insulin requirements are in the order of 0.6–0.8 units/kg/day although considerably higher doses are necessary during the adolescent growth spurt (in early female and late male puberty).

Insulin requirements will vary according to activity levels, intercurrent illness, etc. Insulin resistance will develop when blood glucose levels have been high over a period of days or weeks (perhaps due to injecting into lipohypertrophic sites, eating inappropriately or intercurrent infection or omitting insulin). Increased insulin doses may be necessary for several weeks but it is important then to reduce the dose once more to avoid a vicious cycle of eating more to prevent hypoglycemia, resulting in weight gain and further increased insulin requirements and appetite.

Insulin adjustments are ideally based on home self-monitoring of blood glucose (see below). With consistent abnormalities at a particular time of day the appropriate insulin is adjusted up or down by child or parent, if necessary after consultation by phone with a member of the diabetes team. Development of skills in independent adjustment of insulin varies considerably between individuals and their families but adjustment only every few months in clinic is very unsatisfactory. Written information should be given for 'sick day' management and discussed at annual review appointments.

Subcutaneously injected insulin bioavailability is very variable but basal analogues seem superior in this regard. Absorption varies with injection site – fastest from the abdomen and slower from the thigh than the arm – and with exercise (see below) or if the site is rubbed after injection. If the same injection site is used repeatedly (because the injection becomes painless) lipohypertrophy (Fig. 15.61) is likely and injecting into lipohypertrophic injection sites is an extremely common cause of poor and unpredictable insulin absorption and erratic glycemic control amongst children and young people with type 1 DM.

Of the continuing developments in alternative insulin delivery routes (including oral, transdermal, intranasal), inhaled insulin, absorbed across the alveolar surface of the lungs, is now available for use in adults. Both liquid and dry powder formulations have been developed. There is a rapid onset and early peak action (similar to the time course of s.c. rapid acting analogue insulin) but with a longer period of action (more comparable to s.c. soluble insulin).<sup>386</sup> Insulin could be given by inhalation as often as necessary as preprandial boluses – injections would still be required for basal insulin administration. The relative efficiency of insulin delivery by aerosol, compared to s.c. injection, has been estimated as between 8 and 25%.<sup>387</sup> Initial studies in children and adolescents seem promising<sup>388</sup> but there remain significant anxieties about the use of inhaled insulin in children with still developing lungs and especially in those with common respiratory conditions such as asthma. Observations

**Fig. 15.61** Severe lipohypertrophy in a diabetic child on human insulin who was not adequately rotating the injection sites.

including alterations in pulmonary function tests,<sup>388</sup> a higher frequency of severe hypoglycemia<sup>389</sup> and increased insulin antibody formation<sup>388,389</sup> give particular cause for concern.

If a child with type 1 DM requires emergency or elective surgery, clear protocols or an integrated care pathway should be in place to facilitate safe management. In the perioperative period, additional metabolic demands contributing to unstable glycemic control potentially include preoperative fasting and dehydration, the stress response to surgery and anesthesia and postoperative calorie and fluid deficits. With careful management, mortality and morbidity should be no higher than in children without diabetes.

**Emerging options**

By clinical presentation more than 90% of beta cell function is already destroyed. Nonspecific immunosuppressive therapy at diagnosis, with toxic drugs such as cyclosporin A, has been shown to prolong the partial remission period, but no case of total remission or with normal glucose tolerance has been reported<sup>390</sup> and renal toxicity was common. Nevertheless, less toxic immunosuppressive agents have been developed and the possibility of a potential ‘cure’ for diabetes by pancreatic islet cell transplantation to secrete insulin physiologically in response to endogenous metabolic signals is an extremely attractive proposition if it could be realized.

However, despite the successful reversal of diabetes in small animal models, insulin independence after islet allotransplantation has been very difficult to achieve in the human with the use of diabetogenic immunosuppressive agents to suppress both islet alloimmunity and autoimmunity, the critical islet mass to achieve insulin independence and the detrimental effects of transplanting islets in an ectopic site and loss of graft function with time.<sup>391</sup> Promising approaches to these problems, including xenogeneic sources of cells, engineering islet cells with genes that induce expression of immunoprotective molecules, and neogenesis factors that may sustain populations of transplanted beta cells, are demonstrating that islet allotransplantation still has great potential to become an established treatment option.

Human beta cell lines derived from pancreatic tissue obtained from infants with persisting hyperinsulinemic hypoglycemia of infancy (PHII) which respond to physiological glucose levels are of potential use both in gene therapy for PHII and in cell transplantation studies for administering insulin for the treatment of diabetes mellitus.

**Diet**

If it is to be acceptable to child and family and followed in practice, diet should be closely related to recommendations for nondiabetics, but is inevitably tempered by the family’s eating habits which may fall short of that ideal. Rigid and dogmatic rules encourage noncompliance. In the past, diets have involved ‘quantitative’ advice with a ‘stable’ carbohydrate intake at regular intervals: breakfast, mid-morning snack, lunch, mid-afternoon snack, evening meal, bedtime snack.

A regimen which includes dietary management has been shown to improve glycemic control and is recommended (Grade B recommendation<sup>335</sup>). Specialist dietetic advice should be given by a dietitian with expertise in childhood diabetes wherever possible. Until the 1980s, counting of carbohydrate exchanges was recommended. The carbohydrate (CHO) exchange system (one exchange = 10 g CHO) has the virtue of dogmatic simplicity allowing a wide variety of foods to be eaten, but all nutrients can, of course, be converted directly or indirectly to glucose. The previously conventional guide to CHO intake (100 g per day for a 1 year old plus an extra 10 g per day for each additional year of age) needed to be varied considerably to meet growth and energy requirements of the individual. The proportion of CHO was high enough (40–50%) to enable fat intake to be reasonably low – less than 35% of calories should be from fat, which should be polyunsaturated to reduce long term risks of hyperlipidemia and cardiovascular disease.

The recognition that not all types of carbohydrate have the same effect on blood glucose levels and of the potentially restrictive nature of counting CHO exchanges had led to a change in focus to ‘healthy eating’. However, the emphasis has shifted again towards the view that flexible intensive insulin treatment combining dietary freedom and insulin adjustment can improve both glycemic control and quality of life.<sup>392</sup> Such approaches are being studied in children, and newer insulin regimens (MDI or CSII) require CHO intake assessment once again if short or rapid acting insulin is to be given in appropriate dosage.

CHO type remains important: concentrated, rapidly absorbed, sugary food taken in significant and regular amounts precludes stable glycemic control and should be confined to occasional treats before exercise, or at the end of a meal. Starchy, low fiber foods are acceptable, but starchy high fiber foods (Table 15.20) are best, because of their gradual

**Table 15.20** Some high fiber foods

Wholemeal bread

Vegetables
Brussels sprouts
Cabbage
Peas
Sweetcorn

absorption and metabolism. With education of the general population towards 'healthy eating' these foods are now more socially accepted and more easily obtainable cheaply.

Dietary management is therefore the 'art of the possible' and involves educating the whole family's eating habits. A pediatric dietitian with an interest in diabetes is a crucial part of the management team. A sensible approach to 'treats', fast foods and reasonable flexibility over timing is more likely to lead to cooperation; psychological benefit (not being different to family and friends) is likely to benefit lifestyle and control.

### Exercise

Exercise has major effects and in children is variable and capricious. Regular exercise allows participation in peer group activities and improves self-confidence and physical fitness. Strenuous exercise usually results in rapid but unpredictable falls in blood glucose (increased insulin mobilization results from increased blood flow and muscular activity). Energy stores (and particularly muscle glycogen) are depleted during medium to long duration exercise and hypoglycemia can occur up to many hours afterwards. Before activity, an extra 10–30 g CHO may be necessary depending on age, blood glucose level and the intensity of exercise planned (best taken as pure fruit juice or an isotonic sport drink). Such drinks are best taken during and after exercise as well, rather than loading with carbohydrate before the exercise starts. It is sensible to have a snack within an hour of completing the activity and post- (as well as pre-) exercise insulin doses may need to be reduced.

On a background of under-insulinization, exercise results in counter-regulation and hyperglycemia with ketosis. It is important not to exercise in the presence of ketones – exercise is not a replacement for insulin. On activity holidays it is often sensible to cut insulin by < 50% if severe hypoglycemia is not to result on the first day even with additional snacks.

### Psychological interventions

In the past, there has been a tendency to expect children with diabetes to take on too much responsibility for their diabetes management at too young an age. As they grow older, children with diabetes pass through a stage of 'interdependence' (between total dependence on parents and full independence) where they know what to do and how to do it, in terms of the practicalities of, for example, drawing up and injecting insulin and self blood glucose monitoring (SBGM), but are not ready to take responsibility for injections or monitoring. Maintaining parental involvement improves glycemic control.<sup>393,394</sup>

Managing diabetes is inevitably stressful at times, both for the children with diabetes themselves and for their families. Factors contributing to an increased risk of young people with diabetes developing psychological problems include: too much responsibility being placed on the child; avoidance coping (never coming to terms with diabetes emotionally or developing conscious or unconscious strategies which do not address the problem faced); family conflict or lack of communication both within the family and with the diabetes team; low socioeconomic status or a nontraditional family structure;<sup>395</sup> poor maternal health, especially depression.<sup>396</sup>

Eating disorders are more common in adolescents with diabetes compared with nondiabetic peers, especially in girls, adversely affect glycemic control and can be difficult to treat.<sup>397</sup> Specific psychological problems linked potentially to future poor glycemic control (e.g. maladaptive coping strategies) can be identified at diagnosis and 1–2 years later, using validated tools performed by a trained practitioner.<sup>398</sup> Regular assessment for psychological problems, especially maladaptive coping strategies and eating disorders, is desirable (Grade B recommendation<sup>335</sup>).

Psychological or educational interventions have positive effects on psychological outcomes and knowledge about diabetes and glycemic control.<sup>399</sup> Interventions which promote diabetes-specific coping skills are effective and add to the effectiveness of intensive management.<sup>400</sup> Thus the use of cognitive coping strategies targeted at diabetes-specific problems is recommended (Grade A recommendation<sup>335</sup>) and parental

support and family communication should be encouraged, with targeted psychological treatment of family disruption and related stress factors (Grade B recommendation<sup>335</sup>). Education programs, computer-assisted packages and telephone prompting should be considered as part of a multidisciplinary lifestyle intervention program (Grade B recommendation<sup>335</sup>). It is desirable that health care professionals should receive training in patient-centered interventions in diabetes (Grade B recommendation<sup>335</sup>).

### Glycemic control and its assessment

Many children with type 1 DM enjoy active and healthy lives but some are poorly controlled requiring frequent hospital admissions for ketoacidosis, hypoglycemia or stabilization. Poor control may reflect unhappiness or instability in the family (see above), particularly if there has never been emotional (as opposed to intellectual) acceptance of diabetes.

'Brittle' diabetes<sup>401</sup> is now accepted to be overwhelmingly due to insulin omission – injection sites should be checked for lipohypertrophy, but fruitless searches for underlying metabolic abnormalities are counterproductive. Long term poor control causes severe stunting of growth and pubertal development and may be associated with 'Cushingoid' obesity and hepatomegaly (Mauriac syndrome). Gross abnormalities are now seldom seen and assessment of physical and emotional growth and well-being while essential are, in themselves, insufficient – normal growth and no reported symptoms of hypo- or hyperglycemia may be found even when glycemic control is far from ideal.

Insulin adjustments are ideally based on home self-monitoring of blood glucose (SBGM). Checking for glycosuria gives limited retrospective information about likely previous blood glucose levels (has the level been high enough to exceed the renal threshold for glucose since the bladder was last emptied?), do not warn of impending hypoglycemia, and are valueless with normoglycemia as the optimal therapeutic goal. Even early morning glycosuria may be misleading, reflecting early morning hyperglycemia (excessive insulin the previous evening with counter-regulation, the Somogyi effect), too little insulin, or the 'dawn phenomenon' – decreased insulin sensitivity due to nocturnal GH peaks.

Immediate knowledge of blood glucose levels is only of practical benefit if child and parents understand their significance and relevance and are motivated to take appropriate action on the basis of consistent abnormalities. That SBGM monitoring does not, in itself, lead to better control<sup>402</sup> is not surprising. Blood tests done in rotation once or twice daily just before main meals and at bedtime, and occasionally 60–90 min after main meals, an acceptable regimen for many, will provide most information from fewest tests. Blood glucose estimation is of particular value during illness or symptoms that could relate to hypoglycemia. Nevertheless blood tests are uncomfortable and a chore. Education and motivation will reduce the number omitted, done inaccurately or of results made up to 'keep the doctor happy'. Intensive treatment of type 1 DM (using MDI or CSII) requires more frequent measurements (post- as well as preprandially – '8 point profiles') for optimal glycemic control.

However, conventional daytime SBGM provides incomplete information on nocturnal (hypo)glycemia for which the development and availability of continuous glucose monitoring systems (CGMS) is a major advance. The glucose sensor is inserted (via a needle which is then withdrawn) into s.c. tissue, usually of the anterior abdominal wall. An electrical signal is generated by the oxidation (catalyzed by glucose oxidase in the sensor) of glucose in the interstitial fluid. Systems providing 'real-time' data are available. Patterns of hypo- and hyperglycemia not detectable by conventional SBGM will become apparent in young people using CGMS<sup>403</sup> and improvement in glycemic control can be expected (it has already been documented in adults<sup>404</sup>). As with conventional SBGM, the relative error of the measurements is likely to increase at levels in the hypoglycemia range<sup>404</sup> and the relative importance of pressure or temperature changes (especially overnight) remains to be determined.

Amongst available technologies, the combination of CSII therapy with glucose sensor data from CGMS currently provides the nearest approach to mimicking physiological insulin secretion and allowing

motivated children and young people to achieve and maintain optimal control of their diabetes whilst minimizing hypoglycemia (not least at night).

**Glycosylated hemoglobin (HbA<sub>1c</sub>).** Hemoglobin forms a non-enzymatic link with glucose – percentage of glycosylated hemoglobin (HbA<sub>1c</sub>) is an objective measure of integrated glycemic control over the previous 6–8 weeks. Assessed in this way, the majority of diabetic children are less than ideally controlled<sup>405</sup> and in some control is abysmal. Identifying this group is easier than improving the situation. There has been doubt as to the appropriateness of some laboratory quoted normal ranges for HbA<sub>1c</sub> and the ‘target range’ (6–8% with a DCCT-equivalent method) is lower than previously considered desirable. It is likely that the risk of microvascular complications rises sharply above mean HbA<sub>1c</sub> levels > 9%.<sup>406</sup> This has implications for children, at greater risk of hypoglycemia and its consequences, when ‘tight’ glycemic control is the aim (see below). Finding high values is helpful when home monitoring results apparently indicate excellent control – either monitoring technique is faulty or, commonly, there is deliberate manipulation due to emotional disturbance.

The ideal HbA<sub>1c</sub> value (between 6% and 8%) reflects average blood glucose levels since the last estimation of approximately 6.5 mmol/L and 10.5 mmol/L respectively. A 1% increase in HbA<sub>1c</sub> reflects an average increase in blood glucose levels of 2 mmol/L in the preceding period – a mean HbA<sub>1c</sub> value of 10% will reflect prior mean blood glucose levels of around 14.5 mmol/L, i.e. very poor control.

HbA<sub>1c</sub> estimation is much more valuable if the current result is available in clinic so that appropriate discussion can take place with the child and parent(s) and appropriate advice given. In many clinics, portable or fixed analyzers are available to provide such a service; if that is not the case, capillary blood samples on filter paper or in special containers can be obtained at home shortly before the next clinic visit and posted to the laboratory. Shorter term indices of glycemic control, e.g. plasma proteins such as fructosamine, may be useful when assessing, for example, the efficacy of a specific therapeutic intervention.

## Hypoglycemia

Parents, and many children, worry particularly about ‘hypos’ and, especially, nocturnal hypoglycemia which is likely to be more common with the quest for tighter glycemic control. Recently introduced basal analogue insulins reduce the variability of blood glucose levels, and thus achieve significant relative risk reductions for hypoglycemia, particularly at night.

There are few long term neurophysiological and psychometric studies of effects of frequent mild hypoglycemia. Children’s hypoglycemic symptoms differ from those of adults. In very young children, neuroglycopenic symptoms (dizziness, poor concentration, drowsiness, weakness) and nonspecific symptoms (tearfulness, confusion, tiredness, irritability, aggression) are reported more frequently than autonomic symptoms (hunger, trembling, pallor). Sweating is absent during the early stages of hypoglycemia in prepubertal children with type 1 DM and other symptoms may be minimal. This is despite the fact that children (with and without diabetes) have a much more pronounced catecholamine response to hypoglycemia than do adults. However, the prolonged nature of nocturnal hypoglycemic episodes in children may be explained in part by defective counter-regulation. Weakness is the symptom most commonly reported by children, and the sign most frequently reported by their parents is pallor. Severe hypoglycemia can be associated with transient hemiparesis.<sup>407</sup>

Children diagnosed before 3 years potentially have particular problems with hypoglycemia. This relates both to the common occurrence of hypoglycemia in the children with type 1 DM (the normal young child has a relative inability to maintain normoglycemia during even periods of 6–12 h without food) and to the increased sensitivity to hypoglycemia of the still maturing brain. Children with type 1 DM can have episodes of profound and prolonged hypoglycemia with glucose nadirs of < 2 mmol/L and yet no effect on sleep.<sup>408</sup>

Occasional mild hypoglycemia – a feeling of hunger with faintness, headache or belligerency if a meal is delayed (but see above) – indicates tight control and seems harmless. Hypoglycemia is usually caused by

delayed or missed food, unexpected (or unexpectedly strenuous) exercise or excess insulin administration (by mistake, or, more rarely, deliberately). There is particular risk after diagnosis when endogenous insulin secretion is temporarily partially re-established if exogenous insulin is not reduced.

Both stress and early stages of an intercurrent viral illness can cause hypo- rather than hyperglycemia. Children and young people with diabetes should always carry extra glucose: 3 glucose tablets should be taken at early signs of hypoglycemia (alternatives are 50 ml of Lucozade or 2 teaspoons of glucose powder added to juice) and followed by food. ‘Hypo’ management must be available to families in written form and specifically discussed at annual review clinic appointments.

A child having a moderate or severe hypo will require assistance. A semiconscious or uncooperative child who cannot coordinate swallowing a sweet drink should be given a glucose gel product. This is available on prescription in the UK as GlucoGel and is rubbed into the inside of the cheek but should not be given to an unconscious child unless by a health care professional. In the unconscious or fitting child at home, glucagon (available as a GlucaGen kit, 1 mg i.m. or s.c.) should be given. Both will improve neuroglycopenia and the conscious level sufficiently for oral sugary carbohydrate (e.g. sugary juice plus toast and jam) to be given. If it is not, glucose levels will fall again – sometimes a problem with glucagon as it can induce vomiting. Blood glucose levels should be checked at home every 15 minutes for an hour to ensure that they return to normal. The next dose(s) of insulin may need to be reduced depending on the cause.

Prolonged severe hypoglycemia resulting in cerebral edema is seen following deliberate and massive insulin overdose and in adolescents after significant alcohol intake and can cause death or permanent brain damage. Hypoglycemia may be the major contributing factor to ‘unexplained’ death in otherwise healthy young people with type 1 DM.<sup>465</sup> Young people, including students, who live alone, abuse drugs or have had a previous psychiatric referral are particularly at risk.

## ADOLESCENCE (see also Ch. 35)

Adolescence is characterized by major changes in energy intake, growth and hormonal maturation as well as by profound changes in cognitive function, lifestyle, mood and coping. In nondiabetic adolescents, fasting insulin levels increase in both sexes through puberty until Tanner stages 3 or 4, with higher levels in girls reflecting their earlier growth spurt and marginally earlier pubertal maturation. These increases in both basal and stimulated insulin levels reflect and compensate for decreased insulin sensitivity during puberty which is partly due to the significant increase in growth hormone (GH) secretion.

Optimal glycemic control may be particularly difficult to achieve in adolescents: rapid growth necessitates a high calorie intake and must be paralleled by sufficient increases in insulin at that pubertal stage. Many adolescents are underinsulinized on conventional regimens and the daily insulin dose may need to be increased to around 1.5 units/kg during the pubertal growth spurt. Menstruation may precipitate ketoacidosis; important exams cause stress; emotional lability may cause rebelliousness against dietary restrictions, the need for monitoring control or insulin injections. Eating disorders (anorexia nervosa, bulimia) are also common (see above).

Standard insulin regimens through puberty will not correct all the metabolic abnormalities or maintain optimal glycemic control. However, in practical terms these considerations are overshadowed for many young people by lifestyle and behavior which characterize adolescence (see Ch. 35) and militate against good glycemic control in adolescents with type 1 diabetes.

Psychological transition from childhood to adolescence and beyond requires new approaches to motivation and education, flexible diet, insulin regimens and lifestyle. Maintaining parental involvement through the adolescent stage of ‘interdependence’ (see above) improves glycemic control<sup>393,394</sup> and improved control leads to better quality of life.<sup>409</sup>

Seeking excitement and involvement in risk-taking behaviors is the norm during adolescence. This extends from music and dance

to sexual behavior and the use of drugs. The impact of drug use on diabetes is relatively unknown with most of the evidence anecdotal, apart from information on alcohol and tobacco. Cigarette smoking greatly increases the microvascular risks to the diabetic. Alcohol use, in particular binge drinking which is common in adolescents, potentiates hypos. Adolescents must be aware of these risks and how to avoid the dangers and pitfalls. Health professionals should avoid being judgmental and encourage their patients to discuss these issues openly so that appropriate advice can be given. Drug taking should always be taken into consideration when trying to identify reasons for admission with DKA or severe hypos in this age group. Young female patients need to be very aware of the risks of unplanned pregnancy and health professionals should seek opportunities to discuss contraception and preconception care with adolescent girls with diabetes.

Coping strategies adopted by adolescents with diabetes range from obsessional control to denial of diabetes. Those using denial will generally come to the attention of health professionals reasonably quickly but those who are obsessional may never be recognized and may be seen as 'good diabetics'. Chronic insulin omission ('brittle diabetes') will be reflected in weight loss and is associated with episodes of DKA and poor glycemic control.<sup>410</sup>

Glycemic control is better in adolescents who have supportive families.<sup>411</sup> The adolescent with diabetes may feel isolated and not know anyone else with the condition. Many adolescents appear to benefit from sharing experiences with others in a variety of contexts – diabetes holiday camps and Youth Diabetes projects can be helpful in this regard and health professionals should encourage families to join the appropriate national support organization (Diabetes UK in the UK).

Special adolescent needs are often poorly met. Specific adolescent clinics, jointly staffed by pediatricians and adult diabetologists with empathy for the adolescent and his or her 'world-view', may be the ideal – a paternalistic approach is doomed to failure. Annual screening should be carried out to detect early manifestations of complications (see below). Psychological care should be an integral part of the support offered, particularly in view of the fact that psychological problems are more common where chronic illness exists. Integrated home-based, family-centered community-delivered interventions can result in improved metabolic control, treatment adherence and reduced hospitalization rates but are intensive and costly.<sup>412</sup> There is probably no 'right' time for transition or transfer from pediatric to adult clinic and the timing must both be individualized and determined by local arrangements and resources.

Clinics should be run separately from other diabetes clinics. There are some adolescents who do not attend clinic and refuse support in the community. It is important that these patients are identified and some form of contact, no matter how minimal, should be maintained – ideally with a diabetes nurse specialist with specific responsibilities for the adolescent service.

The overall aims of a service for young people with diabetes should be to ensure normal growth and development, minimize episodes of DKA and hypoglycemia, screen for and minimize the risks of complications (see below), promote social and psychological well-being, reduce risk-taking behavior and give support and education to empower the patient to become independent and in control of their diabetes.

## Complications

Complications are seldom seen before puberty even in long-standing diabetes. Sex steroid secretion at puberty could be important in their development and progression but pathogenesis is still poorly understood.

Early abnormalities in children and adolescents (e.g. microalbuminuria, background retinopathy) predict later development of long term microvascular complications<sup>367,413</sup> and maintaining glycemic control to as near normal as possible significantly reduces the long term risk of microvascular diseases.<sup>367</sup> An HbA<sub>1c</sub> > 10% over time in young people with diabetes increases the risk of the development of retinopathy by approximately 8-fold.<sup>367</sup> Thus with the aim of management of type 1 DM to reduce the risk of long term microvascular complications, the target

for all young people with diabetes is the optimizing of glycemic control towards a normal level (Grade A recommendation<sup>335</sup>).

Microalbuminuria is a marker for early nephropathy in diabetic children and adults. Using the first morning urine sample and relating concentration to creatinine is probably appropriate but its presence is likely to be related to such factors as acute glycemic control, posture, exercise, hydration and BP. It remains unclear how persistent and at what level it must be to cause concern or how justifiable is long term antihypertensive therapy in a child with a raised diastolic BP and microalbuminuria. BP rises concurrently with the onset of microalbuminuria and is also closely related to BMI.<sup>414</sup>

The evidence is unclear about the timing of commencing screening in young people with diabetes – age and puberty are reported without any strict definition. For clarity and simplicity 12 years of age in both boys and girls has been suggested.<sup>335</sup> However, early microvascular abnormalities may occur before puberty, which then appears to accelerate these abnormalities.<sup>415</sup>

The following can be detected and should be screened for in young people with diabetes: retinopathy (by ophthalmoscopy or fundal photography); microalbuminuria (by albumin excretion rate (AER) or albumin/creatinine ratio (ACR)); and hypertension. Young people with diabetes from the age of 12 years should annually receive examination of the retina (Grade C recommendation<sup>335</sup>), have their urine tested for microalbuminuria (overnight AER or first morning ACR) (Grade C recommendation<sup>335</sup>) and have blood pressure measured (Grade D recommendation<sup>335</sup>). There is no evidence that routine screening for autoimmune neuropathy or hyperlipidemia is beneficial.<sup>335</sup>

Every effort should be made to optimize glycemic control in young people with diabetes who have abnormal levels of microalbuminuria or elevated blood pressure for age so as to minimize the chance of progression to microangiopathic disease (retinopathy, nephropathy and neuropathy). There are encouraging data demonstrating that efforts to improve glycemic control can, when successful, halve the cumulative incidence of severe retinopathy and nephropathy over a 25 year follow-up period.<sup>416</sup>

In type 1 diabetes, preproliferative retinopathy has been identified within 3.5 years of diagnosis in postpubertal patients<sup>417</sup> and within 2 months of the onset of puberty. Ideally retinal photography or slit lamp biomicroscopy utilized by trained individuals should be employed in a program of systematic screening for diabetic retinopathy, with dilated direct ophthalmoscopy used for opportunistic screening.<sup>335</sup>

The role of statins and/or ACE inhibitors in the management of adolescents with microalbuminuria is under investigation.

## ASSOCIATIONS – THYROID DISORDERS AND CELIAC DISEASE

Both thyroid<sup>418</sup> and celiac disease<sup>419</sup> are more common in young people with type 1 DM compared with nondiabetic subjects – both may occur with minimal or no symptoms and thus be missed during routine care. It is recommended that young people with diabetes should be screened for thyroid and celiac disease at diabetes onset and at intervals throughout their lives (Grade C recommendation<sup>335</sup>). Screening for other autoimmune endocrine disorders has also been suggested. Standard blood tests exist to screen for thyroid and celiac disease, but there are limited data to support the specific frequency of screening. There are also few data as to which screening tests should be used – the authors measure TSH levels (by capillary sample at the same time as an HbA<sub>1c</sub> check) as part of the annual review.

Dietary management of young people with type 1 DM and celiac disease is complex and can be difficult for the family.

## OTHER DIABETIC SYNDROMES IN CHILDHOOD

### Secondary diabetes mellitus

Diabetes may occur with islet damage secondary to other factors, e.g. pancreatitis and pancreatic disease in cystic fibrosis (see below),

thalassemia and certain drug or poison ingestion. It may occur in association with individually rare genetic syndromes (e.g. Prader–Willi, Down, Alstrom, DIDMOAD – see below) or with abnormalities of insulin or its receptors. It may be secondary to other endocrine disorders (e.g. Cushing syndrome, pheochromocytoma).

### DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy and deafness) syndrome, wolfram syndrome<sup>420</sup>

Optic atrophy (OA) and diabetes insipidus (DI) usually present on a background of established diabetes mellitus. The bilateral progressive OA is present in nearly all by young adulthood causing eventual blindness. DI occurs in about one third and the (high tone) deafness is usually not severe. Inheritance is autosomal recessive and a nuclear gene at chromosome 4p16.1 (WFS1/wolframin), has been identified that segregates with disease status. Mutation analysis of the WFS1 gene in Wolfram syndrome patients has identified mutations in 90% of patients but their biological or clinical significance is not yet established.<sup>421</sup>

### Cystic fibrosis (CF) and diabetes (see also Ch. 20, p. 660)

Longer survival is resulting in diabetes being seen increasingly in CF patients. Although no evidence exists that the presence of diabetes or its treatment affects long term survival, it is recommended that patients with CF should be screened annually for diabetes (testing for hyperglycemia, glycosuria and/or a raised HbA<sub>1c</sub>) from 10 years of age (Grade C recommendation<sup>335</sup>).

### Neonatal diabetes mellitus

Transient neonatal diabetes mellitus is a rare condition (the UK national incidence is 1 in 400 000 live births<sup>422</sup>) generally seen in SGA infants. Presentation is with rapid weight loss, severe dehydration, fever and vomiting without diarrhea. Thirst and polyuria are usually unnoticed. Babies appear pale and lively. Blood glucose is very high with glycosuria but only mild (if any) ketonuria and acidosis. There is extreme insulin sensitivity – treatment is with 0.01 unit/kg/h continuous infusion and normal saline initially. The condition is self-limiting, resolving before 1 year of age (median 3 months). Subsequent glucose tolerance is normal but there is a predisposition to later type 2 diabetes, perhaps because of reduced beta cell functional capacity. Seventy-five percent of cases are associated with either paternal uniparental disomy of chromosome 6 or an unbalanced duplication of paternal chromosome 6 – the imprinted gene responsible maps to chromosome 6q24 and may be important for normal pancreatic development.<sup>423,424</sup>

Infants with permanent neonatal diabetes usually present within the first 3 months of life. Cerebellar hypoplasia, developmental delay, muscle weakness, epilepsy and Walcott–Rallison syndrome are associations, suggesting an autosomal recessive inheritance pattern. A mutation in the insulin promoter factor 1 gene has been identified as a cause of the pancreatic agenesis,<sup>424</sup> and a number of heterozygous missense activating mutations in the gene encoding Kir6.2 (important for ATP-sensitive potassium channels which mediate glucose-stimulated insulin secretion from the pancreatic beta cells) have been identified, leading to the hope that treatment of the disease may be possible with oral sulfonylurea therapy.<sup>425</sup>

## HYPOGLYCEMIA

Hypoglycemia is a common, but often poorly investigated and managed, metabolic abnormality in infancy and childhood but not a diagnosis in itself. If prolonged or recurrent it can result in severe neuroglycopenia, potentially irreversible brain damage and long term mental handicap, particularly in the very young.

Blood glucose regulation and the metabolic consequences of starvation are discussed above (see also Figs 15.57 and 15.58).

Normal neonates (see Chapter 12) and young children tolerate fasting less well than adults. Blood glucose levels may start to fall after

periods as short as 6–12 h which has implications for the preoperative management of children requiring surgery. Glucose levels appear to fall in a cyclical fashion overnight in normal children, some falling into the ‘hypoglycemic’ range before compensation.

Neonatal symptoms are nonspecific and include ‘jitteriness’, hypotonia, feeding difficulties, pallor, apnea, tachypnea, convulsions and coma. In older children, symptoms and signs are attributable to neuroglycopenia (confused or bizarre behavior, bad temper, irritability, headache, visual disturbances, hunger, abdominal pain, convulsions, coma) or to counter-regulation (pallor, sweating, nausea, vomiting).

Blood glucose levels below which there is arbitrarily defined hypoglycemia (e.g. 2.2 mmol/L) are controversial – it is unclear whether ‘low’ but asymptomatic blood glucose levels cause short or long term problems in different age groups. Prolonged or recurrent symptomatic hypoglycemia is undoubtedly associated with permanent neurological damage.

## ETIOLOGY

There are many potential causes of hypoglycemia – the most important are classified by age at presentation in Table 15.21. Endocrine causes are discussed in the section relating to the relevant gland; causes of hyperinsulinism are discussed below.

Persistent neonatal hypoglycemia is usually due to hyperinsulinism, deficiency of a counter-regulatory hormone or of a gluconeogenic or glycogenolytic enzyme. Recent onset recurring hypoglycemia is most commonly due to hyperinsulinism, ‘accelerated starvation’, defective hepatic gluconeogenesis or GH and/or glucocorticoid deficiency. Accidental or nonaccidental administration of hypoglycemic agents must be considered and hypoglycemia anticipated in any child who has ingested alcohol.

## DIFFERENTIAL DIAGNOSIS

History and examination may provide diagnostic clues, for example a family history of neonatal death or acidosis in an inherited metabolic disorder, short stature with micropenis in hypopituitarism, hepatomegaly in galactosemia or gluconeogenic or glycogenolytic disorders, macroglossia and transverse ear lobe creases in Beckwith–Wiedemann syndrome (see Chapter 12, p. 337).

Essential diagnostic information is obtained from blood and urine samples taken *when there is hypoglycemia* and before treatment commences. Blood glucose, ketone bodies, lactate, free fatty acids, branched chain amino acids, insulin, GH, cortisol and catecholamines and urinary ketone bodies, catecholamine metabolites and reducing substances should ideally be measured. If sampling is difficult the most important assays are for blood glucose, plasma insulin and cortisol and urinary ketone bodies, and samples should be deep frozen for future analysis.

The metabolic consequences of starvation with counter-regulation are increased plasma fatty acids, glycerol, ketone bodies, and branched chain amino acids associated with high levels of cortisol, GH and catecholamines. Insulin levels will be low or undetectable. Significant ketosis excludes hyperinsulinism as the cause for hypoglycemia but ‘ketotic hypoglycemia’ is not a diagnosis in itself and requires further elucidation to find the cause. Important endocrine causes of ketotic hypoglycemia include deficiencies of counter-regulatory hormones (GH and ACTH deficiencies, CAH – especially during intercurrent stress or infection – Addison disease, familial glucocorticoid deficiency and adrenomedullary unresponsiveness).

Hyperinsulinism results in hypoglycemia without ketonuria because insulin inhibits lipolysis. Plasma insulin levels may not be elevated but will be high for plasma glucose; plasma ketone bodies may be detectable but will be low for the glucose level.

Further differential diagnosis may necessitate 24 h metabolic profiles, calculation of the glucose infusion rate necessary to maintain

Table 15.21 Causes of hypoglycemia by age

<i>Transient neonatal</i>	
Decreased glucose production	
Birth asphyxia	
Small for gestational age	
Sepsis	
Starvation	
Hypothermia	
Hyperinsulinism	
Infant of diabetic mother	
Erythroblastosis	
Beckwith–Wiedemann syndrome (usually)	
Maternal glucose infusions	
Idiopathic	
<i>Persistent neonatal and infancy</i>	
Hyperinsulinism	
PHHI (nesidioblastosis)	
Islet cell adenoma/hyperplasia/leucine sensitivity	
Beckwith–Wiedemann syndrome (sometimes)	
Hormonal	
Growth hormone deficiency	
Hypopituitarism	
Glucocorticoid	
Congenital adrenal hyperplasia	
ACTH deficiency	
Glucagon deficiency	
Hypothyroidism (?)	
Inborn errors of metabolism (enzyme deficiency – see Fig. 15.57)	
Glucose-6-phosphatase – glycogen storage disease (GSD) type I*	
Amylo-1,6-glucosidase (GSD III)*	
Debrancher*	
Phosphorylase (GSD VI)*	
Phosphorylase kinase*	
Glycogen synthetase*	
Fructose-1,6-diphosphatase*	
Phosphoenolpyruvate carboxykinase*	
Pyruvate carboxylase*	
Galactose-1-phosphate uridyl transferase (galactosemia)	
Beta-oxidation defects*	
Fructose intolerance	
Maple syrup urine disease	
<i>Later childhood</i>	
Accelerated starvation	
Hormonal	
As above	
Addison's disease	
Familial glucocorticoid deficiency	
Enzyme deficiency	
Those marked* above	
Adrenomedullary hyporesponsiveness	
Liver disease	
Fulminant hepatitis	
Reye syndrome	
Jamaican vomiting sickness	
Hyperinsulinism	
Insulin administration (including Munchausen by proxy syndrome)	
Oral hypoglycemics (including Munchausen by proxy syndrome)	
Ingestion	
Alcohol	
Salicylates	

normoglycemia and assessment of glycogen reserve by glucagon provocation tests and of gluconeogenesis.

After exclusion of other causes of ketotic hyperglycemia, there remains a group of children who regularly develop hypoglycemia during periods of fasting – 'accelerated starvation'. Jewish children are absolved from fasting on Yom Kippur (Day of Atonement) until they are 'adult' (13 years). More severe hypoglycemia with convulsions may occur during intercurrent infection (particularly with vomiting), after pronounced physical activity or during preoperative starvation. There is often a history of difficult delivery or intrauterine growth retardation and the child (usually a boy) may be underweight. The hypoglycemic tendency is usually outgrown by later childhood. It is likely that these patients represent one end of a normal distribution of ability to maintain normoglycemia during fasting.

Defects in beta oxidation of fatty acids (see Chapter 26, p. 1067) are increasingly recognized as important causes of hypoglycemia in previously 'idiopathic' groups. Ketone levels are low (cf. ketotic hypoglycemia including 'accelerated starvation'), plasma fatty acid levels are high (cf. hyperinsulinism). Medium chain acyl CoA dehydrogenase (MCAD) deficiency may now be specifically diagnosed by molecular genetic studies and by measuring urinary phenylpropionyl glycine levels which are high following an oral phenylpropionic acid load due to inability to convert phenylpropionic acid to hippuric acid, an essential step in fatty acid oxidation.

## ENDOCRINE PANCREATIC ABNORMALITIES CAUSING HYPOGLYCEMIA

These are almost always due to hyperinsulinism – glucagon deficiency seems very rare. Transient neonatal hypoglycemia due to hyperinsulinism is seen in the infant of a poorly controlled diabetic mother (fetal hyperinsulinism secondary to maternal hyperglycemia) and is found in erythroblastosis fetalis (cause unknown) and Beckwith–Wiedemann syndrome (see Chapter 12, p. 337).

In a minority of infants of diabetic mothers hypoglycemia is delayed, but persisting neonatal hypoglycemia is usually associated with an underlying structural pancreatic abnormality. These conditions may not present until later in the first year, making hyperinsulinism the commonest cause of persistent hypoglycemia in infants below 1 year of age or even in childhood.

It is likely that the spectrum of histological findings, from discrete beta cell adenoma(s) through diffuse beta cell hyperplasia, microadenomatosis and nesidioblastosis to functional beta cell disorder alone, and perhaps also 'leucine sensitive hypoglycemia', all result from the same pathological process, probably in the control of pancreatic endocrine secretion.

### Persistent hyperinsulinemic hypoglycemia of infancy

Persistent hyperinsulinemic hypoglycemia of infancy (HI) is a rare disorder which may be familial or sporadic, and which is characterized by unregulated secretion of insulin and profound hypoglycemia in the neonate (see Chapter 12). Cases may be sporadic, autosomal recessive, dominant or syndromic.

The majority of infants present neonatally with symptoms (including convulsions) of intractable hypoglycemia. Occasionally presentation is later in the first 6 months. There may be a positive family history. The infants are obese, resembling the infant of the poorly controlled diabetic mother (hyperinsulinism is common to both). There may be a history of maternal glucose intolerance during previous pregnancies.

Diagnosis is dependent on demonstrating hyperinsulinemic hypoglycemia without significant ketosis. Very high glucose infusion rates (> 15 mg/kg/min) may be necessary to maintain normoglycemia – rates above 6–9 mg/kg/min are highly suggestive of hyperinsulinism. The demonstration, when hypoglycemic, of a glycemic response to glucagon, low branched chain amino acid levels, and insulin suppression following somatostatin infusion will confirm the diagnosis.

The management priority is to correct hypoglycemia but this can be difficult because of the high glucose infusion rates necessary and technical problems with siting infusion lines.

If a discrete adenoma is found it should be resected – this will be curative. Otherwise, if medical therapies are unsuccessful, surgery is indicated: subtotal (98%) pancreatectomy (more effective than less radical

removal) is performed. This may, commonly, result in 'cure' – normoglycemia without medical therapy, or normoglycemia on diazoxide. If the infant remains glucose infusion-dependent, total pancreatectomy is performed. Postpancreatectomy diabetes is generally easy to manage on small doses of insulin because of associated alpha cell loss causing glucagon deficiency and altered CHO absorption secondary to pancreatic exocrine deficiency.

### NUTRITION, GROWTH, DEVELOPMENT AND DISEASE

Optimal nutrition is the foundation of good health. Malnutrition implies both under- and overnutrition, and is a consequence of disturbance of energy and nutrient balance, between supply and demand. Undernutrition is often manifest as growth failure, which may be due to insufficient energy or nutrient intake, disordered digestion, absorption or metabolism, or excessive losses.<sup>1</sup> Foods deficient in specific nutrients may cause specific diseases (such as scurvy or anemia). Chronic disease is frequently associated with undernutrition and nutrient deficits. However, nutrient deficiencies lead to depletion of tissue stores, derangement of normal biochemistry and disordered tissue function before they are manifest as anatomical changes, and may easily go unrecognized. Awareness of poor nutrition is critical to the effective management of many childhood diseases, particularly those that are chronic, and there is growing evidence that undernutrition in early life may play a part in the genesis of chronic adult disease.

This chapter aims to summarize the knowledge required to evaluate the nutritional needs of normal and sick children and to provide them with a healthy diet or nutritional support. A summary of nutrient requirements is presented, how they are defined and how they should be properly used. Nutritional assessment is an essential prerequisite to the provision of nutritional support and the principal methods used are outlined. Healthy diets for the infant, toddler, child and adolescent are then described briefly. The next section summarizes how nutritional support can be provided to the sick child and is followed by an account of some of the main causes of over- and undernutrition. A trained nutrition

team should work together in the clinic, ward and community to provide nutritional support for sick children. The basic science of nutrition (composition of food, metabolic pathways, gastrointestinal physiology, body composition, etc.) is not covered in detail in this chapter, but references to textbooks on nutritional science are provided.<sup>2,3</sup>

### NUTRITIONAL REQUIREMENTS

#### PRINCIPLES AND DEFINITIONS

Figures for nutrient requirements set by expert committees emphasize the avoidance of nutrient deficiency. They generally do not concern themselves with the safety of excess intake. Underlying the concept of requirement is the assumption that, for most nutrients, need is approximately normally distributed in any population. To recommend requirements of nutrients that are sufficient to meet the needs of almost the entire population, they have been set 'high' in the distribution, at approximately two standard deviations (SDs) above the mean requirement. With the exception of energy (excess energy intake leads to obesity), consumption of a nutrient in excess of requirements of this magnitude is not harmful and setting a high value as a reference nutrient intake (RNI) or recommended daily allowance (RDA) entails minimal risk for most nutrients.

In the UK, the term 'dietary reference values' (DRVs) is used rather than 'recommendations', and DRVs have been in place since 1991.<sup>4</sup> Three reference values are set for each nutrient. These values reflect the range of nutrient requirements (low, medium and high) rather than just one reference value. The three DRVs are:

1. 'estimated average requirement' (EAR), the mean requirement;
  2. 'reference nutrient intake' (RNI), the mean requirement +2 SD; and
  3. 'lower reference nutrient intake' (LRNI), the mean requirement -2 SD.
- For some nutrients the 1991 UK report set a 'safe intake' if there were insufficient data upon which to set DRVs. This was judged to be an intake at which there was no risk of deficiency and below a level where there was a risk of adverse effects.

## APPLICATIONS AND LIMITATIONS OF DIETARY REFERENCE VALUES

There are three main applications of DRVs:

1. to assess the adequacy of the dietary intake of individuals or groups. For example, if a hospital population of children consume a diet below the LRNI for a particular nutrient, their diet is probably deficient in that nutrient.
2. as a guide to prescribing or designing the diet of individuals or groups. The DRVs (often the EAR) can be a useful starting point in setting a diet prescription, in the absence of any other information on the requirements of the patient, and DRVs are also used in the design of infant milk formulae.
3. food labeling. A food might be described as containing X% of the EAR for iron, for example.

When applying DRVs, their limitations must be borne in mind. In childhood, estimates of requirement are usually based on limited data. They change over the years and DRVs should be regarded as best estimates at the time that they were set. There are also variations in the values agreed for the RNI or RDA between different national committees, and estimates in the light of new evidence. For example, older estimates of energy requirements during infancy have been shown to be too high.<sup>5</sup>

## NUTRITIONAL REQUIREMENTS DURING INFANCY AND CHILDHOOD

### ENERGY

Energy is required for physical activity, thermogenesis, tissue maintenance and growth. Dietary energy is consumed in the form of fat, protein and carbohydrate. Dietary protein does not simply build new tissue but is also oxidized to provide energy. In the UK and in most Western countries dietary surveys of children of school age show that they consume about 35–40% of dietary energy in the form of fat, 10–15% as protein and 45–50% as carbohydrate. The main food sources of dietary fat are milk and milk products, fried foods and meat products.<sup>6,7</sup> In developing countries and in vegetarian children the contribution to energy intake of carbohydrate is much higher and the contribution of fat is generally much lower.

In infants and children, the energy requirement is the amount of dietary energy needed to balance energy expended and energy deposited in new tissue (growth). Energy expenditure can be subdivided into basal (BMR) or resting metabolic rate (RMR, around 65% of total energy expenditure [TEE] in most healthy children); energy expended on physical activity (around 25% of TEE in most healthy children) and thermogenesis (approximately 8% of TEE) (Fig. 16.1). BMR or RMR can be considered to be a 'maintenance' cost since it is the energy cost of biosynthesis, turnover, cellular ion pumps, physical work (respiratory and cardiac function). The energy expended on physical activity varies widely between children and is generally reduced when they are sick. The energy expended in thermogenesis is primarily the cost of digesting, absorbing and resynthesizing nutrients ('diet-induced thermogenesis'). Growth demands some energy expended on biosynthesis and the energy content of newly synthesized tissue. This represents up to about 35% of energy intake in rapidly growing infants, but falls for the rest of childhood and adolescence (to < 2% of energy intake) because growth rate is so much slower thereafter.

In clinical or dietetic use the EAR can provide a basis for estimating the energy requirements of individual infants and children. Alternatively a more considered approach involves estimating BMR<sup>4</sup> from equations based on age, weight and gender and multiplying this by a factor to take

Fig. 16.1 Components of total energy expenditure in childhood.

into account physical activity. In most children 1.5–2 times BMR will meet requirements for growth and TEE. Estimation of minimum energy requirements using this approach, though better than depending on the EAR, can lead to large errors for individual children and so the adequacy of diet prescriptions for children with chronic disease should be 'titrated' against clinical observations of growth and weight change.

### PROTEINS AND AMINO ACIDS

Proteins are essential components of every living cell and subserve numerous biological functions. Dietary protein is essential to maintain nitrogen balance in the body and to provide sources of sulfur. All amino acids provide nitrogen for synthesis of human proteins but some dietary amino acids are 'essential' as they cannot be synthesized *de novo*. Adequate intake of these essential amino acids is achievable only with a diet containing a wide variety of protein sources. Average requirements increase with age in absolute terms (EAR at 4 months is 10.6 g/d and at 18 years is 46.1 g/d) but decrease per kg body weight (EAR is 120 mg N/kg/d at 1 year and 96 mg N/kg/d in adults). In Western societies most diets, including the diets of undernourished children, contain protein well in excess of requirements.

### FATS

Fats are a major energy source with an energy density of approximately 37 kJ (9 kcal)/g and they are also essential for the formation of membranes and neural tissue. Different types of fat play particular roles in the structure and function of cell membranes and neural tissue and the quality as well as the quantity, of fat intake is important. Dietary fats (lipids) are mostly triglycerides containing a wide variety of fatty acids. Where a fatty acid is replaced with phosphate a phospholipid is produced and substitutions with other compounds produce other structural and functional lipids such as sphingolipids and glycolipids.

Fats from animal produce tend to contain saturated fatty acids with no double bonds and those from plants and fish tend to contain mono- or polyunsaturated fatty acids (PUFAs). This is not universally true: some plants, such as coconut, produce saturated fat. It is recommended that children over 5 years should adopt a diet with a similar fat content to that recommended for adults. Thus 10% of daily energy needs should be from saturated fat, 12% from monounsaturated fats, 6% from polyunsaturated, with a mixture of n-6 and n-3 fatty acids (with at least linoleic 1%, alpha-linolenic 0.2%) and trans fatty acids 2%, giving a total fatty acid intake of 30% dietary energy or 33% including dietary glycerol.

There are two essential fatty acids – linoleic (C18:2n-6) and alpha-linolenic (C18:3n-3) – which the human body cannot synthesize. These

are precursors of phospholipids, prostaglandins, thromboxane, leukotrienes and arachidonic (AA), eicosapentanoic (EPA) and docosahexaenoic (DHA) acids. Young infants have limited ability to transform linolenic acid to DHA and linoleic to AA, which are both present in human milk. Many infant formulae do not contain DHA and the membrane phospholipids in the brains of infants whose intake of DHA is deficient have substituted saturated fatty acids for DHA. While some infant formulae have been supplemented with PUFAs their impact on neurodevelopment, except in the preterm, is unproven.<sup>8</sup>

## CARBOHYDRATES

Carbohydrates in the diet provide energy of approximately 17 kJ (4 kcal)/g and are also an important component of structural and functional glycoproteins and glycolipids. Glucose is an essential fuel for the brain, which cannot metabolize fat for energy. It can be synthesized by the liver from amino acids and propionic acid, but a minimum amount of dietary carbohydrate is necessary to inhibit ketosis and to allow complete oxidation of fat.

Carbohydrates can be divided into sugars (up to three residues), oligosaccharides (up to 10 residues) and complex carbohydrates (polysaccharides) on the basis of chain length. It is recommended that intake of extrinsic sugar is restricted to less than 10% of energy intake to prevent dental caries and, possibly, obesity.

Some oligosaccharides are undigestible in the human small intestine. These include fructo-oligosaccharides such as raifilose from inulin, and galactosyl-oligosaccharides such as raffinose in beans. Similar oligosaccharides are present in human milk. These pass to the colon, where they are rapidly fermented to short chain fatty acids (SCEAs) and gases and may produce flatulence if eaten in excess. These oligosaccharides are believed to have 'probiotic' properties: that is they promote the growth of beneficial bacteria, mainly bifidobacteria and lactobacilli, in the colon.

Complex carbohydrates include starch and dietary fiber. Starch is found in several forms in food, some of which are less digestible than others. Starch cooked under normal conditions can be rapidly or slowly digestible, but is mostly digested and absorbed in the small intestine, whereas raw starches, as found in unripe bananas or raw potato and some processed starches (retrograded amylose) may be resistant to human enzymes ('resistant starch') and pass into the colon undigested. Other modified starches, included in many foods during manufacture and processing, are also resistant to digestion to some degree. More starch may escape small intestinal digestion in young children than in adults, owing to immaturity of digestion in early life, and this will influence colonic function and the energy absorbed from food.

Nondigestible carbohydrates include nonstarch polysaccharides and lignin. Dietary fiber polysaccharides are undigested in the small intestine and are fermented by the colonic microflora to SCEA and gases. These SCEAs are rapidly absorbed, resulting in an average energy value of 8.4 kJ (2 kcal)/g for dietary fiber.

Because diets high in dietary fiber are less energy dense and more satiating than the converse, it is not recommended that infants and young children consume high-fiber diets. Nevertheless dietary fiber plays an important part in normal large bowel function and is an essential constituent of the healthy diet from an early age. Older children, however, who do not need such an energy-dense diet, should be encouraged to eat foods rich in complex carbohydrates.

## VITAMINS AND MINERALS: STRUCTURE, FUNCTION, DIETARY SOURCES

Vitamins are a group of naturally occurring organic nutrients that have little in common except that they are essential in the diet. They can be divided into water-soluble and fat-soluble vitamins (Tables 16.1 and 16.2). The major dietary sources of vitamins are summarized in Table 16.3. Water-soluble vitamins are easily absorbed, sometimes by active transport, and are not stored in the body to any great extent. Excessive intake normally results in excretion of the excess in the urine.

Fat-soluble vitamins, on the other hand, are absorbed with fat and thus any factor reducing the amount of fat digested and/or absorbed will reduce their absorption. Fat-soluble vitamins are also stored in the body and thus deficiencies in the diet may take some time to affect nutritional status, but they are more likely to have toxic effects if eaten in excess.

Minerals are the inorganic elements (other than carbon, hydrogen and nitrogen) that are found in the body and which are essential constituents of diet. The major dietary sources of minerals are summarized in Table 16.4. They include the 'trace elements' which are required in very small, but vital amounts. Minerals serve many different biological functions ranging from structural (calcium in bone), transport (iron in hemoglobin), energy metabolism (phosphorus in adenosine triphosphate [ATP]), endocrine (iodine in thyroid), neurotransmission (magnesium) and enzyme action (molybdenum).

The dietary sources, function and requirements of vitamins and minerals are provided elsewhere.<sup>2-4</sup> Deficiency and toxicity diseases associated with these micronutrients are described later.

## NUTRITIONAL ASSESSMENT

Nutritional assessment is the evaluation of an individual's nutritional status. It is a means by which the undernourished (or overnourished) child can be identified, the nutritional effects of therapy and the efficacy of nutritional interventions monitored, and the prevalence of under- or overnutrition in a group determined. Undernutrition is common, particularly among sick children in hospital,<sup>9</sup> and evidence that it has important clinical consequences has led to increasing interest in methods for assessing nutritional status in sick children.<sup>10,11</sup>

There are five principal approaches to nutritional assessment: anthropometric; dietary; biochemical; clinical; functional.<sup>11</sup> Each evaluates a different aspect of nutritional status. All have limitations, and there is still much debate over choice of methods, reference values, and interpretation of measurements. Functional assessment, the use of functional deficits (e.g. deficits in immune function or muscle function) to identify or measure undernutrition, is not discussed here since it is so rarely used in children and remains largely restricted to research applications.<sup>11</sup>

## ANTHROPOMETRIC NUTRITIONAL ASSESSMENT

Anthropometry is the measurement of physical dimensions of the human body at different ages. Typically, the measurements are compared with population reference data to identify abnormalities that may result from nutrient deficiencies or excess (usually energy deficiency, with protein deficiency in developing countries).<sup>11</sup>

The body mass index (BMI) – weight (kg)/height (m)<sup>2</sup> – is a simple and useful tool for assessing or monitoring the overweight and underweight which is gradually superseding more traditional indices such as weight for height and weight for age. Many countries have population reference data for BMI from birth to adulthood, and these are available as BMI charts for clinical use. BMI can be expressed as a SD score or as a centile, and a cut-off is often used to define over- or undernutrition. To avoid the problem of changes in population distribution of BMI over time it has been agreed in the UK to 'freeze' the charts based on the 1990 growth charts.<sup>12</sup> In the UK it is suggested that children who cross two centile 'spaces' or who are below the 2nd or above the 98th centile for BMI should be considered as likely to be under- or overnourished and at least require further assessment. It is important to note that the meaning of a particular approach depends on using cut-off points in this way carries the risk of misclassifying individual children, but this is reduced if there is other (e.g. biochemical or clinical) evidence of nutritional abnormalities, or if serial measures of BMI are available.

In clinical practice these whole-body anthropometric indices are useful, but can be limited, as for instance, when a child has ascites, fluid retention, or a large solid tumor. Such conditions can confound weight-based anthropometric indices, and the most useful and widely used alternatives are mid upper arm circumference (MUAC – related to

**Table 16.1** Structure, function and mode of absorption of water-soluble vitamins

Vitamin	Chemical structure	Functions	Absorption
Thiamin	Pyrimidine ring joined to thiazole ring	Thiamin pyrophosphate coenzyme for many reactions in carbohydrate metabolism	Active transport or passive transport at concentration 1 $\mu\text{mol}$ or 5 mg/d
Vitamin B <sub>12</sub>	Cobalamin, porphyrin like ring containing cobalt; 5-deoxyadenosylcobalamin, methyl cobalamin, hydroxycobalamin	Co-factor for methionine synthetase, methylmalonyl-CoA mutase	Absorbed bound to various carrier proteins; R protein in stomach, IF protein in small intestine Transcobalamin in basolateral membrane, 70% efficient
Folic acid	Folate, substituted pteridine ring linked to p-aminobenzoic acid. Exists as polyglutamated reduced or substituted forms of folic acid	Coenzyme for several reactions, transfer of single carbon units in reactions essential to metabolism of several amino acids and nucleic acid synthesis	Various dietary forms need to be hydrolyzed before absorption as monoglutamyl folate by active transport
Vitamin B <sub>6</sub>	Pyridoxine, pyridoxal, pyridoxamine, pyridoxine HCl	Pyridoxal phosphate coenzyme for reactions related to protein metabolism, amino transferase decarboxylase and for amine synthesis, e.g. 5HT, heme synthesis, glycogen metabolism, sphingolipid and niacin synthesis	Hydrolyzed and absorbed passively
Niacin	Nicotinamide	NAD, NADP for oxidoreductases	Absorbed as nicotinic acid, nicotinamide, NMN
Riboflavin	Isoalloxazine ring with ribityl side chain. Flavin mononucleotide, flavin adenosine	Flavoprotein enzymes in oxidative reductive reactions, in metabolic pathways and cellular respiration	By sodium-dependent saturable proteins
Biotin	Imidazole ring fused to tetrahydrothiophene ring with valeric acid side chain	Co-factor for carboxylases in fatty acid synthesis, metabolism, gluconeogenesis branched chain amino acid metabolism	Actively absorbed as free biotin in small intestine
Pantothenic acid	Dimethyl derivative of butyric acid linked to beta-alanine	Constituent of CoA and esters essential for lipid and carbohydrate metabolism	Ingested as part of CoA released by intestinal phosphatase absorbed as pantothenic acid
Vitamin C	Ascorbic acid	Essential for hydroxylation of proline and lysine in collagen synthesis, needed for carnitine and noradrenaline synthesis	Active sodium-linked absorption

IF, intrinsic factor; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NMN, nicotinamide mononucleotide.

**Table 16.2** Structure, function and mode of absorption of fat-soluble vitamins

Vitamin	Chemical structure	Functions	Absorption
Vitamin A	Retinol, beta-carotene, six beta-carotene = one retinol	Cellular differentiation, vision, fetal development, immune system, spermatogenesis, appetite, hearing, growth	With fat 80% absorbed
Vitamin D	Calciferol, ergocalciferol, cholecalciferol Metabolized in skin, liver and kidneys to active forms	Essential for calcium absorption, regulates calcium metabolism, involved in immune system	With fat 80% absorbed
Vitamin E	Tocopherols, tocotrienols; 8 naturally occurring forms	Antioxidant prevents lipid peroxidation	With fat absorption
Vitamin K	2 metholnaphthoquinone rings, with side chains. Phylloquinone, menaquinone, menadione	Needed for gla-proteins. Catalyzes synthesis of prothrombin in liver for clotting factors VII, IX and X	With fat 50–80% absorbed

muscle mass and fat mass, an index of 'protein/energy' status), skin-fold thickness (notably over the triceps: an index of fatness), and indices derived from these (arm muscle area or arm muscle circumference), which are more specific indices of muscle bulk and are particularly useful in measuring small changes.<sup>11</sup>

When reporting and interpreting raw or derived anthropometric indices (e.g. BMI, weight-for-height, height-for-age) relative to a reference population there are three principal approaches: (1) classification with reference to centiles, (2) use of percentage of reference median,

and (3) use of SD or 'Z' scores. While the first two approaches are most commonly used in clinical nutritional assessment, there is now a consensus that the third approach, the calculation of SD scores, is more clinically informative.<sup>13</sup>

## DIETARY NUTRITIONAL ASSESSMENT

Assessment of nutritional status based on dietary intake should take into account current and past food intake. Dietary assessments

Table 16.3 Dietary sources of vitamins

Vitamin	Food sources
Thiamin	Cereals (breakfast cereals, bread), vegetables (potatoes), milk and milk products, meat and meat products, cereal products
Vitamin B <sub>12</sub>	Milk and milk products, meat and meat products, cereals (alternative source: yeast extract for vegetarians)
Folic acid	Cereals, vegetables, milk products, liver <i>Breakfast cereals, bread, vegetables, milk products</i>
Vitamin B <sub>6</sub>	Vegetables, cereal products, milk products, meat products <i>Milk and milk products, vegetables, breakfast cereals</i> (Alternative sources: poultry, fish, eggs, nuts)
Niacin	Cereal products (bread, breakfast cereals), meat products, milk and milk products. <i>Vegetables</i>
Riboflavin	Milk products, cereal products (bread, breakfast cereals), meat products. <i>Cereals, milk</i>
Biotin	(Good sources: liver, egg, cereals, yeast)
Pantothenic acid	(Good sources: widely distributed, meat, cereals, legumes)
Vitamin C	Beverages (fruit juice), vegetables (potatoes), fruit and nuts. <i>Vegetables, beverages</i>
Vitamin A	Retinol: vegetables, milk products, fat spreads, cereal products. <i>Milk products, meat products, vegetables</i> Beta-carotene: vegetables, meat and meat products. <i>Vegetables</i>
Vitamin D	Cereal products, fat spreads, meat products (Alternative source: oily fish) <i>Fat spreads, breakfast cereals, milk and milk products</i>
Vitamin E	Vegetables, fat spreads, cereal products <i>Fat spreads, vegetables, meat and meat products, cereal products</i>
Vitamin K	(Good sources: vegetables, margarines, but synthesized in colon)

Sources of nutrients for infants are shown in italics.  
From UK National Diet and Nutrition Surveys<sup>6,7</sup>

Table 16.4 Dietary sources of minerals

Minerals	Food sources of major minerals	Alternative good sources
Iron	Cereal products (bread, breakfast cereals), vegetables, meat/meat products. <i>Cereals, meat, vegetables</i>	
Calcium	Milk and milk products, cereal products <i>Milk, milk products, cereals</i>	
Phosphorus	Milk products, cereal products, meat products, vegetables <i>Milk and milk products, cereal products, meat</i>	
Potassium	Vegetables, milk products, cereal products, meat products <i>Milk and milk products, vegetables, cereal products</i>	
Copper	Cereal products, vegetables, milk products, fruit <i>Cereal products, meat and meat products, vegetables</i>	
Iodine	Milk products, cereal products <i>Milk and milk products, cereal products</i>	Shellfish, legumes, cereals, liver, seafood, seaweeds, iodized salt
Zinc	Meat and meat products, milk, cereal products, vegetables	
Selenium	(Good sources: cereals, meat, fish)	Amount in foods depends on soil quality
Magnesium	Cereals, milk products, vegetables, meat products <i>Cereals, milk products</i>	Deficiency may occur where soil is poor
Chromium	(Good sources: yeast, meat, cereals, legumes, nuts)	

Sources of nutrients for infants are shown in italics.  
From UK National Diet and Nutrition Surveys<sup>6,7</sup>

should be done by a pediatric dietitian who has the skills to ensure that all aspects of intake are considered, including assessment of the quantities of food eaten. All methods of dietary assessment have limited accuracy and the data obtained should always be interpreted with caution. Dietary assessment in children is best viewed as a means of explaining or solving a nutritional problem, rather than definitively identifying or confirming it. Detailed descriptions of methodology for obtaining dietary and nutrient intakes are provided elsewhere.<sup>2,3,11</sup>

For nutritional assessment of infants (excluding those who are exclusively breast-fed), dietary assessment methods are more accurate, since much food is provided by milk feeds and most mothers can readily

provide a fairly accurate record of the number and volume of feeds and the amount of solids taken.

## BIOCHEMICAL NUTRITIONAL ASSESSMENT

Biochemical nutritional assessment requires measurement of nutrient concentrations in the blood, urine, other fluids or tissues. There is an optimal concentration of nutrients within the body, below and above which deficiency and toxicity can occur. However circulating concentrations of nutrients are not an accurate measurement of tissue stores and reflect the immediate availability of particular nutrients. In the blood some nutrients are found 'free' (e.g. vitamin C), some 'bound'

(e.g. calcium, iron) to carrier proteins, and some as 'precursors' (e.g. beta-carotene). Each nutrient has its own site of storage and function and so universally applicable statements about biochemical nutritional assessment are not possible.

In pediatric practice, measurements of nutrient concentrations or biochemical markers of nutritional status and/or growth are made most commonly in the blood or urine. In certain nutritional deficiency or toxicity states, and in some metabolic diseases, measurements of concentrations of particular nutrients in specific tissues should be made. Changes in circulating concentrations of many nutrients occur only when tissue stores have been depleted and normal blood concentrations do not necessarily indicate normal nutritional status. The nutrients that are commonly measured in the blood are discussed here.

Blood urea reflects not only renal function but also protein intake. It can be low in rapidly growing neonates and in children with hepatic failure. High blood urea can be a marker of the infant or toddler with a high cows' milk intake. Low urea is not an early or a sensitive sign of undernutrition. Plasma amino acids measured quantitatively may show low glutamine. In the fasting state, hepatic uptake of alanine for gluconeogenesis causes blood levels of this amino acid to fall. In patients on vegan diets or where severely reduced protein intake limits lysine availability for its synthesis, carnitine deficiency may develop. In these circumstances clinical effects are rare.

Alkaline phosphatase is a sensitive indicator of nutritional rickets and osteomalacia. Measurement of vitamin D level is not indicated in the presence of normal calcium and phosphate. Prevalence studies have shown how difficult it is to make absolute definitions of iron deficiency. Hemoglobin and red cell indices may not fully reflect iron stores. Ferritin reflects total body iron stores but is also an acute phase protein and concentrations may be falsely high in acute infection. Serum iron, total iron binding capacity (TIBC) and free erythrocyte protoporphyrin (FEP) may be measured: iron falls, and TIBC and FEP rise in iron deficiency anemia.

Deficiency of water-soluble vitamins is rare in developed countries, although this may develop rapidly in patients who are receiving inadequately supplemented i.v. fluids or total parenteral nutrition (PN). Red cell transketolase activity gives an indirect indication of thiamine deficiency, which can occur because of the demands of a high glucose intake for thiamine pyrophosphate cofactor. Deficiency of vitamin B<sub>12</sub>, vitamin A or vitamin E develops late because of large tissue stores. Prothrombin time reflects vitamin K status if liver function is normal.

Circulating concentrations of trace elements (copper, zinc, selenium) decrease late in deficiency. Zinc or magnesium deficiency occurs in Crohn's disease and other causes of chronic diarrhea. Low glutathione peroxidase activity in red cells indirectly indicates selenium deficiency but a direct selenium assay may be preferable.

## CLINICAL NUTRITIONAL ASSESSMENT

Clinical nutritional assessment is limited by its subjectivity, even when performed by specialists.<sup>14</sup> More structured, and objective, forms of clinical assessment are likely to become valuable in clinical practice, but are based on limited evidence at present.<sup>15</sup> Signs of 'pure' or single nutrient deficiencies rarely occur alone and physical signs such as glossitis or angular stomatitis are nonspecific. Physical examination should ideally be interpreted in association with anthropometric, dietary and biochemical nutritional assessment.

The 'classical' physical signs of protein-energy malnutrition, some vitamin and mineral deficiencies are described later. It should be remembered, however, that physical signs are a late manifestation of nutrient deficiency, occurring after tissue stores have been depleted, and adaptive changes have failed to maintain normal nutrient homeostasis and function.

## HEALTHY DIET: INFANCY, CHILDHOOD AND ADOLESCENCE

### INFANT

Milk is believed to be the sufficient and sole source of energy and nutrients for about the first 6 months of life.<sup>16</sup> Complementary (nonmilk, weaning) foods should be introduced at around this time, to fill the gap between the energy and nutrient needs provided by milk and those that the infant requires to maintain normal growth and development.

### Human milk

Human milk is a complex blend of nutrients and immunological and other bioactive substances. The former provide the energy, macronutrients (carbohydrates, fats and proteins) and micronutrients (vitamins and minerals) that the baby needs to grow, develop and function (physical activity, thermogenesis, essential organ function – BMR). The latter confer protection from bacterial and viral infections and assist adaptation to life outside the womb.

### Formula milk

Approved infant formulas provide safe but inferior alternatives to breast milk. They broadly resemble human milk in terms of their chemical composition but lack the enzymes, immunological or other bioactive substances found in human milk. The majority of formulas is based on cows' milk and are either whey or casein predominant. The former have a protein content based on demineralized whey with a whey:casein ratio similar to breast milk (60% whey:40% casein). The protein source of casein-predominant formulas is skimmed cows' milk with a ratio of 80% casein:20% whey. Ideally infants should remain on the formula first used until the end of the first year of life but a follow-on formula may be used from the age of 6 months. Whole cow's milk should not be used as the main milk drink for infants until the age of 1 year.<sup>16</sup>

Soya formulas should be used only for infants with proven intolerance to cows' milk formulas or lactose and for infants of vegetarian mothers who have elected not to breast-feed. Although satisfactory growth has been achieved in babies fed formulas based on cows' milk and soya, their nutritional composition differs from that of human milk, for example in their essential fatty acid contents, non-nutritional factors, and bioavailability of some micronutrients such as iron. Short- and long-term studies on risk of infection, growth and neurological outcome of children who have received these formulas show that human milk is preferable to 'artificial' formulas for the infant.<sup>16</sup>

### Complementary foods

At about 6 months of age complementary foods (nonmilk, 'solids') should be introduced into the diet. The infant's iron stores are becoming depleted, chewing needs to be developed, and milk alone is insufficient to meet the growing nutritional requirements of the infant.<sup>16</sup> In addition to a nonmilk diet, infants should continue to receive at least 500–600 ml of breast milk or formula daily. Nonwheat cereals, fruit, vegetables and potatoes are all suitable first weaning foods. Between 6 and 9 months of age, meat, fish, all cereals, pulses, fish and eggs can be introduced. No salt should be added to home-prepared foods, and only enough sugar used to make sour fruits palatable. Complementary foods should aim to have an energy density of at least 1 kcal/g (4.2 kJ/g).

### TODDLER

By the end of the first year infants are taking a widening range of foods and beginning to share those eaten by the rest of the family. The feeding of the preschool child progresses through many skill-learning processes, from the semi-solid/liquid diet of the weanling, through finger-feeding of bits of food which require chewing at around 1 year of age, to spoon-feeding by the age of 2 years, to mastering child-sized cutlery and adult-type food by the age of 5 years.

Nutritionally, toddler foods bridge the gap between the energy-dense diet of the infant, which provides around 50% of energy from fat, and that of the adult, where around 35% of energy should be derived from fat. Toddlers, however, have smaller gastric capacities than adults, and a balance must be struck between the gradual reduction of energy-dense, fat-containing foods and the introduction of lower fat foods. Toddlers are at risk of iron deficiency and care should be taken that foods containing adequate iron are used. The toddler should continue to consume around 500 ml of milk daily (or equivalent from other foods such as yoghurt and cheese). Full-fat milk should be used from 1–2 years of age. Thereafter, as long as growth and energy intake are satisfactory, semi-skimmed milk can be given from 2–5 years of age. After 2 years of age other lower fat dairy products such as yoghurt, spreads and cheese may be used. Many toddlers become fussy and difficult with meals and it may be more appropriate to follow a feeding regimen based on three small meals and three snacks daily. Some young children begin to prefer easily assimilated liquids, particularly if given from bottles, for solid food, which requires chewing and the use of cutlery. After the first year all drinks taken during the day should be taken from a cup. National surveys have shown that some toddlers and young children are at risk of inadequate energy, vitamin A, iron and zinc intakes.<sup>6,7</sup> There has also been concern about the risk of rickets in Asian children, who should receive vitamin D supplementation up to the age of 5 years.

## SCHOOLCHILD

After the age of 5 years the diet can change towards that advised for adults. Fiber intake should increase with generous consumption of fruits, vegetables and high fiber cereals such as wholemeal bread, pasta and breakfast cereals. Saturated fat intake should be moderated by the use of skimmed or semi-skimmed milk, low fat or polyunsaturated spreads, low fat dairy products and eating fish, poultry and lean meats. The intake of non-milk extrinsic sugar should be avoided because of its association with dental caries and possibly obesity.

## ADOLESCENT

The timing of the adolescent growth spurt varies between individuals so that nutrient requirements should be related to weight and height rather than age.<sup>4</sup> Weight gain during puberty in girls is mainly due to fat deposition whereas boys accumulate more muscle and skeletal tissue.

Eating habits show a trend to persist with time and a healthy adolescent diet should anticipate and minimize the long-term risks of chronic cardiovascular diseases, obesity, diabetes and other adult conditions associated with a poor diet.

Many adolescents will experiment with different diets. 'Vegetarian' diets which include some animal foods such as milk, cheese or eggs usually achieve adequate nutrient intakes. Teenagers who elect to follow a vegan regimen should take supplements of vitamin B<sub>12</sub>, calcium, vitamin D, iron and zinc. Avoidance of specific foods on religious or cult grounds may result in severe nutrient deficiencies unless the dietary regimen has been based on long established traditional practices.

## PRINCIPLES OF NUTRITIONAL SUPPORT

The skills required to deal with assessment, prescription, administration and monitoring of treatment increasingly fall outside the expertise of a single practitioner. Nutritional support should be provided by a team, led by a pediatrician trained and experienced in clinical nutrition, comprising dietitians, nutrition nurse specialists, a pharmacist in charge of the preparation and prescription of parenteral solutions, a biochemist responsible for monitoring biochemical outcome and a surgeon with experience of gastrostomies and insertion of i.v. long lines for PN (Table 16.5). Introduction of nutrition teams is associated with a reduction of mechanical, metabolic and infection-related complications of PN, shorter duration in hospital and decline in the cost of nutrition

**Table 16.5** Composition and functions of members of a hospital nutrition team

Dietitian	Assesses nutritional status Calculates nutritional requirements Designs enteral or parenteral feeding regimens
Nurse specialist	Acts jointly with clinician, dietitian and pharmacist in practical aspects of nutrition support Patient and community care training Care of enterostomy tubes and central venous lines
Clinician	Overall responsibility for nutritional care Monitors outcome and liaises with medical/surgical team Diagnosis and management of underlying conditions and of complications of nutritional support
Pharmacist	Responsible for provision of enteral and parenteral nutrition solutions Advises on compatibility and drug interactions
Surgeon	Fashions enterostomies and inserts i.v. catheters
Biochemist	Monitors biochemical indices of nutritional status
Bacteriologist	Detection and advice on treatment of i.v. line infections

support. Nutrition support may be provided either enterally or parenterally. Before starting nutrition support it is essential to properly assess the patient's nutritional status and nutritional needs (see before and Bresson et al<sup>17</sup>).

## ENTERAL NUTRITION

Enteral feeding should be used if the gastrointestinal tract is accessible and functional. PN should be reserved for conditions where enteral nutrition cannot meet energy and nutrient requirements via the gut alone. There are many indications for enteral tube feeding (Table 16.6), and this form of feeding has a number of advantages and disadvantages, summarized in Table 16.7.

### Delivery routes and systems

Enteral feeding is a means by which nutrients can be delivered to the gastrointestinal tract by tube or enterostomy. This can be done continuously, as bolus feeds or as intermittent continuous feeds. In continuous feeding the enteral feed is infused over a period of hours (usually from 8–24 h) using a pump, which regulates the volume administered. Bolus feeding simulates the usual pattern of feeding, generating a postprandial metabolic response that is greater than that when continuous feeds are given. Feeds can be given at intervals from hourly to 4 hourly. Intermittent continuous feeding combines the feeding techniques of bolus and continuous feeds.

The choice of mode of delivery can be made using the algorithm shown in Figure 16.2. Nasogastric tubes are easy to introduce and have fewer complications than nasojejunal tubes. Nasogastric tube feeding is also more 'physiological' in that the defense and digestive functions of the stomach are utilized, but gastroesophageal reflux and aspiration are more likely to occur. Nasojejunal tubes are used when these risks are high, such as in children with neuromuscular disease, severe neurological handicap and gastrointestinal motility disorders.

Enterostomies offer a means of delivering enteral feeds directly into the stomach or jejunum, bypassing proximal mechanical, surgical or pathological obstructions. They are also preferred when pharyngeal discomfort is intolerable or the risk of aspiration high. Percutaneous endoscopic gastrostomy (PEG) is an increasingly popular technique of tube placement, and the gastrostomy button is a useful innovation for long-term feeding. Flush with the skin the button can be connected to a

Table 16.6 Conditions in which nutrition support may be indicated

Gastrointestinal disease	
<ul style="list-style-type: none"> <li>• Short bowel syndrome</li> <li>• Inflammatory bowel disease</li> <li>• Following gastrointestinal surgery</li> <li>• Chronic liver disease</li> <li>• Glycogen storage disease types I and III</li> <li>• Fatty acid oxidation defects</li> <li>• Severe enteropathies and disorders of digestion</li> </ul>	
Neurological disease	
<ul style="list-style-type: none"> <li>• Coma and severe facial and head injury</li> <li>• Severe mental retardation and cerebral palsy</li> <li>• Dysphagia secondary to cranial nerve palsy, muscular dystrophy, myasthenia gravis</li> </ul>	
Malignant disease	
<ul style="list-style-type: none"> <li>• Obstruction of esophagus and upper gut</li> <li>• Head and neck</li> <li>• Abnormality of deglutition following surgical intervention</li> <li>• Gastrointestinal side-effects from chemotherapy and/or radiotherapy</li> <li>• Terminal support care</li> </ul>	
Pulmonary disease	
<ul style="list-style-type: none"> <li>• Bronchopulmonary dysplasia</li> <li>• Cystic fibrosis</li> <li>• Chronic lung disease</li> </ul>	
Congenital anomalies	
<ul style="list-style-type: none"> <li>• Tracheoesophageal fistula</li> <li>• Esophageal atresia</li> <li>• Cleft palate</li> <li>• Pierre Robin syndrome</li> </ul>	
Other	
<ul style="list-style-type: none"> <li>• Primary malnutrition</li> <li>• Anorexia nervosa</li> <li>• Cardiac failure</li> <li>• Chronic renal disease</li> <li>• Severe burns</li> <li>• Severe sepsis</li> <li>• Severe trauma</li> </ul>	

feeding tube at the child's convenience and avoids a long tube protruding from the abdomen. Many children who require long-term enteral nutrition have gastrostomies, including many who receive home enteral feeding. In some children a fundoplication may be required to prevent gastric regurgitation.

## Enteral formulas

There is a range of enteral feeds available for children. Many are based on cows' milk and are suitable for children with an intact and functional gastrointestinal tract. These whole protein formulas are used to provide full or partial nutritional support and can be supplemented with extra energy (in the form of a glucose polymer or fat emulsion) and protein. Specialized formulas are designed to meet the altered nutrient needs and gastrointestinal and/or metabolic problems of children with different diseases. These include: (1) elemental formulas based on amino acids, vegetable oils (composed of a mixture of medium chain and long chain triglycerides) and glucose, designed for children with protracted diarrhea and severe enteropathies; (2) protein hydrolysates for children with sensitivity to food proteins; (3) formulas that are lactose-free by substitution of lactose with another carbohydrate; and (4) feeds based on soya, which are free of lactose and cows' milk protein. Modular feeds allow each macronutrient to be combined in amounts and source appropriate for the special needs of the child. Almost all clinical needs can be met by ready-prepared, commercially available formulas, and the reader should consult the literature produced by the manufacturers for full details of their composition and indications.

Home-prepared feeds and liquidized foods should not be used for enteral nutrition of children because of uncertain nutrient quality, a risk of bacterial contamination and of the feeding tube becoming blocked with food particles. During the first year of life infants who require enteral feeding and have a normal functioning gastrointestinal tract and require no nutrient modification, should receive one of the standard infant formulas.

## Home enteral tube feeding

Home enteral feeding (HEF) should be considered when the sole reason for the child being in hospital is enteral nutritional support.<sup>1</sup> It has been estimated that the expense and effort (of providing equipment, feeds and training) is justified by a minimum of 10 d of HEF. Children with chronic diseases, such as cystic fibrosis, neuromuscular disorders, malignant disease and renal failure, can greatly benefit from HEF; some have received it for more than 10 years, and its use is growing. Many children who are happy and able to pass their own nasogastric tubes, prefer night-time HEF. Children with enterostomies may also receive HEF.

## PARENTERAL NUTRITION

PN is a means by which nutrients are delivered to the patient via the vein. It may provide complete nutritional support – total parenteral nutrition (TPN) – or be combined with enteral feeding. The administration and monitoring of PN is complex and should be undertaken by

Table 16.7 Advantages and disadvantages of enteral feeding methods

Feeding method	Advantages	Disadvantages
Continuous infusion	<ul style="list-style-type: none"> <li>• Larger volumes of feed can be administered</li> <li>• Smaller bore tubes can be used</li> <li>• Less gastric distension</li> <li>• Less 'dumping' so that feeds with higher nutrient densities can be given</li> </ul>	<ul style="list-style-type: none"> <li>• Tube may become dislodged during feed administration with risk of aspiration</li> <li>• Electric feeding pumps, reservoirs and giving-sets are expensive</li> <li>• Some feeds containing insoluble substances cannot be given</li> </ul>
Bolus feeds	<ul style="list-style-type: none"> <li>• Mimics the normal feeding gut hormonal response</li> <li>• Position of feeding tube can be checked prior to each feed</li> <li>• Simple procedure only: a syringe required for feed to be administered</li> <li>• Contact with child at each feed time</li> </ul>	<ul style="list-style-type: none"> <li>• Gastric distension and vomiting</li> <li>• A wider bore feeding tube may be required, which may cause discomfort in nasopharynx if nasogastric feeding route used</li> <li>• 'Dumping' may be experienced especially if high nutrient dense feeds given</li> <li>• Adequate fluid requirement may be difficult to achieve</li> </ul>
Intermittent continuous feeds	<ul style="list-style-type: none"> <li>• Larger volumes can be tolerated</li> <li>• Fine-bore tubes can be used</li> <li>• The feeding tube position can be checked</li> <li>• Nutrient-dense feeds can be administered</li> </ul>	<ul style="list-style-type: none"> <li>• Requires a great deal of supervision</li> <li>• Electric feeding pumps, reservoirs and giving-sets are expensive prior to each feed</li> </ul>

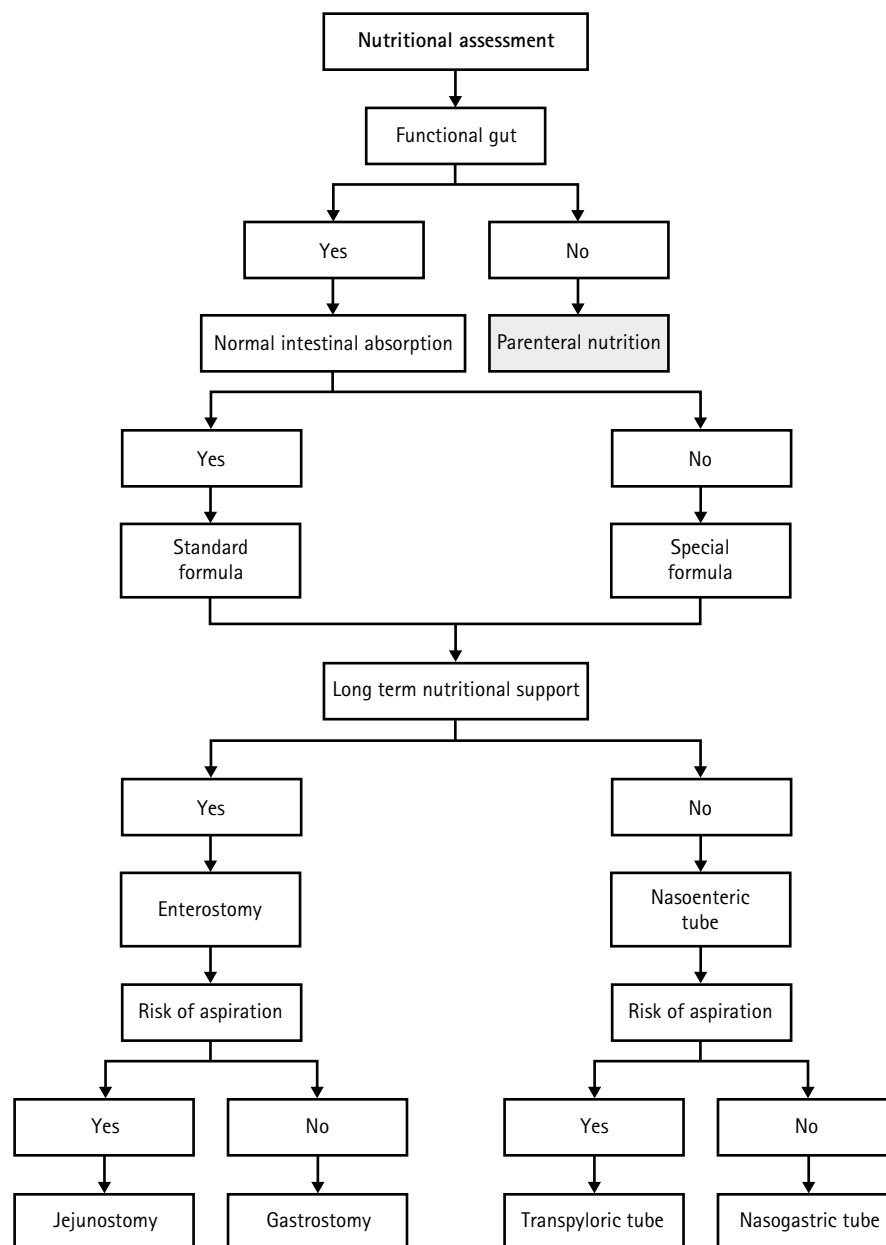

Fig. 16.2 Algorithm for choice of route of delivery of enteral feeds.

the nutrition support team. The process by which energy and nutrient requirements are calculated, techniques of delivery and assessment of PN are described in greater detail elsewhere.<sup>10,11</sup>

### Indications and complications of PN

The principal indications for PN are shown in Table 16.8. Although sometimes life-saving, PN has been subjected to few controlled clinical trials and its precise benefits remain unclear. PN is both complex and expensive when compared with enteral nutrition, and because of the risk of serious complications (summarized in Table 16.9) and evidence that enteral nutrition helps to maintain gastrointestinal structure and function, there has been a reappraisal of its use in some groups of patients, for example in those receiving intensive care. Whilst there can be little doubt that gastrointestinal 'failure' (from whatever cause) is an absolute indication for PN, complete exclusion of luminal nutrients is frequently neither essential nor desirable. When planning nutritional intervention it is important to use the gastrointestinal tract if possible. Total enteral nutrition may be feasible if a transpyloric or jejunostomy tube is used. Even if only minimal volumes of enteral feed can be given

in addition to PN, this can help to prevent cholestasis by stimulating bile flow and pancreatic secretions, maintaining splanchnic blood flow and providing mucosal nutrition.

Overall, the most frequent recipients of PN are preterm infants. Infants with surgical problems comprise the next largest group, and are fed parenterally usually because of gut failure following surgery for congenital or acquired gastrointestinal disease, and PN has undoubtedly had a major impact on survival in children with short bowel syndrome. Children undergoing gastrointestinal surgery, those with protracted diarrhea or severe dysmotility, and others receiving intensive care often with multiorgan failure account for much of the remaining PN usage.

Ethical dilemmas arise in relation to the care of children in whom there is little or no prospect of establishing full enteral feeding at any time in the future, such as those with congenital enteropathies. The prognosis in short bowel syndrome has improved considerably. Small bowel transplantation offers hope for some children who are chronically dependent on TPN.

For children receiving PN for more than a few weeks, cyclical nutrition should be considered. This involves a gradual decrease in the time

Table 16.8 Common indications for parenteral nutrition

	Neonates	Older infants and children (relative)	
Absolute indications	Intestinal failure (e.g. functional immaturity, short bowel, pseudo-obstruction) Necrotizing enterocolitis	Gastrointestinal failure	Short bowel syndrome Protracted diarrhea Chronic pseudo-obstruction Postoperative gastrointestinal surgery Radiation/cytotoxic drug therapy (e.g. bone marrow transplantation)
Relative indications	Respiratory failure requiring IPPV Promotion of growth in preterm infants	Intensive care and multiorgan failure	Severe IBD Acute pancreatitis Acute renal failure Acute liver failure Extensive burns Severe trauma

IBD, inflammatory bowel disease; IPPV, intermittent positive pressure ventilation.

over which it is given, so that eventually the PN can be infused overnight and the central venous line left clamped for 12 h during the day. This helps to encourage mobility and psychomotor development and reduce the adverse effects of prolonged hospitalization. Oromotor skills should be promoted with comforters and, when possible, small amounts of enteral feed by mouth. The expert advice of a speech therapist should be sought at an early stage. Cyclical PN may help protect against cholestasis and hepatic dysfunction.

Catheter-related sepsis is a serious complication of PN and its incidence is greatly reduced by scrupulous attention to sterile procedures and minimal handling of i.v. lines. Other complications of long-term PN include electrolyte and micronutrient disturbances, thromboembolism and pulmonary hypertension.

### Home parenteral nutrition

For those children committed to long-term PN, home treatment should be considered. The nutritional support industry and hospital outreach services should together provide the organizational and support infrastructure. Home PN offers children who would otherwise become hospitalized the possibility of realizing growth and developmental potential, a good quality of life, and a reduced risk of complications such as i.v. line

sepsis. Suitable patients are those with long-term gastrointestinal failure who are medically stable and have adequate home circumstances. The carers must be highly motivated, well supported by the nutrition support team and capable of becoming expert in home care including sterile technique, setting up infusions, managing lines, setting pumps, and recognizing and reacting appropriately to problems. The most frequent diagnoses in children receiving home PN are short bowel, severe dysmotility, congenital enteropathy, and Crohn's disease.

## OBESITY

### PREVALENCE AND DIAGNOSIS

Obesity is now a major pediatric health problem. In England, for example, in 2004 16% of 2–10-year-olds and 25% of 11–15-year-olds were obese (defined as BMI > 95th percentile<sup>17</sup>).

Systematic reviews have consistently concluded that obesity must be assessed using objective measurements.<sup>18</sup> Measuring body weight alone is inadequate: weight must be adjusted for height. This adjustment is best done by calculating BMI, weight (kg) divided by height squared (m<sup>2</sup>). Since BMI changes with age and differs between the sexes, interpretation of a single value requires a comparison to population reference data, i.e. a cut-off point in the BMI distribution must be applied to define overweight and obese. A high BMI for age and sex identifies the fattest children with moderate sensitivity and high specificity (low false-positive rate), and this definition has clinical/biological significance: children with high BMI for age and sex have a high probability of remaining obese, and of experiencing the morbidity associated with obesity.<sup>18</sup> Clinically there are limitations to the interpretation of BMI for individual children: while BMI is highly correlated with body fat (and with visceral fat mass, which is probably the best predictor of adverse effects) on a population basis, a particular BMI may be associated with a wide range of body fat in different individuals; there appear to be significant ethnic differences in the relationship between BMI and body fat; body composition may change as a result of exercise or dieting without change in BMI.<sup>19</sup>

### CLINICAL CONSEQUENCES

A systematic review concluded that childhood obesity causes morbidity in childhood, and increases morbidity and mortality in adulthood.<sup>20</sup> Psychosocial morbidity is common, and a range of other problems (respiratory, metabolic, hepatic, orthopedic) less common. In adolescents and young adults, obesity has adverse 'social' effects, particularly in girls. These include reduced educational attainment and income in both the UK and the USA.<sup>20</sup> Cardiovascular risk factors are associated with obesity, even in childhood, and they tend to 'cluster' in the obese child. Childhood obesity has a strong tendency to persist after the age of about

3 years, and it probably increases morbidity and premature mortality in adult life, particularly from cardiovascular disease and diabetes.

## CAUSES

Obesity is a disorder of energy balance. Excess dietary (food) energy is stored as fat and lean tissue, so that obese children have both a larger fat mass and lean body mass than their non-obese peers. Larger fat-free mass and body mass means that the energy requirements of the obese child are considerably *higher* than those of the non-obese child. Obese patients tend to report low food intakes, implying reduced metabolic rate as a cause of obesity. This is rarely the case and most obese children and adolescents substantially under-report their true dietary intake.<sup>21</sup> One consequence is that dietary intakes reported by obese patients/their families must be viewed with caution, and can only provide a crude estimate of eating habits.

## TREATMENT

Detailed descriptions of therapeutic strategies for treating childhood obesity are provided elsewhere.<sup>21,22</sup> Recent systematic reviews of both treatment<sup>23–25</sup> and preventive interventions<sup>23,26</sup> have concluded that we lack good evidence on generalizable intervention strategies from high-quality, long-term, randomized, controlled trials (RCTs). More recent RCTs have been of higher quality and have generally had longer term follow-up, but the effects of pharmacological treatment (adolescents) and lifestyle therapy have usually been modest.<sup>27</sup> The systematic reviews have concluded that the 'best bets' in therapy are: modest dietary restriction and 'healthy eating' (to reduce energy intake), reductions in sedentary behavior (TV viewing and other screen time, to less than 2 h/d, to increase energy expenditure and reduce energy intake), and increases in 'lifestyle physical activity' (such as walking, to increase energy expenditure). As in adults, childhood obesity is often resistant to treatment so therapy should be offered only where the child/family perceive the need to make lifestyle changes, or where there is severe obesity-related co-morbidity (such as sleep apnea). Therapy should involve changing family lifestyle and not simply focus on the child.

## SECONDARY OBESITY

Careful history and examination will usually differentiate between 'simple obesity' and any underlying pathology which may be responsible<sup>21–23</sup> (usually very rare). The child with simple obesity often has relatively tall stature. In contrast children with Cushing's syndrome and hypothyroidism have relative or short stature, and growth failure. Hyperphagic dysmorphic syndromes include the Prader–Willi and Laurence–Moon–Biedl syndromes, but many dysmorphic syndromes with learning disability can be associated with voracious appetite. Some chromosomal abnormalities (Down and Klinefelter's syndromes) are associated with obesity. Recurrent headaches with recent increases in severity and frequency may indicate a hypothalamic or pituitary tumor. Severe mood disturbance, unstable temperature, polyuria and polydipsia and visual disturbance support this diagnosis. It is vital to identify causes of secondary obesity early. Management of secondary obesity involves treatment of the underlying disease.

## MALNUTRITION

'Malnutrition' describes conditions that result from a diet (supply) that does not satisfy nutritional requirements (demand). 'Secondary malnutrition' refers to malnutrition resulting from disease or trauma, such as inflammatory bowel disease or severe burns.<sup>28</sup> Primary malnutrition, which accounts for the vast majority of cases, is associated with poverty, involving inter alia inadequate food, recurrent infections and lack of health care. It is extremely common, affecting a quarter of the world's children<sup>29</sup> because so many live in poverty in the 'developing' world. It contributes to almost 60% of all child deaths.<sup>30</sup> Lack of effective

prevention and treatment accounts for almost all of these unnecessary deaths. In the survivors, malnutrition leads to permanent suboptimal physical and mental development affecting billions of adults mainly in south and south-east Asia, Africa and South America. Fortunately, in most of the world except sub-Saharan Africa, the prevalence of malnutrition is falling slowly.<sup>29</sup>

## CLASSIFICATION OF MALNUTRITION

When nutritional supply fails to meet demand, reductive adaptation occurs: in children, weight gain and development are abnormally slow and sometimes negative, and physiological functions become impaired. Malnutrition is characterized initially by thinness (wasting) and later, by shortness (stunting), and there is often evidence of specific nutrient deficiencies. Bilateral (nutritional) edema is a less common complication associated with characteristic abnormalities of metabolism and a poor prognosis. Its cause is unclear.

Malnutrition is most easily diagnosed and classified using anthropometry, measuring the child's dimensions and weight, and relating them to what would be expected normally, based on reference data. Several classifications of malnutrition have been proposed over 50 years. The Wellcome and Waterlow classifications are useful together as they identify which children need which treatment and the degree of urgency (Table 16.10). Recently, the WHO<sup>31</sup> classified moderate malnutrition as wasting (weight  $-3$  to  $-2$  standard deviation score [SDS] or 70–79% of reference weight for height) or stunting (height  $-3$  to  $-2$  SDS or 85–89% height for age); and severe malnutrition as severe wasting (weight lower than  $-3$  SDS or  $< 70\%$  of reference weight for height) or/and nutritional edema or/and severe stunting (height lower than  $-3$  SDS or  $< 85\%$  of reference height for age). Supine length, rather than height, is measured in children up to 2 years and those unable to stand. Without appropriate intervention, children with severe wasting or nutritional edema usually deteriorate rapidly until they are at high risk of imminent death. Even more recently,<sup>32</sup> mid-upper arm circumference (MUAC) has emerged as the most useful index of the severity of malnutrition when large numbers are affected, as in complex emergencies. Its particular value is its ease of measurement and classification (Table 16.10).

Wasting and edema can develop rapidly and resolve rapidly: measurable stunting develops slowly and, even with intervention, usually carries on until puberty in a poor environment. Although puberty tends to be delayed, final height is usually less than predicted. This applies to whole populations living in poverty. Stunting is associated with lower than expected IQ. The combination reduces the chances of having normal pregnancies, births and birth weights; good employment and prosperity; and improved life opportunities in the next generation.

## CLINICAL FEATURES

Clinical features of malnutrition vary enormously and none distinguishes primary from secondary malnutrition. In an infant, because head size is better preserved than length or weight, the trunk and limbs often appear relatively small. Abdominal girth is variable and sometimes relatively large. The older child, on the other hand, may appear well-proportioned and healthy but diminutive. This implies predominant stunting and thus mild to moderate problems over a long period. However, an acute severe problem in a previously well-nourished child may be visible first as wasting alone. Severely malnourished children are usually wasted and stunted.

In general, edema is less common in very young infants. It often arises over a few days, when a child, already compromised nutritionally and failing to thrive, develops an infection like measles or gastroenteritis. If at the walking stage, edema is first noted on both feet; if younger, it may be seen first in the hands or around the eyes. The child usually appears ill, and is apathetic, irritable and anorexic. Skin lesions tend to be more common and more severe in the edematous child. Typically, they start as a darkening and thickening of the keratin layer which when damaged splits or flakes off, leaving patches of hypopigmented thin skin

Table 16.10 Some classifications of childhood malnutrition

Classification	Variable	Grade	Nutritional edema
Wellcome	Weight for age % 60–80	Undernourished	Absent
		Kwashiorkor	Present
	< 60 ( $\approx -4$ SDS) <sup>a</sup>	Marasmus	Absent
		Marasmic-kwashiorkor	Present
Waterlow	Weight for height <sup>2,3</sup> % 80–90 70–80 < 70 ( $\approx -3$ SDS)	Mild wasting	
		Moderate wasting	
		Severe wasting	
		Height <sup>b,c</sup> for age % 90–95 85–90 < 85 ( $\approx -3$ SDS)	Mild stunting
		Moderate stunting	
		Severe stunting	
CTC <sup>d</sup>	Mid upper arm circumference (6 months to 5 years old only) < 110 mm	Acute malnutrition	

<sup>a</sup>SDS = standard deviation score = number of standard deviations from median of reference data (NCHS/WHO).

<sup>b</sup>'Height', for standing children, 'length' for those unable to stand.

<sup>c</sup>Weight for height = child's weight  $\times$  100/weight of 'reference' child of same height; Height for age = child's height  $\times$  100/height of 'reference' child of same age.

WHO;<sup>31</sup> Valid International.<sup>32</sup>

and sometimes oozing sores that refuse to heal. Such skin damage tends to occur round the orifices (mouth, perianal and perineal), over joints and on the extremities. It also occurs where edema stretches the skin, as on the foot and lower leg. Firm, smooth hepatomegaly, associated sometimes with vast deposits of lipid, is also frequent in the edematous child. However, abdominal distension, which is common, is usually mainly gaseous. Ascites is rare in children. Stools tend to be frequent, small and often loose, green and mucousy.

Other clinical features include depigmentation, thinning and straightening of the hair associated with increased fragility and pluckability. In contrast, in longstanding malnutrition, eyelashes tend to be long and silky and in some children, lanugo hair grows luxuriantly. Many of these clinical signs can be recognized in Figures 16.3 and 16.4, which show infants with kwashiorkor (edematous malnutrition) and marasmus (severe wasting), respectively. Clinical features of specific

Fig. 16.3 Child with kwashiorkor. (With permission of R.G. Whitehead)

Fig. 16.4 Child with nutritional marasmus. (With permission of R.G. Whitehead)

nutrient deficiencies may also be present, such as rickets, scurvy, keratomalacia, etc. (see later). When a child is severely malnourished, he or she may develop any or all of the following: extreme apathy, hypotonia, pallor, hypothermia, cold extremities with prolonged capillary refill time, a weak pulse, dyspnea, petechiae, purpura and jaundice. They are, in their various ways, evidence of sepsis, cardiac and hepatic failure and eventually, loss of cell homeostasis which, untreated, is fatal.

## LABORATORY INVESTIGATIONS

Laboratory investigations are generally unhelpful. Hemoglobin falls but serum ferritin tends to rise and there is anisocytosis. Severely malnourished children, with their damaged skin and mucosae, prolonged intestinal transit time and reduced secretions, are very susceptible to skin,

gastrointestinal and respiratory infections. They also have impaired resistance to infection, in particular, their acute phase and cell-mediated immune responses. Fever and the cardinal signs of inflammation tend to be slight or absent. White cell counts and C-reactive protein (CRP) rise little. In very ill children, neutropenia may occur, with hypothermia and hypoglycemia when feeding has been withheld for only a couple of hours. Serum electrolytes do not reflect body content, only circulating concentrations. Thus, high serum potassium masks intracellular potassium deficiency, and in hospital, is most likely due to i.v. delivery and impaired cellular uptake. A low serum sodium masks sodium overload and the only useful interpretation is that the child is very ill. Magnesium deficiency occurs. Serum urea tends to be low, reflecting low protein intake and reduced catabolism. Serum albumin is almost invariably low in edematous children. This finding led the way to the protein deficiency theory of development of nutritional edema in some children. However, edema is not due to low serum albumin alone, protein deficient diets are not limited to those children who develop edema and dietary protein repletion does not cure it.<sup>33</sup> At present, the most likely pathogenesis of edematous malnutrition involves extensive membrane dysfunction associated with lipid peroxidation, a product of antioxidant deficiency in the face of acute oxidative stress.<sup>34</sup> As evidence of this, red blood cell glutathione and plasma zinc, copper, selenium and glutathione peroxidase, vitamin E and carotene are all particularly low in edematous children while *free* iron, a major pro-oxidant, circulates because transferrin concentrations are very low.

## MANAGEMENT

Successful management of malnutrition should mean complete catch-up followed by sustained normal growth, health and development. This is rarely achieved. Effective home management should be widely implemented for children with less than severe wasting (weight for height above  $-3$  SDS of WHO reference values) and those with stunting. Continuing poverty means this is also rarely achieved. It requires education and practical help to ensure exclusive breast-feeding to 6 months; continued breast-feeding to 2 years; good hygiene; more energy-dense diets containing all essential nutrients, taking into account their bio-availability; regular monitoring of body weight; early, appropriate treatment of complications like infections; and mental and physical stimulation to allow normal development.

Community-based therapeutic care, when feasible and carried out according to specific guidelines<sup>32</sup> can also be successful for many severely malnourished children including some with nutritional edema. Those who respond well are the uncomplicated ones who still have good appetites. However, for the more severely affected, and all anorexic children, a period of specialized treatment within a well-staffed and equipped specialized unit, or 'stabilization center', is essential to prevent early death, treat infection successfully and repair the child's metabolism in preparation for catch-up growth. Thus, in complex emergencies, when vast numbers of children are acutely malnourished, triage is essential to distinguish those in need of early specialized management. The same principles of management apply to all. Provided they are adhered to, the mortality from severe malnutrition should be less than 5%,<sup>35</sup> a vast improvement over traditional hospital figures of 20–30%.<sup>30</sup>

### Phases of treatment

Management of severely wasted or/and edematous children is described in detail in a WHO manual<sup>31</sup> and several other publications.<sup>32,36</sup> It is best divided into phases. Following triage and, if necessary, resuscitation, the *Initial phase* involves treatment of infection and correction of disordered metabolism. The latter requires prevention and often treatment of electrolyte imbalance, specific deficits, hypoglycemia, hypothermia, dehydration, heart failure and shock, all of which will continue until death or their successful treatment. Bacterial infection must be assumed and treated with broad-spectrum antibiotics unless and until specific infections are diagnosed which require different, available therapy.

Intravenous fluids pose a major risk (cardiac failure or arrest) and should be avoided if possible. Oral or nasogastric rehydration is recommended for dehydration. However, compared with the standard WHO Oral Rehydration Solution, the solution should contain less sodium but more potassium and magnesium, zinc and copper, all of which are grossly deficient in the malnourished child with acute diarrhea. Such a solution is available commercially (ReSoMal) but this can also be prepared from WHO ORS.<sup>31</sup> Frequent breast-feeding is encouraged. Instead of or in addition to this, a special cows' milk based formula, 'F-75' (0.31 MJ [75 kcal]/100 ml) with relatively low protein, fat and sodium contents and osmolarity is recommended, to provide minimal stress. In the absence of F-75, recipes, from ingredients likely to be available, are also provided in the WHO manual.<sup>31</sup> In this initial phase, every effort is made to ensure that children receive sufficient intake for maintenance of body weight (0.42 MJ [100 kcal]/kg/d) but not growth. This may require very frequent, small tube-feeds if anorexia and vomiting are major problems. It is very important to feed regularly throughout the night to avoid hypoglycemia. Hypothermia also tends to occur then, and both of these suggest that sepsis may not have been treated successfully. F-75 contains extra minerals and vitamins but further supplements of vitamin A and folic acid are also recommended initially. Iron is contraindicated because of its potential toxicity and aggravation of infection.

Usually within a week, the second or *Rehabilitation phase* is heralded by increased appetite and improvement of mood and major abnormalities including loss of edema. The principles of management change to include feeding for growth, and stimulating mental and physical development. The transition between the first and second phases is a period of risk when 'refeeding syndrome' tends to occur. This may resolve on returning to the Initial phase and proceeding more slowly. Depending on circumstances, in particular, the availability of trained support within the community, the child may now be better managed at home. At this stage, the formula feed is changed to one that provides more energy and protein. Commercially available F-100 contains 0.42 MJ/100 ml, 12% energy from protein and 53% from fat. Like F-75, it also provides extra minerals and vitamins but not iron. However, supplementary iron is necessary during this phase for new hemoglobin synthesis. Like F-75, F-100 can also be prepared from usually available ingredients but both 'home-prepared' feeds benefit from the addition of extra minerals and vitamins. These are best provided as a commercial preparation whose composition is given in the WHO manual.<sup>31</sup> Another product, ready-to-use-therapeutic food (RUTF),<sup>32</sup> which is a vegetable oil (originally peanut)-based feed of similar nutrient and energy content to F-100, is now available within many malnourished populations, mainly in African countries. This is a welcome substitute for F-100 as it is much easier to store safely for long periods, needs no preparation and is popular among older infants and children. Like F-100, it can often be manufactured locally according to the 'free' recipe.

During this *Rehabilitation phase*, the child should be offered increasing amounts of feed until some is left at each meal – 'ad libitum' feeding. The frequency of feeding is reduced. Provided there are no setbacks, dietary intake increases steadily, and weight gain is rapid, up to 20 times normal, on average 10 g/kg/d. The child's mother or closest carer must be taught how to make home as conducive as possible to continuing catch-up growth and development of her child. This includes teaching nutrition, hygiene, play for mental and physical development, and also when and how to get help. Depending on circumstances, 'cure' may be defined as attainment of 80% ( $-2$  SDS), 85% or 90% ( $-1$  SDS) of reference weight for height or a MUAC, in 6-month to 5-year-old children only, of for example 110 mm or 125 mm. Ideally, a final *Follow-up phase* ensues in which the child is reviewed at increasing intervals to ensure that recurrence of malnutrition is prevented and health and normal development are promoted, supported and achieved.

## PREVENTION

A few severely malnourished children in a poor community imply a large number of moderately malnourished children. If the

moderately malnourished are ignored, as usually happens, some deteriorate, some die and all are blighted for the rest of their lives by not realizing their potential. The ideal solution to primary malnutrition is prevention. However, this requires what we are presently unwilling or unable to provide to a large section of the world's population, improved standards of living: health care, education, sanitation, security, sufficient good quality food and more, to permit the birth of healthy well-nourished infants, tolerable burdens of infection during childhood and hence, normal growth and development. In the 'resource rich' world, however, prevention of secondary malnutrition is achieved to varying extents within good health care systems in, for example, children with inflammatory bowel disease, cystic fibrosis and those with various inborn errors of metabolism.

## MICRONUTRIENT DEFICIENCY AND EXCESS

Micronutrients are generally recognized as the vitamins and essential trace elements. Vitamins are preformed organic compounds required in the diet each within a given physiological range to ensure optimal health. The same requirement applies to the 10–17 essential trace elements<sup>37</sup> which, in total, comprise about 0.03% of body weight. The most abundant and best known is iron while one of the least abundant but also well known, is iodine. Cobalt, a less obvious essential trace element, is required at only one hundred-thousandth the intake of iron and, in humans but not ruminants, has to be supplied within vitamin B<sub>12</sub>.

Nutrients essential for optimal health can be divided into type I and type II nutrients, distinguished by their roles.<sup>37</sup> Type I nutrients include all of the vitamins and essential trace elements except zinc. Each has a limited number of specific functions and most have body stores. After the stores are depleted, specific signs of deficiency appear, which makes specific diagnosis relatively easy. Type II nutrients include major body elements such as potassium, calcium and the essential amino acids – also zinc, which is a micronutrient. These are required for maintenance and growth of all cells and they tend not to have effective stores. Deficiency limits, first and foremost, cell hyperplasia and hypertrophy. In childhood, the consequence is growth failure. This, in turn, reduces the requirement for all nutrients. Thus deficiencies of type II nutrients are difficult to diagnose and often overlooked. However, they are no less important than type I nutrient deficiencies and should be considered as possible contributors to growth failure, particularly when the diet is monotonous or specialized.

Interactions among nutrients and other components within diets influence the final balance of nutrients absorbed. This is particularly important when therapeutic diets, enteral feeds or food supplements are prescribed, or when the diet is monotonous. For example, a diet with a high phytate content (the storage form of phosphate in plants) reduces the availability of nutrients such as zinc, iron and copper; a diet high in ascorbic acid content increases iron but decreases copper absorption, and many trace elements interfere with one another's absorption. Thus, the intake of a particular micronutrient does not necessarily reflect its bioavailability. Important characteristics of a few of the essential micronutrients are summarized below and further information can be found elsewhere.<sup>37</sup>

### IRON

For body iron, 70% is contained within heme, where it is intimately involved in O<sub>2</sub> carriage. Iron is a highly reactive element as ferrous ion releases an electron to become ferric ion. The freed electron takes part in many normal metabolic events such as electron transfer in the mitochondrial respiratory chain and free radical production which, on the one hand, is used to kill pathogens but on the other, may result in peroxidation of membrane lipids, a highly dangerous complication. This hazard is reduced by an elaborate system of iron-binding proteins, the main ones being heme, which holds ferrous iron, ferritin (which binds stored ferric iron), and transferrin (which carries ferric iron between cells).<sup>38</sup>

Iron deficiency causes a microcytic, hypochromic anemia after iron stores are depleted. This is a particular hazard of preterm birth because iron stores accumulate first in the fetal liver in late gestation. Iron deficiency anemia in infants also occurs when they are fed largely cows' milk mainly because it is a poor source of iron.<sup>39</sup> Appropriate advice is to introduce heme-containing foods like meat and liver, replace cow's milk with breast milk or formula and, if necessary, provide iron supplements. Iron deficiency is also relatively common in adolescent boys and girls. Vegetarians are at higher risk than omnivores because non-heme iron is less bioavailable than heme iron and their phytate intake tends to be high. As well as anemia, which is probably a late manifestation, iron deficiency is associated with reduced exercise tolerance, impaired resistance to infection and poor psychomotor development.

Iron toxicity can occur. Acute iron poisoning is less common than it used to be. Hemochromatosis and multiple blood transfusions are relatively rare in childhood but malnutrition is commonly complicated by iron excess and toxicity.<sup>38</sup> In edematous malnutrition, although anemia is usual, plasma ferritin and hepatic iron content are high while plasma transferrin, but not plasma iron, is low. This leads to an increased risk of circulating free iron which, together with antioxidant deficiencies, may lead to lipid peroxidation in membranes and contributes to at least some of the features of edematous malnutrition. Iron supplementation may also increase the severity of infection in malnourished children. Thus, although the treatment of anemia with iron is usually appropriate, it may be deleterious in children with malnutrition or if the anemia is not due to iron deficiency.

Iron status can be measured in different ways, some more specific than others. For example, anemia is a nonspecific measure, which may be due to many nutrient deficiencies or indeed, other non-nutritional causes. In contrast, low plasma ferritin and high transferrin receptor concentrations are quite specific, each for a different aspect of iron status: the former implies low iron stores, the latter, low uptake of iron for heme synthesis.

### COPPER

Though the dietary requirement for copper is only about one tenth that of iron or zinc, it is also crucial to normal metabolism. Copper shares several features with iron. It is reactive, cuprous copper releasing an electron to become cupric copper and vice versa. It circulates bound largely within caeruloplasmin, otherwise known as ferroxidase I, which catalyzes the oxidation of ferrous to ferric iron. Thus copper deficiency interferes with iron metabolism. Located at the active site of several other oxidases, copper is also involved in the crosslinking of connective tissue proteins such as collagen and elastin and responsible for end-oxidation in the respiratory chain. The main features of copper deficiency are microcytic, hypochromic anemia indistinguishable from that of iron deficiency, neutropenia, tortuous dilatations of blood vessels, herniae, 'osteoporosis' clinically not unlike infantile rickets, skin and hair hypopigmentation and neurological problems.

Like iron, copper stores accumulate in the fetal liver in late gestation. Similarly, cows' milk is a poor source of copper. Thus, copper deficiency tends to occur in preterm infants and infants fed largely cows' milk. It also accompanies malnutrition, particularly edematous malnutrition.

Copper toxicity is usually insidious, most commonly from chronic ingestion associated with copper piping or utensils carrying relatively acidic fluids. The excess copper ends up in the liver and cirrhosis ensues. Two inherited inborn errors of metabolism involve copper transporting ATPases, Wilson disease and Menkes syndrome. Wilson disease, an autosomal recessive defect, usually presents in adolescence with cirrhosis associated with excessive hepatic copper. High concentrations of copper in the brain, eye and kidneys also occur: biliary excretion of copper and plasma caeruloplasmin are low (see Chapter 26). Treatment with copper chelators or zinc, which inhibits copper absorption, is partially effective in controlling copper accumulation. Menkes, or steely hair syndrome, is also autosomal recessive in origin

but more like copper deficiency in presentation in that progressive anemia, hypopigmentation, hypothermia, osteoporosis, cardiovascular abnormalities and mental deterioration occur from infancy and plasma copper is low. However, this syndrome is unresponsive to copper (see Chapter 26).

Plasma copper is a poor measure of copper status because it follows closely plasma caeruloplasmin, which is an acute phase protein whose concentration rises during an acute phase response. Erythrocyte superoxide dismutase level reflects copper status more reliably.

## IODINE

Iodine plays its major role in the hormone thyroxine, whose function and disorders are covered in Chapter 15. Iodine deficiency disorders are of worldwide importance accounting for stunting and suboptimal mental development in many millions of children and, subsequently, adults in developing regions with low iodine water supplies. Selenium deficiency, which is also widespread, may influence the response to iodine deficiency, particularly in regions within China.<sup>37</sup> Iodine excess also impairs thyroid function in communities with a high intake of food of marine origin.

## ZINC

The dietary requirement for zinc is similar to that of iron and its body content is about half as much. However, unlike iron or copper, zinc is relatively unreactive. About 60% of plasma zinc is bound loosely to albumin, about 25% is bound to alpha-2 macroglobulin and the rest to amino acids and other small molecules. Zinc is a classic type II nutrient without an effective store. Its association with several hundred ubiquitous enzymes, including those necessary for DNA, RNA and protein syntheses, means that it is necessary for normal cell metabolism, hyperplasia and hypertrophy. Zinc deficiency decreases growth until the demand for zinc meets the supply. Clinically this means that zinc deficiency in childhood presents with growth failure. Other features are skin lesions in areas subject to trauma, poor wound healing, impaired cell mediated immunity and diarrhea associated with intestinal mucosal atrophy.

Conditions in which zinc deficiency is common include poverty and thus, inadequate, monotonous, relatively low protein, low zinc diets; increased zinc loss from burns or protein losing enteropathies; and increased zinc demand for healing or for rapid growth. The autosomal recessive inherited disease, acrodermatitis enteropathica, appears to involve reduced zinc absorption. Its clinical features are those of simple zinc deficiency as described earlier. It can be treated successfully with zinc supplements thereby overcoming the intestinal block (see Chapters 19 and 30).

Zinc status is particularly difficult to define or measure because intracellular concentrations are controlled within narrow limits and there is no store to sample. In zinc deficiency, hair and plasma zinc fall. However, hair zinc is hard to measure accurately. Low plasma zinc often implies an ongoing acute phase response rather than zinc deficiency. Thus its interpretation requires an independent measure of the acute phase response and preferably knowledge of zinc intake and demand. In practice, a trial of zinc supplementation is often the most helpful test provided that its endpoint is defined at the outset. If zinc deficiency is present the child should respond within a month by, for example, gaining weight more rapidly than before supplementation.

Zinc toxicity is very unusual in childhood because homeostatic mechanisms prevent excess intestinal absorption. A recent syndrome featuring hyperzincemia with clinical features of persistent, gross inflammation has been described. There is no evidence however that zinc excess causes the clinical features.<sup>40</sup>

## VITAMIN A

The vitamin A family is headed by all-*trans* retinol and includes all naturally occurring compounds with the biological activity of retinol, as well

as the provitamin A carotenoids, such as beta-carotene. Preformed vitamin A is found in liver, dairy products and oily fish and over 80% may be absorbed (Table 16.2). The carotenoids are present in many plant foods and absorption varies from 5 to 50%. They act as anti-oxidants themselves and are also converted to vitamin A by oxidative cleavage. The vitamin A family members are fat soluble and bound in plasma to specific retinoid-binding proteins (RBPs), which protect them from oxidation. They are stored mainly in the liver.

In childhood, vitamin A is best known for its roles in vision, in immunity and in cell differentiation. Vitamin A deficiency is a major public health problem, affecting at least 200 million of the world's children, particularly malnourished children.<sup>39</sup> Only a small proportion has overt clinical signs. These start with night blindness, photophobia and Bitot's spots on the conjunctivae, which result from squamous metaplasia, then xerophthalmia, keratomalacia and eventually blindness. At the same time children suffer increased severity of infections and mortality is high. Prevention is possible using a 'massive dose' approach, which depends on the ability of vitamin A to be stored and used slowly. A large oral dose is also used for xerophthalmia.

Vitamin A toxicity can occur, which can be acute or chronic. Both are usually iatrogenic, resulting from gross overdoses of vitamin preparations. Typically the former resolves completely on stopping supplementation but the chronic form, which is more common, occasionally causes permanent damage to liver, muscle, vision and bones.

Vitamin A status is assessed by different methods in different situations, often by serum retinol in hospital; and by presence or absence of Bitot's spots or conjunctival impression cytology in populations. Serum retinol is depressed in the acute phase response and affected by protein and zinc intake, therefore relative dose response tests are becoming more popular where serum retinol is measured before and after a supplement of vitamin A.

## VITAMIN D

This comprises vitamins D<sub>2</sub> and D<sub>3</sub>, which are both fat soluble and stored within adipose tissue. D<sub>3</sub> is hydroxylated in the liver to 25-hydroxyvitamin D, which is further hydroxylated in the kidney to 1,25-dihydroxyvitamin D, which acts as a hormone and is the most biologically active form of the vitamin. It stimulates calcium absorption in the small intestine and calcium resorption from bone. It also promotes cell maturation within the intestine and it increases bone formation and growth plate mineralization by providing sufficient circulating calcium. The vitamin has several other roles including improving resistance to infections.

Egg yolk, fortified margarines and spreads and especially cod liver oil are rich in vitamin D (Table 16.3); breast milk is a poor source. By far the major source is photoconversion of 7-dehydrocholesterol, through exposure of the skin to ultraviolet B light. This means that breast-fed infants in the UK who are mostly indoors or covered up, or whose mothers are vitamin D deficient, are at particular risk of deficiency. Daily supplementation is recommended. Very preterm infants are also prone to deficiency signs but other factors contribute as well as vitamin D deficiency. Fat malabsorption for any reason is associated with vitamin D deficiency.

In early life, deficiency results in rickets, which is characterized by failure of skeletal growth, poor bone mineralization and muscle weakness. In infancy, frontal bossing, craniotabes and rachitic rosary are more distinctive. Bone pain, anemia and respiratory infections are common. Plasma 25-hydroxyvitamin D is low; plasma alkaline phosphatase is high but this is not specific for vitamin D deficiency. Radiological changes include poor mineralization, delayed epiphyseal development and marked metaphyseal changes including cupping, fraying and splaying (Fig. 16.5).

Vitamin D toxicity usually results from injudicious supplementation and is associated first with failure to thrive and gastrointestinal features including constipation, and later, urinary tract features with

Fig. 16.5 Rickets: X-ray of wrist showing frayed radial and ulnar metaphyses with slight expansion.

nephrocalcinosis and eventually renal failure. Hypercalcemia and increased bone mineralization occur. Therapy includes glucocorticoids and a low-calcium diet.

## FOLATE

Folate comprises the double aromatic ring of a pteridine linked to para-aminobenzoate and glutamate. It is water soluble and functions as a coenzyme receiving and donating single carbon fragments. It provides methylene groups for pyrimidine synthesis and formyl groups for purine synthesis for DNA and RNA biosynthetic cycles. It also participates in methylation of a variety of substrates, for example, DNA, myelin and phospholipids.<sup>37</sup> Over half of natural folates are in the 5-tetrahydrofolate form attached to a polyglutamyl chain. The best dietary source is liver (Table 16.3). Synthetic folic acid is twice as bioavailable as natural folates.

Marginal folate deficiency is very common but the extent to which this contributes to suboptimal health is not yet clear. However there is good evidence that high maternal folate status during the first few weeks after conception reduces the risk of neural tube defects in their offspring (see Chapter 11). Folate deficiency accompanies malnutrition and also occurs as a complication of increased requirements for growth or erythropoiesis, malabsorption syndromes, impaired utilization due to vitamin B<sub>12</sub> deficiency and as a result of prolonged treatment with methotrexate, trimethoprim and some anticonvulsants. Overt folate deficiency is characterized by megaloblastic anemia with thrombocytopenia, leukopenia and increased segmentation of polymorph nuclei.

The risk of folate toxicity has become an important issue since recognition of the need for relatively high doses of folic acid to prevent neural tube defects. High doses may mask vitamin B<sub>12</sub> deficiency, allowing the neuropathy induced by the latter to progress. They may also interfere with anticonvulsive therapy and with anti-folate therapy for malignancies.

Folate status is best estimated as erythrocyte folate concentration but, due to the long life of erythrocytes, this does not change quickly in response to deficiency or excess. In contrast, serum folate falls quickly when folate absorption falls but this is not necessarily associated with folate deficiency.

## INTRODUCTION

Disturbances of the 'internal milieu' are common in pediatric illness. This chapter will focus mainly upon the background (i.e. the reasons why they are so common) and the associated clinical issues that arise as a consequence. Two appendices are also provided as references for the less clinical material. The 'Physical and physiological influences on the internal distribution of water and electrolytes' and 'Acid–base chemistry and blood gas measurement' are nonetheless essential knowledge for the clinician. Otherwise the layout of the chapter is intended to provide the reader with the information required to deal with clinical situations of increasing complexity as the chapter proceeds. Wherever possible, generic descriptions have been favored over specific diseases since the intended focus is not upon the differential diagnosis of deranged laboratory results. This is because in the first instance and to a large extent, abnormalities of fluid balance, electrolytes and acid–base can be characterized, assessed and treated on their own merits. Clinical situations often arise where this approach is necessary whilst the diagnosis is still being determined. Nevertheless the best clinical solution will always involve treatment of the cause.

Careful assessment is an essential prerequisite to proper management of fluid, electrolytes and acid–base in children. In this respect clinical judgment and laboratory assessment are complementary to each other. Therapeutic decisions should not be made on laboratory findings alone though in hospital, patients cannot be managed to modern clinical standards without appropriate measurement and monitoring.

The first priority when a patient presents, is a rapid assessment of the need for resuscitation following an 'ABC' approach (see Ch. 35). Then a comprehensive history of the disorder should be taken and skilled clinical examination performed to determine the speed and extent of investigation and the intensity of treatment. The patient should be weighed at

this point. Biochemical investigation also forms part of the assessment and should be performed whenever fluid therapy is contemplated, particularly if by the intravenous (i.v.) route. Baseline investigations should include the determination of serum urea, creatinine, electrolytes, osmolality and some indication of acid–base status such as serum bicarbonate along with the hematological profile. Patients with abnormalities of acid–base detected by this screening and those with significant respiratory problems should be further investigated with arterial blood gases. Urine electrolyte content, urea, pH and osmolality should be measured if there is a clinical suspicion of an abnormality of fluid balance or renal function. During the subsequent care of acutely unwell babies and children, the volume of urine production should be monitored, with repetition of laboratory urinary analysis where relevant. While it is helpful if accurate urine collections can be obtained to calculate electrolyte excretion, measurements performed on casual spot urine specimens can be interpreted by relating sodium and potassium concentrations to the urinary creatinine content (see 'Fractional sodium excretion' below). Further assessment both clinically and biochemically should be made as soon as the response to treatment can be assessed.

The body content and internal distribution of fluid and electrolytes are subject to tight physiological controls and are conveniently interpreted using 'compartment' models. The most important distinction for fluid, electrolyte and acid–base is between the intra- and extracellular environment, which is preserved by the cell membrane. Likewise the composition of the various extracellular fluids depends heavily on the integrity and function of epithelia and the vascular endothelium. The extracellular fluid (ECF) consists of intravascular fluid (plasma) and extravascular fluid. The latter includes 'tissue' or 'interstitial' fluid as well as specialized collections of transcellular fluids formed by secretory activity which include gastrointestinal (GI) secretions, synovial fluid, ocular and cerebrospinal fluids. Body compartments can also be

conceptualized if not defined anatomically, by the behavior/distribution of solutes within them. This latter approach is more commonly applied in pharmacology than physiology but it usefully defines some aspects of the behavior of the body as a compartmentalized vessel. In a 'one-compartment' model the drug, once administered, is assumed to instantly distribute homogeneously throughout the volume of distribution. In a two-compartment model the drug distributes rapidly through a small-volume, central compartment that usually corresponds to blood and the ECF of highly vascular organs and more slowly through a larger compartment, which usually includes adipose tissue and intracellular fluid (ICF).

Both total ECF volume and the distribution of fluid between extracellular compartments can vary widely in disease. Furthermore, one of the main consequences of ECF changes is corresponding or consequential change within the ICF. These changes are dictated by the interplay of hydrostatic, oncotic and osmotic forces, endothelial and cell membrane permeability and the integrity of active homeostatic systems such as membranous  $\text{Na}^+/\text{K}^+$  ATPase.

## DIFFERENCES AMONG BABIES, CHILDREN AND ADULTS

The physiological differences between premature and term neonates and among babies, older children and adults are extreme. From a constitutional perspective, neonates have proportionally the greatest water content and obese adults the least. The 'total body water' accounts for 80% of mass at birth and this percentage falls to 60% by 1 year of age. The change is the result of a disproportionate increase in cell mass (due to growth) compared to the volume of ECF. The percentage of water in postpubertal females is lower than males due largely to their higher percentage of body fat. In both sexes, throughout adulthood, the body water content falls with advancing age.

Children need higher water and electrolyte intakes than adults, making them more susceptible to dehydration. Their increased water losses are due to the:

- caloric expenses of a high metabolic rate;
- high insensible loss (high minute ventilation, high surface area: volume ratio, immature epidermis in premature babies);
- decreased ability to concentrate urine.

The distribution of water between the 'compartments' also differs between infants and adults (Table 17.1). During the first few days of life there is a transfer of water from ICF to ECF. This mechanism, which may protect the infant against the effects of dehydration, increases the already large ECF volume and could be a factor in the occurrence of edema sometimes observed at this time. After this the ICF accounts for an increasing percentage of total body water up to 1 year of age but this is mostly a reflection of the reduction in ECF volume. The ratio of ICF: ECF volume increases from unity, nearing the adult value of 2:1 some time after the age of 1 year.

The sodium content per kilogram body weight is 35–50% higher in the infant than in the adult due to the greater amount of extracellular fluid. With the relative reduction of ECF with growth, adult values are reached at about 2 years of age. Neonatal calcium and phosphate levels are higher than maternal levels, the former as a result of active placental

transfer and the latter as a consequence of the resulting fetal parathyroid hormone levels. Intracellular calcium stores are lower however, making muscle function (particularly myocardium) more dependent upon the serum ionized calcium.<sup>1</sup> The average plasma concentration of chloride is also higher in babies, like the phosphate levels. Anion/cation balance must exist for there to be electroneutrality and both are balanced by a lower bicarbonate level. Age- and gender-related reference ranges should be available from the laboratory for each electrolyte being measured.

As already stated, babies have a higher obligatory urinary water loss than older children and adults, a consequence of a higher urinary solute load and a decreased concentrating ability (to about 600 mosm/L).<sup>2</sup> These features are a consequence of tubular immaturity, one aspect of which is that fewer nephrons have loops which extend into the renal medulla. The result is a much higher flux of water and electrolytes. A term infant exchanges about one half of his ECF in the day whilst an adult exchanges only one seventh. Renal immaturity is accentuated in the premature infant.<sup>2</sup> It manifests in a number of ways including a tubular leak of bicarbonate creating a tendency towards metabolic acidosis and an almost unique ability to develop genuine sodium depletion through urinary losses even in the absence of diuretics.

Babies also have a reduced ability to deal with a water load,<sup>2</sup> a consequence of a low glomerular filtration rate (GFR). The GFR subsequently increases over the first 6 months of life.

## MAINTENANCE FLUID AND ELECTROLYTE REQUIREMENTS

The prescription of fluids for children has three components:

1. meeting maintenance requirements;
2. coping with ongoing losses;
3. correcting fluid and electrolyte deficits.

The first two components will be dealt with here. The correction of fluid and electrolyte deficits is covered under 'Fluid and electrolyte disturbances' below.

Normal water requirement is closely linked to energy requirements, both on account of the associated heat production and the urinary solute load resulting from the diet. A normal infant requires 110 cal/kg body weight/day and, it is claimed, approximately 150 ml fluid (i.e. solution) per 100 cal expended. For babies an enteral food source is available which balances calories and volume perfectly. A breast-fed term newborn drinks approximately 150 ml/kg/day. This gives the baby 100 kcal/kg/day of energy (the creatinocrit of breast milk increases during a feed but on average it contains 67 kcal/100 ml or 20 kcal/ounce). This ratio of water to energy promotes optimum growth. As milk has a significant fat content, 150 ml of milk is not the same as 150 ml of water and the volume requirement of enteral milk (150 ml/kg/day) does not transpose to the prescription of parenteral fluids. In contrast to fats, carbohydrates and salts dissolve in solution.

When parenteral fluids and nutrition are limited to a few days in a previously healthy child, a calorie intake of 20–35% of the average normal requirement will suffice. After a few days a more comprehensive approach is required. Catabolism due to illness is unresponsive to hyperalimentation and feeding in excess of metabolic requirements during illness increases morbidity.<sup>3,4</sup> Fluid provision needs to be adapted to the

Table 17.1 Partition of body fluids (average figures)

	Adult (70 kg; 1.85 m <sup>2</sup> )			Infant (3 kg; 0.2 m <sup>2</sup> )		
	% Body weight	Liters	Liters/m <sup>2</sup>	% Body weight	Liters	Liters/m <sup>2</sup>
Intracellular	40	28	15.2	38	1.14	5.70
Extracellular						
Interstitial*	16	11.2	6.0	33	0.99	4.95
Plasma	4	2.8	1.5	5	0.15	0.75
Total	60	42	22.7	76	2.28	11.4

\*Includes transcellular fluids.

circumstances. Even when water intake is zero during illness, appreciable quantities of water are being produced by the oxidation of the hydrogen content of tissues undergoing catabolism. Water is also preserved by increased antidiuretic hormone (ADH) levels. Baseline ‘maintenance’ fluids are a considerable overestimation of water requirement for most hospitalized patients. Indeed unrestricted fluid regimens should only be allowed in enterally fed patients when relying on satiety. Mandatory reductions to baseline fluids apply for patients receiving i.v. fluids, nursed in bed, paralyzed, breathing humidified gases or being nursed in a humidified environment. All fluids administered must be taken into account in the fluid balance, including drugs, flushes for i.v. and intra-arterial (i.a.) lines, etc. A regimen for making interactive decisions about fluid management is summarized in Table 17.2.

For example, using this regimen, a 10-kg child being ventilated for bacterial pneumonia might be prescribed an i.v. fluid regimen of 100 ml/kg × 0.75 (for breathing humidified gases) × 0.7 (if paralyzed) × 0.7 (for the risk of high ADH levels) = 37 ml/kg/day. Subsequent provision would be judged in the light of fluid balance (weight), plasma urea and electrolytes and urinalysis. A normal dietary sodium intake ranges between 1 and 4 mmol (23–92 mg)/kg body weight/day. The normal daily dietary potassium intake ranges between 1 and 3 mmol (39–117 mg)/kg body weight. To administer these quantities of electrolytes within the fluid restrictions that are commonly required may necessitate the use of tailor made solutions. However 40 ml/kg/day of 0.45% saline and 5% dextrose with 20 mmol of potassium added to each 500 ml bag provides 3 mmol/kg/day of sodium and 1.6 mmol/kg/day of potassium (but only 8 calories/kg/day).

### ONGOING LOSSES

Stipulated ‘normal’ maintenance requirements include an allowance for natural sensible and insensible losses. To prospectively compensate for abnormal fluid and electrolyte losses, the volumes involved must be measured and recorded and the composition of the fluid determined (Table 17.3). At first the primary fluid loss is always from the extracellular compartment and its composition can often be anticipated according to its origin. Acute losses from the intravascular compartment can be replaced directly. With time and continuing losses, there is equilibration of fluid and electrolytes occurs between compartments (particularly between the ICFs and ECFs). As the ICF is not directly accessible, replacement regimens devised to compensate for previous (as opposed to current) losses are different to simple plasma/ECF and are considered in more detail below under ‘Fluid and electrolyte disturbance’.

**Table 17.2** Volume of Intravenous fluid administered. (From Shann 1999<sup>5</sup> with permission)

		Fluid regimen/adjustment
Baseline	1 day of age	50 ml/kg/day
	2 days of age	75 ml/kg/day
	3+ days of age	100 ml/kg/day
	<10 kg	100 ml/kg/day
	10–20 kg	1000 ml/day + 50 ml/kg/day for every kg >10 kg
	>20 kg	1500 ml/day + 20 ml/kg/day for every kg >20 kg
Decreases	Humidified gases	× 0.75
	Paralyzed	× 0.7
	High ADH (e.g. IPPV or coma)	× 0.7
	Hypothermia	– 12% per °C core temp. is <37
	High ambient humidity	× 0.7
	Renal failure	× 0.3 (+ urine output)
Increases	Full activity and oral feeds	× 1.5/free fluids
	Fever	+ 12% per °C core temp. is >37
	Room temp. >31°C	+ 30% per °C
	Hyperventilation	× 1.2
	Preterm neonate (< 1.5 kg)	× 1.2
	Radiant heater	× 1.5
	Phototherapy	× 1.5
	Burns day 1	+ 4% per 1% of body surface area affected
	Burns day 2+	+ 2% per 1% of body surface area affected

ADH, antidiuretic hormone; IPPV, intermittent positive pressure ventilation.

### MONITORING

The intensity with which patients are monitored in respect of fluid electrolytes and acid–base is, like other aspects of their care, based primarily on the clinical impression of illness severity. At the highest levels of intensity, intake and sensible losses may be monitored to allow fluid balance to be determined several times per hour. Electrolyte levels and acid–base status may also be measured as frequently. At the other end of

**Table 17.3** Composition of solutes in body fluids

	Na <sup>+</sup> (mmol/L)	K <sup>+</sup> (mmol/L)	Cl <sup>-</sup> (mmol/L)	HCO <sub>3</sub> <sup>-</sup> (mmol/L <sup>-1</sup> )
Plasma	135–145	3.5–5	98–110	18–25
Interstitial fluid	145	4.1	117	27

Saliva	10–25	20–35	10–30	2–10
Gastric	20–80	5–20	100–150	0
Jejunal	130–150	5–10	100–130	10–20
Ileal	50–150	3–15	20–120	30–50
Diarrheal	10–90	10–80	10–110	20–70
Sweat (normal)	10–30	3–10	10–35	0
Sweat (cystic fibrosis)	50–130	5–25	50–110	0
Burn exudate (includes 30–50 g/L of protein)	140	5	110	20

the spectrum an experienced clinician, given a good history of a child with reasonable renal function, can treat the majority of cases effectively with limited resources and little or no laboratory help. On a normal pediatric ward, the sickest patients and those exclusively dependent upon i.v. fluids should have their weight, fluid balance and serum urea electrolytes and bicarbonate determined daily.

Monitoring fluid balance by means of daily weight measurements is considered the practical standard when issues of fluid balance are of importance. It has the advantage that it includes the impact of abnormal insensible losses, which are otherwise difficult to quantify. Clearly strict attention to technique should be maintained to provide interpretable results. Patients should not be clothed during measurement and the weight of any medical kit that is attached to them should be the same at each measurement. The results should be graphed with particular attention to the accuracy of the plot. The relationship between total body water and body weight is linear over short time scales within an individual, but there is considerable variation between individuals. This is largely accounted for by variation in the amount of adipose tissue (which contains < 10% water). Hence at the point of clinical presentation with significant illness, the patient's weight must be measured and recorded so that subsequent changes can be correctly interpreted.

## TOTAL BODY WATER AND SODIUM BALANCE

The proportion of body weight that is attributable to its water content varies with age, sex and the amount of adipose tissue present. Total body water can be measured by indicator dilution methods (e.g. deuterium) or bioimpedance. For dilution methods the results differ between the chosen solutes according to their true distribution and the relative truth of the assumption that the material will diffuse rapidly throughout the water of the body before significant metabolism or excretion occurs. The results obtained from bioimpedance measurements are also dependent upon scrupulous technique. Water loss from the body occurs by various routes such as insensible perspiration, transpiration from lungs, and loss in urine, feces and sweat. Normally losses in feces and sweat are minimal. Insensible perspiration is essential to dissipate heat generated by metabolism and is augmented as required by sweating.

Of the sensible water losses, the principal physiological control is over the volume and content of urine production. This is reduced by ADH, which works on the collecting duct and increased by atrial natriuretic peptide (ANP), which is released from the heart when the ECF is expanded. ANP inhibits sodium reabsorption in the distal nephron and increases GFR by increasing blood pressure and the filtration fraction. There are however obligatory water losses in the urine – the volume required to excrete the solute load – which are higher in babies. ADH release occurs in response to osmoreceptors in the hypothalamus and baroreceptors (really stretch receptors) in the circulation. The osmoreceptors are by far the more sensitive, enabling fine control over plasma osmolality, but the ADH response that they initiate is muted compared to that caused by a fall in plasma volume. Strong releases of ADH occur in response to reduced plasma volume irrespective of the tonicity of the plasma. Water balance naturally fluctuates with the dictates of sodium balance (renin-angiotensin system). The urine sodium content can be used to differentiate oliguric states since it is a reasonably reliable predictor of ECF. If renal perfusion pressure falls to levels short of those that produce acute renal failure, the kidneys produce good 'quality' concentrated urine (osmolality > 300 mosm/L, urine:plasma urea ratio > 5) with a urine sodium < 20 mmol/L. The fractional sodium excretion = (urinary sodium × plasma creatinine)/(plasma sodium × urinary creatinine) is also low ≈ 0.4. These findings are negated by diuretic therapy. In acute tubular necrosis the urine 'quality' is poor, urine sodium is > 40 mmol/L and fractional sodium excretion is ≥ 7.

Most of the sodium excretion from the body occurs via the kidney which can compensate within wide limits for variation in the dietary intake. Normal glomerular filtrate has an osmolality of 300 mosmol/kg but the osmolality of the urine excreted by adolescents and adults may range from 30 to 1200 mosmol/kg (specific gravity 1.001–1.035).

The infant kidney is unable to form such concentrated or dilute urine, a more realistic range being 100–600 mosmol/kg (specific gravity 1.003–1.023). Sodium depletion (unlike water depletion) does not occur under conditions of reduced intake but requires some abnormal loss – in sweat, alimentary secretions or urine.

The regulation of body sodium is closely linked to water.<sup>6</sup> Control of the osmolality of the ECF through changes in thirst and renal water excretion would otherwise lead to large changes in body volume in the face of sodium imbalance. Control over absorption and excretion of sodium is mediated primarily by the renin-angiotensin system. Adequacy of circulating blood volume and blood pressure affect perfusion of the juxtaglomerular apparatus, which if inadequate leads to the production of renin and thus aldosterone. The principal site of sodium control by aldosterone is the distal nephron (after the essential resorption of the majority of the sodium in the glomerular filtrate which occurs in the proximal tubule). In hypervolemia, renin production is decreased and atrial natriuretic peptide is released. The GFR increases, supplying more sodium (and water) to the distal convoluted tubule where it passes on into the urine.

## COMPARTMENTAL DISTRIBUTION OF WATER AND ELECTROLYTES

The physical and physiological influences on the internal distribution of water and electrolytes are described in Appendix 1. Figure 17.1 highlights the difference in composition between various ECFs and ICF. In essence, ECF is rich in sodium and chloride with relatively small amounts of potassium. The reverse applies to ICF where potassium, protein and phosphate predominate. Indeed the internal distribution of potassium is related to cell mass, about 70% of the total body content being found in muscle. The concentration of magnesium is also greater in ICF, with 50% of the body's content being in the cells of soft tissue and

Fig. 17.1 Ionic composition of body fluids. The ionic composition of intra- and extracellular fluids. Cations are displayed above the dark horizontal line and anions below it. (From Ichikawa 1990<sup>7</sup> with permission)

most of the remainder in bone. The sum of anions and cations in ICF is greater than that in ECF. Normal osmotic equilibrium is present however, because there is an excess of divalent and polyvalent anions in ICF each contributing several electrical charges but only one osmotic particle. Secondly, some intracellular univalent ions (especially potassium) are not in free ionic form, but in combination with anions.

The two divisions of ECF most frequently involved in the understanding of disease states are plasma and interstitial fluid. Normally, plasma water accounts for approximately 93% of the plasma volume. The remaining 7%, although predominantly proteins, includes lipids, electrolytes, glucose and urea. The plasma volume occupied by electrolytes is always insignificant.

## ACID–BASE

Most disturbances of fluid and electrolyte metabolism are associated with changes in the acid–base state of the blood. For example reduction in ECF volume leads to circulatory failure or ‘shock’. The associated cellular hypoxia causes acidosis predominantly by the production of lactate. Some relevant details of acid–base chemistry and blood gas measurement are contained in Appendix 2.

Hydrogen ion concentration ( $[H^+]$ ) within the body is closely controlled under normal conditions but the extreme concentrations that can arise during illness can range from 40 to 400% of the normal mean. Thus the body can be considered tolerant of changes in hydrogen ion concentration even if these conditions are not favored. The normal  $[H^+]$  is 37–48 nmol/L in babies corresponding to pH 7.43–7.32. The normal  $[H^+]$  range in infants and children is 37–46 nmol/L corresponding to a pH of 7.43–7.34. Values higher than the upper limit of normal  $[H^+]$  (lower pH) are acidotic and values lower than the lower limit (higher pH) are alkalotic.

For there to be long term stability of  $[H^+]$ , metabolic production of acid must be balanced by respiratory and renal excretion. Respiration controls  $[H^+]$  by clearing carbon dioxide. The kidney controls urinary excretion of  $[H^+]$ , the resorption of bicarbonate and the excretion of the nonvolatile acids that are produced during metabolism. The latter are derived principally from the sulfur contained in the methionine and cysteine of protein and form the titratable acid and ammonium in the urine.

Fluctuations in acid–base are tempered by:

- dilution of any acid produced;
- buffering;
- regulation of respiratory rate to control plasma  $CO_2$  tension;
- renal resorption of filtered bicarbonate, and excretion of excess hydrogen ion (Fig. 17.2).<sup>8</sup>

Derangements of acid–base that are due primarily to fluctuations in  $PaCO_2$  (and hence carbonic acid) are termed ‘respiratory’, all others are ‘metabolic’. These acid–base fluctuations have a variety of consequences:

- Serum potassium levels change: Acute rises in  $[H^+]$  (acidosis) equilibrate across the cell membrane. An efflux of intracellular potassium ions preserves the transmembrane electrical potential but results in hyperkalemia. Similarly alkalosis from any cause results in an influx of potassium into the cells and hypokalemia. These changes occur without perturbing the whole body potassium. The relationship between acid–base and potassium flux is complicated if insulin is being administered since it promotes potassium movement into cells along with glucose.
- Albumin binding is affected: For example, alkalosis increases the ratio of bound to unbound (ionized)  $Ca^{2+}$  and can lead to tetany.
- Hemoglobin dissociation is affected: Acidosis increases the P50 of the hemoglobin dissociation curve creating potential problems with oxygen delivery, and alkalosis decreases it creating potential problems with oxygen uptake.
- Regional blood flow may change:  $[H^+]$  fluctuations (especially those caused by  $CO_2$ ) affect vascular tone. Hypercapnic acidosis causes cerebral vasodilatation and pulmonary vasoconstriction.<sup>9</sup>
- Pharmacodynamic and pharmacokinetic effects occur: For a variety of drugs, e.g. weak acids and alkalis, tissue penetration is affected by ionization.

Most importantly a level of compensation is achieved via the alternate mechanism (changing levels of  $CO_2$  or bicarbonate respectively). The rapid respiratory compensation for metabolic derangements is mediated by changes in respiratory drive and is effected as altered minute ventilation controls the  $PaCO_2$ . Metabolic compensation for respiratory acidosis is much slower and is effected by renal conservation of bicarbonate. In either case, full compensation is unusual but would bring the  $[H^+]$  right back into the normal range if it worked.

Fig. 17.2 Reabsorption of filtered bicarbonate. Reabsorption of filtered bicarbonate is achieved via  $H^+$  secretion. The secreted  $H^+$  (derived from carbonic acid) reacts with bicarbonate in the tubular fluid to reform carbonic acid which dissociates into carbon dioxide and water. Hence a bicarbonate anion is lost from the tubular fluid. But since the hydrogen ion came from a reaction which also generated a bicarbonate anion in the peritubular fluid, the net result is bicarbonate reabsorption. This figure illustrates the situation in the proximal convoluted tubule where 90% of filtered bicarbonate is reabsorbed. CA, carbonic anhydrase. (From West 1989<sup>8</sup> with permission)

## DISTURBANCE OF ACID–BASE

### RESPIRATORY ALKALOSIS

Hyperventilation causes a reduction in PaCO<sub>2</sub> and acute changes in PaCO<sub>2</sub> have a linear effect on [H<sup>+</sup>] (1 kPa to 5.5 nmol/L). Thus [H<sup>+</sup>] is low and PaCO<sub>2</sub> is low. Common causes include excessive mechanical ventilation, central hyperventilation associated with encephalopathy, central nervous system (CNS) infection, trauma, etc. Acutely hypoxic and acidotic patients can hyperventilate. In the latter case some degree of compensation for the high [H<sup>+</sup>] is achieved. One would expect the calculated bicarbonate and base excess from the blood gas machine to be normal. Treatment is directed at the specific cause.

### RESPIRATORY ACIDOSIS

Hypoventilation causes a rise in PaCO<sub>2</sub>. Acute changes in PaCO<sub>2</sub> have a linear effect on [H<sup>+</sup>] (1 kPa to 5.5 nmol/L). Thus [H<sup>+</sup>] is high and PaCO<sub>2</sub> is high. Common causes include respiratory depression, obstructive and restrictive respiratory diseases, terminal exhaustion, inadequate mechanical ventilation, etc. Similar derangements may be caused by muscle weakness and increased CO<sub>2</sub> production (malignant hyperthermia, seizures, ...). One would expect the calculated bicarbonate and base excess to be normal. Treatment is directed at improving respiratory function/support and to a lesser extent minimizing CO<sub>2</sub> load, e.g. by lowering the metabolic rate and providing fat as a metabolic substrate. If it is unsuccessful then compensation occurs over several days through renal conservation of bicarbonate. A compensated respiratory acidosis therefore has a near normal (but high) [H<sup>+</sup>] and a high PaCO<sub>2</sub> and one would expect the bicarbonate level calculated by the blood gas machine to be high.

### METABOLIC ALKALOSIS

An acute fall in hydrogen ion concentration without a fall in CO<sub>2</sub> may be due to a rise in bicarbonate concentration or, less commonly, a loss of [H<sup>+</sup>] ions. Some compensatory CO<sub>2</sub> retention may occur and reduced respiratory drive should be anticipated, for example if one is attempting to wean mechanical ventilation. The calculated base excess would be expected to be high (see below) but under most circumstances confusion should not occur with a compensated respiratory acidosis because the [H<sup>+</sup>] will be near normal (but low). If the patient is being mechanically ventilated to a low PaCO<sub>2</sub> then the true interpretation of the blood gas may only be possible when placed in the wider clinical context.

During potassium deficiency renal conservation of K<sup>+</sup> occurs at the expense of H<sup>+</sup> which creates a metabolic alkalosis with a paradoxically acid urine. The problem is aggravated by hyponatremia. Intracellular acidosis occurs by a similar mechanism (lost K<sup>+</sup> replaced by H<sup>+</sup> and Na<sup>+</sup>).

Chloride depletion is a common consequence of loop diuretic therapy but can also occur from gastrointestinal losses or as a secondary consequence of chronic respiratory acidosis. It is associated with increased sodium reabsorption in the proximal convoluted tubule and excess H<sup>+</sup> and K<sup>+</sup> loss, the former resulting in increased bicarbonate absorption from the filtrate. Chloride-sensitive causes of metabolic alkalosis are associated with low urinary chloride (< 20 mmol/L) and chloride-insensitive forms with higher urinary chloride. The former include diuretic therapy, vomiting and chloridorrhea and the latter, citrate poisoning. Diminished ECF volume will perpetuate a metabolic alkalosis because it is associated with an obligatory increase in proximal tubular Na<sup>+</sup> reabsorption.

By analogy, a metabolic alkalosis can be produced by the loss of hydrogen ion by vomiting, or by the introduction of bicarbonate-containing material into the body. In either event the blood pH tends to increase. In the former case an increase in total buffer base occurs and a reduction in H<sub>2</sub>CO<sub>3</sub>. In the latter an increase in total buffer base occurs but with an increase in H<sub>2</sub>CO<sub>3</sub>. Renal compensation corrects both imbalances.

In the rare circumstances where a metabolic alkalosis requires treatment it is important to treat the cause rather than the effect. Treat hypokalemia with potassium supplements and hypochloremia with saline

infusion. Acid loads can be delivered where necessary however in the form of ammonium chloride (avoid in liver failure in favor of dilute hydrochloric acid 200 mmol/L in 5% dextrose).

### METABOLIC ACIDOSIS

An acute rise in [H<sup>+</sup>] with a normal or even reduced PaCO<sub>2</sub> (attempted compensation) results from an abnormal bicarbonate loss or excess H<sup>+</sup>. The calculated base deficit (negative base excess) would be expected to be high and the calculated bicarbonate would be expected to be low. Treatment must be directed at the cause. Routine investigation of a metabolic acidosis in order to determine the cause includes measurement of urine pH, anion and osmolar gaps and measurement of the serum lactate and/or arteriovenous oxygen difference as markers of the adequacy of tissue perfusion/oxygen delivery.

The anion gap is calculated according to the formula:

$$[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

An anion gap greater than 12 implies the presence of a 'non-Henderson–Hasselbalch' source of acid. The osmolar gap is the difference between measured and calculated osmolality. If measured osmolality is > 15 mosm/L higher than calculated then this implies the presence of additional osmotically active solutes:

$$\text{Calculated osmolality} = (2 \times [\text{Na}]) + [\text{glucose}] + [\text{urea}] \text{ mmol/L}$$

Under certain circumstances it is justifiable to attempt to compensate a metabolic acidosis therapeutically by administering exogenous base such as sodium bicarbonate, for example to supplement recognized bicarbonate losses (e.g. urine, ileostomy fluid) or to treat drug overdoses involving agents that are weak acids. Bicarbonate can also be used as emergency therapy if there is associated symptomatic hyperkalemia or an inadequate response to inotropic support in the context of severe acidosis ([H<sup>+</sup>] > 63 nmol/L, pH < 7.2). This bicarbonate rapidly forms CO<sub>2</sub> because of the prevailing pH. It thus creates a respiratory load. Furthermore although CO<sub>2</sub> diffuses fairly freely across the various membranes in the body, the bicarbonate ion may take several hours to attain access to all phases. It is possible therefore for exogenous bicarbonate to aggravate intracellular acidosis and similarly to lower the pH of cerebrospinal fluid. This latter effect explains the persistent respiratory alkalosis which occurs when metabolic acidosis is artificially corrected rapidly by administration of exogenous bicarbonate.

### MIXED DISTURBANCES

A number of mixed acid–base disturbances are worthy of mention. For example mixed metabolic and respiratory acidosis is common in critical illness. Disease processes that cause combined effects such as these inevitably limit or curtail physiological compensation, causing more severe and persistent increases in [H<sup>+</sup>]. Similarly the combination of heart failure (hence diuretic therapy) and chronic respiratory disease can cause hypokalemic/hypochloremic metabolic alkalosis and compensated respiratory acidosis, in which case [H<sup>+</sup>] levels fall, bicarbonate levels rise and CO<sub>2</sub> retention may be exacerbated.

Severe vomiting (e.g. in pyloric stenosis) causes loss of hydrogen and chloride ions causing hypochloremic alkalosis. Concurrent hypokalemia can lead to production of a paradoxically acid urine. In diabetic ketoacidosis complicated by severe vomiting the concurrent loss of hydrogen ions may lead to an apparent discordance with the severity of hyperglycemia and dehydration.

In salicylate poisoning the initial upset is usually respiratory alkalosis, partly compensation for the acid load but mostly from direct stimulation of respiratory drive. The supervening metabolic acidosis is due to uncoupled oxidative phosphorylation and increased metabolism of lipid, carbohydrate and amino acids. Blood gases show a high anion gap metabolic acidosis due to the salicylic acid, ketones, free amino acids and

lactate. Respiratory alkalosis which is commonly associated with low ionized calcium levels gives way to respiratory acidosis as the conscious level is reduced. Hyperglycemia is common and may mimic diabetic ketoacidosis. Hypoglycemia may occur in small children.

## CAUTIONARY NOTES ON LABORATORY TESTS OF FLUID AND ELECTROLYTES

The diagnosis of dehydration is essentially a clinical one. The total body water is not a particularly useful measurement under most circumstances since it is hard to standardize between individuals. The common assumption in clinical practice is that uremia indicates dehydration (and usually a contraction of the ECF volume) or renal failure. There are other causes of uremia however, such as excessive protein catabolism and the metabolism of ingested blood. In water depletion, the packed cell volume (PCV) tends to remain normal, whilst the concentrations of hemoglobin and plasma proteins show only slight increases. Unfortunately these observations are usually obscured because the predehydration figures are not known.

In hyperlipidemia, uremia or diabetes mellitus, the amount of lipids, urea or glucose may be large enough to produce a reduction in sodium concentration per unit volume. In hyperlipidemia the amount of water in plasma may be reduced to 75% of the norm and consequently the concentration of sodium apparently reduced. Nevertheless when expressed per liter of water (rather than solution) it is normal.

Serum potassium measurements must be interpreted in context since levels may not reflect total body levels. Beta-adrenergic stimuli, alkalosis or insulin therapy all lower serum potassium. However confidence that total body levels have not changed should not translate to a reticence to treat the serum level whether it is high or low because of the physiological consequences.

Serum phosphate levels like those of potassium are poor predictors of body levels since it is principally an intracellular anion. Plasma levels fluctuate as the result of shifts between ECF and ICF, they are also closely linked to ionized calcium levels. False low values/assay interference occur after mannitol administration or in the presence of lipemia, free hemoglobin (hemolysis) or bilirubinemia.

Calcium and magnesium homeostasis are closely linked to phosphate levels. Interpretation of total calcium levels must also be put into context with the serum albumin although it is more physiological to look directly at the ionized (free) component. Albumin binding of all species (drugs, bilirubin, calcium, ...) changes radically with acid-base. Respiratory alkalosis is capable of inducing tetany.

## FLUID AND ELECTROLYTE DISTURBANCE

### EDEMA

Edema is common in a variety of clinical situations particularly in the severely ill and malnourished. It is a common manifestation of

a systemic inflammatory response and is therefore not necessarily a manifestation of fluid overload. Indeed in many clinical situations the edematous patient has a reduced intravascular volume. Indicators of hypervolemia such as hepatomegaly, high pulmonary blood flow and pulmonary edema make the clinical diagnosis of fluid overload more likely. However water intoxication causes hyponatremia long before significant edema occurs. Diuretic-resistant edema may occur in renal or cardiac failure: the implication is that renal excretion is impaired in spite of the possible presence of an increased ECF volume. The total body sodium under these circumstances may be increased but water retention is even more marked, resulting in hyponatremia.

Where capillary endothelial damage has occurred, for example as a consequence of a systemic inflammatory response, then the resultant edema may again be resistant to treatment with diuretics and fluid restriction. Hyponatremia may occur due to the associated leak of protein into the interstitial fluid. Treatment with supplemental i.v. infusion of albumin under such circumstances contributes to the interstitial albumin load unless endothelial repair has occurred. The sequence of events leading to this syndrome is complicated and involves excessive secretion and/or diminished inactivation of aldosterone and ADH together with the changes in capillary permeability. The outcome is an increase in the volume of interstitial fluid but a decrease in plasma volume. This results in prerenal uremia which is further aggravated by sodium restriction. Hypoalbuminemia such as occurs in nephrosis causes edema by altering the balance between hydrostatic and colloid osmotic pressures.

### CLINICAL SIGNS OF DEHYDRATION

A history of increased thirst and oliguria implies dehydration, the clinical signs of which include reduced skin turgor, dry mucous membranes, sunken eyes and a sunken fontanelle. In the extreme case, signs of shock are present such as poor peripheral perfusion (prolonged capillary refill), cold peripheries, poor peripheral pulses, Kussmaul respiration (from metabolic acidosis) and ultimately hypotension and prostration. The clinical severity of dehydration can be matched to a pragmatic scale (mild, moderate, severe) (Table 17.4). This can then be used as a guide to the proportion of the premorbid weight that has been lost as fluid (e.g. 3%, 6%, 9%) and subsequently the fluid deficit that needs to be replaced (30 ml/kg, 60 ml/kg or 90 ml/kg). Dehydration severe enough to cause weight loss of 15% of the premorbid weight (as water) can reputedly occur and does not preclude successful salvage. However there is good evidence that even relatively experienced pediatricians overestimate the degree of dehydration during clinical examination. The danger is that this overestimate will then lead to excessive fluid administration. Furthermore individual clinical signs such as dry mucous membranes and a sunken fontanelle prove to be remarkably poor objective predictors of dehydration as determined retrospectively.<sup>10</sup>

Table 17.4 Fluid deficit in dehydration

	% Body weight	L		Signs and symptoms
		Adult (70 kg)	Infant (6 kg)	
Mild	3	2.0	0.18	Thirst; oliguria; dry mucous membranes
Moderate	6	4.0	0.36	Thirst; oliguria; restlessness; weakness and tachycardia
Very severe	7–14	5–10	0.42–0.84	Collapse, convulsions, blood pressure low; sunken eyeballs and fontanelle; loss of skin turgor with 'doughy' feeling; plasma sodium, urea and osmolality all raised

## DEHYDRATION

Water and electrolyte losses occur in tandem but not always in strict proportion depending upon the source of the fluid loss and the nature of intake or replacement at the time. Thus the result may leave the plasma isotonic with respect to normal values, hypertonic or hypotonic. The loss of water and sodium in proportion leads to isotonic dehydration. An excess loss of water or the use of hypertonic fluids as intake leads to hypertonic dehydration. An excess loss of electrolyte or the use of hypotonic fluids as intake leads to hypotonic dehydration.

Hyperosmolar dehydration can result from the provision of incorrectly reconstituted feed or hyperosmolar (e.g. sugary) drinks. The infant's inability to handle the solute load causes an osmotic diuresis and the hyperosmolar intake compounds the situation. Water is lost initially from the ECF but the hyperosmolar plasma equilibrates with the intracellular environment. ECF volume is hence relatively preserved and the ICF experiences a greater fluid loss than in other forms of dehydration. Thus more of the total body water is lost for the same degree of hemodynamic compromise. Thrombosis, most notably of intracranial venous sinuses and renal veins, may occur. More importantly, rehydration involves re-expansion of the ICF volume and carries a high risk of cerebral swelling. It should therefore be performed slowly (over at least 48 h). Hyperosmolality is usually but not exclusively recognized by hypernatremia. It is also present in hyperglycemic dehydration due to diabetic ketoacidosis.

By contrast in hypo-osmolar dehydration the predominant water loss is from the extracellular (hence including the vascular) space and so hypotension and shock occur earlier and are more severe for a given amount of water loss. Relative preservation of intracellular turgor may increase the risk of cerebral ischemia during hypotension.

*In all forms of dehydration, shock, acidosis and hypoglycemia are treated aggressively but rehydration should be more controlled, using normal saline initially irrespective of the serum sodium.*

Thus salt is replaced in hypo-osmolar dehydration and in hyperosmolar dehydration the serum osmolality is sustained during the early stages of rehydration – reducing the risk of cerebral edema. A policy of aiming to replace water deficit over at least 48 h in all forms of dehydration protects against the common tendency to overestimate the water deficit. Replacement of potassium stores may take days as the rate of administration has to be limited to allow time for redistribution into the ICF. The associated protein calorie deficit may take weeks to correct.

## ENTERAL REHYDRATION

When dehydration complicates illness in children, hospital admission is reserved for the younger patients and the more severe cases. There is therefore a tendency towards i.v. rehydration regimens for these patients. This may not always be appropriate. For example, from a wider perspective oral rehydration regimens for diarrhea are appropriate in over 90% of cases and most do not require hospitalization. The therapeutic effects of oral rehydration solutions (ORS) include facilitation of sodium transport across the bowel wall driven by glucose. A variety of proprietary preparations are available. Those intended for pre-emptive use contain less sodium than those designed specifically for rehydration of the dehydrated patient. Preference should be given to those in which the carbohydrate content is provided as monosaccharides (glucose), since disaccharidases are brush border enzymes which may be depleted by the illness. Loss of brush border lactase is the cause of postenteric lactose intolerance which, when present, causes osmotic diarrhea if dairy products are introduced too early during recovery.

The principles of enteral fluid management in treating diarrhea are:

1. It is usually wrong to interrupt breast-feeding.
2. Supplemental water is allowed during treatment with ORS provided sufficient ORS has been administered.
3. A guide to the required volume of ORS is that it should normally equal the volume of stool produced.

When dehydration is evident at presentation as much as 50–100 ml/kg of ORS can be given enterally over 4–6 h depending upon its severity.

Subsequent treatment with as much as 200–300 ml/kg/day is usually well tolerated, if faced with equivalent losses.

## HYPONATREMIA

Hyponatremia causes ileus, listlessness and ultimately cerebral edema and convulsions, the extent of the symptoms being more closely related to the rapidity of change in serum sodium than the absolute value. There are some patients whose plasma sodium concentrations remain below the lower limit of the normal range (e.g. 132 mmol/L) without symptoms and who excrete supplemental sodium to maintain this 'new' steady state.

Hyponatremia can occur in the face of normal total body sodium [syndrome of inappropriate secretion of antidiuretic hormone (SIADH), glucocorticoid deficiency, water overload ...], raised total body sodium with greater retention of water (heart failure, cirrhosis, nephrotic syndrome and sequestration) or decreased total body sodium (increased losses – particularly enteral, diuretic therapy or inadequate intake). Sodium loss is usually associated with a concomitant water loss and, as described above, the resultant serum sodium depends upon the balance between the two. Hyponatremia is common in preterm infants because of their high urinary losses. Breast milk on its own contains inadequate amounts of sodium for their needs.

Hyponatremia occurs as the result of water intoxication in a variety of circumstances including:

- the prescription of hypotonic i.v. fluids particularly if too much fluid is prescribed (see [Table 17.2](#));
- SIADH;
- missed cases of acute renal failure, e.g. in hemolytic uremic syndrome.

Babies are susceptible to water intoxication because of their relatively low GFR. Clinical manifestations may appear when water amounting to as little as 5% of body weight is retained. The excess water is widely distributed between both ECF and ICF.

SIADH is well recognized but it is frequently a misnomer. ADH secretion can be considered an appropriate evolutionary physiological response to injuries/illnesses which are of sufficient severity to preclude drinking for several days. The most common causes are CNS injury and bacterial pneumonia. The retained water however often does not come from a physiological source but from a prescription to administer fluid in quantities that did not anticipate the ADH secretion.<sup>11</sup> In any case the clinical picture of water intoxication (hyponatremia) develops. The diagnosis is made by proving that urine osmolality exceeds that of a hypo-osmolar plasma (i.e. inappropriate retention of water by the kidney) and the treatment is usually fluid restriction (see below and [Table 17.2](#)).

Two 'salt wasting' syndromes are worthy of individual mention because of the extraordinary scale of the sodium loss involved. In the salt-losing forms of congenital adrenal hyperplasia, deficiency of cortisol and aldosterone leads to natriuresis in the neonatal period. The clinical presentation however is with vomiting and weight loss. 'Cerebral salt wasting' is a condition which can appear in the first week after brain injury and spontaneously resolves in 2–4 weeks. It is characterized by natriuresis and subsequent hyponatraemic dehydration. It can be confused with SIADH in its early stages. Both conditions display coincident urine hyperosmolality and hypo-osmolar plasma. The distinction is made by 24 h urinary sodium content which is high in salt wasting and normal in SIADH. The pathogenesis is unclear but it may prove to be a dopaminergic phenomenon or related to other circulating natriuretics such as atrial natriuretic peptide.<sup>12</sup> The treatment is to supply adequate salt and water (as opposed to fluid restriction in SIADH) but fludrocortisone may also be required.

Euvolemic hyponatremia with or without hyperkalemia can occur in a variety of critical illness states in the absence of renal dysfunction. Known precipitants include anoxia, septicemia and malnourishment. Pragmatically these should be assumed to be Addisonian crises (i.e. they should prompt the administration of steroids) but some may be due to failure of the Na<sup>+</sup>/K<sup>+</sup> ATPase, the so called 'sick cell syndrome'.<sup>13</sup>

Rapid correction of hyponatremia is justified in circumstances where severe symptoms have resulted from a rapid fall in serum sodium. If a good history is not available, symptoms are severe and serum  $\text{Na}^+$  is  $< 120 \text{ mmol/L}$ , a rapid initial correction is justifiable to values of  $125 \text{ mmol/L}$ . To increase the serum sodium by  $2 \text{ mmol/L/h}$  (maximum safe rate).<sup>14</sup>

$$\text{Infusion rate (ml/h)} = 8 \times \text{wt (kg)} / (\% \text{ saline being used}).$$

Further increase in serum sodium is best achieved more gradually with fluid restriction. In all other circumstances slow correction is advisable by fluid restriction alone and the provision of normal rather than increased sodium supplements.<sup>15</sup> Acute hyponatremia causes cerebral edema which may improve with the hypertonic saline as the brain shrinks.<sup>16</sup> The rapid correction of chronic hyponatraemia can lead to 'central pontine myelinosis' which can lead to quadriplegia.

## HYPERNATREMIA

Hypernatremia can occur in association with low total body sodium, in which case the salt loss has occurred in the context of a greater water loss (e.g. osmotic diuresis, vomiting/diarrhea). When losses are predominantly water, total body sodium balance may be close to normal (e.g. fever, radiant heater, phototherapy, diabetes insipidus) as is the case when the interstitial fluid space expands at the expense of the plasma volume (e.g. capillary leak). True excess of sodium can also occur (e.g. when i.v. sodium bicarbonate is used to repeatedly correct metabolic acidosis without treating the cause or when malreconstituted formula is fed to a baby).

In all hyperosmolar states, water moves from ICF to ECF and so the ICF is dehydrated. Neurological symptoms predominate (irritability, seizures and coma). The loss of volume of brain cells can even cause cerebrovascular disruptions and bleeding. Treatment of hypernatremia should be aimed at the primary cause and any necessary rehydration should be slow because of the risks of cerebral edema. These risks are compounded by the formation of idiogenic osmoles within the cell. This term is used to describe additional osmotically active substances formed apparently in response to the hyperosmolar ECFs that serve to counter the shrinkage of the cell volume. The term 'idiogenic' has persisted since it was originally coined, despite the fact that at least some of the molecular species concerned have been established.<sup>17</sup>

True sodium overload without dehydration can be recognized by acute changes in weight (up in response to the overload and down as normality is restored) combined with calculation of the fractional sodium excretion. It requires removal with loop diuretics or renal replacement therapy as required. [Renal replacement therapy now includes hemofiltration (both low and high flow), hemodiafiltration, plasma filtration, plasmapheresis, peritoneal dialysis and hemodialysis.]

There is no such thing as pure water depletion; however excessive fluid losses from very high in the GI tract (saliva) and diabetes insipidus can lead to severe water depletion in the face of trivial sodium losses. Diabetes insipidus describes a situation where there is inadequate ADH resulting from injuries to the neurohypophysis, or alternatively there is resistance to the effects of ADH on the kidney (nephrogenic). The diagnosis is usually made when polyuria is recognized in association with hypernatremia. If necessary a dehydration test exaggerates the discrepancy between urine and plasma tonicity. Central causes can be treated with vasopressin ( $1 \text{ unit/kg}$  in  $50 \text{ ml}$  at  $1 \text{ ml/h}$ ). Nephrogenic causes necessitate treatment with dietary sodium restriction and if necessary deliberate sodium depletion induced by thiazide diuretics (presumed to enhance sodium and therefore water absorption in the proximal convoluted tubule).

## HYPOKALEMIA

Hypokalemia without a true deficit in potassium can result from redistribution into the cells in response to a beta-adrenergic stimulus, alkalosis,

excess insulin or rarer causes like familial hypokalemic periodic paralysis. Since the body potassium level is closely linked to muscle mass, reduction in muscle mass is associated with reduction in total body potassium but the relative amount of potassium and nitrogen remains constant. Hypokalemia with a deficit in potassium can result from inadequate intake, or increased renal (diuretic) or GI losses introducing a host of potential diagnoses including endocrine disturbances such as Cushing's syndrome and primary hyperaldosteronism. One situation that requires clinical caution is where i.v. therapy is employed to correct severe dehydration and associated acidosis (e.g. diabetic ketoacidosis). The patient's initial plasma potassium concentration is artificially elevated due to compartment shifts that have occurred as a consequence of the acidosis. A whole body potassium deficit means that, in the absence of renal failure, hypokalemia is inevitable during rehydration unless potassium supplements are included in the regimen.

Irrespective of the cause, hypokalemia has cardiovascular, neuromuscular and metabolic consequences including a propensity for dysrhythmias, ileus, muscle weakness and effects on carbohydrate and protein metabolism. Electrocardiograph (ECG) changes include ST depression, flattening or inversion of the T wave, prolonged Q-T interval and prominent or even bifid U waves. Potassium replacement has to be given into the ECF even though the principal destination is the ICF. Infusion rates should never exceed  $0.5 \text{ mmol/kg/h}$  for fear of deranging the myocardial membrane potential and hence causing lethal arrhythmia. The ECG changes associated with serum potassium levels reflect the cell membrane potential and so hyperkalemic changes may be seen with a normal serum potassium if correction of hypokalemia is performed too rapidly. Adequate replacement may take days where there is whole body depletion. Potassium supplements/replacement should not be given in the presence of oligo/anuria without regular monitoring of serum levels.

## HYPERKALEMIA

Hyperkalemia without true overload (or even deficit) may result from measurement error (e.g. hemolysis in the sample), acidosis, insulin deficiency, or drugs such as digoxin, beta blockers and depolarizing muscle relaxants. There is also a hyperkalemic form of familial periodic paralysis. High serum potassium occurs in instances of increased load (e.g. iatrogenic infusion, tissue destruction, GI bleed and tumor lysis syndrome) usually in combination with decreased excretion (e.g. renal failure or mineralocorticoid deficiency). Significant elevation of the whole body potassium:nitrogen ratio is rare since fatal hyperkalemia occurs early. Hyperkalemia is dangerous because of its effects upon cell membrane potential and therefore upon cardiac rhythm (sinus arrest and ventricular fibrillation). The point at which such rhythm supervenes is unpredictable but depends upon the rate of rise of the serum level and the age/maturity of the patient. Neonates are far more tolerant of hyperkalemia than older children and adults, particularly in relation to the propensity for ventricular dysrhythmias. The normal range of serum level extends higher in preterm babies.

The principal recognizable ECG changes, where rhythm is preserved, are tall peaked T waves and prolonged p waves.

In acute renal failure hyperkalemia may be dramatic and easily aggravated by simultaneous injury to other organs and tissues increasing the load. In chronic renal failure GFR has to get down to 5–10% before hyperkalemia results although the 'renal reserve' for potassium excretion is reduced before this. The most severe consequence of hyperkalemia is cardiac arrest, which can occur at any point in the progression of the ECG abnormalities and arrhythmias. If the problem is detected before cardiac arrest then possible emergency therapeutic measures cause compartment shifts from ECF to ICF:

- correction of acidosis (mild acidosis  $1 \text{ mmol/kg}$ , severe acidosis  $2\text{--}3 \text{ mmol/kg}$  of  $\text{NaHCO}_3$ );
- salbutamol administration ( $2.5\text{--}5 \text{ mg}$  nebulized or i.v.  $1\text{--}5 \mu\text{g/kg/min}$ );
- glucose and insulin ( $2 \text{ ml/kg}$  of 50% dextrose and  $0.1 \text{ U/kg}$  of soluble insulin).

A slower response can be obtained using ion exchange resins such as calcium polystyrene sulfonate (Resonium) 0.5 g/kg dose per rectum. An i.v. bolus of calcium (0.1 mmol/kg to a maximum of 5 mmol) can temporarily stabilize the heart rhythm whilst other treatments are initiated. Renal replacement therapy (dialysis) is indicated if the hyperkalemia is recalcitrant (as it will be if it is due to renal failure).

## CALCIUM AND MAGNESIUM

Parathormone (PTH) increases calcium by promoting bone resorption, increasing calcium reabsorption from the renal tubule and increasing activation of vitamin D, which increases enteral absorption of calcium and phosphate. Calcitonin is secreted by the thyroid and thymus in response to hypercalcemia and lowers both calcium and phosphate levels.

Hypocalcemia is common in sick infants due to high levels of PTH antagonists like glucocorticoids and calcitonin. It may also be due to i.v. bicarbonate therapy or the use of citrated blood products. If persistent in the newborn it may be due to DiGeorge syndrome, maternal vitamin D deficiency, cows' milk feeding or magnesium deficiency. It causes jittery symptoms in babies, multifocal clonic convulsions and rarely ECG abnormalities, dysrhythmias or heart failure. Normal requirements are 0.3 mmol/kg/day increased to 1 mmol/kg/day when treating deficiency. Calcium infusion has vasoconstrictive and inotropic effects of greater significance in children than in adults. Vasoconstriction predominates in hypomagnesemic states. Calcium opposes the negative inotropic effects of hyperkalemia.

Hypomagnesemia usually occurs in the context of parenteral nutrition because of solubility problems caused by the concurrent administration of phosphate. Clinical problems are rare until levels fall below 0.5 mmol/L but do include lethal arrhythmias such as ventricular fibrillation/ventricular tachycardia (VF/VT) and torsade de pointes. Deficiency also reduces cardiac contractility but during infusion, magnesium salts are reasonably potent vasodilators and will drop the blood pressure. Magnesium has also been used to treat pulmonary hypertension and asthma. Hypocalcemia and hypokalemia may not respond to supplementation if concurrent hypomagnesemia is uncorrected.

Hypercalcemia is rare but occurs in the recovery phase of acute renal failure, a variety of endocrine diseases, hypervitaminosis D and granulomatous disorders. Idiopathic hypercalcemia is a feature of Williams syndrome. Most cases of hypercalcemia are iatrogenic. Symptoms include neurological problems (hypotonia, seizures and coma), cardiovascular problems (tachyarrhythmias) and in chronic cases hypertension. Severe cases are treated with renal replacement therapy (dialysis).

Hypermagnesemia occurs when excessive administration (cathartics or enemas) coincides with renal failure. Symptoms are similar to hypercalcemia but include bradyarrhythmias with first degree block and broad QRS complexes. Treatment is again focused upon enhanced excretion. Serious arrhythmias may respond to calcium.

## PHOSPHATE

Phosphate excretion involves free filtration at the glomerulus with passive reabsorption of 80% in the proximal convoluted tubule (PCT) as a symport with sodium. [A symport is a membrane carrier that combines the movement of more than one type of molecule (species) in a given direction. Both species bind on one side of the membrane and are then translocated to the other side.] Although PTH results in phosphate release from bone and increased phosphate absorption from the gut, its net effect at high levels is to decrease plasma phosphate because it inhibits its renal tubular reabsorption. The fetus is relatively hypoparathyroid in response to active calcium influx across the placenta.

Hypophosphatemia occurs from:

- inadequate intake: e.g. breast-fed preterm infants;
- impaired GI absorption: e.g. as a consequence of antacids containing calcium, magnesium or aluminum (such as sucralfate);

- cellular redistribution: e.g. alkalosis, therapy for diabetic ketoacidosis, beta 2-adrenergic stimulation;
- carbohydrate infusions and other forms of hyperalimentation which can lead to hypophosphatemia by stimulating insulin release (phosphate moves into cells with glucose in response to insulin) (successful stimulation of an anabolic state after critical illness can be associated with a profound and symptomatic hypophosphatemia);
- excessive losses: e.g. as a consequence of diuretics, steroids, cytotoxic regimens or paracetamol poisoning;
- trauma (including burns);
- hereditary hypophosphatemic rickets.

The most important feature of phosphate physiology is the formation of adenosine triphosphate (ATP). Symptomatic hypophosphatemia occurs in severe depletion and causes muscle weakness that can aggravate respiratory failure and reduce myocardial contractility. When necessary, phosphate supplementation should aim to provide a dose of up to 1 mmol/kg/day (max 20 mmol) (beware some proprietary phosphate supplements have a high potassium content).

Hyperphosphatemia occurs in neonates fed cows' milk or inadequately adjusted formula feed, tumor lysis syndrome and renal failure, severe hemolysis, hyperthyroidism, acromegaly, hypoparathyroidism and phosphate poisoning. Symptoms are those of the consequent hypocalcemia and deposition of hydroxyapatite crystals in cornea, lungs, heart, etc. Treatment includes resuscitation to restore ECF volume. In the absence of renal failure, phosphate binders and alkaline diuresis may be used.

## CONCLUSION

The intention of this chapter has been to cover fluid, electrolyte and acid-base from a clinical perspective. This has necessarily led to the omission of some essential basic science, some of which is contained in the following two appendices. However the key point is that while fluid, electrolyte and acid-base disturbances can and should be evaluated and treated on their own merits, they should be considered as effects of illness. To 'cure' them the cause must be treated.

## APPENDIX 1: PHYSICAL AND PHYSIOLOGICAL INFLUENCES ON THE INTERNAL DISTRIBUTION OF WATER AND ELECTROLYTES

### MEMBRANE PROPERTIES AND FUNCTION

The homeostasis of body fluids is intricately related to the integrity and function of their adjacent membranes. An 'ideal' membrane permits only water to pass through, and is impermeable to dissolved substances. Membranes resemble molecular sieves with the added influence of the solubility of substances in the membrane lipids. Isolated cellular membranes are partially permeable. They are fully permeable to water and small crystalloid molecules but will not permit the passage of larger molecules such as proteins and mucopolysaccharides. The metabolic activity of the cell also maintains differences between the intracellular and extracellular concentrations of various ions. This ability decreases if the cell is cooled or poisoned. Cell membranes carry negative internal and positive external charges and the membrane potential is governed by the ratio of internal to external concentration of ions.

Substances cross membranes in several ways. Water or solutes may simply flow through pores. Solutes may also dissolve in the membrane and diffuse through it in solution or they may be actively transported from one side to the other. Potassium penetrates cells more rapidly than sodium, probably in part due to the smaller diameter of the potassium ion. At equilibrium the rate of movement of any material across a membrane is equal in both directions.

Under normal circumstances exchange between physical compartments in the body is tightly regulated by both steroid hormones (cortisol, aldosterone) and peptide hormones (ADH and thyroxine). Water and

small solutes pass freely through intercellular pores in endothelium and in and out of cells through a facilitative transport mechanism in the cell membrane mediated by specialized transmembrane proteins – ‘aquaporins’. The expression of aquaporins within a membrane may provide a mechanism for physiological control of the movement of small solutes as well as water.<sup>18</sup> The nature of such transcellular transport mechanisms, which also include epithelial sodium channels (ENaC), and their role in health and disease is only now becoming apparent.

The structure of the capillary endothelium varies according to site but there are common features in the basic structure that persist throughout. A layer of thin endothelial cells, one cell thick, lines the luminal surface of a basement membrane. The luminal surfaces of these cells bear a negative charge, imparted by a layer of glycosaminoglycans. These species restrict the permeability of the membrane with regard to negatively charged molecules such as albumin. The cellular lining may be fenestrated (depending upon the site) and there are numerous clefts between cells and tubular channels that traverse the epithelial cells themselves. Endothelial cells may change shape with changes in pressure and they have physiological responses to blood flow and shear stress, which include the release of vasoactive mediators and anticoagulants.

For the diffusion of small water-soluble molecules (e.g. sodium, chloride and glucose) across capillary endothelium, the size and number of the pores (which vary depending upon the site) is not rate limiting and movement is dictated by the blood supply, i.e. is ‘flow limited’. These movements are dictated by the Fick equation (diffusion rate = blood flow/arteriovenous concentration difference) and Fick’s law of diffusion which relates the diffusion rate:

- directly to the diffusion coefficient of the solute (related to molecular size and therefore weight);
- directly to the area of the capillary membrane;
- directly to the concentration gradient;
- inversely to the thickness (and hence permeability) of the membrane.

Capillary diffusion gradients depend on capillary size. As intercapillary distances increase, there will be islands of tissue where supply or removal of solutes becomes inadequate.

In addition to solute diffusion, bulk movement of fluid across membranes (filtration) also carries solutes across the membrane or through its pores. This occurs irrespective of whether it is initiated by hydrostatic or osmotic influences. The anatomical variation in the size and number of clefts between endothelial cells is related to their filtration properties. By far the most important homeostatic mechanism controlling this process is the vasomotor control of precapillary vessels. Glomeruli are specialized exceptions where control is exerted over pre- and postcapillary vessels. The filtration of fluid is a passive process proceeding at a rate dictated by:

- the filtration coefficient of the membrane (influenced by its surface area and permeability);
- the hydrostatic pressure gradient (greater within the arterial end of the capillary but consistent across a glomerulus);
- the colloid osmotic pressure gradient;

in a relationship described by Starling’s law of ultrafiltration. The net filtration is out of the capillary at the arterial end and into the capillary at the venous end.

Epithelial and endothelial function are profoundly affected by the processes of acute inflammation in which both cell destruction and damage to basement membranes occur. Endothelial damage can be initiated and/or aggravated by activated neutrophils, which degranulate releasing proteolytic enzymes such as elastase, and reactive oxygen species in addition to cationic proteins. Activated platelets also contribute. Further endothelial cell destruction involves the stripping of glycosaminoglycans from the luminal surface of capillaries. The loss of their negative luminal charge increases the permeability of the endothelium to albumin. An interstitial edema of relatively protein rich fluid results.

The physical factors that govern transport across all membranes (cell membrane, capillary endothelium, etc.), include total osmotic pressure, hydrostatic pressure, colloidal (oncotic) pressure of proteins, Donnan

equilibrium and the law of electroneutrality. (Properties that are determined by the number rather than the nature of the particles present are termed ‘colligative’. One of the most important points about colligative properties is that they are interrelated. They include such characteristics as the lowering of vapor pressure, the elevation of boiling point, the reduction of freezing point and osmotic pressure.)

The equivalent weight (gram equivalent) of an electrolyte

$$= \frac{\text{molecular weight in grams}}{\text{valency}}$$

e.g. sodium  $\frac{23}{1} = 23$ , calcium  $\frac{40}{2} = 20$ .

In the SI system (Système International d’Unités), the preferred unit for chemical measurement, is the mole (the amount of a substance with a mass equal to its molecular weight expressed in grams). According to this system concentrations are expressed in millimoles/liter (mmol/L) rather than as milliequivalents/litre. The relationship between the numerical values is:

$$\frac{\text{mEq/L}}{\text{valency}} = \text{mmol/L}$$

therefore for monovalent species  $\text{mEq L}^{-1} = \text{mmol L}^{-1}$

## MOLARITY

Molarity is defined as the gram molecules (moles) of solute *per liter of solution*.

## MOLALITY

Molality is defined as the gram molecules (moles) of solute *per kilogram of solvent*.

At all body temperatures 1 kg of water is regarded as occupying 1 liter.

The terms molarity and molality should not be confused. For dilute aqueous solutions they are approximately equal, but in the body the distinction is marked.

## OSMOLARITY

One liter of solution containing 1 mole of undissociated solute represents an osmolarity of 1 osmol/L or 1000 mosmol/L. An aqueous solution of such concentration will exert an osmotic pressure of 22.4 atmospheres under ideal conditions and with an ideal membrane.

## OSMOLALITY

Osmolality is applicable when the concentration of solute is molal. This term, unlike osmolarity, takes account of the solute volume.

For undissociated non-electrolyte solutions the molarity (molality) and osmolar (osmolal) concentrations are identical. For a substance dissociating fully into ions, however, each ion has the same osmotic effect as an undissociated molecule (i.e. dissociation increases the osmotic effect beyond that expected in terms of the molar content of the undissociated solute). A molar solution of sodium chloride ( $\text{Na}^+\text{Cl}^-$ ) has, therefore, an ideal osmotic pressure of  $2 \times 22.4$  atmospheres (2 osmoles). Calcium chloride ( $\text{Ca}^{2+}2\text{Cl}^-$ ) yields three osmotically active ions if fully dissociated. In practice it is only with very dilute solutions that full dissociation occurs and the appropriate correction factor (osmotic coefficient) must be applied to calculate the osmolality when only the molality is known. Conversely association of macromolecules will result in a lowering of the theoretical osmotic pressure.

Solutions with the same osmotic pressure are termed isosmotic, and if separated by an ‘ideal’ membrane are termed isotonic when no net transfer of water occurs between them. Naturally most compartments in the body are in osmotic equilibrium although this does not apply to fluids such as

urine and saliva. It is most convenient to determine osmolality by using an osmometer which actually measures the freezing point of plasma. Normal plasma osmolality is approximately 285 mosmol/kg body water.

Plasma and extracellular osmolality are closely related to the concentration of the major cation, sodium. A similar relationship exists between the osmolality of ICF and intracellular potassium concentration. The polyvalent protein anions contribute about 16 electrical milliequivalents per liter of plasma water but they only represent approximately two osmotically active particles per liter.

## PHYSIOLOGICAL MOVEMENTS OF WATER AND ELECTROLYTES

When a solute is added to a solution on one side of a membrane there is a potential difference in concentration between the phases. Equilibrium can be established by:

- free distribution of the solute on both sides of the membrane (this is possible only with a diffusible solute and permeable membranes);
- passage of water through the membranes, thereby eliminating the potential difference by equalizing the number of water molecules per unit area on each side of the membrane;
- applying pressure to the solution to increase the potential again to that of pure water.

The addition of a diffusible solute to one compartment thus results in an increase of total osmolality in both compartments without net water transfer. A nondiffusible solute increases the effective as well as total osmolality and results in a transfer of water from one compartment to the other (Fig. 17.3).

Physiologically, urea may be regarded as being a freely diffusible (penetrating) solute, and increasing the concentration of urea in the body causes no transfer of water between the phases. An exception is when urea is rapidly removed from the plasma by hemodialysis, when water moves into the ICF before outward diffusion of intracellular urea can occur. In diabetes mellitus the elevated plasma glucose concentration causes intracellular water loss, because glucose is not a diffusible solute in the absence of insulin.

Although sodium, potassium and chloride are freely diffusible, the fact that most of the sodium and chloride are found in the ECF and that the potassium is mainly intracellular demonstrates the presence of an active transport mechanism. The distribution of potassium between the ICF and ECF is heavily dependent upon the action of the  $\text{Na}^+/\text{K}^+$  ATPase. This latter enzyme imports  $2 \times \text{K}^+$  from the ECF and exports  $3 \times \text{Na}^+$

from the ICF. Electrical neutrality may be preserved by the efflux of a  $\text{Cl}^-$ , which adds to the osmotic effect leading to a reduction of the ICF volume. The balance of potassium across the cell membrane otherwise contributes to the resting membrane electrical potential. Acid–base status, insulin and catecholamines all exert effects upon the distribution of potassium across the cell membrane. Acidosis causes an efflux of potassium from the cell and alkalosis the reverse. The greatest effect occurs with mineral acids rather than lactic or keto acids where the cell is more permeable to the accompanying anions and the effects on potassium levels lag behind those of pH.

The fixed intracellular anions (protein and phosphate) are unable to traverse the membrane and their concentrations will largely determine the concentration of potassium in the ICF. Inhibiting cellular metabolism by cooling or by enzyme inhibitors results in the disappearance of the sodium and potassium gradients normally present. The maintenance of a high intracellular potassium content by cells in a saline medium requires the presence of oxygen, glucose and L-glutamate. The absence of any one of these materials results in entry of sodium into the cell and diffusion of potassium into the ECF. Thereafter, application of Donnan equilibrium (see below) allows entry of water and further sodium ions, causing swelling, and finally rupture of the cell.

The diffusion of chloride ions into or out of the cell is intimately related to the membrane potential.

## Membrane potential

The cell membrane may be regarded as being permeable to water, potassium and chloride, but impermeable to protein, phosphate and sodium. An electrochemical potential difference exists between the two sides of the membrane, referred to as the membrane potential. This has been measured in various cells and within experimental error the relationship for calculating its value depends upon the relative concentrations of diffusible ions in the ECF and in the ICF.

A potential difference also exists across the membrane separating the intravascular phase of ECF (plasma) from the extravascular phase (interstitial fluid). This  $E_m$  is small since the gradients exhibited by sodium, potassium and chloride are not great. This is because sodium ions can penetrate capillary membranes freely, there being no active transport, and the electrolyte gradients result only from the presence of nondiffusible protein anions in plasma.

## Donnan membrane equilibrium

When a diffusible solute is added to water on one side of a partially permeable membrane, rapid diffusion of the solute and water occurs between the phases. Small electrolyte differences occur when a nondiffusible ion (e.g. a plasma protein with anionic charge) is present on one side of the membrane. The drive to maintain electrical neutrality then causes movement of diffusible ions ( $\text{Na}^+$  in our example) against their own concentration gradient. The number of diffusible ions that move increases disproportionately as the concentration gradient of protein rises and the result is a greater concentration of osmotically active particles in the phase containing the nonpenetrating protein ion. The movement of protein itself across capillary membranes is resisted by a negative charge on the luminal surface of the vascular endothelium largely generated by glycosaminoglycan molecules. The osmotic effect exerted by colloids (colloid osmotic pressure or oncotic pressure) is quantitatively small but nevertheless it may be crucial in the fine balance of fluid movement across capillary beds.

These conditions exist even in the absence of active transport such as between plasma and interstitial fluid but can be magnified or opposed by active transport, which can maintain an intracellular ion at a constant concentration as though it were a nonpenetrating ion. Unless opposed, there is a tendency for water to move into the compartment containing the constrained anion. The metabolic process preventing the entry of water into cells is directly related to the extrusion of sodium ( $\text{Na}^+/\text{K}^+$  ATPase).

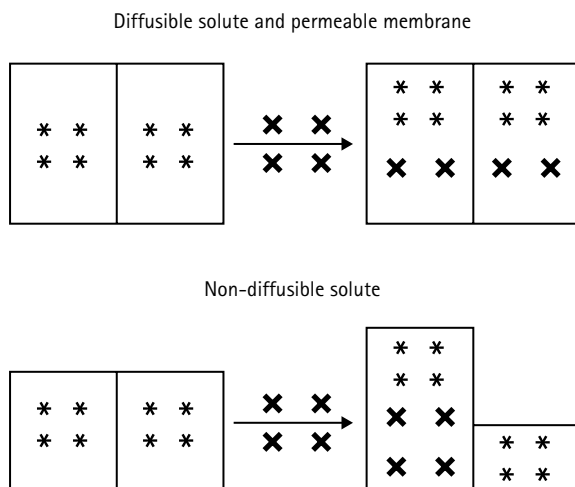

Fig. 17.3 Water distribution in response to changes in tonicity. In each example two fluid spaces are separated by a membrane which is permeable to water. The effect of adding solute to the left hand compartment is displayed on the right. Relative changes in volume accompany the movement of water.

### Hydrostatic and colloid osmotic pressure

Equilibrium in plasma is established between the formation and the reabsorption of interstitial fluid by the interplay of hydrostatic and colloid osmotic pressures.

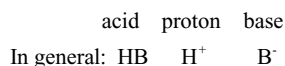

The total osmotic pressure of plasma (285 mosmol/kg body water) is equivalent to about 6.5 atmospheres (5000 mmHg), but the proportion due to the colloid osmotic pressure of the proteins is small, being less than 30 mmHg. Since the interstitial fluid contains only small amounts of protein, the difference in colloid osmotic pressure (oncotic pressure) is equivalent to about 25 mmHg.

Although it is small, this figure is of fundamental physiological importance in controlling the flow of water between plasma and tissue fluids.

Since albumins have smaller molecular weights than globulins, approximately 80% of the plasma protein osmotic effect is due to albumin. Thus hypoalbuminemia predisposes to the formation of increased amounts of interstitial fluid, causing clinically detectable edema.

## APPENDIX 2: ACID–BASE CHEMISTRY AND BLOOD GAS MEASUREMENT

An ‘acid’ is any molecule or ion which tends to donate a proton (H<sup>+</sup>) and a ‘base’ is any molecule or ion which tends to accept a proton. Hence (as implied) the acidity of a solution is its hydrogen ion concentration:

B<sup>-</sup> is referred to as the conjugate base of the acid HB (conjugate acid).

The more readily an acid donates a proton the stronger it is. The more readily a base accepts a proton the stronger it is. The dissociation of a conjugate acid to produce a proton occurs as part of an equilibrium described by an equilibrium constant ‘K’

$$\text{where } K = \frac{[\text{H}^+][\text{B}^-]}{[\text{HB}]}$$

K is large for strong acids and small for weak acids. Hence pK [the negative logarithm (to base 10) of K] is low for strong acids and high for weak acids. Biological acids may be neutral molecules, cations or anions. Biological bases may be anions or neutral molecules. Water is amphoteric (i.e. acts either as an acid or a base).

Sorensen introduced the term pH, which is the negative logarithm (to base 10) of the molal hydrogen ion activity. The term simplifies the appreciation of hydrogen ion concentration in relation to the behavior of buffers. Its use however can be misleading in clinical situations and the hydrogen ion concentration is the preferred nomenclature (see below).

Hydrogen ion activity (H<sup>+</sup>) = [H<sup>+</sup>] × f, where f = activity coefficient.

In dilute aqueous solution f tends to 1.0 and (H<sup>+</sup>) tends to [H<sup>+</sup>].

It is, therefore, justifiable to derive the equation:

$$\text{pH} = \text{pK} + \log \frac{[\text{conjugate base}]}{[\text{conjugate acid}]}$$

In clinical practice acid–base discussions are conducted using a shorthand based upon the carbonic acid/bicarbonate system which is quantitatively the most important buffer in plasma and whole blood. All the buffer systems are however in equilibrium so the approach may have some shortcomings. With these provisos the Henderson–Hasselbalch equation applies:

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

When considering the roles of respiratory and renal physiology on acid–base the equation may be considered as:

$$\text{pH} = \text{pK} + \log \frac{\text{renal component}}{\text{respiratory component}}$$

‘Buffers’ are substances which tend to prevent a change in pH occurring within a system when either an acid or a base is added. Biological buffer systems are composed of a solution of weak acids together with their conjugate bases. Increases in the [H<sup>+</sup>] of the system cause conjugation of the buffer and vice versa. For any given addition of acid or base the change in ratio will be least (most efficient buffering) when:

$$[\text{conjugate base}] = [\text{conjugate acid}],$$

$$\text{i.e. when } \log \frac{[\text{conjugate base}]}{[\text{conjugate acid}]} = 0 \text{ and } \text{pH} = \text{pK}$$

Chemically, the carbonic acid bicarbonate buffer system is not ideal for maintaining pH = 7.40, since the pK ≈ 6.1 and the ratio of buffer base:buffer acid is 20:1.

Fortunately the respiratory center is extremely sensitive to changes both in the CO<sub>2</sub> tension and the pH of plasma. This is the main reason why the system is effective physiologically in conserving blood pH within narrow limits.

### BIOLOGICAL BUFFER SYSTEMS (Table 17.5)

The relative importance of the various buffers depends both upon their concentrations in the body compartments concerned and on the prevailing pH values. The bicarbonate system is the most important in plasma, with proteins and phosphate making smaller contributions. Hemoglobin is the most important buffer within erythrocytes, whilst within other cells the major buffers are phosphates and proteins.

Blood gas machines measure pH, PCO<sub>2</sub> and PO<sub>2</sub> and it is best to limit one’s interpretation to these parameters. The machines however can perform calculations using assumptions (that may be erroneous) to derive other parameters such as the base excess. The sort of assumptions made in these calculations are: the relevant hemoglobin concentration (if it has not been measured), the solubility coefficient of carbon dioxide in plasma (which is assigned a designated value whereas it may vary) and constancy of the pK of the Henderson–Hasselbalch equation (which again may vary significantly). Given these assumptions, the following parameters may be presented:

- Base excess. The difference between the observed buffer base and the normal buffer base. The base excess is a measure of the metabolic contribution to the hydrogen ion concentration. It is an empirical expression which approximates (by calculation) the amount of acid (or base for a ‘base deficit’) which would be needed to titrate 1 liter of blood to a [H<sup>+</sup>] of 40 nmol/L (pH 7.4). The base excess of blood with a [H<sup>+</sup>] of 40 nmol/L, PaCO<sub>2</sub> 40 mmHg (5.33 kPa), total [Hb] 15 g/dl at 37°C is zero. In a metabolic acidosis where nonvolatile acids such as lactic acid have accumulated, a negative base excess or base deficit results. Conversely, in a metabolic alkalosis the buffer base may increase, giving a positive base excess. In respiratory acidosis, for each moiety of H<sup>+</sup> produced, a corresponding increase in HCO<sub>3</sub><sup>-</sup> occurs and total buffer base remains unaltered. A comparable situation occurs in respiratory

Table 17.5 Biological buffer systems

Approximate % contribution to buffering of whole blood	Buffer acid (HB)	H <sup>+</sup>	+	Buffer base <sup>-</sup> (B <sup>-</sup> )
64	H <sub>2</sub> CO <sub>3</sub>	H <sup>+</sup>	+	HCO <sub>3</sub> <sup>-</sup>
1	H <sub>2</sub> PO <sub>4</sub> <sup>-</sup>	H <sup>+</sup>	+	HPO <sub>4</sub> <sup>2-</sup>
6	HPr	H <sup>+</sup>	+	Pr <sup>-</sup>
29	Hb	H <sup>+</sup>	+	Hb <sup>-</sup>

Hb, hemoglobin; Pr, protein.

alkalosis. Respiratory acidosis and alkalosis thus produce no change in the base excess unless renal compensation occurs.

- Standard bicarbonate. This is another index of the metabolic component. It is the calculated concentration of plasma bicarbonate in fully oxygenated blood at a  $PCO_2$  of 40 mmHg and at 37°C. Normal range = 22–26 mmol/L plasma.
- Actual bicarbonate (mmol/L plasma) is the calculated bicarbonate content of the plasma.
- Total  $CO_2$  content = actual bicarbonate + ( $PCO_2$  mmHg  $\times$  0.03). This parameter is by definition a measure of both the metabolic and respiratory components of blood acid–base status. It is of interest to consider the possible effect of  $PCO_2$  on the actual bicarbonate and total  $CO_2$  content values, and to compare these with the unaltered standard bicarbonate.

The strong ion theory has been proposed as a more comprehensive approach towards interpretation of acid–base.<sup>19–21</sup> The term ‘strong ion’ is used to describe species which are almost entirely dissociated at physiological pH ( $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Mg^{2+}$ ,  $Cl^-$ , lactate). The ‘strong ion difference’ is essentially a more comprehensive ‘anion gap’ calculated as the charge difference between the sum of measured strong cations and that of strong anions. It is regarded as an independent variable determining  $[H^+]$  and as such is comparable to the ‘buffer base’ (the sum of the buffer anions in the blood). Hence falls in strong ion difference have an acidifying effect. The two other independent variables regarded as affecting  $[H^+]$  are the  $PCO_2$  and the charge from weak acids, increases of which also increase  $[H^+]$ . All three effect their influence on  $[H^+]$  by altering the degree of dissociation of water (which is amphoteric) into hydrogen ions and hydroxyl groups. Other variables such as the concentration of bicarbonate ions are regarded as dependent variables to be, in essence, ignored. Changes in dependent variables are impossible without changes in independent ones. Thus if  $PCO_2$  and the charge from weak acids remain constant, hydrogen ion and bicarbonate can only be changed by altering the concentration of strong ions. The latter maneuver requires their movement between compartments or out of the body.<sup>20,21</sup>

To use the strong ion difference as an analytical approach in clinical practice requires more extensive laboratory activity. It has been asserted to be useful in some acid–base derangements such as hyperchloremic acidosis.<sup>22</sup>

## PH VERSUS $[H^+]$

Hydrogen ion concentration ( $[H^+]$ ) has been used in place of pH in this chapter because in clinical practice physiological measurements and therapeutic influences create changes that are linear in  $[H^+]$  (as opposed to inverse logarithmic in pH) and therefore more easily interpreted.<sup>23</sup> For example, acute changes in  $PaCO_2$  affect  $[H^+]$  in the ratio 1 kPa to 5.5 nmol/L. Tracking the  $[H^+]$  is intuitively easier and makes it easier to monitor the effect of therapeutic interventions, which have their effects primarily on the molar  $[H^+]$ .

A change of 0.3 pH units is equivalent to a twofold change in the concentration of hydrogen ion because  $\log_{10} 2$  is 0.3. A pH of 7.4 corresponds to a  $[H^+]$  of 40 nmol/L. An increase of 40 nmol/L reduces the pH to 7.1. A similar numerical change in pH towards alkalosis (pH 7.7) involves a reduction in  $[H^+]$  of only 20 nmol/L (to halve the concentration). A drop in pH from 7.4 to 6.8 involves a sixfold increase in  $[H^+]$ .

There is a counter to this argument which is becoming less relevant as the technology of blood gas machines improves. It is again linked to the linear versus logarithmic nature of the variables. When using ion specific electrodes (like a pH electrode) a precise value for the potential difference being measured is necessary to minimize error in the calculation of ionic concentration. The logarithmic transformation hides the errors in measurement of the potential difference in the decimal places of the pH. For example each millivolt error in measurement creates a 4% error in the calculated  $[H^+]$ , whereas an error of more than 5 millivolts creates a change of only 0.1 pH units. Thus, when using  $[H^+]$  for clinical decisions, greater technical precision may be required and therefore better performance of the electrode in terms of drift and other errors.

Online Mendelian Inheritance in Man (OMIM) is a freely accessible source of information which communicates the recent advances in the discovery of important genes and proteins responsible for inherited diseases. The reference numbers for inherited renal diseases described in this chapter are shown in brackets after the disease is mentioned. This should allow the reader to access up-to-date information regarding the molecular biology of the disease of interest. Web page: <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM>

## RENAL PHYSIOLOGY

The kidneys comprise of two organs located posteriorly in the extraperitoneal space of the abdomen. Each kidney normally contains approximately 1 million nephrons, which are the functional units of this organ. There are seven major physiological functions of the kidney, which are shown in Table 18.1. The nephron for simplicity can be considered functionally in five parts (Fig. 18.1), each of which will be discussed in turn:

1. **Glomerulus.** This is the filtering unit of the kidney and allows a massive amount of water and small molecules to freely pass across the filtration barrier from the circulation into Bowman's capsule (equivalent to approximately 25–35 times the entire circulating

7. Bone modeling

Fig. 18.1 Simplified drawing of a nephron. Isonatremic reabsorption of tubular fluid takes place in the proximal tubule in the cortex. The thick ascending limb of the loop of Henlé is a diluting segment in which sodium chloride is avidly recovered but water does not follow. All the distal nephron can be regarded as a functional whole. It is derived from the original ureteric bud. It is responsive to hormones that regulate volume osmolality and potassium concentrate. Note that the junction between the diluting and concentrating segments meets at the juxtaglomerular apparatus of the self-same nephron providing a point at which tubular performance regulates the rate of glomerular filtration.

volume a day in a child, or in an adult 180L/d). However very little protein traverses the filtration barrier. The glomerular filtration barrier (GFB) consists of three layers: the capillary endothelial cell, the glomerular basement membrane and adjacent to the urinary space the podocyte (Fig. 18.2). The negatively charged 50 kDa protein *albumin* is one of the first proteins to leak into the urine when the glomerular filtration barrier breaks down and is used as a marker in glomerular disease. In recent years the importance of the podocyte in the prevention of proteinuria has become obvious, as at least six different inherited human forms of nephrotic syndromes have been described, all of which have genetic mutations of genes coding for proteins expressed almost exclusively in the podocyte in the kidney (see **Nephrotic syndrome** section and Table 18.14).

Filtration across the GFB is passive and is driven by the glomerular intracapillary pressure, the work for which is generated by the left ventricle. The glomerular filtration rate (GFR) is closely regulated by adjusting intracapillary pressure through afferent and efferent arteriolar tone. Autoregulation keeps the GFR constant over a wide range of blood pressure. Superimposed on this there is also a circadian rhythm, which has an amplitude of about 25%. GFR also responds to physiological events, such as a high protein meal and pregnancy. In early infancy, the GFR, whether standardized for body surface area or for weight, is a fraction of that in older children and adults. Outside of the neonatal period it is conventional to express GFR per body surface area as this relationship holds constant from about 3 years of age until late adulthood, the normal being between 85 and 140 ml/min/1.73 m<sup>2</sup>.

2. **Proximal tubule.** At least 80% of filtered salt and water is recovered in the proximal tubule in the cortex of the kidney. This requires

Fig. 18.2 Transmission electron microscopy through the GFB of the glomerulus. From blood to urine the three layers are fenestrated endothelial cells (Δ), glomerular basement membrane (○), and the foot processes of podocytes (\*). Between the foot processes are the slit diaphragms, which restrict albumin passage into the urine (arrowed).

energy expenditure through  $\text{Na}^+-\text{K}^+-\text{ATPase}$ , however the process is facilitated by the fact that plasma in the peritubular capillaries has a high oncotic pressure. The plasma leaving the glomerulus, which goes on to supply the peritubular capillaries, is hyperoncotic and contributes an additional driving force for water reabsorption. The active export of sodium from the basolateral surface of the proximal tubular cells by  $\text{Na}^+-\text{K}^+-\text{ATPase}$  creates an ionic and sodium gradient across the epithelium. This gradient is responsible for the co-transport systems, which recover glucose, phosphate and amino acids. Hydrogen ion secretion by the proximal epithelium is essential for the recovery of filtered bicarbonate. In the presence of apical carbonic anhydrase,  $\text{H}^+$  and  $\text{HCO}_3^-$  combine to form carbonic acid. This dissociates to carbon dioxide, which can readily enter the cell and is converted back to bicarbonate. The essential luminal hydrogen ion secretion, which permits this process, also depends on the sodium gradient. Failure of the sodium gradient for any reason gives rise to the Fanconi syndrome of impaired proximal tubular reabsorption of bicarbonate, glucose, phosphate and amino acids (see **Fanconi syndrome**).

- Loop of Henlé.** In the thick ascending limb of the loop of Henlé sodium is actively pumped into the renal interstitium. However, owing to the waterproofing effect of Tamm–Horsfall protein, uniquely secreted into the lumen of this part of the nephron, water cannot follow. Nascent urine flowing along this section of the nephron therefore becomes increasingly dilute, achieving an osmolality of  $< 80 \text{ mOsm/kg}$ . Meanwhile the renal interstitium becomes hyperosmolar, reaching  $1400 \text{ mOsm/kg}$  in the renal papillae, the deepest part of the medulla. This is important for water resorption from the collecting ducts.

An important anatomical feature is that at the end of the diluting section, the nephron is reflected back to pass by the hilum of its own glomerulus. Here the specialized tubular cells of the macula densa relate intimately with the juxtaglomerular apparatus and both the afferent and efferent arterioles. At this site tubular performance is policed, and filtration regulated by a process referred to as tubuloglomerular feedback. If there is a major failure of tubular reabsorption upstream of the macula densa there will be increased sodium chloride delivery to this site which in turn signals for downregulation of filtration. The kidney fails safely. It can be appreciated that the low GFR observed in infancy is an appropriate response to the smaller capacity for salt and water recovery by the relatively short proximal tubules. Newborns are much more dependent on the distal nephron for electrolyte reabsorption. This is one of the reasons why mineralocorticoid deficiency has such profound effects in the newborn compared to older subjects.

- Distal convoluted tubule.** This region of the nephron is responsible for fine tuning the acid–base regulation of the body and also for further reabsorption and secretion of salts. The distal convoluted tubule (DCT) is found beyond the macula densa the distal nephron, and is derived originally from the ureteric bud. Three cell types are particularly worthy of review in this region as their transport systems have important homeostatic roles in salt and acid–base regulation. The first transport system is located in the principal cell of the DCT. This cell regulates potassium secretion into, and sodium resorption from the urine. For potassium this is the principal route of excretion into the urine, as the potassium freely filtered through the glomerulus is re-absorbed (predominantly in the proximal tubule) prior to reaching the DCT. This transport system is dependent on the hormone aldosterone and on the delivery of sodium to the lumen of the distal convoluted tubule to be exchanged with potassium. A number of channels on the apical (urine) and basal (blood) side of the principal cell regulate the movement of potassium out of, and sodium into, the cell. The epithelial sodium channels (EnaC) are located on the apical aspect of the cell. EnaC are the rate-limiting step for sodium recovery and are synthesized in response to aldosterone. The second important cell is the intercalated cell. This regulates the secretion of hydrogen ions into the urine in exchange for potassium.

In conditions of decreased aldosterone production (e.g. congenital adrenal hyperplasia due to 21 hydroxylase deficiency) or end organ resistance (pseudohypoaldosteronism) there is reduced secretion of potassium into the tubular lumen of the DCT at the principal cells, which then results in less potassium to exchange with hydrogen ions in the intercalated cells. The net end result is decreased excretion of potassium and hydrogen ions from the body (hyperkalemic metabolic acidosis). The combined effect of both cells is shown pictorially in **Figure 18.3**. The final cell type worthy of note is the sodium chloride co-transporter (NCCL) cell which contains the  $\text{Na}-\text{Cl}$  cotransporter channel. At this channel sodium and chloride are resorbed from the tubular fluid (**Fig. 18.4**). It is here that the thiazide diuretics exert their action by inhibiting this channel. Furthermore this channel is mutated in the hypokalemic metabolic alkalotic condition known as Gitelman syndrome. This cell also has an important role in the resorption of calcium from the urine.

Healthy children exposed to salt restriction can almost fully recover sodium in the nephron, with less than 1% of the sodium filtered at the glomerulus being excreted in the urine (fractional sodium excretion). However, newborns commonly have a fractional excretion of 1%, and in preterm infants as much as 5% of the filtered sodium load. Aldosterone is stimulated not only by the renin–angiotensin system but also directly by the plasma potassium concentration, a feature which assists in excretion of a potassium load.

- Collecting ducts.** Collecting ducts are embryologically derived from the ureteric bud. They are responsible for the resorption of water

**Fig. 18.3** Simplified diagram illustrating the important physiological effects of the principal and intercalated cells of the kidney.

**Fig. 18.4** Simplified diagram illustrating the physiologically important ion channels in the NCCL cells of the kidney.

through the action of vasopressin (also known as anti-diuretic hormone [ADH]) on water-permeable channels called aquaporins. Aquaporins (particularly aquaporin 2) are able to rapidly move from intracytoplasmic vesicles into the plasma membrane of the collecting ducts in response to vasopressin. After this occurs, water moves down an osmotic gradient from the dilute urine arriving in the distal nephron to the hyperosmolar medullary interstitium surrounding the collecting ducts, which has been generated by the loop of Henlé. The maximum urine concentration capacity thus depends on the presence of vasopressin, the integrity of vasopressin-2 receptor and aquaporin assembly, as well as a high medullary interstitial solute (sodium and urea). In breast-fed infants, whose dietary protein is efficiently used for anabolism, there is proportionately less for urea generation. Thus the maximal medullary concentration and urine concentration capacity is reduced. In health, and with adequate protein intake, children over 6 months of age can generate urine concentration  $> 870 \text{ mOsm/kg}$  and figures approaching this can be achieved from the early weeks of life.

**At least 80% of the filtered salt and water is recovered in the proximal tubule.**

*Over 6 months of age urine concentrations of  $> 800 \text{ mosmol/kg}$  can be generated and this concentration would be the end point in a water deprivation test for diabetes insipidus.*

*Predicted GFR ml/min/1.73m<sup>2</sup> = 40 × ht(cm)/plasma creatinine μmol/L (Schwartz formula).*

## ASSESSMENT OF RENAL FUNCTION

### MEASUREMENT OF GFR

It is helpful to measure the GFR in children as it is predictive of renal damage and informative of when renal support may be necessary. A GFR of  $< 60 \text{ ml/L.73 m}^2/\text{min}$  indicates chronic kidney disease (CKD) and the need for medical intervention to prevent metabolic bone disease, acidosis, anemia and hypertension. When the GFR is less than  $15 \text{ ml/1.73 m}^2/\text{min}$  pharmacological medical management is often inadequate and the child needs renal support by dialysis (hemodialysis or peritoneal dialysis) or renal transplantation. This is defined as end stage renal failure.

Unfortunately there are no easy and accurate methods of measuring the GFR in a child. The ideal filtration marker is a substance that is freely filtered by the glomerulus and then not reabsorbed or secreted along the nephron. A time-honored marker is inulin, an inert sugar with a molecular weight of 5500 Da which can be measured with accuracy in plasma and urine. After an i.v. loading dose, an infusion is maintained to provide a constant plasma concentration of inulin (P). Then either the mass of inulin excreted over a fixed time (urine volume × urine concentration, UV), or, assuming a steady state the dose of inulin infused must be known, which should be the same. The theoretical volume of plasma that contains the mass of inulin excreted per minute using the formula: (UV)/P can then be deduced. The volume of plasma cleared of its inulin can then be regarded as the net volume of water that has been filtered; the glomerular filtration rate. It is convention to express this rate per  $1.73 \text{ m}^2$ , the average body surface area of an adult man. This allows comparison of rate between individuals of different stature and holds true down to 3 years of age. Other methods that can be used include the use of exogenous markers including Chromium-51 Ethylenediamine tetra-acetic acid (EDTA), diethylene triamine penta-acetic acid (DTPA) and iohexol.

In clinical practice, the precision of inulin clearance methods are seldom required and such tests are best reserved for specialist departments. The same can be said for slope clearance methods, although they have the important advantage that timed urine collections are not required. In slope clearance methods, a bolus of a marker (inulin, <sup>51</sup>Cr edetic acid, or <sup>99m</sup>Tc DTPA) is injected rapidly into a vein. Following this there is a complex distribution into the extracellular fluid space, as well as clearance from the circulation by glomerular filtration. After approximately 1h, the plasma concentration falls exponentially. Two or more plasma

samples are then taken over the next few hours and from the slope of the declining concentration the following can be estimated: the theoretical volume of distribution at the moment of injection and the half-time when 50% of the marker has been cleared. From this information, GFR can be estimated. Precision of this method is excellent except at very high filtration rates.

Endogenous creatinine is a useful, although imperfect, marker with which to measure clearance. Formal creatinine clearance studies relying on timed urine samples have poor precision, probably because children are unable to void to completion on demand. There is *no* place for such tests in routine pediatric practice. More accurate, reproducible and user friendly is the interpretation of plasma creatinine in relation to a child's height. In the steady state creatinine excretion (UV creatinine) is matched by creatinine synthesis in muscle and is thus related in turn to muscle mass and body weight. Body weight and height also feature in the calculation of surface area in the denominator of the GFR expression. Although the logic is tortuous this conveniently resolves to the formula which is known as the Schwartz equation:

$$\text{GFR/body surface area} = (\text{body height/plasma creatinine}) \times \text{constant (40)}$$

Much hinges on the accuracy of plasma creatinine measurement, especially at the low concentrations of normal range. New automated methods overcome errors from drugs or non-creatinine chromogens. Using these methods, and with the child's height in cm and plasma creatinine expressed in μmol/L, the constant in the above equation is approximately 40. The formula performs well when used sequentially to follow GFR in an individual. Recently there has been interest in the use of serum cystatin A as a marker of GFR. This is a small molecule (molecular weight 13 KD) which is synthesized in a less variable manner in the body, and is less dependent on the height or sex of the child, compared with creatinine. It is freely filtered by the glomerulus and then metabolized by the tubules, with very little escaping in the urine. A number of groups have demonstrated that estimation of a child's GFR can be improved by measuring cystatin A on its own or in combination with the serum creatinine.<sup>1</sup>

Given that tubular performance upstream of the macula densa governs filtration rate by tubular glomerular feedback mechanisms, clinicians are able to use estimates of GFR as a guide to whole kidney performance. It is not surprising that some of the most abrupt and severe reductions of GFR are caused by interstitial or tubular injury rather than isolated glomerulonephritis. The corollary of this is that extensive glomerular destruction may occur with little, if any, change in plasma creatinine. In a disorder, which gives a progressive loss of nephrons over time, surviving nephrons will exhibit hyperfiltration. Thus considerable nephron loss has to occur before there is any downward trend in GFR; renal impairment is a late indicator. It is helpful to correlate impaired GFR with kidney size as determined, for example, by ultrasound. If kidney size is normal, or perhaps increased, while GFR is impaired, it is likely that the nephron population is intact but parenchymal injury has induced a shutdown of filtration. The causes may be inflammatory, drug induced, metabolic as in hypoxia or recent ischemia, or secondary to malignant infiltration. By contrast, if both kidneys are small it is likely that the nephron population is reduced because of some previous destructive process. Small echobright kidneys with normal contours might suggest a previous glomerulonephritis. Small kidneys with an irregular outline are seen following the coarse scarring of pyelonephritis or secondary to renal dysplasia.

### PROXIMAL TUBULAR FUNCTION

Glucose is not normally detected by conventional glucose oxidase strip reagent until the plasma glucose concentration exceeds  $10 \text{ mmol/L}$ , the renal threshold for glucose. Glycosuria occurring at a lower threshold may indicate an isolated transport defect, idiopathic renal glycosuria. If this occurs in conjunction with other markers of proximal tubular dysfunction it implies either renoparenchymal injury, chronic renal failure or the Fanconi syndrome.

*Amino acids* are readily filtered in the glomerulus and extensively reabsorbed in the proximal tubule by five separate cotransport systems:

1. basic amino acids and cystine;
2. glutamic and aspartic acids;
3. neutral amino acids;
4. imino acids;
5. glycine.

At very high plasma concentrations an amino acid may overflow into the urine. With normal plasma concentrations, newborns frequently have mild generalized aminoaciduria as a transient event. Otherwise, generalized aminoaciduria with normal plasma concentrations indicates tubulopathy in exactly the same way as glycosuria (above). Specific patterns of aminoaciduria imply isolated transport defects, e.g. cystinuria.

*Phosphate* is extensively recovered in the proximal tubule. However, the amount of phosphate filtered is close to the maximum rate of recovery, so that small changes in recovery rate govern plasma phosphate concentrations. Under normal conditions phosphate reabsorption will exceed 80% and the fractional excretion will therefore be less than 20% of filtered load. The fractional excretion can be calculated easily for any compound freely filtered at the glomerulus by comparing its clearance with that of creatinine:

$$\text{Fractional excretion of } x \text{ (\%)} = (\text{urine } x / \text{plasma } x) \div (\text{urine creatinine} / \text{plasma creatinine}) \times 100$$

*Calcium* is partly bound to protein and only the ionized fraction, about 50% of the total, is available for filtration. In the proximal tubule calcium reabsorption is proportionate to salt and water reabsorption. Thereafter there is both passive and active reabsorption in the loop of Henlé. Ten percent of the filtered calcium then reaches the distal nephron and of this two thirds will be reabsorbed. Hypercalciuria can be readily diagnosed by urine calcium/creatinine ratio. The 95th centile for children is given below:

Age range	Urine calcium/creatinine (molar)
0–6 months	< 2.0 mmol/mmol
7–18 months	< 1.4 mmol/mmol
1 1/2 > –6 years	< 0.78 mmol/mmol
7 years–adult	0.56 mmol/mmol

## TESTS OF URINE CONCENTRATION CAPACITY

Although the ability to excrete a water load can be tested, it has little clinical relevance. Impairment of water excretion occurs in the syndrome of inappropriate antidiuretic hormone (ADH) secretion and an extremely rare familial condition that mimics it in which ADH is not the cause. These conditions are suggested by a low plasma sodium concentration in the absence of dehydration.

*Tests of urine concentration capacity*, by contrast, are important. A simple screening test is to measure the urine osmolality on the first urine sample voided in the morning after fluids are restricted at bedtime. A urine osmolality value of 600 mosmol/kg is generally taken as excluding significant impairment of urinary concentration. However, in a study in 318 apparently healthy children with a median age of 9.8 years the median osmolality was 845 mOsm/kg (range 275–1344). Only 82% of males and 75% of females had an osmolality of 600 mosmol or more.<sup>2</sup>

If the diagnosis of diabetes insipidus is entertained, a water deprivation test should only be undertaken in hospital with close observation of hydration status. The end point is either a urine concentration capacity > 800 mosmol/kg or a 3% body weight loss, by which time the plasma osmolality should be rising and in excess of 295 mOsm/kg. If the latter, the final urine osmolality would be accepted as the concentration capacity. In fully expressed diabetes insipidus a urine osmolality will remain lower than that of plasma. As well as the obvious risks, young children find water deprivation disagreeable. A screening test for the ability to concentrate urine is to administer DDAVP 20 µg nasally (10 µg for infants) in the normally hydrated state. At 1 h children are asked to void and that urine sample is discarded. Between 1 and 5 h

after DDAVP normal children will produce a urine osmolality in excess of 800 mOsm/kg (infants <600 mosmol/kg). Patients with pituitary diabetes insipidus will respond to this test either normally or they will achieve osmolalities close to normal. Failure to respond implies either nephrogenic diabetes insipidus, in which case the urine osmolality will be below that of plasma, or chronic renoparenchymal disease, where the urine osmolality will be similar to plasma concentrations. Normality and fully expressed diabetes insipidus are easy to distinguish. Problems arise when the urine osmolality falls between 300 and 870 mOsm/kg. Often this is because the water deprivation study has not been conducted rigorously. Also habitual water drinkers, especially those with poor dietary protein intake, have a reduced medullary solute concentration and underachieve for this reason. Reductions in maximal urine concentration capacity may be seen in any renoparenchymal disorder, including recent upper urinary tract infection. As chronic renal failure progresses, concentrating and diluting capacity is lost and urine osmolality approaches that of plasma.

## TESTS OF RENAL TUBULAR ACIDOSIS

The kidney is responsible for the excretion of a small proportion of the total acid production of the body, this being those acids which cannot be metabolized to carbon dioxide and water and eliminated by respiration. Thus in severe renal failure patients develop a moderate acidosis with an *increased* anion gap. The anion gap is a measurement of the interval between the sum of the 'routinely' measured cations minus the 'routinely' measured anions in the blood, i.e.  $(\text{Na} + \text{K}) - (\text{Cl} + \text{HCO}_3)$ . The acidosis of chronic renal failure is readily corrected by 1–2 mmol/kg/d of administered bicarbonate. Renal tubular acidosis describes the hyperchloremic acidemia with a *normal* anion gap,  $(\text{Na} + \text{K}) - (\text{Cl} + \text{HCO}_3) = < 20 \text{ mmol/L}$ , which occurs with normal glomerular function. There is either a failure to recover filtered bicarbonate, an inability to secrete hydrogen ion, or both.

In the proximal tubule  $\text{H}^+$  is buffered by bicarbonate and leads to net bicarbonate recovery via the formation of carbon dioxide. Less than 10% of the filtered bicarbonate is presented to the distal nephron. In the distal nephron, where luminal bicarbonate is at a low concentration, two other buffering systems are proportionately more important. One is the tubular secretion of ammonia ( $\text{NH}_3$ ) generated by the deamination of glutamine. In the presence of  $\text{H}^+$  an ammonium ( $\text{NH}_4^+$ ) ion forms which is unable to diffuse back across the tubular epithelium. The second is the conversion of filtered alkaline phosphate  $\text{HPO}_4^{2-}$  to acid phosphate  $\text{H}_2\text{PO}_4^-$ . These buffers allow the urine to 'carry' more hydrogen ions. In health, the actual  $\text{H}^+$  gradient becomes apparent in that the urine can be made acid with a pH as low as 4.5.

To test the maximum  $\text{H}^+$  gradient delivered by the distal nephron it may be necessary to induce a metabolic acidemia by administration of ammonium chloride enterically, although this is rarely clinically required. In distal renal tubular acidosis (*type 1 RTA*) urine pH remains above 6.5 even if the plasma bicarbonate is reduced to < 22 mmol/L. This test is seldom required as type 1 RTA patients typically present with sufficient systemic acidosis to observe the inappropriately alkaline urine. As a general rule if the urine pH < 5.5 when the serum bicarbonate is < 16 mmol this excludes a distal renal tubular acidosis as the kidney is able to appropriately acidify the urine in response to systemic acidosis. Moreover, correction of acidosis occurs at modest doses of sodium bicarbonate such as 3–5 mmol/kg body weight per day.

90% of bicarbonate is recovered in the proximal tubule and the remainder distally, so that the threshold at which bicarbonate normally starts to appear in the urine is a plasma concentration of 25–26 mmol/L. In infants this threshold is rather lower at approximately 22 mmol/L. In patients presenting with hyperchloremic acidosis in whom proximal renal tubular acidosis is suspected, sodium bicarbonate is infused intravenously to lift the plasma concentration of bicarbonate. The bicarbonate concentrations in paired plasma and urine samples are plotted, thus determining the renal threshold. Note that while the plasma bicarbonate concentration is below the threshold for bicarbonate recovery it is

possible for normal distal mechanisms of urinary acidification to produce an acid urine. A simple clue to proximal renal tubular acidosis is the very large requirement for replacement bicarbonate to improve the acidemia. Often this amounts to more than 10 mmol/kg/d which is quite unlike that required to control the acidemia of chronic renal failure or distal (type 1) renal tubular acidosis.

## RENAL TUBULAR DISORDERS

Defects in renal tubular transport may result in marked derangements in electrolyte and mineral homeostasis with significant morbidity. Within the past decade advances in understanding of the molecular genetics and biology of a number of inherited renal tubular disorders have provided exciting new insights into the function of specific transport proteins and the physiology of renal tubular handling of solutes.<sup>3</sup>

### FANCONI SYNDROME

The Fanconi syndrome consists of a generalized failure of proximal tubular reabsorption. This leads to glycosuria, phosphaturia, calciuria, bicarbonaturia and generalized hyperaminoaciduria. Proximal sodium and potassium reabsorption also fails and the distal nephron, driven by aldosterone, attempts to recover sodium, but only at the expense of potassium and hydrogen ion secretion, potentiating severe hypokalemia. The salt and water wasting gives rise to polyuria, polydipsia and failure to thrive. Usually children exhibit a metabolic acidosis secondary to the urinary loss of bicarbonate (type 2 renal tubular acidosis). However, distal hydrogen ion secretion in most forms of Fanconi syndrome is normal, and during periods of hypovolemia and reduced glomerular filtration, the pH of urine may actually fall below 5.5. In states of extreme dehydration hypokalemic alkalosis may be seen. At other times hypokalemia with acidosis is a strong pointer to a proximal tubular lesion. The hypokalemia itself may aggravate the proximal tubular nephropathy as well as giving rise to muscle weakness, growth retardation and constipation. The glycosuria and aminoaciduria, in themselves have little in the way of clinical sequelae. The hypercalciuria is not associated with urinary stone formation, probably because of the very high urine flow rate. Plasma calcium concentrations tend to be normal. By contrast hypophosphatemia is the principal cause of the osteopenia and rickets of the Fanconi syndrome.

In clinical practice Fanconi syndrome is rare. The causes are legion and include primary disorders, sometimes familial with a variety of inherited patterns. Some of these are likely to prove to be secondary to respiratory chain defects and one type has been described in which the brush border of the proximal tubular cell is absent. The condition can arise secondarily due to intoxication by heavy metals or drugs and in relation to other inborn errors of metabolism (see Table 18.2). However, by far the commonest single cause of the Fanconi syndrome is *nephropathic cystinosis* and this condition is therefore dealt with in more detail.

**Table 18.2** Associations with Fanconi syndrome

<i>Inborn errors of metabolism</i>
Nephropathic cystinosis
Lowe syndrome (oculocerebrorenal dystrophy)
Glycogen storage
Galactosemia
Fructose intolerance
Tyrosinemia type 1
Wilson disease (hepatolenticular dystrophy)
<i>Tubulotoxic events</i>
Drugs, e.g. tetracycline, ifosfamide
Heavy metals, e.g. lead, cadmium, uranium, mercury, thallium
Maleic acid (experimental)

### Cystinosis (OMIM #219800)

Cystinosis<sup>4</sup> is a rare metabolic disorder inherited as an autosomal recessive trait. The gene responsible for the condition lies on chromosome 17p, and codes for cystinosisin, a lysosomal transmembrane protein essential for the transport of cystine. In the disorder cystine is stored intracellularly in lysosomes and there is a defect in the ability to transport cystine back into the cytoplasm. How this disrupts tubular function is unknown at present. Various patterns of cystinosis have been described. In the benign adult form cystine crystals are deposited only in the cornea, bone marrow and leukocytes; there appears to be no renal involvement. A juvenile form of the disorder includes a slowly progressive nephropathy, which becomes manifest in the second decade of life. By contrast, infantile nephropathic cystinosis is the most severe form. These infants appear normal at birth and the disorder becomes apparent at around 6 months of age with failure to thrive, polyuria, polydipsia, episodes of dehydration and unexplained fever. Rickets occurs early.

Over the first few years the glomerular filtration rate remains normal, and it is during this early stage that abrupt episodes of dehydration and electrolyte disturbance precipitated by intercurrent infective illnesses can prove fatal. The GFR declines with time so that end-stage renal failure is reached in untreated patients within 10 years of diagnosis. There is profound growth retardation and photophobia is a universal complaint due to cystine deposition in the eye. In later childhood, children have biochemical evidence of hypothyroidism and hypercholesterolemia.

The diagnosis is confirmed by the positive identification of cystine deposition within cells. In the first months of life the kidneys look histologically normal, but later the birefringent crystals of cystine can be seen in the interstitial tissue between tubules. Interstitial fibrosis then occurs so that the kidneys in time become small and contracted. Crystals can be seen in the cornea by slit lamp examination of the eye. The cystine concentration of leukocytes can be measured, and this test can be applied shortly after birth. Antenatal diagnosis is also possible, cystine measurements being made on fibroblasts obtained from amniotic fluid or chorionic villus sampling. It may also be diagnosed by genetic testing in informative families.

Cystinosis patients are difficult to manage and require careful electrolyte supplementation. Many need tube feeding to ensure an adequate salt, water and calorific intake.<sup>5</sup> Attempts to reduce the glomerular filtration rate, and thus the electrolyte loss, using indometacin are advocated. Cysteamine treatment can mobilize intralysosomal cystine and deplete cystine in cells. Cysteamine has a foul taste and compliance with this therapy is often poor. However, where cysteamine therapy or phosphocysteamine therapy has been given early with rigid compliance, children have retained kidney function longer than expected.

Once end-stage renal failure is reached, renal transplantation is an effective treatment. The transplant may become colonized by host cells, which will store cystine, but the tubular cells of the donor do not have the underlying biochemical defect and long-term kidney function is satisfactory. Concern is raised, however, that long-term survivors risk previously unrecognized complications such as corneal degeneration, diabetes mellitus, and cerebral atrophy.

### **Renal tubular disorders are rare but important causes of failure to thrive and electrolyte disturbances.**

*Cystinosis is the commonest cause of a Fanconi syndrome.*

*Nephrocalcinosis is an early complication of type 1 renal tubular acidosis but does not occur in type 2 proximal RTA.*

## RENAL TUBULAR ACIDOSIS

Renal tubular acidosis refers to conditions in which there are defects in the tubular reabsorption of bicarbonate, the excretion of hydrogen ion or both. They can be primary disorders, or secondary to a wide range of pathogenic insults to the tubular cells. Four types are described (Table 18.3).

Table 18.3 Classification of renal tubular acidosis (RTA)

<i>Type 1 – Distal RTA</i>
Primary
– sporadic, familial (autosomal dominant)
– transient infantile
Secondary
– interstitial nephritis, hypergammaglobulinemia, transplant rejection
– hypercalciuria, nephrocalcinosis
– drugs, lithium, amphotericin
<i>Type 2 – Proximal RTA</i>
Primary
Secondary – Fanconi syndrome
<i>Type 3 – Mixed proximal and distal RTA</i>
<i>Type 4 – Hyperkalemic RTA</i>
Hypoaldosteronism, Addison disease, congenital adrenal hyperplasia
Pseudohypoaldosteronism
Distal tubular dysfunction, e.g. obstructive uropathy
Hyperreninemia, hypoaldosteronism in chronic renal failure
Angiotensin-converting enzyme inhibitors
Early childhood hyperkalemia RTA (transient)

### Type 1 renal tubular acidosis

Permanent distal renal tubular acidosis (*type 1 RTA*) is more often a sporadic disease, although families with autosomal dominant and recessive inheritance are described. The nature of the cellular defect is known in some cases. For example, an autosomal recessive form with accompanying sensorineural deafness is caused by a mutation in the beta subunit of H<sup>+</sup>-ATPase located in the apical membrane of intercalated cells of the distal nephron.<sup>5</sup> A mutation of a 116 kDa subunit of H<sup>+</sup>-ATPase is found in autosomal recessive type 1 RTA without hearing loss.<sup>6</sup> The resulting functional defect prevents active hydrogen ion secretion. Defects in anion exchange mechanisms have been found in autosomal dominant forms of type 1 RTA.<sup>7</sup> Infants present with growth retardation, vomiting, polydipsia, constipation and dehydration, although these symptoms may be mild and in sporadic or autosomal dominant cases the diagnosis is often not made until the child is more than 2 years of age. Osteomalacia and rickets do not occur, with the exception of the autosomal recessive form with normal hearing, but nephrocalcinosis is an early complication secondary to the accompanying hypercalciuria and hypocitraturia. Treatment demands life-long therapy with bicarbonate or citrate. While the acidosis is readily correctable with modest doses of bicarbonate, 3–5 mmol/kg body weight per day, higher doses of 5–7 mmol/kg and good compliance with therapy is essential if progressive nephrocalcinosis is to be avoided. The long-term stability of renal function depends on control of nephrocalcinosis.

### Type 2 renal tubular acidosis

Proximal renal tubular acidosis (*type 2 RTA*) occurs because of failed bicarbonate reabsorption in the nephron. As a primary disorder both autosomal recessive and autosomal dominant inheritance patterns have been described. The molecular mechanisms are less well understood than in type 1 RTA, but abnormalities in the Na/HCO<sub>3</sub><sup>-</sup> cotransporter have been found in a case with ocular lesions. A transient form of type 2 RTA occurs in infants. In any child suspected of having type 2 RTA it is important to look for other evidence of proximal tubular dysfunction as bicarbonate wasting occurs as part of the Fanconi syndrome. Patients with type 2 RTA present with growth retardation and vomiting. Because they have normal urine acidification mechanisms in the distal nephron nephrocalcinosis does not occur. The low bicarbonate threshold means that the more the plasma concentration is increased therapeutically, the greater the urine loss. Thus massive bicarbonate replacement is needed to control the acidemia, often more than 10–15 mmol of bicarbonate/kg body weight/d.

### Type 3 renal tubular acidosis

The term *type 3 RTA* is used to describe a mixed picture of both proximal and tubular defects and can occur with almost any renoparenchymal injury.

### Type 4 renal tubular acidosis

*Type 4 RTA* is probably the most common subtype in children. In this there is hyperchloremic acidosis with hyperkalemia and usually an acid urine during acidosis. The pathogenesis is linked to H<sup>+</sup>/K<sup>+</sup>/Na<sup>+</sup> exchange in the collecting duct. It is therefore seen in states of mineralocorticoid deficiency such as congenital adrenal hyperplasia and Addison disease. Similarly it is seen in pseudohypoaldosteronism in which there is end organ unresponsiveness to aldosterone, for example with mutations causing loss of function of the epithelial sodium channel, or occasionally in conditions where there is direct damage to the renal medulla as in obstructive uropathy. In all these cases there is accompanying salt wasting which is most evident in the very young child who relies heavily on the distal nephron for physiological sodium reabsorption. Type 4 RTA can also occur with hyporeninism and hypoaldosteronism in chronic renal failure patients who are not volume depleted. An isolated early childhood form of type 4 RTA has been described. This occurs without salt wasting and the condition resolves by 5 years of age. Both sexes are affected and the disorder appears in siblings. High-dose alkaline therapy may be required (up to 20 mmol/kg/d), but this dose independently corrects the hyperkalemia. Nephrocalcinosis does not occur and the underlying nature of the defect is not known.

## HYPOKALEMIC ALKALOSIS

Severe potassium chloride wasting can occur from either the gastrointestinal tract or from the kidney. Examples of the first include pyloric stenosis, laxative abuse or familial chloride diarrhea. In these situations the kidney will initially respond appropriately by avid electrolyte conservation and a reduction in urine output. However, if potassium deficiency is severe enough, proximal tubular cells become vacuolated and lose their ability to reabsorb salt and water. In this situation, there can be an additional proximal tubular defect causing inappropriate salt and water loss – hypokalemic nephropathy.

Renal potassium wasting occurs in covert diuretic abuse, notably with furosemide (frusemide), or as a group of primary disorders generally referred to as *Bartter syndrome*. The hypokalemic alkalosis of all of the above disorders is accompanied by various degrees of *extracellular fluid volume depletion*. It is this feature that distinguishes them from the hypokalemia and alkalosis of actual or apparent mineralocorticoid excess, in which there is enhanced sodium and water reabsorption in the distal nephron giving rise to *extracellular sodium expansion* and hypertension (see later).

### Bartter syndrome

Bartter syndrome is a rare disorder, either familial or sporadic, which can affect both children and adults. The pathogenesis is best explained by a failure of chloride reabsorption in the thick ascending limb of the loop of Henlé, thus resembling the pharmacological effect of furosemide (frusemide). Three subtypes have been described with loss of function mutations in the furosemide (frusemide)-sensitive Na–K–2Cl cotransporter (type 1) (OMIM #601678), the potassium channel regulator ROMK (type 2) (OMIM #241200) or the basolateral chloride channel CLCNKB (type 3) (OMIM #607364). However there are cases where the molecular abnormality has not been found. As a secondary response to salt wasting, there is activation of the renin–angiotensin–aldosterone pathway in an attempt to recover sodium chloride in the distal nephron. This is achieved at the expense of increased potassium and hydrogen ion secretion, which largely explains the hypokalemic alkalosis.

Children present with failure to thrive, hypotonia, lethargy, poor feeding, polydipsia and polyuria. There is a wide spectrum of disease expression with a severe form presenting in the neonatal period. Such infants are usually born prematurely after a pregnancy complicated by polyhydramnios. In early life they may become so volume depleted as to

experience secondary oliguric renal failure, during which time the hypokalemic alkalosis is masked. Dehydration also gives rise to episodes of fever and developmental delay. In this group, there is hypercalciuria and bone demineralization, which may be secondary to the increased production of prostaglandins PGE<sub>2</sub> and PGI<sub>2</sub>, which are found in this and other forms of Bartter syndrome. Nephrocalcinosis is a serious and early complication except in type 3. The neonatal form of Bartter syndrome, first described by Fanconi in 1971, has at times been inappropriately titled 'calcium losing tubulopathy', or 'primary hyperprostaglandin E syndrome'.

Management consists of potassium, sodium and chloride replacement. Prostaglandin inhibitors such as indometacin 3 mg/kg daily in divided dose are indicated, and angiotensin-converting enzyme inhibitors such as captopril may give additional control.

Bartter syndrome presenting in older children may run a relatively mild course without hypercalciuria or nephrocalcinosis. Simple potassium supplementation may be all that is required.

### Gitelman syndrome

Gitelman syndrome (OMIM #263800) is a distinct autosomal recessive disorder in which there is renal loss of both potassium and magnesium so that hypokalemia and hypomagnesemia are combined with metabolic alkalosis and hypocalciuria. If Bartter syndrome is analogous to the effects of furosemide (frusemide), Gitelman syndrome mimics the effects of thiazide diuretics, and mutations have been confirmed in the thiazide sensitive cotransporter gene (NCCT). These patients present with muscle weakness, particularly after exercise. Many patients come to medical attention incidentally when they are investigated for intercurrent illnesses. The salt wasting is mild in comparison to Bartter syndrome and growth and renal function are unaffected. Potassium and/or magnesium supplements help to ameliorate symptoms.

### Hypokalemic alkalosis with extracellular sodium expansion

Hypokalemic alkalosis, with volume expansion and hypertension, can occur because of increased sodium recovery by the epithelial sodium channel with consequent secretion of potassium and hydrogen ions. An obvious cause of this is mineralocorticoid excess, as in *Conn syndrome*; vanishingly rare in childhood. However, there are other conditions with similar dynamics of increased distal sodium recovery in which plasma aldosterone concentrations are suppressed or normal. These are referred to as disorders of *apparent mineralocorticoid excess*. One of these is 11β-hydroxysteroid dehydrogenase deficiency, a rare inherited disorder in which the conversion of cortisol to cortisone at the site of the mineralocorticoid receptor is defective. As a result, physiologically normal amounts of cortisol can directly activate the mineralocorticoid receptor in the collecting duct, thus driving distal sodium reabsorption. Children present with severe labile hypertension and failure to thrive. Hypercalciuria and nephrocalcinosis occur. It is inherited as an autosomal recessive condition. Another is *Liddle syndrome* (OMIM #177200). In this, mutations in the beta or gamma subunit of the amiloride-sensitive epithelial sodium channel give rise to a constitutive gain of function; the opposite of pseudohypoaldosteronism type 1. The syndrome is autosomal dominant and can present clinically either in childhood or adult life. Treatment of both these disorders consists of amiloride to reverse the salt and water retention. This controls blood pressure and normalizes plasma potassium.

### Renal tubular hyperkalemia

This refers to the failure of the tubules to secrete potassium in conditions other than chronic renal failure. This can occur if there is a failure in the renin-angiotensin-aldosterone pathway. Examples would include treatment with angiotensin-converting enzyme inhibitors such as captopril and the failure to synthesize mineralocorticoid in the salt-losing forms of congenital adrenal hypoplasia. In these situations, there will also be reduced ability to secrete hydrogen ion resulting in type 4 renal tubular acidosis (see earlier).

### Primary pseudohypoaldosteronism type I

An abnormality in the end organ receptor responsiveness to aldosterone results in primary pseudohypoaldosteronism (PHA) type 1. *Renal type 1 PHA* is inherited in an autosomal dominant fashion with variable penetrance (OMIM #177735). It is caused by abnormality of the mineralocorticoid receptor and predominantly affects the distal tubular cells of the kidney. Infants classically present with salt losing states, dehydration and failure to thrive early in life, but clinical features are variable. It is treated with sodium chloride and sodium bicarbonate supplementation normally with good effect. In severe cases dietary potassium restriction and potassium exchange resins may be necessary. Improvement in this condition commonly occurs as the child grows enabling cessation of medication as the proximal tubule matures and is able to increase its reabsorption of sodium. A much rarer form of type 1 PHA affects multiple organs (*multiple type 1 PHA*) (OMIM #264350). This is normally inherited in an autosomal recessive manner and is due to a mutation in the gene coding for the epithelial sodium channel (EnaC) resulting in the lack of its function. As this channel is widely expressed in other tissues in the body it results in a more severe phenotype of children affected. Children again present with salt losing crisis in the neonatal period but also suffer from lower respiratory tract infection which may result in confusion with cystic fibrosis. Multiple type 1 PHA is much less responsive to the supplements used in the dominant form and often requires the addition of indomethacin and thiazide diuretics. It rarely improves with age and is associated with considerable mortality.

### Gordon syndrome

Pseudohypoaldosteronism type II, or 'chloride shunt' syndrome; OMIM #145260) is a rare autosomal dominant disorder of hyperkalemia, hyperchloremic metabolic acidosis, volume expansion and hypertension. Plasma renin activity and aldosterone levels are suppressed. Patients may also have hypercalciuria and a tendency to stone formation. The molecular basis of this condition has recently been unraveled. Mutations of either WNK4 kinase (17q21) or WNK1 kinase (12p)<sup>8</sup> result in the increased action of the Na-Cl thiazide channel which causes increased tubular resorption of sodium and chloride (with resulting volume overload). This results in less sodium delivery to the principal and intercalated cells of the distal tubule with less sodium to be exchanged with potassium and hydrogen ions. Treatment is with a thiazide diuretic.

### Action of diuretics on the kidney

There are three broad mechanisms by which diuretics affect the kidney (Table 18.4). Oncotic diuretics decrease the resorption of water from the nephron and effectively 'pull' water with them. Osmotic diuretics include Mannitol and glucose. The majority of diuretics used in clinical practice prevent the resorption of sodium from the nephron, which results in increased water clearance. These diuretics effect different sodium channels in the kidney and inherited loss of function mutations in all of these channels result in tubulopathies. The final group of drugs that result in increased water clearance from the kidney effect the collecting tubules and mimic the effects of nephrogenic diabetes insipidus. Drugs that cause this include lithium and amphotericin B.

*Cystinuria causes renal calculi and is associated with excess excretion of cystine, ornithine, lysine and arginine ('cola') amino acids.*

*Severe primary hyperoxaluria may require liver and kidney transplantation.*

*Nephrogenic diabetes insipidus can cause hypernatremia and mental retardation if not recognized.*

## HEREDITARY TUBULAR DISORDERS

### Cystinuria

Cystinuria (OMIM #220100) is a complex genetic disorder involving at least three alleles governing dibasic amino acid (lysine, ornithine, arginine) and cystine transport.<sup>9</sup> It is more common in Japanese and

**Table 18.4** Mechanisms of action of diuretics on the kidney, and genetic diseases which physiologically affect the same region of tubule

Location in nephron	Class of diuretic or drug side-effect	Known inherited condition mimicking effect
A. Proximal tubule	Carbonic anhydrase inhibitors	Osteopetrosis
B. Loop of Henlé	Loop	Bartter syndromes
C. Distal tubule – NaCl channel	Thiazide	Gitelman syndrome
D. Distal tubule – ENaC channel	Amiloride	Liddle syndrome, Autosomal recessive pseudohypoaldosteronism type 1
E. Distal tubule – mineralocorticoid receptor	Spironolactone	Autosomal dominant pseudohypoaldosteronism type 1
F. Collecting duct	Lithium	Nephrogenic diabetes insipidus
G. Throughout the nephron (Osmotic effects)	Mannitol Glucose	Fanconi syndrome

Caucasians, with an incidence of 1:18 000 in Japan and 1:20 000 in the UK. Defects are seen in both renal tubular and intestinal epithelial transport. Nutritional disturbances probably do not arise because amino acids are absorbed from the gut as oligopeptides rather than free amino acids. Renal tubular cells demonstrate an inability to take up cystine from their brush border, but can do so from the basolateral surface. Because the excretion of cystine can exceed the amount filtered, there is evidence of net cystine secretion by the tubule.

The clinical manifestations are confined to individuals in whom the cystine concentration in urine exceeds its solubility product and leads to calculus formation. This occurs in homozygotes and in those heterozygous for the type II allele.<sup>10</sup> Family studies show that heterozygotes excrete different amounts of cystine depending on the allele type (see later). Two genes have been found to be mutated in this condition SLC3A1 (rBAT), which codes for the heavy subunit of the renal aminoacid transporter and is found on chromosome 2p, together with SLC7A9, which codes for the light subunit of the transporter and is found on chromosome 19. Almost all untreated homozygotes will experience calculi at some time in their lives, a quarter of them before 20 years of age. Obstruction and infection cause lasting damage to the urinary tract. Patients present with renal colic or episodes of hematuria. The stones are radiopaque because of their high sulfur content. Ultrasound is a good way of identifying calculi in both the renal collecting system and the bladder but often misses calculi in ureters. Microscopy of the urine reveals flat hexagonal birefringent crystals under polarized light, and the nitroprusside test for urinary disulfides is positive. Confirmation is by quantification of urinary cystine secretion:

<i>Cystine excretion as urinary cystine/creatinine ratio</i>	
Normal	<100 μmol/g creatinine
Heterozygote	type I <100 μmol/g creatinine (recessive)
	type II >1000 μmol/g creatinine (dominant)
	type III 100–1000 μmol/g creatinine (partially dominant)
Homozygous cystinuria	>2000–5000 μmol/g creatinine

This classification is not perfect but it does give some clues to the underlying genetic defect the child has inherited. Heterozygous rBAT mutations always excrete cystine in the normal range (phenotype 1) and homozygotes excrete cystine in the range of 200–500 mmol/mmol. Heterozygous SLC7A9 mutations cause the majority of partially dominant cystinuria (80%). However the genotype–phenotype association with SLC7A9 mutations is not consistent with mutations in this gene also resulting in type I and type III cystine excretion in probands. A number of series have been unable to identify both of the above described gene mutations in their cystinuric patients suggesting that other cystinuria causing genes exist.

The mainstay of treatment is to keep the urine volume sufficiently high that cystine is kept below its solubility maximum of 1.25 mmol/L (300 mg/L). This necessitates fluid loading, especially at night to overcome the normal night-time antidiuresis. The solubility maximum of cystine increases to 2.0 mmol/L (500 mg/L) where the urine pH exceeds 7.5. A

second line of treatment, additional to and not a substitute for the first is to prescribe bicarbonate or citrate to ensure that the early morning urine pH is alkaline.

Family members should be screened so that presymptomatic, affected members can be treated early. It is easier to prevent stone formation than to dissolve existing stones. In difficult cases with existing calculi a further increase in cystine solubility can be achieved by forming a thiol-cysteine disulfide with agents such as D-penicillamine.

## Hyperoxaluria

Hyperoxaluria is a rare but important metabolic disorder to consider in a child with renal calculi or nephrocalcinosis. The majority of urine oxalate is derived from the hepatic metabolism of glyoxalate and ascorbate with a small proportion being ingested with diet. Oxalate is a metabolic end product, which is excreted via the kidneys, and its relative insolubility may lead to nephrocalcinosis or stone formation.

Enteric hyperoxaluria can occur in patients with chronic diarrhea due to short gut syndromes or other enteropathy.

Primary hyperoxaluria is a rare autosomal recessive disorder of oxalate metabolism due to a deficiency of hepatic alanine glyoxylate transferase (AGT) (type 1) (OMIM #259900) or glycerate reductase/D-glycerate dehydrogenase (type 2) (OMIM #260000). Both types lead to excessive urine oxalate excretion. In type 1 there is excess urinary glycolic acid, whereas type 2 is characterized by increased urinary L-glycerate.

Random urine samples for urine oxalate:creatinine ratio is part of the standard workup for children with renal stones but the normal ranges vary considerably with age and it is important to consult the laboratory for age-specific reference data. Normal results require measurement of 24-hour urinary oxalate and glycolate excretion and organic analysis of urine (for L-glycerate).

Treatment of hyperoxaluria includes high fluid intake, crystal inhibitors such as citrate, orthophosphate, magnesium and pyridoxine to act as a co-factor for AGT deficient type 1 patients. Dietary advice should aim to avoid high oxalate foods and beverages such as black tea or cocoa as part of a high fluid intake. Patients with obstructing stones require urgent urological assessment to avoid renal damage due to obstruction and infection.

Anyone with significant renal impairment, i.e. GFR < 75 ml/min/1.73 m<sup>2</sup> should undergo specialist review. Oxalosis is a term used to describe the final stage of primary hyperoxaluria when reduction of glomerular filtration rate produces systemic oxalate excretion, with crystals being deposited in bone, muscles, artery walls, eyes, skin and nerves. Isolated renal transplantation has now been replaced by combined liver and kidney transplantation with good results.<sup>11</sup>

## Oculocerebrorenal (Lowe) syndrome

Oculocerebrorenal (Lowe) syndrome (OMIM #309000) describes a rare syndrome of mental retardation, excess aminoaciduria, cataract and glaucoma. It is transmitted as an X-linked recessive trait mapped to Xp24–24. Most carriers are normal, or at worst have early onset of

cataract, but several female cases have been reported. The gene appears to code for a phosphatidyl inositol biphosphate phosphatase localized in the Golgi complex.

### **Clinical features**

Boys present from 2 months of age with the facial features of large ears, prominent forehead, flattened nasal bridge and prominent scalp veins in a pale skin. Cataract is typical and in the early stages may only be detected by slit lamp examination. The severity of the cataract varies, as does its distribution. Buphthalmos and congenital glaucoma may be present.

Intermittent pyrexia and failure to thrive are usual, and growth retardation, osteoporosis and rickets often occur. The mental deficiency is usually severe, with loss of muscle tone, hypermobility of joints and absent or greatly diminished tendon jerks. The eyes often roll in pseudonystagmus and it is commonly noted that children press on their eyeballs with their fingers to produce visual 'hallucinations'. The EEG may show the fast 24 cycles per second general activity. The blood pressure is normal and ultrasound of the kidneys is often normal. Proteinuria occurs with complex tubular dysfunction, which may not manifest itself until the second year of life. Tubular acidosis, usually of classical 'distal type' is present and there is hyperphosphaturia with hypophosphatemia, normocalcemia and elevated levels of alkaline phosphatase.

### **Treatment**

Treatment is supportive with adequate replacement of bicarbonate, potassium, phosphate and vitamin D metabolites. As with all rare conditions, parents may obtain benefit from contact with other families.

### **Hereditary hypophosphatemic rickets (vitamin D-resistant rickets)**

Hypophosphatemic rickets is a rare dominantly transmitted X-linked disease, for which the affected gene (PHEX, phosphate regulating gene; OMIM #307800), has recently been identified. Hypophosphatemia is due to a urinary leak of phosphate, which is itself secondary to a defect of proximal tubular sodium/phosphate co-transport.

*Clinical signs* are rickets in a child, and sometimes osteomalacia or bone deformities in the adult. Hypophosphatemia is associated with hyperphosphaturia, elevated serum alkaline phosphatase but with normal plasma calcium, calcitriol and PTH levels. No other tubular defects can be found and there is never the aminoaciduria associated with nutritional rickets or Fanconi syndrome.

*Treatment* is with phosphate supplements which, if given on a regular basis, should improve bone mineralization and prevent bony deformities. Oral neutral phosphate (Phosphate Sandoz) should be pushed to the limit of tolerability in a dose of 50–100 mg/kg/d given as at least four, preferably five, doses. High doses produce diarrhea and compliance with the medication must be constantly encouraged. Alfacalcidol is also introduced in an initial dose of 20–40 ng/kg/d but a careful watch must be kept for hypercalcemia and hypercalciuria.<sup>12</sup> Hypophosphatemic rickets can also be inherited in an autosomal dominant (OMIM #193100) and recessive (OMIM 241520) manner. Interestingly these conditions can often be treated with either phosphate supplementation (autosomal recessive) or vitamin D supplementation (autosomal dominant) alone.

### **Nephrogenic diabetes insipidus**

Nephrogenic diabetes insipidus (NDI) is the isolated inability of the kidney to concentrate urine in response to circulating arginine vasopressin. Although acquired forms exist, the disorder mostly occurs in infants and is congenital. At a molecular level, two disease mechanisms have been found. In 90% of congenital cases NDI is an X-linked disorder so that the full expression of the disease is confined to males (OMIM #304800). Mutations can occur in the arginine vasopressin-2 receptor (AVP2R) encoded at Xq28. AVP2R is normally located in the basolateral membrane of the collecting duct epithelial cell. On recognizing AVP the receptor signals to the cell nucleus through cyclic AMP leading to

synthesis of the water channel aquaporin-2 and its insertion into the apical membrane. In this way, vasopressin regulates the ability of water to flow down the osmolar gradient from the dilute tubular fluid to the hyperoncotic medullary interstitium. Among the remaining families with congenital nephrogenic diabetes insipidus, mutations have been found in the gene coding for aquaporin-2 on 12q13 (OMIM #125800). These can be inherited in an autosomal dominant or recessive manner. It appears that the aquaporin molecule is synthesized, but not routed to its apical destination, resulting in a loss of water transport. It is possible to distinguish between these forms, in that those with an aquaporin-2 defect show a rise in urinary cyclic AMP with vasopressin stimulation, while those with the receptor defect do not.

### **Clinical features**

The condition usually presents in infancy but a late recognition can occur. Polyuria and polydipsia are prominent features but difficult to recognize in infancy, although a preference for water rather than milk feeds may be evident. Water loss leads to recurring episodes of hypernatremic dehydration, fever, constipation and vomiting. Episodes of dehydration can seriously compromise intellectual development, and many cases exhibit growth retardation. The renal defect is permanent, but with increasing age water intake spontaneously increases to compensate for the persistent polyuria so that patients learn to avoid episodes of dehydration.

### **Diagnosis and differential diagnosis**

Plasma sodium and chloride concentrations are increased and, when dehydration is severe, renal plasma flow falls leading to raised blood urea and serum creatinine levels. The osmolality of the urine is commonly less than 100 mOsm/kg. If a paired plasma and urine osmolality is obtained as soon as an infant presents with a dehydrational state, this is often sufficient to lead to the diagnosis. Always ensure that the kidneys are structurally normal by ultrasound. Renal dysplasia and reflux nephropathy may present with a water losing crisis in infancy. In apparently normally hydrated children fluid restriction to test renal concentrating ability must be carried out with very careful inpatient supervision, as severe dehydration may rapidly ensue. DDAVP has no effect on urine concentration and this forms the basis for the diagnosis.

### **Treatment**

Replacement of urinary water losses, by increasing the fluid intake, is the basis of treatment. This may need to be by nasogastric tube feeding in the very young, although most infants will readily drink extra water given between milk feeds, even when appetite is poor. Paradoxically, thiazide diuretics have been shown to decrease free water clearance and urine flow rate in this condition. This action depends on the induction of a state of salt depletion, which causes an increase in proximal tubular reabsorption, and therefore diminished excretion of sodium and water to the distal nephron. The effect can be maintained by a low-salt diet, when thiazide diuretics are stopped. Unfortunately, the urine volume may decrease only by about one third. The addition of prostaglandin synthetase inhibitors such as indometacin to this treatment causes a further fall in urine volume. It does not enhance urine concentration but, by reducing GFR and enhancing tubular sodium reabsorption, restricts salt (and thus water) delivery to the collecting duct, reducing total water losses. Provided adequate supplies of water are maintained from early infancy, mental development is preserved but physical growth often remains a problem. The prognosis depends on making the diagnosis early and fastidious parental supervision of hydration.

In later childhood it is often preferable to discontinue the thiazide/indometacin therapy because it carries significant hazards, particularly peptic ulceration and haemorrhage, and interstitial renal fibrosis. Most older children adapt well to the inconvenience of polydipsia and polyuria. Therapy can be reintroduced for longer or shorter periods as needed – for example during a holiday to a hot climate where excessive thirst could be a serious problem.

## CONGENITAL ABNORMALITIES OF THE URINARY TRACT

Development of the renal tract has been described in Chapter 12. The increasing use and accuracy of obstetric ultrasound has added considerably to our recognition of urinary tract abnormalities (see neonatal renal). This is a family of disorders with a diverse anatomical spectrum including kidney anomalies, pelvi-ureteric anomalies, ureterovesical junction abnormalities, duplex systems and anomalies of the bladder and urethra. These abnormalities often occur concurrently in a variable pattern. Abnormalities in the genetic mechanisms underlying renal tract development may explain how many of these arise.<sup>13</sup>

Some of these are obviously important to recognize, because of their potential for causing considerable renal damage, e.g. posterior urethral valves in a male infant, but others produce no symptoms in infancy or childhood and their natural history is still being defined, e.g. unilateral multicystic dysplastic kidney.

### RENAL AGENESIS, ECTOPIA AND FUSION

These anomalies may occur in isolation but may also be associated with a large number of chromosomal and nonchromosomal syndromes. A careful clinical assessment should be made in all individuals with these anomalies. If there are other associated malformations an evaluation for a specific diagnosis should be made. In all cases evaluation for any other renal or urological problem should be made. This may include a renal tract ultrasound, a micturating cystogram and a MAG3 or a DMSA scan. A check of renal function is often made at the time of the isotope scan unless there is an indication to do so sooner.

### RENAL AGENESIS

Bilateral renal agenesis is incompatible with prolonged life, due to the associated pulmonary hypoplasia and oligohydramnios sequence.

Unilateral renal agenesis occurs in about 0.1% of the infant population, is more common in males and has been described in association with abnormalities of the external ear on the ipsilateral side. Atresia of the corresponding ureter is frequent and supports the view that unilateral renal agenesis is commonly the result of failure of formation of the ureteric bud or its inability to stimulate differentiation of the nephrogenic mesoderm. There is now a strong suspicion that many cases of unilateral renal agenesis are due to multicystic dysplastic kidneys, which have become involuted in utero.

Ultrasound and dimercaptosuccinic acid (DMSA) scan, including views of the whole abdomen to exclude ectopic location, should be undertaken. The presence of a normal hypertrophied kidney on the contralateral side should lead to reassurance and there is no need for long-term follow-up unless there are associated abnormalities.

### RENAL FUSION AND ECTOPIA

The metanephric blastema is originally sited in the pelvis and ascends to its subdiaphragmatic position during early fetal life. During the ascent, some rotation occurs, so that the renal pelvis, which originally lies anterior to the disc-shaped pelvic metanephros, comes to lie medial to the lumbar kidney. Moreover, the kidney assumes its reniform shape by virtue of its lumbar position and the rotation it undergoes. An ectopic non-ascended kidney is therefore likely to be non-reniform in shape, being usually discoid, and to have a pelvis and ureter arising anteriorly. The ureter may have a normal vesical opening but may also open in an ectopic position in the bladder, bladder neck, urethra or vaginal vault. The blood supply is derived from nearby arteries such as the common iliac. A frequent site for the ectopic kidney is in the pelvis but it may be higher up the posterior abdominal wall or crossed to the opposite side. Such 'crossed' ectopia is more often than not fused with the normal kidney – 'crossed fused ectopia'. Fusion of normally placed kidneys may also occur – commonly

Fig. 18.5 Horseshoe kidney. I.v. urogram showing rotated kidneys with calyces overlying pelvis and ureters running inferiorly and then medially to produce 'flower vase' configuration.

at the lower poles – and gives rise to the 'horseshoe kidney' (Fig. 18.5). The fusion of such kidneys prevents normal medial rotation, and the ureters arise from an anterior or lateral, rather than medial, position relative to the renal parenchyma.

The site of an ectopic kidney may render it more vulnerable to trauma or liable to obstruct the delivery of an infant (although most pelvic kidneys do not). The usual route of the ureter may impede urinary drainage and lead to stasis and dilatation with subsequent infection. Dysplastic tissue is not infrequently also found, increasing the risk of infection. An ectopic ureteric orifice in the bladder may lead to vesicoureteric reflux. If the ureter opens into the urethra or vagina there may be incessant urinary incontinence. Despite these problems many malpositioned or fused kidneys function well and are quite unproductive of symptoms.

Diagnosis is made by appropriate radiological investigations, particularly ultrasound and radionuclide imaging.

### DUPLEX SYSTEMS

Varying degrees of duplication occur. Double and completely separate pelvises may occur (on one or both sides), draining via separate ureters to separate ureteric orifices in the bladder. There may be two pelvises and one ureter or the two ureters may unite in Y fashion during the descent to the bladder. Such duplication is sometimes associated with vesicoureteric reflux or other abnormalities and this gives rise to problems such as recurrent infection.

However, a duplex kidney is probably one of the commonest abnormalities detected on imaging of the urinary tract and in the absence of other urinary tract disease requires no treatment. Occasionally one of the ureters is associated with a ureterocele (cystic dilatation of the intravesical portion of the ureter), which can lead to obstruction and hydronephrosis (Fig. 18.6).

The ureter leading from the lower pelvis to the upper ureteric orifice is most often the abnormal one. Either ureteric orifice may open ectopically elsewhere in the bladder, urethra or vagina. It can give rise to the problem of continued wetting and is one of the conditions to consider when a child is referred with a wetting problem and has never apparently had a dry day.

(b)

Fig. 18.6 (a) IVU in a 3-year-old girl with UTI, duplex system of left side and gross hydronephrosis on right side. (b) Hydronephrosis associated with large ureterocele seen as filling defect in bladder.

### RENAL DYSPLASIA AND HYPOPLASIA

It is unlikely that these two conditions should be separated. True hypoplasia (i.e. a normally developed but unduly small kidney) is rare. It is best identified by its small size and diminution of the number of papillae and calyces present. Most cases are associated with some degree of dysplasia as well. Renal dysplasia may produce diminution or increase in total renal size, but its characteristic is the presence of pluripotent undifferentiated mesenchyme which may give rise to aberrant tissue such as cartilage and smooth muscle within the kidney. Cyst formation is common and has been attributed to premature cessation of branching by the ureteric bud which, being unable to induce nephron formation, degenerates and becomes cystic. Obstruction to the ureter in fetal life is also a factor in pathogenesis, and causes well marked

dilatation of Bowman's capsule in some cases. The dysplasia may be unilateral when the opposite kidney functions normally, or may be bilateral. Gene mutations that have dominant inheritance and cause renal hypodysplasia, urinary tract anomalies, and defined extrarenal symptoms have been identified in *TCF2* (renal cysts and diabetes syndrome, OMIM #137920), *PAX2* (renal-coloboma syndrome, OMIM #120330), *EYA1* and *SIX1* (branchio-oto-renal syndrome, OMIM #113650, #608389), and *SALL1* (Townes-Brocks syndrome, OMIM #107480). It has been estimated that 17% of patients with renal hypodysplasia have one of these mutations.

Renal hypodysplasia contributes significantly to the causes of chronic renal failure in childhood, especially now that dialysis and transplantation are possible, even for small infants. Many children may go undetected but progress into chronic renal failure at the end of the first decade when their body size begins to outgrow their kidney reserve.

Oligomeganephronia is one form of dysplastic kidney when there is a reduced number of very large nephrons, which undergo progressive focal sclerosis.

### MULTICYSTIC DYSPLASTIC KIDNEY

The most common cystic lesion recognized antenatally is a multicystic dysplastic kidney (MCDK) disease (Fig. 18.7). In this disorder renal dysplasia is associated with a variable number of cysts and is believed to result from failed coordination development of the metanephros and the branching ureteric bud. Al-Khaldi et al<sup>14</sup> reported 44 fetuses with MCDK disease. In 14 fetuses the disease was bilateral and there were associated lethal abnormalities or syndromes. All 30 surviving infants had unilateral disease, six (20%) having significant reflux into the normal contralateral kidney. Although there have been occasional reports of sepsis, hypertension and even malignancy in association with cystic dysplastic kidneys, in many centers current management is conservative as many MCDK kidneys involute with time.<sup>15</sup>

### POSTERIOR URETHRAL VALVES

This affects male infants with an incidence of approximately 1 in 12 000 pregnancies.<sup>16</sup> The back pressure produced by the valves results in vesico-ureteric reflux, hydronephrosis, renal dysplasia and impaired renal function. This most commonly presents antenatally although the scan appearances may vary from an apparently normal 18–20-week scan to severe bilateral hydronephrosis and hydroureter with renal parenchymal loss. Even with antenatal detection and, occasionally, intervention with vesicoamniotic shunts in utero, many fetuses do not survive to term, or die in the neonatal period, because of the associated oligohydramnios and the severe lung abnormalities.

However, posterior urethral valves represent a spectrum of disorders, with some neonates presenting with bladder outflow obstruction, infection and acute renal failure (ARF) in the newborn period in association with urosepsis (Fig. 18.8). Other children present later with apparently minor symptoms. When the diagnosis of posterior urethral valves is suspected a urethral catheter should be passed and an ultrasound and a micturating cysto-urethrogram (MCUG) arranged urgently. After relief of obstruction there will often be a diuretic phase resulting in electrolyte and water loss which require careful monitoring and replacement. Most cases are managed in conjunction with a pediatric urologist and the prognosis will depend upon the degree of associated renal dysplasia and bladder abnormality. The reported experience of one tertiary referral center suggests that the long-term outcome is good for approximately two thirds of patients but a poor outcome, i.e. death in childhood or end-stage renal failure occurs in one third.<sup>17</sup>

### PELVIVETERIC JUNCTION (PUJ) AND VESICOURETERIC JUNCTION OBSTRUCTION (VUJ)

These two conditions cause hydronephrosis antenatally and have provided some of the biggest dilemmas in respect of postnatal management.

Fig. 18.7 (a) Postnatal ultrasound of infant with left MCDK showing numerous cysts in enlarged kidney. (b) Nonfunction confirmed on DMSA scan.

Fig. 18.8 Micturating cystourethrogram in a male infant presenting with septicemia and acute renal failure. Gross dilatation of posterior urethra, bladder diverticulum and reflux into dilated ureter.

PUJ and VUJ can occur at any time of life in association with intermittent abdominal pain, hematuria, urinary tract infection and asymptomatic flank mass. Such symptoms or signs are justification for a pyeloplasty or reimplant operation.

However, most infants with antenatally detected hydronephrosis have little in the way of signs or symptoms postnatally. In the rare

instances where there is a large tense kidney, with much diminished function, then an initial nephrostomy is undertaken. Most infants are assessed by a combination of ultrasound, micturating cystourethrogram (MCUG) (to exclude associated reflux) and a radionuclide scan, which is preferably MAG 3 ( $^{99m}\text{Tc}$ -labeled mercaptoacetyl triglycine), rather than DTPA ( $^{99m}\text{Tc}$ -labeled diethylenetriamine-pentaacetic acid). The general consensus is that a combination of significant calyceal, as well as pelvic, dilatation, accompanied by a reduction of differential function below 40% on the radionuclide scan, are indicators for an operative approach (Fig. 18.9).<sup>18</sup> There are no controlled trials to guide us and information concerning patients with significant dilatation is best reviewed by pediatric nephrologists, pediatric urologists and pediatric radiologists in combined nephrourology meetings.

**MCDK is usually a unilateral condition and most involute with time.**

*Posterior urethral valves must always be considered in a male infant with urosepsis.*

*Severe vesicoureteric reflux can be associated with small dysplastic kidneys and apparent global 'scarring' in the absence of infection.*

#### VESICoureTERIC REFLUX (see later)

Even minimal hydronephrosis on the antenatal or postnatal scan may be associated with gross degrees of reflux on the MCUG (Fig. 18.10). Care should be taken in neonates, where gross reflux is detected on the MCUG, to ensure that a 5-day course of full-dose antibiotics is prescribed before recommending prophylactic antibiotics, as fatal urosepsis has occurred after this investigation.

#### RENAL CYSTIC DISEASE

There are a number of disorders that share renal cysts as a common feature (Table 18.5).

These disorders may be inherited or acquired in the clinical context and associated systemic manifestations may help distinguish cystic disorders one from another. A solitary cyst in a young child may indicate a calyceal diverticulum rather than a simple cyst, which is more common in adult life. Bilateral enlarged kidneys in a neonatal infant would raise the suspicion of autosomal recessive polycystic kidney disease, which is more likely in this context than of autosomal

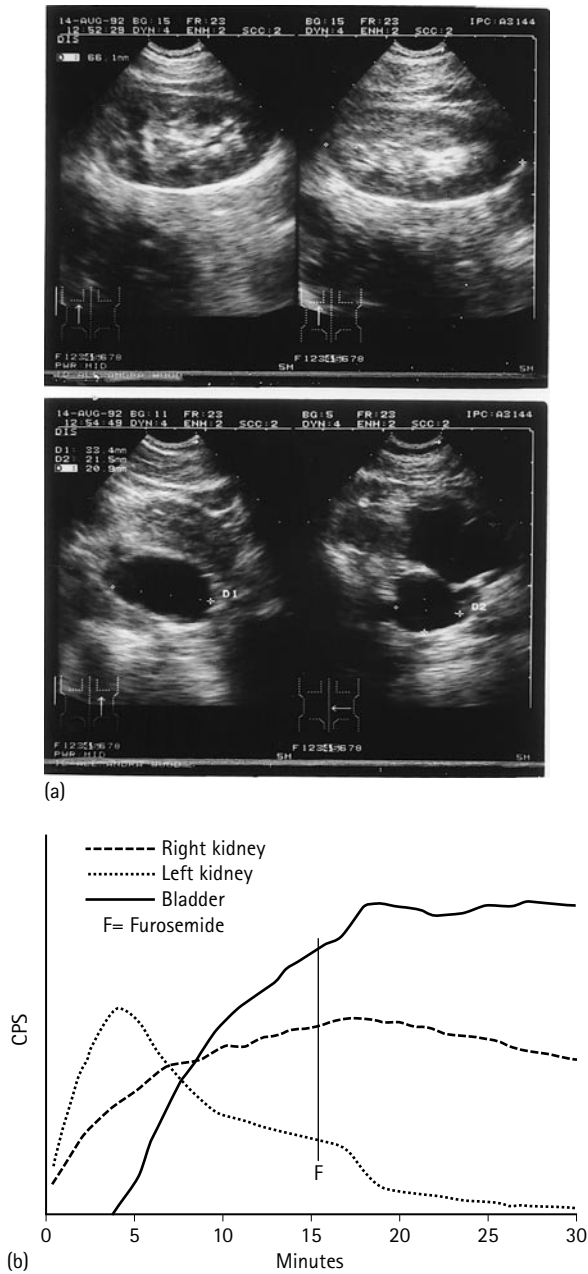

Fig. 18.9 (a) Ultrasound of 1-month-old infant with antenatally detected right hydronephrosis showing normal left kidney and dilatation of pelvis and calyces on right side. (b) Excretion curves of MAG 3 scan in the same infant showing normal excretion left kidney and delayed excretion right side with poor response to furosemide (frusemide). Differential function: right 36%, left 64%.

dominant polycystic kidney disease or tuberous sclerosis complex. Renal insufficiency in an adolescent might suggest juvenile nephronphthisis or autosomal recessive polycystic kidney disease as possible etiologies.

#### AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE (OMIM #263200)

Autosomal recessive polycystic kidney disease (ARPKD) is an inherited malformation complex with varying degrees of renal collecting duct dilatation and biliary ectasia.<sup>19</sup> There is an estimated incidence of 1 in 20 000 live births and it appears to occur more frequently in Caucasians than in other ethnic populations.

(a)

(b)

Fig. 18.10 (a) Postnatal MCUG on infant with antenatally detected hydronephrosis showing gross reflux bilaterally with pseudo PUJ appearance on right side. (b) DMSA scan in same infant showing very poor function on right side suggesting dysplastic kidney (no history of infection).

#### Etiology and pathogenesis

Genetic linkage studies indicate that mutations at a single locus, PKHD1 (polycystic kidney and hepatic disease 1), located on human chromosome region 6p21.1-p12, are responsible for all phenotypes of ARPKD. The gene product, polyductin/fibrocytin, is located in the primary cilium, an epithelial cell organ sensing fluid movement.

Late in the 1970s ARPKD was subdivided into four distinct phenotypes according to the age of presentation and the proportion of dilated renal collecting ducts (perinatal, neonatal, infantile, and juvenile). However, the process typically begins in utero and the renal cystic lesions appear to be superimposed on a normal developmental sequence. The tubular abnormality primarily involves fusiform dilatation of the collecting ducts. The early liver lesion appears to involve defective remodelling of the ductal plate in utero such that primitive bile duct configurations persist and progressive portal fibrosis evolves.

#### Clinical features

The clinical spectrum of ARPKD is variable and depends on the age at presentation. Most patients are identified either in utero or at birth. The most severely affected fetuses present in pregnancies with oligohydramnios and have enlarged echogenic kidneys. They may die at birth because of pulmonary hypoplasia. Those infants who survive the perinatal period have hypertension, renal failure and portal hypertension. Renal

*Acquired*

Simple cysts

Hypokalemic cystic disease

Acquired cystic disease (in advanced renal failure)

hypertension usually develops in the first few months and ultimately affects 70–80% of patients. There is also an increase in the incidence of urinary tract infections.

Portal hypertension can be the predominant clinical abnormality in older children and adolescents with ARPKD. These children typically present with hepatosplenomegaly and bleeding esophageal or gastric varices as well as hypersplenism. Hepatocellular function is usually preserved but ascending suppurative cholangitis is a serious complication and can cause hepatic failure.

**Diagnosis**

In the antenatal period, oligohydramnios or enlarged echogenic kidneys suggest ARPKD. Postnatally, ultrasound can reveal symmetrically enlarged diffusely echogenic kidneys, with poor demarcation from surrounding tissues, as well as cortex, medulla and renal sinus (Fig. 18.11). With high resolution ultrasound the regular ray of dilated collecting ducts may be imaged and i.v. urography and computed tomography scanning will show similar features. In older children the development of scattered small cysts and progressive fibrosis can alter the reniform character and ARPKD in older children can be mistaken for ADPKD.

The liver may be normal in size or enlarged and is usually less echogenic than the kidneys. Prominent intrahepatic bile duct dilatation suggests associated Caroli disease. With age, the portal fibrosis tends to progress and there may be hepatosplenomegaly and a patchy increase in hepatic echogenicity.

**Genetic testing**

Although haplotype-based analysis is feasible in most cases, it is associated with a risk of misdiagnosis in families without patho-anatomically proven diagnosis. Linkage analysis is impossible in families where DNA of the index patient is not available. Direct mutation analysis of the PKHD 1 gene opens new options in families for prenatal diagnosis, though this is not yet widely available, partly because this is an exceptionally large gene to screen, with hundreds of described mutations.

**Outcome**

The estimated perinatal mortality is 30–50%. For those who survive the first month of life the reported mean 5-year patient survival rate is 80–95%.<sup>20</sup> The prognosis outside the perinatal period is improved, because

Fig. 18.11 Ultrasound showing diffuse increase in echogenicity. Bilateral enlargement in newborn with ARPKD.

of the availability of aggressive interventions such as unilateral or bilateral nephrectomy, and the availability of dialysis and transplantation for this group of children. For those with end-stage renal failure and severe portal hypertension, combined liver and kidney transplantation may be indicated.

**AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE (OMIM #173900)**

ADPKD is a multisystem disorder characterized by multiple bilateral renal cysts and associated with cysts in other organs such as liver, pancreas and arachnoid membranes. It is one of the most common hereditary diseases affecting approximately 1 in 400 to 1 in 1000 individuals.

**Etiology and pathogenesis**

The genes responsible for ADPKD have provided a major breakthrough in the study of the disease. PKD1 is the gene on chromosome 16 and is responsible for 85% of clinically detected cases and PKD2 has been identified in the long arm of chromosome 4 and there is likely to be a third gene. Proteins encoded by PKD1 and PKD2 are named polycystin 1 and polycystin 2, respectively. Recently, biologic evidence documented the crucial role of the renal primary cilia on the formation of polycystins to induce cystogenesis. Molecular genetic work has stimulated a great deal of research into variation in disease progression between patients and this appears to depend upon underlying mutations, modifying genes, somatic mutations and environmental factors.<sup>21</sup>

**Clinical features**

It is very rare for ADPKD to manifest clinically in childhood, but an occasional child may have significant renal enlargement with hypertension. Urinary tract infections are also known to exacerbate kidney disease in adults. Although ADPKD may be recognized incidentally on renal

ultrasound scans done for urinary tract infection (UTI) investigation etc., there is a general consensus that asymptomatic children from affected families should not be routinely screened for this condition either by ultrasound or genetic studies. They should be free to make their own autonomous decision as to whether they want to be investigated when they reach adulthood.

### FAMILIAL JUVENILE NEPHRONOPHTHISIS AND MEDULLARY CYSTIC DISEASE COMPLEX

Juvenile nephronophthisis (NPHP) and medullary cystic disease complex are histologically similar diseases differing in their mode of transmission and age of onset. They are now shown genetically to be distinct diseases. Medullary cystic kidney disease (MCKD; OMIM #174000) is an autosomal dominant form of tubulointerstitial nephropathy characterized by formation of renal cysts at the corticomedullary junction. Progression to end-stage renal failure occurs in the third to fourth decade of life.

Three loci have been mapped for nephronophthisis, the leading genetic cause of chronic renal failure in young adults: juvenile NPHP1 (OMIM #256100) on 2q13; infantile nephronophthisis (NPHP2; OMIM #602088) on 9q22-q31; and adolescent nephronophthisis (NPHP3; OMIM #604387) on 3q21-q22. By renal histology the three forms of the disease are indistinguishable, all three exhibiting a triad of interstitial-cell infiltrates, renal tubular-cell atrophy with cysts arising from the corticomedullary junction of the kidneys, and renal interstitial fibrosis. Clinically, there is a statistically different age at onset at end-stage renal disease: terminal renal failure develops at median ages of 1 year, 13 years, and 19 years, in NPHP2, NPHP1, and NPHP3, respectively. The chromosomal localization of a fourth gene locus, NPHP4 has been reported, in which end-stage renal disease commences within a wide age range, 11–34 years.

#### Clinical features

Reduced urinary concentrating capacity is common in patients with NPHP and this usually precedes a decline in renal function. The mean age of onset is 4 years. Polyuria and polydipsia are common symptoms and the patients may be anemic, even before the onset of renal insufficiency. Growth retardation, out of proportion with the degree of renal insufficiency, is a common finding.<sup>22</sup> A gradual decline in renal function is typical and end-stage renal failure usually develops by adolescence. The disease is not known to recur in renal allografts.

In 10–15% of NPHP, now shown to link to NPHP4, there is an association with retinitis pigmentosa caused by retinal degeneration (Senior-Løken syndrome) and presents with coarse nystagmus and early blindness. NPHP associated with ocular motor apraxia and coexisting retinal degeneration (Cogan syndrome) has been reported in several kindreds and a subset of these patients has also had mental retardation. Congenital hepatic fibrosis occurs occasionally in patients with NPHP

### MEDULLARY SPONGE KIDNEY

This developmental disorder is characterized by cystic anomalies of precalyceal ducts, which is frequently associated with nephrocalcinosis and renal stones. Again this condition more commonly comes to light in adult life, when calcification in the renal pyramids may give rise to calculi, abdominal pain and hematuria. It is occasionally identified in childhood for the same reasons, but more often because of the urographic appearance of streaky opacification in the renal pyramids.

### TUBEROUS SCLEROSIS COMPLEX (OMIM #191100)

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder in which tumor-like malformations, called hamartomas, develop in multiple organ systems. This affects 1 in 10 000 individuals but spontaneous mutations appear to occur at high frequency and are estimated to account for 60% of new cases.

Renal cystic disease is the earliest finding in TSC and may be the presenting manifestation in infants and children before even the seizures and mental retardation have become manifest alongside the facial angiofibromas, hypomelanotic macules and periungual fibromas.

The principal hamartomas in TSC are angiomyolipomas. They rarely occur before 5 years of age but increase in frequency and size and give rise to hemorrhage or mass effects leading to severe hypertension and progressive decrease in renal function. Malignant tumors, found in TSC patients, were originally thought to be a renal cell carcinoma but are now regarded as malignant epitheloid angiomyolipomas.<sup>23</sup>

## URINARY TRACT INFECTIONS

### EPIDEMIOLOGY

Urinary tract infections are common in childhood and adolescence. Up to 7% of girls and 2% of boys will have a symptomatic, culture-confirmed UTI by 6 years of age.<sup>24</sup>

### RISK FACTORS ASSOCIATED WITH THE DEVELOPMENT OF UTI

- Age and sex.** The highest rates of childhood UTI are reported in males younger than 1 year of age and females younger than 6 years of age.<sup>24</sup> The prevalence of UTI in febrile infants is higher than that in older children and increases with younger age. In a recent prospective, multicentre, cross-sectional study the highest rate of UTI in febrile infants was seen in uncircumcised male infants (21.3%) compared with female (5.0%) and circumcised male (2.3%) infants.<sup>25</sup> In males, circumcision is reported to significantly reduce the risk of UTI.<sup>26</sup>
- Race.** Higher rates of UTI have been reported in Caucasian children as compared to African-American children.<sup>27</sup>
- Family history.** There is an increased incidence of UTI in children whose first-degree relatives have had UTIs.<sup>28</sup>
- Constipation** in children increases the likelihood of urinary incontinence, dysfunctional voiding, a large capacity, poorly emptying bladder, and UTI.
- Sexual activity.** Adolescents with UTIs have a significant frequency of sexual activity and information pertaining to this should be sought in this group of patients.<sup>29</sup>
- Bladder catheterization** may predispose to UTI, although this is generally asymptomatic bacteriuria.<sup>30</sup>
- Abnormalities of the urinary tract.**
  - Vesico-ureteric reflux (VUR)** is present in 30–40% of children investigated for UTI.<sup>31</sup> The importance of VUR as a causative factor in the initiation of UTIs with consequential renal scarring is controversial. Historically it was widely held that the combination of VUR and UTI resulted in renal damage in the form of scarring. More recently these assumptions have been challenged. This is explored in more detail in the section on vesicoureteric reflux.
  - Obstruction.** Anatomical defects of the urinary tract that predispose to obstruction are infrequent causes of UTI. These include pelvi-ureteric junction (PUJ) obstruction, vesico-ureteric junction (VUJ) obstruction, ureterocoele, posterior urethral valves and myelomeningocele with neurogenic bladder. Renal stones may also (rarely) present as UTIs.

### PATHOPHYSIOLOGY OF UTIs

Infection of the urinary tract is related to both the characteristics of the invading bacteria and those of the host urinary tract. The most common bacterial species to invade the urinary tract is *Escherichia coli* (*E. coli*), which accounts for up to 92% of UTI in children.<sup>32</sup> Other organisms include *Klebsiella*, *Proteus*, *Enterobacter*, *Enterococcus*, *Pseudomonas* and *Citrobacter*. Virulence factors have been well studied in *E. coli* and most strains isolated from patients with suspected upper UTIs have pili or fimbriae, which are polypeptides with tubular receptors specific for

glycolipid components of human cell membranes. Such fimbriae allow attachment to receptors expressed on uroepithelial cells, enabling bacteria to ascend into the bladder and kidney. *P. fimbriae* expression is associated with increased severity of infection. Over 90% of *E. coli* isolated from children with a first episode of pyelonephritis expressed *P. fimbriae* compared with 19.2% of isolates of children with cystitis.<sup>32</sup>

### CLINICAL PRESENTATION OF UTI

The younger the child the more nonspecific the symptoms:

1. **Neonates.** Prolonged jaundice is a classical association of bacteriuria in the newborn. A high index of suspicion should be maintained in any baby 'going off', or who has abdominal distension, disturbance of temperature regulation, changing ventilation requirements or metabolic disturbance.
2. **Infants and toddlers** may present with vomiting, diarrhea, poor feeding and failure to thrive or fever. UTI should be excluded in any infant with an unexplained temperature.
  - a. Young infants with an abnormal urinary tract can present with acute renal failure and gross electrolyte abnormalities.
3. **Preschool and older children** may have cystitis-like symptoms such as frequency and dysuria, often accompanied by 'new' bed-wetting and daytime accidents. There may be mild lower abdominal discomfort and hematuria. Such symptoms do not exclude involvement of the upper urinary tract.

The classical symptoms of high fever, vomiting, abdominal or loin pain and rigors in the child is suggestive of acute pyelonephritis. The presence of such symptoms, or septicemia, in a young infant will influence subsequent management and intensity of the investigations.

### PHYSICAL EXAMINATION OF INFANTS AND CHILDREN WITH SUSPECTED UTI

This should include:

1. **Abdominal palpation** for renal masses and fecal loading:
  - a. A palpable bladder combined with a poor urinary stream may indicate neuropathic bladder.
2. **Examination of the spine and lower limb reflexes** should be undertaken to examine for the presence of spina bifida occulta with associated neuropathic bladder.
3. **Examination of the anal and genital areas** may be appropriate and might suggest signs of sexual abuse in a female infant.
4. **Height, weight and blood pressure** should be recorded.

### INVESTIGATION OF INFANTS AND CHILDREN WITH SUSPECTED UTI

1. urine dipsticks incorporate strips for the detection of white blood cells (leukocyte esterase) and nitrite production (by reduction of nitrate). These are increasingly used as a first-line investigation of UTI. Dipstick analysis for nitrite and leukocyte esterase has similar sensitivity to gram stain in the detection of UTI in children.<sup>33</sup> Hence a urine specimen obtained in an asymptomatic child in the outpatient department which is clear and negative on dipstick does not need laboratory assessment and culture. Conversely, a positive nitrite and leukocyte result is an indication for urine culture and empirical treatment with antibiotics, while awaiting culture, if the child is symptomatic; Dipstick analysis may not be reliable in the following situations:
  - a. in infants, due to frequent micturition and dilute urine, there may be insufficient leukocytes and nitrates to cause a positive reaction;
  - b. in patients with inadequate dietary nitrate there may be a low sensitivity rate;
  - c. infection with enzyme deficient bacteria.
2. urinalysis;
3. C-reactive protein, full blood count, blood cultures and urea and electrolytes if the child is systemically unwell.

### METHODS OF URINE COLLECTION:

1. **Suprapubic aspirate (SPA).** This is the 'gold standard' against which all other sampling methods are compared.<sup>34-36</sup> Although SPC can be undertaken in people of all ages, it is usually only attempted in infants under 6 months in whom the bladder is an abdominal organ. If performed correctly, aspirating the needle while advancing, the sample should be uncontaminated and any organisms seen should be regarded as significant.<sup>34</sup> The procedure may be unsuccessful if the bladder is empty and it may be worthwhile confirming that the bladder is full by ultrasound examination prior to commencing the procedure. We would recommend that SPA should be performed in unwell neonates and infants under 6 months with a suspicion of UTI unless the child's clinical condition allows for collection of urine by the 'clean-catch' method.
2. **Catheter specimen of urine (CSU)** is generally undertaken when an urgent sample is required and a suprapubic sample is not practical because of age/parental wishes. CSU is often more acceptable to parents than SPA and has a low false-positive rate.<sup>35</sup> However there is a risk of introducing an infection if one isn't already present.
3. **Clean catch urine** (or mid-stream urine in continent children). These are reliable methods of collecting urine with lower contamination rates than bag urines. They are recommended by the Royal College of Paediatrics and Child Health as the preferred non-invasive methods of urine collection.<sup>36</sup> If possible, two samples should be sent prior to commencing treatment. In the infant, micturition can be encouraged by tapping in the suprapubic region, stroking alongside the spine or even exposure to cold while undressing. Sterile trays should always be to hand and parents should be encouraged to participate in this method of urine collection. The older continent boy can easily introduce a sterile container into the urinary stream and there is no need for specific cleansing of the glans or withdrawal of the prepuce. Similarly the vulva does not require cleansing (antiseptics are to be avoided) in older girls, but cleaning with sterile water may be required in younger girls where a sterile container placed inside a potty is usually employed. Using the child's own potty is not satisfactory and is a common reason for erroneous results in general practice.
4. **Bag urine samples** are a commonly used method of collecting urine in non-toilet trained children. However, the current authors would not recommend their use routinely due to high contamination rates of up to 40%.<sup>37</sup> If bag urine samples are to be used, sending a second sample (prior to the commencement of treatment) has been reported to reduce the contamination rate to 12%.<sup>38</sup>
5. **Pad urine collection.** This is an easy but unreliable method of collecting urine. The pad is easily applied to the nappy and urine is removed from the pad by syringe. The current authors would not recommend their use routinely due to high contamination rates.<sup>39</sup>
6. **Dip slides** for transmitting urine specimens or bottles containing boric acid have been promoted as a means of collecting specimens at home where there are transport difficulties to the laboratory. However, technical failures with dip slides may be disappointingly high and if the container with boric acid is not filled with urine to the appropriate level then growth may be inhibited.<sup>40</sup>

### HANDLING OF URINE CULTURE SPECIMENS

Since practitioners are so reliant upon urine culture to confirm the UTI, it is important that all urine cultures should be submitted to the laboratory with the minimum delay. If there is any delay, storage at 4 °C will still permit accurate diagnosis for 24 h and possibly longer.

### MICROSCOPY

Although the finding of pyuria is good supportive evidence of UTI, up to 50% of patients with significant bacteriuria will not demonstrate a significant number of white cells (> 5 white cells per high powered field) in the centrifuged

urine specimen. Furthermore, pyuria may be present in sepsis and does not always imply a UTI.<sup>41</sup> Gram stain at the time of urgent microscopy may help direct antibiotics, however negative gram stain is unhelpful in refuting a UTI.

## CULTURE

The classical definition of significant bacteriuria [ $10^5$  organisms per ml ( $10^8/L$ ) of urine] is still applied in childhood with the proviso that any bacteriology reports should always be interpreted in the clinical context. It is possible that a lower colony count, especially with a pure growth on repeated samples, is clinically important. Any growth obtained on a suprapubic urine sample or 'in-out' catheter specimen urine is regarded as significant. Growth of more than one strain of bacteria is an indication of contamination and if not already done a repeat sample should be obtained.

## TREATMENT OF UTIs

Empiric antibiotic therapy is recommended while awaiting culture results if there is a high clinical suspicion of UTI (Table 18.6). If there is no clinical improvement within 2 d of commencing antibiotic therapy, repeat urine culture should be undertaken and consideration given to renal/bladder ultrasound.<sup>42</sup>

In two randomized controlled trials<sup>43,44</sup> comparing oral and parenteral regimens in children with fever and positive urine cultures, there were no differences in cure rates or speed of improvement between the two regimens. Parenteral antibiotics may be indicated in cases of suspected septicemia, or where there is intolerance to oral administration (e.g. vomiting). Neonates should be treated as per local unit protocols.

Trimethoprim is commonly used as first-line oral therapy for urinary tract infections, however choice of therapy will depend upon information from the local microbiology laboratory about changing patterns of antibiotic resistance locally. Patients on trimethoprim prophylaxis with 'breakthrough' infection suggestive of resistant organisms are often treated with third or fourth generation cephalosporins, nitrofurantoin or augmentin. Amoxicillin has also been used, however, resistance rates of over 70% have been reported.<sup>45,46</sup> Ciprofloxacin is the antibiotic of choice for *Pseudomonas* infections.

Parenteral agents include second- and third-line cephalosporins and aminoglycosides, as directed by local policy.

One-day courses of antibiotics should not be used to manage UTI in children.<sup>47</sup> Shorter courses (3–5 d) are reported to be as effective longer courses for uncomplicated UTIs without systemic features and in the

absence of structural anomalies of the urinary tract.<sup>47,48</sup> We would recommend a 3–5-day course in these children and a 7–14 day course in children with features suggestive of acute pyelonephritis.

There is no evidence to support a recommendation for routine post-treatment urine cultures in children with UTIs.<sup>49</sup>

Children with obstructive uropathy such as posterior urethral valves should be managed in centers where there is both nephrology and urology expertise.

## IMAGING IN CHILDREN WITH UTI

At present the consensus is that all children, boys and girls, should undergo imaging of the urinary tract after the first proven urinary tract infection. This is in line with the published guidelines of the Royal College of Physicians (UK).<sup>50</sup> However, these recommendations are followed in a minority of cases, as the assumptions upon which they were based have been challenged in recent years.<sup>51</sup> There is increasing evidence that imaging for children with a first uncomplicated UTI may not improve patient care.<sup>52,53</sup>

The following imaging techniques are employed for the investigation of children with proven UTI:

1. Ultrasound will provide basic information on the structure of the urinary tract (Fig. 18.12). Kidney sizes should be recorded with reference to centile charts based on the child's height. Ultrasound is useful in the detection of obstruction of the urinary tract and bladder abnormalities as well as stones and gives an estimation of postmicturition residual volumes. It is relatively cheap and requires no radiation. However, ultrasound is operator-dependent and is difficult in uncooperative children. It is not useful for the detection of subtle renal scars and does not detect vesicoureteric reflux, which may be present with a normal ultrasound especially in the newborn period.<sup>54</sup>
2. Dimercaptosuccinic acid (DMSA) demonstrates acute renal involvement in UTIs and is the best technique for detection of scars and determining differential renal function (Fig. 18.13). A DMSA scan performed during or soon after the acute illness may show acute defects of the renal parenchyma, which do not necessarily result in permanent scars<sup>55</sup> and DMSA should therefore be delayed for 6 months after the infection if using this technique to determine permanent renal damage.
3. Micturating cystourethrogram (MCUG) is the 'gold standard' for detecting and grading vesicoureteric reflux. MCUG permits identification of posterior urethral valves and bladder anomalies (e.g. ureteroceles, diverticulae). The MCUG is the most traumatic of the imaging investigations for UTI<sup>56</sup> and carries a significant radiation burden.<sup>57</sup> There is also a risk of introducing infection and antibiotic prophylaxis should be prescribed for 24 h prior to the MCUG and for 48 h following the MCUG (usually trimethoprim).
4. Abdominal X-ray (AXR) is generally only indicated where stones are suspected from the history, or there is the suggestion of a spinal abnormality on abdominal examination.
5. Isotope renography (MAG 3 or DTPA) is useful for detecting VUR in cooperative children, usually age 3+ (Fig. 18.14). This is the basis of indirect micturating cystography, which has a lower radiation dose than the direct MCUG. Although catheterization is avoided, the technique still requires i.v. injection of isotope. MAG 3 and DTPA will give information on drainage and therefore urinary tract obstruction. Excretion curves permit calculation of differential kidney function. MAG 3 is favored over DTPA as the resolution of the former is better. MAG 3 is useful for the detection of large scars but is less sensitive than DMSA in the detection of smaller scars.

## PREVENTION OF FURTHER INFECTION

Recurrence of UTI is common in children, with about 30% of girls having another UTI within 1 year.<sup>58</sup> Look for and treat constipation.

**Table 18.6** Antibiotics used in the treatment and prophylaxis of UTIs

	Treatment (dose in mg/kg/d)	Dose interval (h)	Prophylaxis (dose in mg/kg/d)
Co-amoxiclav	75 mg i.v.	8	NR
	20–40 oral	8	NR
	amox content		
Amoxicillin	25–45 oral	12 (duo suspension)	NR
	amox content		
Amoxicillin	25 oral	8	NR
Trimethoprim	8 oral	12	2
Nalidixic acid	50 oral	6	12.5
Nitrofurantoin	3–5 oral	6	1
Cefotaxime	100 i.v.	12	NR
Cefradine	25–50 oral	8–12	NR
Cefuroxime	60 mg i.v.	8	NR
	6.25–25 oral	12	NR
Gentamicin	2 mg/kg/dose i.v.	Depends upon renal function and levels	NR

NR, not recommended for prophylaxis

(a)

(c)

**Fig. 18.12** Investigation in a 2-year-old boy with proven UTI: (a) ultrasound revealed normal left kidney (6.6cm) with right kidney (shown) 5.6cm and extensively scarred, especially at lower pole; (b) MCUG showed bilateral vesicoureteric reflux, gross right side; (c) DMSA shows scarring at both poles laterally of right kidney (40% of differential function).

(a)

(b)

**Fig. 18.13** (a) DMSA scan showing parenchymal defects in left kidney of 3-year-old with pyelonephritis. (b) DMSA scan in the same child 4 months later showing resolution of acute changes.

The following simple measures should be discussed at consultations to reduce the risk of further infections:

1. avoid local irritants (bubble bath, soaps);
2. avoid excessive clothing and nylon underwear;
3. maintain a good fluid input;
4. avoid excessive 'holding on' and not emptying the bladder adequately;
5. cranberry juice has been reported to prevent (not treat) UTIs in women with recurrent UTI.<sup>59,60</sup> There are no data in children;
6. live yoghurt/lactobacillus has also been shown in adults to prevent UTI.<sup>61</sup> Again, there are no conclusive data in children, however it would seem reasonable to consider for older children;
7. prompt treatment of UTI is likely to be as beneficial as prophylaxis.<sup>34,62</sup> Therefore the importance of early recognition and treatment of UTI should be stressed to the child's parents.

Uncircumcised febrile male infants have a higher prevalence of UTIs than circumcised male infants. In a recent meta-analysis, circumcision was associated with a significantly reduced risk of UTI.<sup>26</sup> These data do not, however, support the routine circumcision of boys to prevent UTI, rather, support the principle that circumcision should be considered in those with recurrent UTI or significantly increased risk of UTI.

### Prophylaxis

Antibiotic prophylaxis, given as a single dose at night has been shown to be beneficial in reducing risk of recurrent infections to 36% of the control group.<sup>63</sup> However, a recent systematic review suggests that most published studies to date have been poorly designed with biases known to overestimate the true treatment effect. Large, properly randomized, double-blinded trials are still needed to determine the efficacy of long-term antibiotics for the prevention of UTI in susceptible children.<sup>64</sup>

(a)

(b)

(c)

(d)

(e)

Fig. 18.14 (a) MAG 3 scan in 6-year-old boy with history of UTI and small right kidney on scan. (b–e) Indirect micturating cystogram showing gross reflux right side, as bladder empties, reflected in increased counts over right ureter and kidney.

Trimethoprim and nitrofurantoin are common choices for prophylaxis, trimethoprim seems to be better tolerated.<sup>63,65</sup>

### Screening for bacteriuria

There is no evidence that screening for bacteriuria in healthy children is of value in preventing renal disease and general screening programs are not advocated.<sup>66</sup>

### FURTHER MANAGEMENT OF CHILDREN WITH UTI

This will depend in part on the results of investigations. In the unusual situation where a child presents with an obstructive uropathy or stones,

a surgical consultation will be required. Children with suspected neurogenic bladder require further imaging, such as MRI scans of the spine and urodynamic evaluation of the bladder.<sup>58</sup> There is a significant group of children with dysfunctional voiding patterns (see under Wetting problems) who are prone to recurrent infections. Such children may require assessment of bladder emptying by ultrasound and stressing the importance of double or triple voiding. Children with recurrent UTIs may benefit from prophylactic antibiotics given for 6–12 months to break the vicious cycle of re-infection. The risk of 'breakthrough' infections due to antibiotic resistance can be reduced by 'rotating' trimethoprim (single dose at night) for 3 months, followed by nitrofurantoin (single dose at night) for 3 months.

**SUMMARY: MANAGEMENT OF UTI IN CHILDHOOD**

Guidance for the management of Urinary Tract Infection in Childhood has been produced in 2007 by the National Institute for Clinical Excellence (UK) (NICE). This guidance, currently in draft form, can be found at [www.nice.org.uk](http://www.nice.org.uk). In developing this guidance it has been acknowledged that further research is required to better understand the epidemiology of UTI in children and provide a robust evidence base for the management of UTI in children. In particular, well-designed randomized, double blinded, placebo controlled trials are now urgently required to determine the effectiveness of prophylactic antibiotics in the prevention of renal parenchymal defects in children with UTIs. The following algorithms in **Figures 18.15 and 18.16** detail the proposed NICE guidance for diagnosis and management of UTI in children.

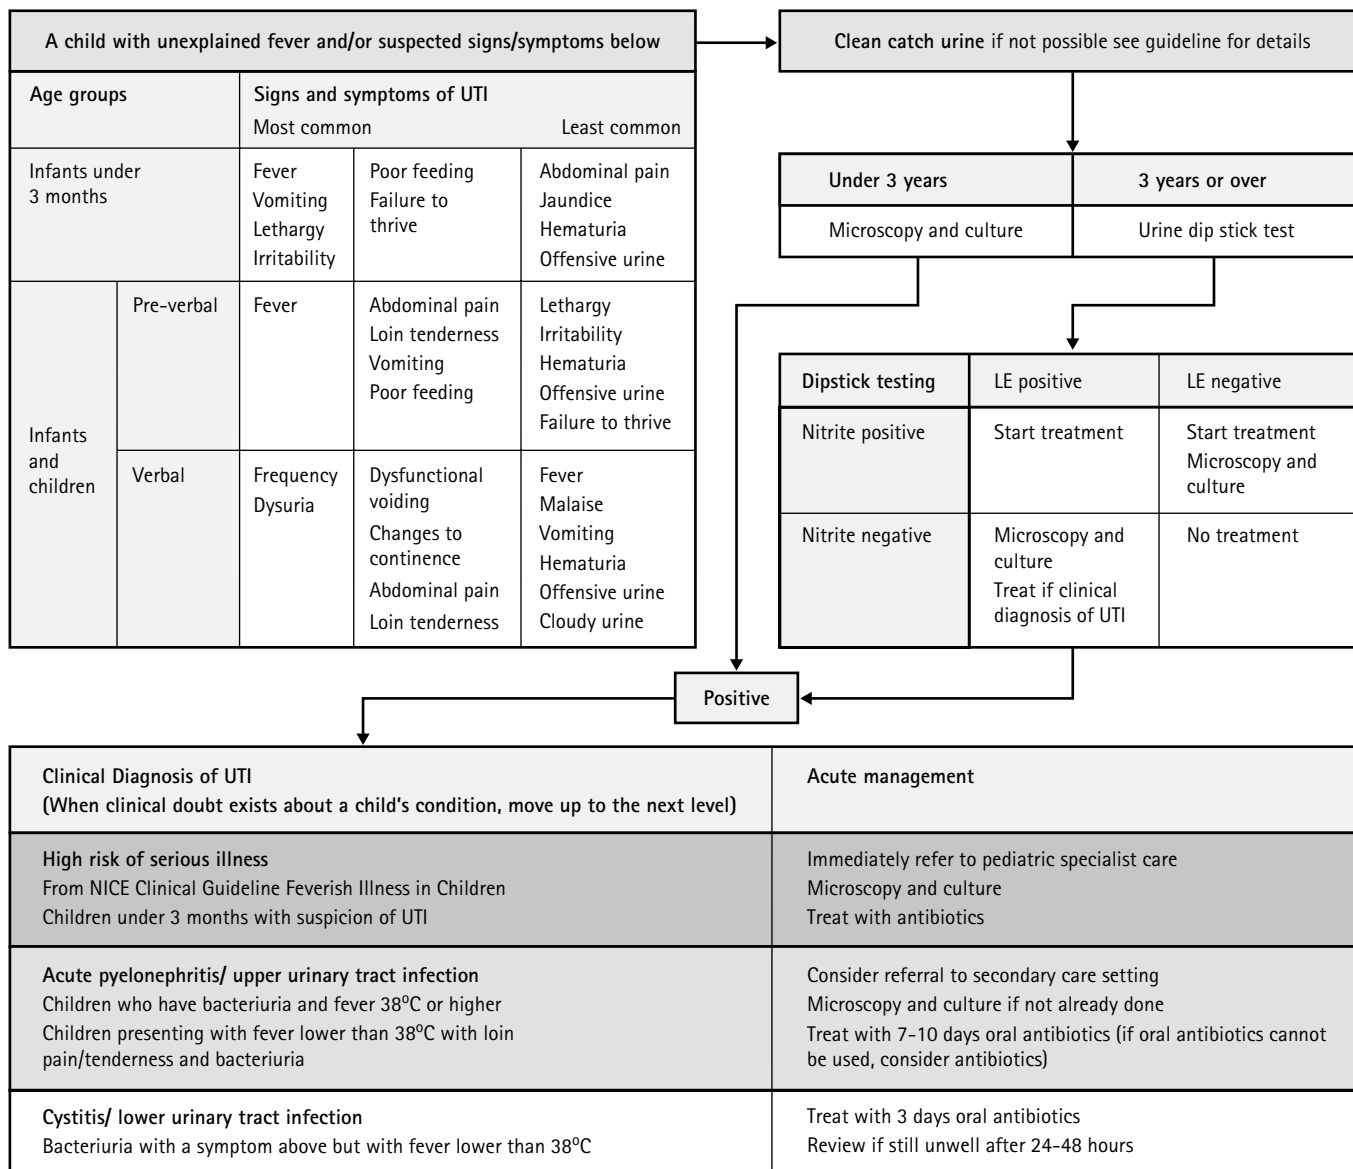

**VESICoureTERIC REFLUX**

Vesicoureteric reflux (VUR) is the retrograde passage of urine from the bladder into the kidneys and/or ureters. Primary VUR is likely to be due to a maturational abnormality of the vesicoureteric junction. VUR may also occur as a secondary effect of anatomical or neurological bladder outflow obstruction.

VUR is most commonly detected during the course of investigation of urinary tract infection in children, where it is reported to be present in 30–40% of cases.<sup>67,68</sup> VUR is also detected in 15–40% of infants investigated for antenatal hydronephrosis.<sup>69–71</sup> Primary VUR is associated with other anomalies of the urinary tract (duplex systems, renal aplasia and multicystic dysplastic kidney)<sup>72,73</sup> implying a common pathogenic link between these conditions.

**INHERITANCE OF VUR**

Hereditary factors are strongly implicated in the development of VUR, which has been reported to occur in up to 65% of first-degree relatives of affected individuals.<sup>74,75</sup> On the basis of these data, it has been proposed that VUR is inherited in an autosomal dominant manner. However, the search for the responsible gene(s) has, to date, proved elusive. Candidate loci have been identified on chromosomes 1p13, 6p21, 10q26, and 19q13<sup>76–82</sup> and a further search for candidate genes in sibling pairs is currently underway. The variable severity of VUR even in affected individuals within the same family, together with the association of VUR with diverse and complex anomalies of the urinary tract implies that VUR may be genetically heterogeneous.

**Fig. 18.15** NICE Clinical Guideline 'UTI in children': Diagnosis and acute management for first time UTI (with permission). See [www.nice.org.uk/nicemedia/pdf/cg54algorithm](http://www.nice.org.uk/nicemedia/pdf/cg54algorithm) for latest update.

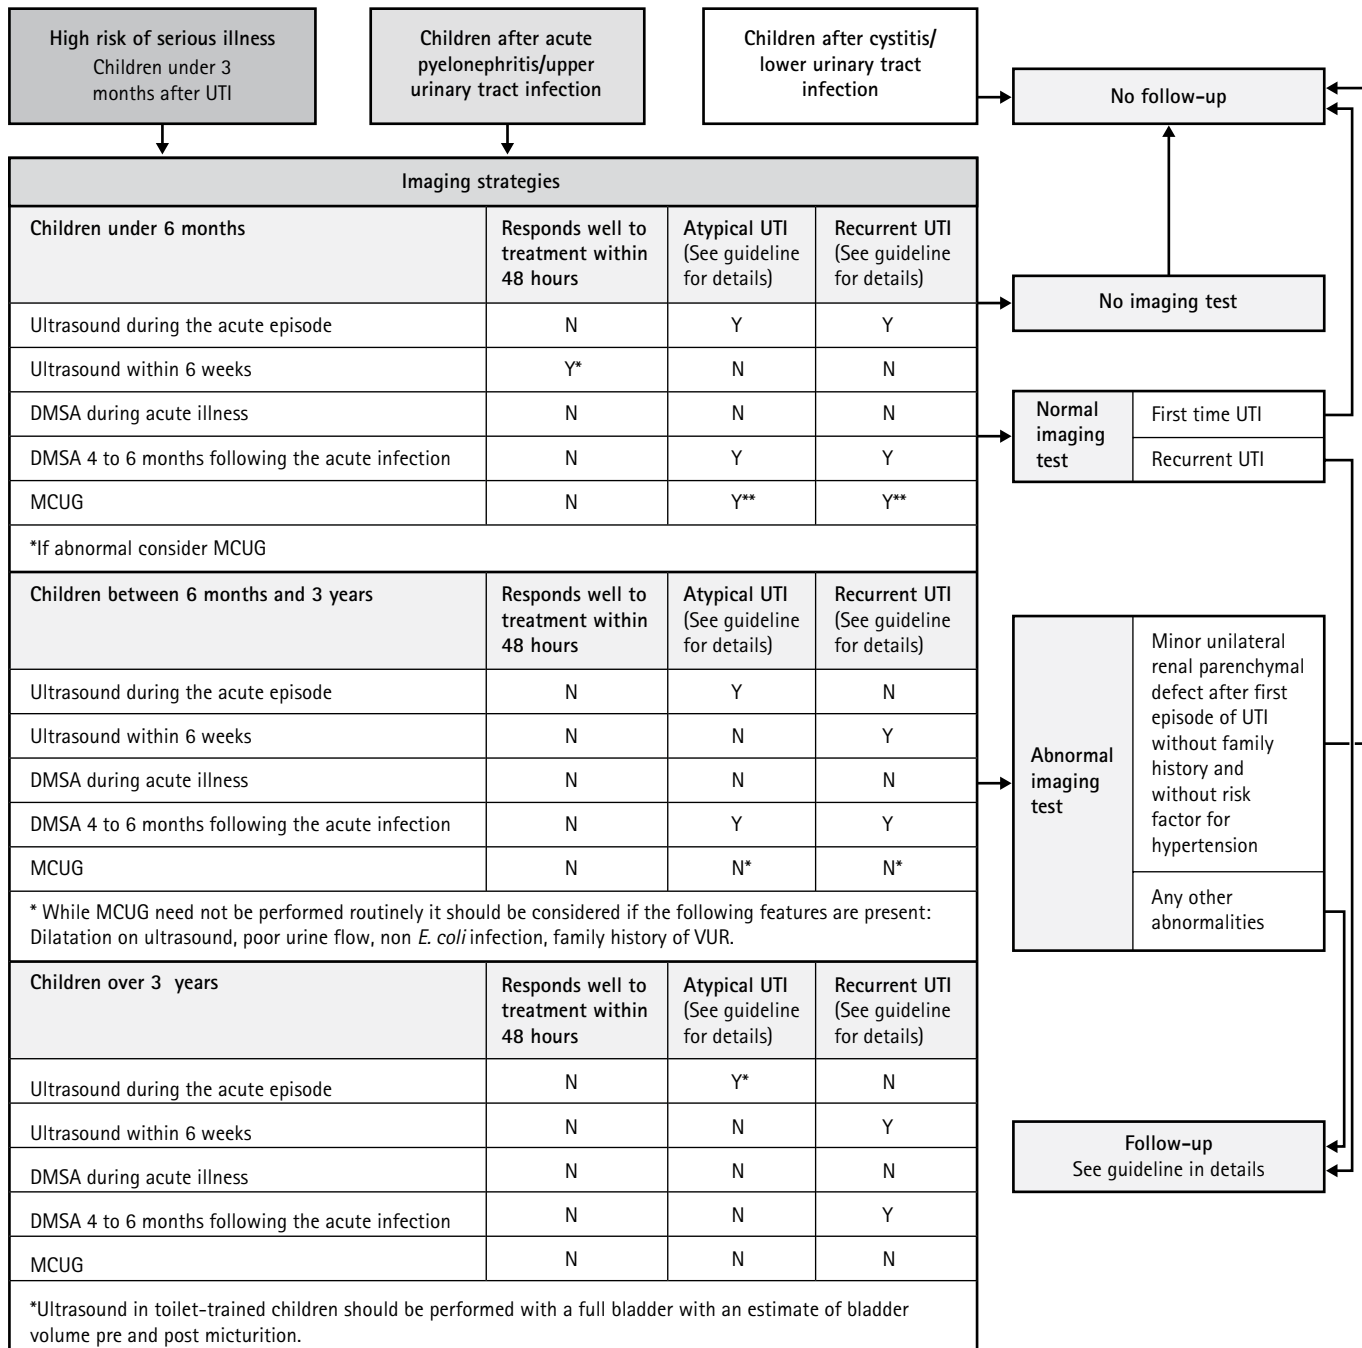

Fig. 18.16 NICE Clinical Guideline 'UTI in children' Imaging tests (with permission). See [www.nice.org.uk/nicemedia/pdf/cg54algorithm](http://www.nice.org.uk/nicemedia/pdf/cg54algorithm) for latest update.

**DIAGNOSIS OF VUR**

VUR is currently best detected by a MCUG, which is regarded as the 'gold standard' for assessing the presence of VUR. Radiopaque contrast medium is instilled into the bladder producing images of the bladder and renal fossae during filling and voiding.

Nuclear cystography is at least as sensitive for the detection of reflux as a standard VCUg and exposes the child to less radiation.<sup>83</sup> However, grading of reflux is less precise, and associated bladder abnormalities cannot be excluded with nuclear cystography. Therefore, a VCUg is preferred as the initial study for the initial detection of VUR. Nuclear cystography is used in follow-up of patients with known VUR.

**CLASSIFICATION SYSTEM FOR GRADING VUR (FIG. 18.17)**

The classification of grading of VUR is based upon the extent of filling and dilatation by VUR of the ureter, the renal pelvis and the calyces.<sup>67</sup>

**VUR AND RENAL SCARRING**

Renal parenchymal defects or scars are reported in approximately one third of children with VUR detected during the course of investigation of urinary tract infection.<sup>84</sup> The association of VUR and bilateral renal scarring is called 'reflux nephropathy'. This association was initially described by Hodson and colleagues in 1960 in children during

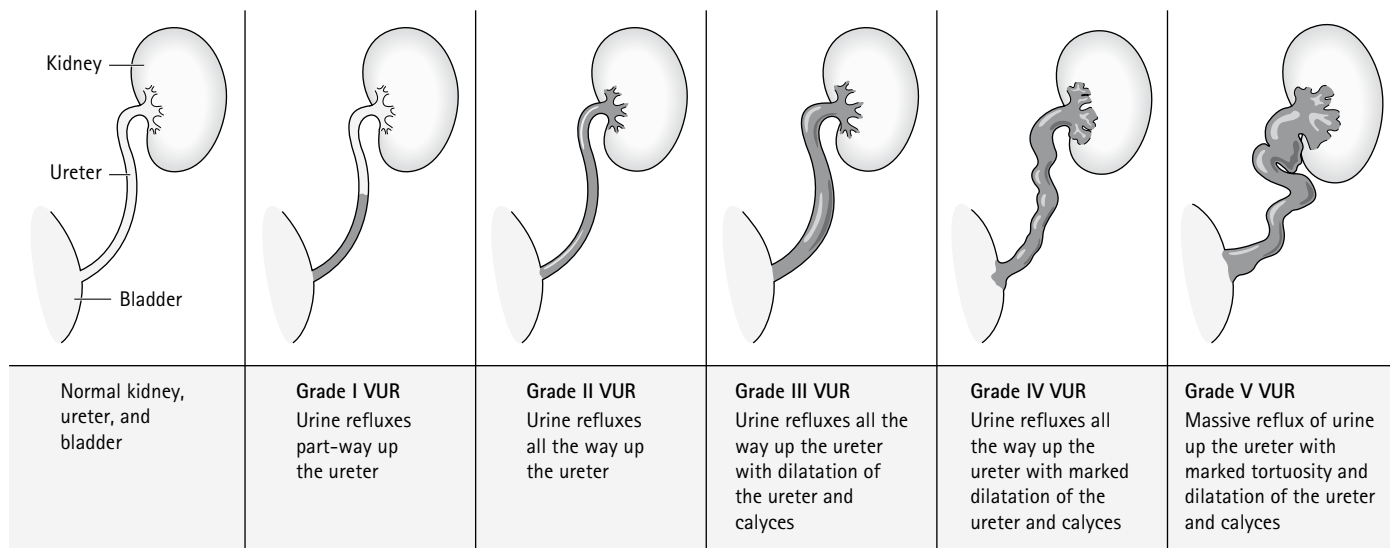

Fig. 18.17 VUR grading, reproduced with kind permission from Pamela Lally.

the course of investigation of children with UTI.<sup>85</sup> As a result of this and other observations, there was a call for the investigation of all children with their first UTI to look for the presence of VUR. During this period and subsequently, reflux nephropathy has been identified as the cause of up to 25% of cases of end stage renal failure in children and young adults.<sup>86</sup> Between 10 and 23% of children with VUR and scarring (either unilateral or bilateral) are reported at risk of developing hypertension.<sup>87</sup> There are, however important issues to consider pertaining to these outcomes:

Firstly, the risk of such adverse outcomes may have been overestimated in these reports for the following reasons:

1. Many children had secondary VUR as a cause of their end-stage renal failure (ESRF) in association with obstructive uropathy and other abnormalities of the urinary tract.<sup>88</sup> In a recent analysis of causes of ESRF in 686 UK children reflux nephropathy accounted for 7.2% of cases.<sup>89</sup>
2. The incidence of hypertension in association with renal scars may be overestimated as the reports are from specialist centers. Wolfish and colleagues reported a lack of association between hypertension, renal scarring and primary vesicoureteric reflux.<sup>90</sup>

Secondly, there is an historic assumption that renal scarring is both acquired and preventable. The evidence to support this assumption is sparse. In the last two decades antenatal ultrasound has led to the identification of infants with vesicoureteric reflux, with associated 'scars' in up to 30% of cases in the absence of infection, suggesting underlying dysplasia.<sup>71,91</sup> Similar rates of renal scarring have been reported in asymptomatic siblings of children with VUR.<sup>92</sup> Thus, rates of renal scarring are similar in children with confirmed VUR whether or not there has been an associated UTI. These observations, together with the finding that the development of new scars is very unusual after the first UTI raise the possibility that many children with assumed 'acquired' renal scars, in fact have 'congenital' reflux nephropathy that is not amenable to modification by treatment.

## MANAGEMENT OF CHILDREN WITH VUR

### Conservative management of VUR

The majority of children will have resolution of their VUR over time.<sup>93,94</sup> Infants with confirmed VUR receive antibiotic prophylaxis, generally until potty trained. At this stage prophylaxis is discontinued if the child has been free of infections. Many clinicians will undertake nuclear cystography to ensure that the VUR has resolved prior to discontinuing the antibiotics.

Even after resolution of VUR, children with confirmed scars will need regular review to monitor for hypertension and in the case of bilateral renal scarring, progressive renal damage leading to chronic renal failure.

MCUG is an invasive procedure that generates distress in the child and parents and carries a significant radiation burden. Therefore the only indication to repeat this should be where surgery is contemplated.

### Surgical management of VUR

In children with VUR identified following UTI, no significant differences in the risk for UTI or renal parenchymal injury were found in a meta-analysis of seven trials comprising 833 patients comparing antibiotic prophylaxis with combined surgery and antibiotics.<sup>95</sup> Surgical intervention should therefore be restricted to difficult cases with complex anomalies of the urinary tract. Such children are best referred to a unit where there is joint discussion between a paediatric urologist, nephrologist and radiologist. The standard reimplantation procedure is the Cohen or Leadbetter Politano technique, which involves changing the intramural segment of ureter through the bladder wall.<sup>96</sup> Newer, less invasive techniques, which involve endoscopic periureteral injection of polytetrafluoroethylene, glutaraldehyde cross-linked bovine collagen, dextranomer/hyaluronic acid copolymer, or polydimethylsiloxane have been trialled with promising results.<sup>97-99</sup>

### SCREENING OF ASYMPTOMATIC SIBLINGS FOR VUR

In any family where VUR is detected parents are advised to keep a close eye out for UTI in other children. Ultrasound and MCUG are currently offered to newborn siblings of children with known VUR.

### SUMMARY

At the present time, the diagnosis of VUR is most commonly made after urinary tract infection in childhood. The exact prevalence of VUR in childhood is unknown but is estimated to be in the region of 1–3%.<sup>100</sup> Although there is a strong association between VUR, UTI and renal scarring, evidence that vesicoureteric reflux is a modifiable risk factor in the development of kidney damage is weak. The effectiveness of antibiotic prophylaxis in the prevention of renal scarring has never been proven and urgently needs to be evaluated in a prospective, placebo-controlled trial.

## ENURESIS (WETTING)

### BLADDER MATURATION

Normal bladder function is established through a complex arrangement of autonomic and somatic nerves, integrated at various sites in the spinal cord, brainstem, midbrain and cerebral cortex.

In the neonatal period, micturition occurs in the region of 20 times per day due to uncontrolled detrusor contractions in a small capacity bladder. Bladder capacity increases during early childhood from 60–70 ml in the neonatal period to 120–140 ml at 4 years.<sup>101</sup> Bladder 'awareness' or sensation of bladder fullness develops in the first few years of life. Approximately 30% of 2-year-olds, 80% of 3-year-olds and 100% of 4-year-olds are able to indicate bladder awareness.<sup>101</sup> Concomitantly, children acquire the ability to suppress detrusor contractions voluntarily and coordinate sphincter and detrusor function. Daytime bladder control is achieved in most children by 4 years of age, while night-time bladder control is generally achieved by 5–7 years of age.<sup>102,103</sup>

### IDIOPATHIC (PRIMARY) NOCTURNAL ENURESIS (bed wetting)

Nocturnal enuresis is the involuntary loss of urine at night, in the absence of structural abnormality of the urinary tract, at an age when a child could reasonably be expected to be dry (by consensus, at a developmental age of 5 years).<sup>104</sup> Nocturnal enuresis is often termed primary in children who have never achieved a satisfactory period of night-time dryness (approximately 80%). The remaining 20% have secondary enuresis, in that they have had a period of dryness, usually for at least 6 months, before the onset of wetting. Secondary enuresis is often ascribed to an unusually stressful event (e.g. parental separation, birth of a sibling).

Diurnal enuresis (daytime wetting) is often associated with bedwetting, however, the two conditions are generally considered separately. Daytime symptoms should prompt investigations to identify underlying causes such as congenital malformations and neurogenic disorders (see later).<sup>105</sup>

In the UK nocturnal enuresis is reported to be prevalent in approximately 15–20% of 5-year-olds, 7% of 7-year-olds, 5% of 10-year-olds, 2–3% of 12–14-year-olds and 1–2% of those aged 15 and over.<sup>106,107</sup>

### PATHOPHYSIOLOGY OF NOCTURNAL ENURESIS

The pathophysiology of nocturnal enuresis is not clear, however the following factors alone, or in combination have been proposed to play a role (Table 18.7):

1. **Genetics.** There is often a family history of nocturnal enuresis in close relatives. Epidemiological studies show that if one parent has a history of nocturnal enuresis, his/her children are five to seven times more likely to have the disorder than those without an affected parent. Recent genetic studies in families with nocturnal enuresis have located two markers known as ENUR1 which flank the enuresis gene on chromosome 13.<sup>108</sup> Additional genetic loci for enuresis have been identified on chromosomes 12q and 22q11.<sup>109</sup>
2. **Delayed bladder maturation.** The high spontaneous resolution rate (approximately 15%/year<sup>110</sup>) of nocturnal enuresis implies a role for delayed maturation of a normal developmental process.<sup>111</sup> Nocturnal enuresis has been described as a genetically determined maturational disorder of the central nervous system due to an inhibition defect of the micturition reflex combined with a failure of conscious arousal in response to the sensation of bladder fullness.<sup>111</sup>
3. **Small bladder capacity.** Children with nocturnal enuresis have been noted to have a smaller bladder capacity than age-matched children who do not have nocturnal enuresis.<sup>112</sup>
4. **Decreased nocturnal antidiuretic hormone (ADH) secretion and polyuria.** Some children with nocturnal enuresis have decreased nocturnal secretion of ADH and increased urine production at night.<sup>113</sup> Since ADH secretion is thought to increase with bladder distension, small bladder capacity may contribute to this.<sup>114</sup>

Table 18.7 Differential diagnosis of enuresis

Diagnosis	Clinical indicators
Urinary tract infection	Other urinary tract symptoms, secondary onset wetting
Detrusor instability	Daytime symptoms of urinary frequency, urgency and urge incontinence usually with a minor degree of wetness and worse in the afternoons
Neuropathic bladder	Constant severe daytime wetting, soiling, lumbosacral dimple or nevus, abnormal gait, abnormal perianal or lower limb neurology, palpable bladder
Ectopic ureter	Constant dribble of urine between voidings
Posterior urethral valves	Poor urinary stream, daytime wetting, palpable bladder
Chronic renal disease	Chronic ill health, hypertension, palpable kidneys or bladder, anemia, polydipsia
Diabetes mellitus	Recent illness with weight loss, thirst and polydipsia

5. **Sleep disorders.** Elevated arousal thresholds have been reported in boys with nocturnal enuresis compared with non-enuretic boys,<sup>115,116</sup> however, sleep studies show that sleep patterns among children with and without enuresis are similar.<sup>117</sup>

### MANAGEMENT OF NOCTURNAL ENURESIS

This should include a careful history and physical examination. The history should attempt to:

1. establish toileting history and distinguish primary from secondary enuresis;
2. identify predisposing environmental factors such as stress and emotional disturbances (particularly important in secondary enuresis);
3. establish the frequency of wet nights, fluid intake (day and night), the presence of daytime wetting or symptoms (frequency, dribbling) and the presence of constipation;
4. ascertain whether there is a family history of nocturnal enuresis.

The physical examination of the child with nocturnal enuresis should include:

1. documentation of growth and blood pressure (poor growth and/or hypertension may indicate renal disease);
2. abdominal palpation (assessment of constipation, enlarged bladder, renal masses);
3. examination of the spine and lower limb reflexes (spina bifida occulta).

Urinalysis may be useful to evaluate the presence of diabetes mellitus, diabetes insipidus, water intoxication, and urinary tract infection.

If no underlying pathology is suggested from the history and examination ('isolated' nocturnal enuresis), imaging of the urinary tract is not generally required. Children with concomitant kidney disease, urinary tract infection, neurogenic bladder or daytime bladder problems and children with refractory nocturnal enuresis that has failed to respond to treatment<sup>118</sup> should be referred to a pediatrician/pediatric nephrologist/urologist for further evaluation.

### TREATMENT OF NOCTURNAL ENURESIS

In children aged between 5 and 7 years, the strategy of explanation, reassurance, star charts and praise or small rewards for dry nights is usually all that is necessary. For older children conditioning therapy with an enuresis alarm is the most effective treatment.<sup>119</sup> However, it is

hard work and the child and family need to be closely supervised and supported.<sup>120</sup>

The role of medication remains controversial but may give some short-term relief. Desmopressin, a synthetic analogue of antidiuretic hormone, can be given as a nasal spray or tablet but relapse is usual when treatment finishes.<sup>121</sup> Imipramine is also effective but has a higher incidence of side-effects and is potentially lethal to children in accidental overdose.<sup>122</sup> There may be benefit from combining desmopressin with an alarm but again there are significant relapse rates.<sup>123</sup>

### DIURNAL ENURESIS DUE TO BLADDER INSTABILITY

Wetting occurs during the day (and night), due to a functional disturbance of the detrusor muscle, which intermittently contracts during the filling/storage phase of the bladder at a time when the muscle is normally relaxed. The child has difficulty suppressing these contractions (normally an involuntary reflex), which therefore results in leakage of urine and urgency/urge incontinence before the child contracts the pelvic floor to stop micturition. The condition has a strong association with urinary tract infection and constipation, and emotional stresses may precipitate the problem in some children. Ectopic ureter is a rare cause of day- and night-time wetting and is suggested by a history of never having been dry in the day and dribbling of urine.

Treatment is again aimed at providing information and support along with establishing a routine of complete and regular emptying of the bladder to restore the child's confidence. Star charts and rewards may be helpful. Constipation must be vigorously treated and urine infection eradicated. If infections are proven, then the child will justify an ultrasound of the urinary tract with a check on bladder emptying. Day case assessment by experienced urology nurses may help to promote biofeedback training and promote compliance. An anticholinergic drug such as oxybutynin is usually effective but more conservative measures should be tried first. Some families require the support of a psychologist.

### NEUROPATHIC BLADDER

Myelomeningocele is the main cause of neuropathic bladder in the pediatric population. Although children with myelomeningocele are usually born with normal kidneys, the function of the obstructed neuropathic bladder can result in chronic kidney damage if unrecognized.<sup>124</sup> Neuropathic bladder/sphincter dysfunction is complex and these children require careful assessment in specialist centers with expertise in urodynamics. The detrusor and/or striated pelvic floor muscles may lack spinal motor innervation (inactivity); with lesions above the level of the spinal motor neuron pelvic floor muscles are overactive during filling and voiding. This dyssynergic pelvic floor activity constitutes a functional infravesical obstruction during voiding, implying a high risk of kidney damage because of high emptying pressures.

Clean intermittent catheterization has been the major advance in the management of children with neuropathic bladders. It provides a means of both promoting continence as well as safeguarding kidney function. Oxybutynin to inhibit detrusor overactivity is often combined with intermittent catheterization.

Small capacity bladders may require augmentation procedures using the patient's own ureter or bowel. At the same time, the appendix can be used to fashion a Mitrofanoff channel to the umbilicus or laterally for intermittent catheterization. Patients and families derive great benefit from close support by a specialist nurse.

### HEMATURIA

Children may present with gross (or macroscopic) hematuria, in which case they are usually quickly brought to medical attention, or they may be found to have microscopic hematuria on routine urinalysis using one of the many types of urinary testing strips (dipsticks). The degree of

hematuria is a poor guide to the severity of any underlying disease, but careful examination of the urine is an important non-invasive diagnostic tool (Fig. 18.18).

Urinary dipsticks are very sensitive for blood and it is important that the manufacturer's instructions are followed closely and the test repeated on further samples. Microscopic hematuria may be transient and can occur in the context of exercise or stress. Urine could also be contaminated with blood from the external genital area, urethral meatus or menstrual blood.

Gross hematuria may be described as coke- or tea-colored due to the oxidized heme pigment, but it may also be bright red, suggesting an extrarenal or lower urinary tract source. Inquiry should be made of other possible causes of red urine, such as foods (beetroot, berries and food dyes) and drugs (e.g. rifampicin). Hemoglobinuria and myoglobinuria should also be considered (Table 18.8). Urate crystals may give the urine a pinkish tinge when present in high concentration, particularly in young infants.

### URINE MICROSCOPY

Microscopy of fresh urine should be performed in all cases of hematuria to confirm the presence of red blood cells. Red cells hemolyze in standing urine, and fresh urine is also better for the identification of red cell or heme granular casts, which are strong pointers to a renal source for the hematuria (Fig. 18.19). Microscopy may also reveal pyuria and/or motile bacteria (suggesting infection) or crystals (using contrast microscopy). It may be possible to differentiate glomerular bleeding, when the red cells appear dysmorphic, from bleeding originating from the lower urinary tract, when the red cells tend to be of uniform shape and size.<sup>125</sup>

### CAUSES OF HEMATURIA

The causes of hematuria are listed in Table 18.9. Many of the causes can be differentiated on the basis of the history, examination and urinalysis. If gross hematuria is reported, then the child or observer should be asked if it is more prominent in the initial or terminal parts of the urinary stream. Initial hematuria suggests a urethral cause, but this line of questioning is unlikely to be as relevant as it is in the adult patient, where bladder tumors and stones are much more prominent causes of hematuria.

Fig. 18.18 Red cell granular cast. The outlines of many erythrocytes can still be made out clearly ( $\times 400$ ).

Table 18.8 Interpretation of urine dipsticks in renal disease

Feature	Method	Comment
pH	Methyl red Bromothymol blue	Normal range 4.5–8; typically in early morning urine pH 8: renal tubular acidosis, infection with urea-splitting organisms
Hemoglobin	Ortholidine + peroxidase	Detects hemoglobin and myoglobin; does not distinguish hemoglobinuria from hematuria False negative: ascorbic acid, rifampin (rifampicin) False positive: iodine, hypochlorite
Protein	Protein binding to tetrabromophenol blue	Only detects albumin, does not detect light chains False positive: alkaline urine
Glucose	Glucose oxidase peroxidase	Also detects fructose, lactose, galactose False negative: ascorbic acid
Leukocyte esterase	3-Hydroxy-5-phenolpyrrole + leukocyte esterase Griess's test	Detects intact or lysed leukocytes; sensitivity/specificity contentious False positive: vaginal contamination
Nitrite		Some organisms do not reduce nitrate Urine in bladder > 4 h for accurate result

## Infection

Hematuria associated with dysuria, frequency, enuresis and suprapubic discomfort suggests a hemorrhagic cystitis, while systemic upset, fever, abdominal pain or loin tenderness suggest pyelone-

phritis. Urinary tract infection, either proven or suspected, remains a common cause of hematuria. Since other symptoms and signs may be minimal, it is essential that appropriate urine cultures are taken before treatment is initiated.

Viral infections can result in acute hemorrhagic cystitis, particularly adenovirus types 11 and 21. This is usually a self-limiting illness with resolution towards the end of the first week.

Persistent dysuria, hematuria and sterile pyuria would suggest tuberculosis, in the right clinical context, but this would be a very rare cause of hematuria in children in Western countries. Infection with *Schistosoma haematobium* is an important cause of hematuria in endemic areas such as the Middle East and Africa. The ova can cause a granulomatous reaction in the bladder wall and lower ureter, and prompt treatment is essential (see Ch. 28).

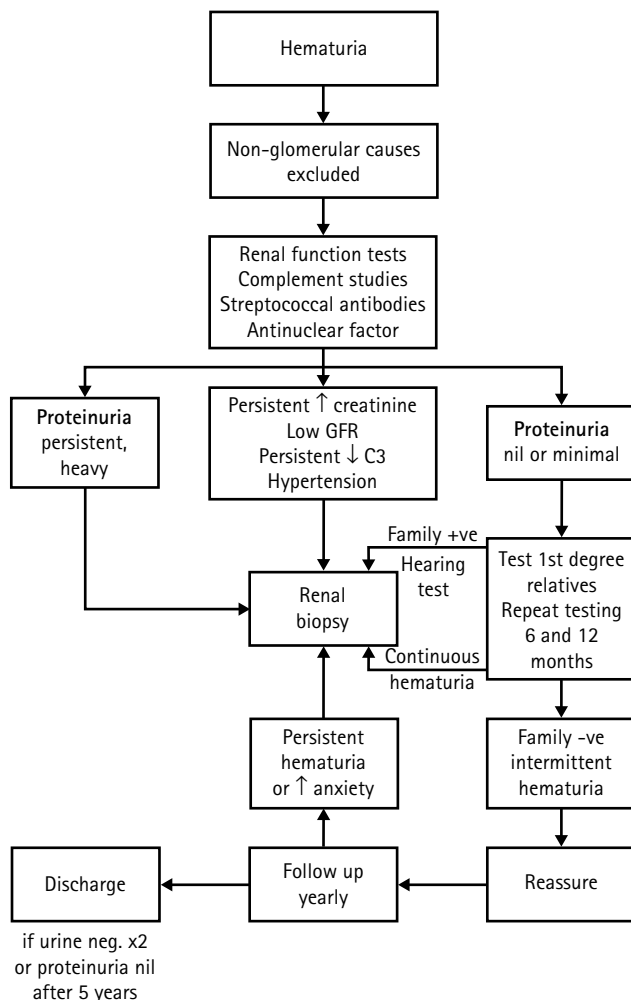

Fig. 18.19 A scheme for the management of children with hematuria.

Table 18.9 Causes of hematuria

1. Infection	a. Bacterial b. Viral c. Schistosomiasis d. Tuberculosis
2. Glomerular diseases	
3. Stones	a. Urolithiasis b. Idiopathic hypercalciuria
4. Trauma	
5. Anatomic abnormalities	a. Congenital abnormalities, e.g. pelviureteric junction obstruction b. Polycystic kidneys c. Tumor
6. Vascular	a. Arteritis b. Infarction and thrombosis c. Loin pain-hematuria syndrome
7. Hematological	a. Coagulopathies b. Sickle-cell disease
8. Drugs	e.g. Cyclophosphamide
9. Exercise-induced	
10. Factitious	

**Table 18.10** Investigations for children with renal calculi

1. Urinalysis including pH and urine for amino acids
2. Urine culture
3. Plasma biochemistry including creatinine, chloride, bicarbonate, calcium, phosphate, urate, magnesium levels
4. Second morning urine sample for calcium:creatinine and oxalate:creatinine ratios (24 h urine collections to confirm hypercalciuria or hyperoxaluria in older children)
5. Analysis of calculus if available

### Glomerulonephritis

The history of an upper respiratory tract or other infection, particularly if associated with gross hematuria, is suggestive of some form of acute postinfectious glomerulonephritis. Recurrent macroscopic hematuria in the older child raises the suspicion of IgA nephropathy.

A positive family history of renal disease with or without deafness suggests the possibility of hereditary nephritis (see section on [Glomerulonephritis](#)).

### Renal calculi

#### Incidence

The incidence of urinary tract calculi in children is approximately 1–5/100 000 in resource rich countries. It is much higher in areas of the world where stone disease is endemic, e.g. the Middle East. In these areas, there are more likely to be urate calculi, whereas in Europe most children with stones will have them as a result of infective causes. These are more likely to occur in the presence of obstruction to the urinary flow combined with infection, reduced fluid intake and episodes of dehydration. Stone formation may also occur due to underlying genetic factors such as hyperoxaluria or tubular transport problems such as cystinuria and hypercalciuria syndromes.

#### Clinical features

The classical presentation of renal colic, common in adult patients, is rare in childhood. More often calculi are recognized as a result of investigations in children for urinary tract infection or hematuria. Many children are diagnosed incidentally when imaging techniques such as ultrasound are carried out for investigation of abdominal pain. Certain children are at high risk of renal calculi and these include ex-premature babies (risk factors include transient hypercalciuria and/or furosemide use), those who are immobilized or who have a neuropathic bladder. A family history of renal calculi should always be sought.

#### Investigation

Most stones are associated with infection and magnesium/ammonium phosphate complex. However, screening investigations, as listed in [Table 18.10](#), are necessary, as hypercalciuria and hyperoxaluria may both need treatment, and the amino acid profile should define cystinuria.<sup>126</sup> Rare inborn errors of purine metabolism, xanthinuria and 2,8-dihydroxyadenine due to adenine phosphoribosyl transferase deficiency need to be remembered.

#### Management

This will depend upon the severity of the presentation, but percutaneous nephrostomy to treat an obstructed kidney, due to stones, is rarely required. Renal ultrasound is the most sensitive method for identifying stones within the kidney or renal pelvis, as these will show as echobright densities casting acoustic shadows. Occasionally, ultrasound will miss ureteric calculi in a child with acute renal colic with or without hematuria. A plain abdominal X-ray and Intravenous Urogram (IVU) will possibly be required.

Extracorporeal shockwave lithotripsy (ESWL) can be successfully performed under general anesthesia in children, but may be less successful if the stone is very hard (e.g. cystine), if it is located at the lower pole

calyx or if it is very large and fragments are likely to obstruct the ureter. There is some evidence that ESWL causes a short term of reduction in renal function and may have long-term effects on developing kidneys.

Direct nephrolithotomy may be required for a large staghorn calculus in the renal pelvis. Other urological techniques such as percutaneous nephrolithotomy and ureteroscopy may be attempted in some children.

### Trauma

Hematuria is associated with an obvious history of a damaging event. There is often bruising and other signs of external injury. With increasing recognition of the spectrum of sexual abuse, it is important that a careful history be taken if the injury involves the anogenital region.

### Anatomic abnormalities

Although it is sometimes hard to equate abnormalities on X-ray with hematuria, there is no doubt that problems such as hydronephrosis, due for example to pelviureteric junction obstruction, can be a cause of hematuria. Although autosomal dominant polycystic kidney disease is increasingly recognized in childhood by the use of ultrasound scanning, it very rarely results in hematuria in the pediatric population.

The major kidney tumor of childhood is nephroblastoma (Wilms' tumor), and this usually presents as an abdominal mass, with one third of patients having associated hematuria, mainly microscopic. Bladder tumors are very rare in childhood<sup>127</sup> and so cystoscopy is rarely indicated, unlike the case in the adult population.

### Vascular and hematological causes

Hematuria may occur in the context of any child with a problem such as hemophilia, leukemia or sickle-cell disease. The hematuria in the latter condition is presumably due to sickling of erythrocytes in the hypertonic, hypoxic medulla, with resulting local papillary infarcts. It is unlikely to be the initial presentation.

Gross hematuria, associated with a palpable mass, in a newborn infant, would suggest renal vein thrombosis. Hematuria may be part of the symptom complex in a multisystem disorder such as polyarteritis.

The loin pain-hematuria syndrome, which predominantly affects young women, is rare in childhood and requires renal angiography in suspected cases.

### Drugs

There is an extensive list of drugs, poisons and ingested substances which can give rise to hematuria.<sup>128</sup> Cyclophosphamide is a well-recognized cause of a sterile hemorrhagic cystitis, and a high fluid intake should be maintained during the use of this drug. Other drugs such as sulfonamides can cause crystalluria.

### Exercise-induced

Hematuria may occur after severe exercise and has usually disappeared within 48 h. It would appear to have a glomerular origin and is an accentuation of the small amount of blood excreted by a number of people after heavy exercise.

### Factitious hematuria

This may be part of the spectrum of Munchausen syndrome by proxy, where the child's carer (usually the mother) adds blood to the urine sample after it has been passed. There may be other pointers in the history or behavioral observations, which suggest this diagnosis.<sup>129</sup> A forensic laboratory may be able to determine whether the origin of the blood is from the parent or child.

## INVESTIGATIONS IN A CHILD WITH HEMATURIA

The tests performed will depend upon the information provided from the history, examination and urinalysis ([Fig. 18.19](#)). Again, it should be stressed that *microscopy* on a fresh urine sample can be invaluable, as identification of dysmorphic red cells and heme granular or red cell casts (the urine should be centrifuged for 3 min at 3000 rev/min)

strongly suggests a nephritic process and the child will be investigated accordingly. A *familial* condition may be detected by testing the urine of all immediate family members, particularly in cases of persistent microscopic hematuria.

### Urine culture

A proven bacterial infection will lead to the appropriate investigations. Urine is rarely cultured for viruses, but should be considered in epidemics.

### Hematology

Full blood count and film. Coagulation tests if appropriate.

### Biochemistry

1. plasma urea, electrolytes, creatinine, calcium, phosphate, alkaline phosphatase, albumin, total protein;
2. urine calcium/creatinine ratio on second morning sample (if > 0.7 mmol/mmol confirm with a 24-hour collection).

### Radiology

1. An ultrasound of the urinary tract in experienced hands should define any hydronephrosis, masses, renal calculi, etc. A plain abdominal X-ray is not required routinely.
2. An i.v. urogram may be ordered to confirm any suspicion raised on the initial screening ultrasound or to define the level of obstruction if ureteric stones are suspected.
3. An MCUG or cystoscopy is *rarely* necessary in childhood, but may be indicated based on the history. If there is recurrent or persistent gross unexplained hematuria then cystoscopy during an episode may localize the bleeding to one kidney (in which an anatomic abnormality is probably present) or to both kidneys (making glomerulonephritis more likely).
4. Further radiological investigations may include CT scanning or MRI for renal masses, radionuclide scans to define parenchymal masses or rarely renal arteriography.

### Further tests for glomerulonephritis

Glomerulonephritis should be suspected if there are characteristic urinary changes or if the hematuria is persistent and no other cause can be found. The appropriate investigations will be discussed in detail later but should include:

1. throat swab for bacteria and viruses;
2. antistreptolysin O titer and other streptococcal antigens;
3. complement studies;
4. autoantibody screen including antinuclear factor antibody;
5. viral titers including screening for hepatitis B surface antigen.

### Hearing test

In cases of suspected familial nephritis (Alport syndrome), in which a high tone sensorineural deafness is present.

### Renal biopsy

This is never routine and is only performed when there are indications of a more serious and potentially progressive disease, such as: progressive or persistent renal impairment; hypertension; persistent hypocomplementemia; heavy proteinuria; a familial disease that has not been characterized; or a systemic disorder where therapy may be influenced by the histopathological findings, e.g. systemic lupus erythematosus (SLE). Renal biopsies are also carried out in children with persistent microscopic hematuria (usually of greater than 1 year's duration), often because of the family's request to know a specific diagnosis and prognosis (Fig. 18.19).

Only nephrologists or radiologists experienced in the technique should carry out a renal biopsy. They should have access to expert pathology advice, based on light and electron microscopy as well as immunofluorescence (or immunohistochemistry). In most instances, the biopsy is performed under ultrasound guidance in the sedated child. The biopsy can be carried out as a day case procedure with appropriate preparation of the child and family.<sup>130</sup> An open renal biopsy under

general anesthetic is only necessary in the very young child. In expert hands the morbidity associated with renal biopsy is low.

*The commonest cause of hematuria in childhood is infection*

*Children with macroscopic hematuria and persistent microscopic hematuria should undergo a renal tract ultrasound but rarely need cystoscopy*

*Hypercalciuria can cause hematuria and can be screened for by a second morning urine calcium/creatinine ratio*

## GLOMERULONEPHRITIS

Glomerulonephritis, or more simply nephritis, is both a generic term for several diseases, and a histopathological term signifying inflammation and proliferation of cells within the glomerulus. In many instances the inflammatory changes are initiated by immunological mechanisms, but in others the pathogenesis is unknown.

Injury may be limited to the kidney alone, or the immune or non-immune mechanisms may be part of a systemic disorder (Table 18.11).

There is still very little understanding of the specific events involved with glomerulonephritis, and so when therapy has been employed it has tended to be 'blunderbuss' in nature, with broad-spectrum immunosuppressive drugs such as corticosteroids, azathioprine and cyclophosphamide, or other therapies such as plasma exchange.

### PATHOLOGY

Many of the categories of so-called primary glomerulonephritis (Table 18.11) are based on histopathological descriptions obtained from renal biopsy specimens. The terminology is derived from changes that are found on light, electron and immunofluorescent microscopy (Figs 18.20, 18.21).

### CLINICAL PATTERNS OF GLOMERULONEPHRITIS

Patients with glomerulonephritis may present with:

1. asymptomatic *hematuria* and/or proteinuria;
2. *acute nephritic syndrome* characterized by hematuria, oliguria, edema and hypertension. The hematuria is heavy with red cell casts on microscopy. Proteinuria is variable;

Table 18.11 Classification of glomerular disorders

#### *Primary glomerulonephritis*

1. Immune complex glomerulonephritis
  - a. Postinfectious acute glomerulonephritis
  - b. IgA nephropathy (Berger disease)
  - c. Membranoproliferative glomerulonephritis (types I to III)
  - d. Membranous glomerulonephritis (idiopathic)
2. Anti-GBM-antibody-mediated glomerulonephritis
3. Uncertain etiology, e.g. minimal lesion glomerulonephritis, focal segmental glomerulosclerosis

#### *Glomerulonephritis associated with systemic disorders*

1. Immunologically mediated
  - a. Henoch-Schönlein purpura
  - b. Systemic lupus erythematosus and other collagen disorders, e.g. scleroderma
  - c. Polyarteritis nodosa, Wegener's granulomatosis and other vasculitides
  - d. Mixed cryoglobulinemia
  - e. Systemic infections (subacute bacterial endocarditis, shunt nephritis, syphilis, malaria, hepatitis B, HIV)
2. Hereditary disorders
  - a. Familial nephritis, e.g. Alport syndrome
  - b. Sickle cell anemia
3. Other conditions
  - a. Diabetes mellitus
  - b. Amyloidosis

Fig. 18.20 Light microscopy of a normal glomerulus. Part of the proximal tubule at upper left-hand corner and hilum on the right.

Fig. 18.21 Schematic depiction of the anatomy of the glomerulus and possible sites of immune complex deposition (CP, capillary space; EN, endothelial; EP, epithelial; GBM, glomerular basement membrane; M, mesangial cell). Deposits are in the following locations: 1, subepithelial lumps; 2, intramembranous; 3, subendothelial; 4, mesangial.

3. *nephrotic syndrome* characterized by heavy proteinuria leading to hypoalbuminemia and edema with hyperlipidemia. The urinalysis shows heavy proteinuria (+++ or > 5 g/L) with variable hematuria. Microscopy may show fatty casts and free fat droplets.

It is important to appreciate that there is a spectrum of clinical presentation and patients may have a mixed picture of nephritis/nephrosis. For example, the majority of children with Henoch–Schönlein purpura (HSP) have nephritis with asymptomatic hematuria and/or proteinuria, which usually resolves, but may progress into a nephritic syndrome. If the proteinuria is so heavy that hypoalbuminemia results, then the patient may have the clinical picture of nephrotic syndrome.

### ACUTE GLOMERULONEPHRITIS

Acute glomerulonephritis usually presents as acute nephritic syndrome. This is a constellation of clinical signs including acute fluid overload, hematuria (often 'cola' colored urine) and hypertension. Proteinuria is often present as is some degree of renal insufficiency. The etiology of acute nephritic syndrome is varied but is most commonly due to post-infectious glomerulonephritis of which group A beta hemolytic *Streptococcus* is the most frequent organism involved. Other

causes include SLE, antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, and Goodpasture syndrome (Anti-GBM disease) but any of the more chronic forms of glomerulonephritis may present with acute nephritis.

Initial investigations should therefore include the following:

- urine;
- urine microscopy: red cells and casts;
- protein/creatinine ratio;
- hematology;
- full blood count and film (for example to exclude haemolytic uremic syndrome);
- CRP/ESR;
- biochemistry;
- renal function: urea, creatinine, electrolytes (including calcium status) and acid–base status;
- immunology;
- C3, C4;
- antinuclear antibody (ANA), dsDNA (double-stranded DNA) Ab;
- ANCA;
- anti-glomerular basement membrane (GBM) Ab;
- microbiology;
- throat swab;
- ASOT (anti-streptolysin-O-titre);
- anti-DNAse B;
- urine culture.

### ACUTE POST-STREPTOCOCCAL GLOMERULONEPHRITIS (APSGN)

Group A beta hemolytic *Streptococcus* is the most common organism implicated in post infectious glomerulonephritis. In resource rich countries it usually follows a nasopharyngeal infection whilst in developing countries antecedent skin infections are more common.<sup>131</sup> Although the disease is uncommon in Western countries, it is still prevalent in many parts of the world where overcrowding, poor nutrition and widespread skin sepsis still prevail.

Other organisms that have been implicated in post infectious glomerulonephritis include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Escherichia coli*, *Salmonella* and *Mycoplasma* species. Viruses such as Coxsackie, ECHO, Epstein–Barr, varicella, hanta and influenza as well as rickettsial, fungal and parasitic organisms have also been etiological agents.

### Clinical features

Acute post streptococcal glomerulonephritis (APSGN) usually affects children aged 5–15 years but can occur at any age. The nephritic complication of streptococcal infection is commoner in males. The onset on symptoms usually occurs about 7–14 d after the pharyngeal infection but several weeks after skin infection (Fig. 18.22). Children present with features of an acute nephritic syndrome. There is often a history of general malaise, anorexia, abdominal pain and headache but the development of frank hematuria and generalized edema are often the features that bring the child to medical attention. Oliguria may only be revealed on direct questioning.

Examination may reveal signs of fluid overload including generalized edema, pulmonary edema, pleural effusions and occasionally congestive cardiac failure. Hypertension is found in 60–80% and rarely patients develop hypertensive encephalopathy with headaches, alteration in mental state, convulsions and coma.

### Investigations

The investigations are as for acute glomerulonephritis (p. 573)

Urinary abnormalities include hematuria, microscopic and macroscopic and variable proteinuria. Urine microscopy reveals numerous dysmorphic red cells and heme granular casts. Other findings include pyuria, white cell, granular and hyaline casts.

Fig. 18.22 Course of acute poststreptococcal glomerulonephritis.

A full blood count may demonstrate a mild normochromic, normocytic anemia due to dilution. Renal function tests including plasma electrolytes, bicarbonate, urea and creatinine may show a variable degree of renal impairment, hyperkalemia and acidosis. Serum albumin levels and total protein may be low but generally not to levels seen in nephrotic syndrome.

The diagnosis is confirmed by the association of evidence of a previous streptococcal infection together with the presence of hypocomplementemia. Throat swabs should be cultured but in addition blood should be sent to identify antibody titers to streptococcal antigens. The antistreptolysin O (ASO) titer is present in 16–18% of healthy children and may not rise after skin infections and therefore anti-DNAse B and hyaluronidase antibodies may be useful in making the diagnosis. Measurement of total hemolytic complement and C3 and C4 are essential in making the diagnosis. C3 is nearly always significantly low in APSGN, often to levels < 50% of normal. C4 is usually normal or very mildly depressed. Other immunological tests including antinuclear antibodies, anti-neutrophil cytoplasmic antibody, anti-glomerular basement membrane antibody (anti-GBM), immunoglobulin and cryoglobulin titers are done to exclude other diagnoses.

Radiological investigations include a chest X-ray to assess for cardiomegaly, pleural effusions and pulmonary edema and a renal ultrasound, which may show large bright kidneys in support of the diagnosis.

Renal biopsy is indicated only if there is significant deterioration of the renal function, nephrotic syndrome or other atypical features, particularly if any of the other immunological tests are abnormal, suggesting an alternative diagnosis. In rapidly progressive glomerulonephritis (a rapid progression of renal failure) renal biopsy may demonstrate extensive crescent formation. In APSGN the C3 levels normalize within 6–8 weeks and failure to do so would be another indication for renal biopsy at this stage to assess for an alternative diagnosis (usually membranoproliferative glomerulonephritis).

## Treatment

A 10-day course of penicillin is prescribed for the patient and any culture-positive family members. Although there is no evidence that it affects the natural history of the glomerulonephritis, it is known to limit the spread of the nephritogenic strains. The management of the acute nephritis is otherwise supportive and depends on the degree of renal impairment and hypertension. It may include careful fluid balance, diuretics, antihypertensives and management of electrolyte imbalance. In a small number who develop a rapidly progressive nephritis dialysis is required, although most can be managed conservatively.

## Prognosis

Children with APSGN can usually be discharged once renal function is improving and hypertension is controlled. Complement levels need to be rechecked at 6–8 weeks to confirm that these have normalized. Complete recovery occurs in over 95% of children with APSGN.<sup>132</sup> The incidence

of chronic renal insufficiency post APSGN is <1% although a small number may have persistent hypertension or proteinuria. Microscopic hematuria may last up to 1–2 years. Some patients with a pre-existing chronic glomerulonephritis may present with an exacerbation secondary to a streptococcal illness and persistence of urinary abnormalities may be an indication for renal biopsy, which can identify an underlying diagnosis.

Second attacks of APSGN are rare and there is no evidence that penicillin prevents future recurrences. Once the urinalysis, blood pressure and renal function have normalized the patient can be discharged from long-term follow up.

## IgA NEPHROPATHY

IgA nephropathy was first described in 1968 and is thought to be the most common primary glomerulonephritis worldwide. There is marked geographical variation in the incidence, IgA nephropathy accounting for 18–40% of glomerulonephritides in Japan, France, Italy and Australia compared with 2–10% in the UK, US and Canada.<sup>133</sup> Part of this variation may be due to the regional difference in practice. For example in Japan all children aged 6–18 have routine urinalysis screening thus identifying patients who might otherwise have failed to present to medical services for investigation. There is a 2:1 to 6:1 male-to-female ratio for IgA nephropathy, with the peak incidence in the second and third decades of life.

## Clinical features

The commonest feature is macroscopic hematuria, which has been reported in more than 80% of children from Europe and the USA. Asymptomatic microscopic hematuria with or without proteinuria is the second most common method of presentation with acute nephritic syndrome, nephrotic syndrome or a mixed picture being relatively unusual. The classical picture is of recurrent episodes of macroscopic hematuria occurring 1–3 d after an upper respiratory tract infection. This is in contrast with APSGN, where the latent period is about 7 d. Following acute episodes the macroscopic hematuria resolves but microscopic hematuria may persist with or without proteinuria. Acute renal failure, if present, usually resolves.

## Diagnosis

The condition is often recognized from the typical clinical pattern of recurrent episodes of macroscopic hematuria. Laboratory investigations are necessary to exclude other causes of hematuria: In particular, normal complements and ANA/dsDNA to exclude postinfectious glomerulonephritis and SLE, respectively. Serum IgA levels are only elevated in 6–16% of children and therefore not helpful in making the diagnosis. There is therefore no specific diagnostic test apart from the histological findings on renal biopsy.

## Renal biopsy

The diagnostic finding on renal biopsy is the presence of mesangial IgA, immunofluorescent deposits together with lesser amounts of IgG, IgM and C3. Light microscopy usually reveals mesangial proliferation and increased mesangial matrix. These findings also occur in HSP, which is histopathologically indistinguishable although clinical features differentiate the two. However, IgA nephropathy and HSP have been known to occur in the same patient separated by several years or in members of the same family, suggesting that the two conditions do have a common immunopathological basis.

## Treatment

There is a lack of multicentre randomized, controlled trials to assess the efficacy of treatment modalities in children with IgA nephropathy. Some small studies on the use of tonsillectomy have found a reduction in episodes of macroscopic hematuria but none have shown an effect on the progression of renal disease. There is some evidence in adults that fish oil supplements (FOS) may delay the loss of renal function but this has not been demonstrated in children to date.<sup>134</sup>

In children with significant proteinuria and/or progressive renal disease, angiotensin-converting enzyme (ACE) inhibitors +/- angiotensin II receptor antagonists<sup>135</sup> and rigorous control of hypertension are advocated.

The use of immunosuppression in the management of chronic IgA nephropathy remains controversial due to the lack of randomized, controlled studies but for those with a rapidly progressive glomerulonephritis small studies have shown a benefit from high-dose methylprednisolone, cyclophosphamide and plasma exchange.

The results of further trials involving ACE inhibitors, fish oils and methyphenolate are awaited.

### Prognosis

In the past it was thought that IgA nephropathy in childhood was a benign disease. It is known that about 25% of adults develop renal failure over 20 years. A long-term follow-up study of 241 Japanese children showed that 5% of children developed chronic renal failure by 5 years, 6% by 10 years and 11% by 15 years from the onset of the disease. Another study of 103 children found predicted kidney survival to be 94% at 5 years, 87% at 10 years and 70% at 20 years. The difference in outcome may relate to different populations. Poor prognostic features include older age at onset, proteinuria, hypertension, renal impairment and glomerulosclerosis on renal biopsy.

In children with intermittent macroscopic hematuria with or without persistent microscopic hematuria there is little to be gained from renal biopsy as no specific treatment is available. If proteinuria is present then biopsy is advised to make the diagnosis and exclude other diagnoses which may benefit from treatment. Some advocate renal biopsy if microscopic hematuria persists for more than 1–2 years in order to give a clearer prognosis and to allay parental anxiety. The results may also be relevant for future employment counseling, particularly with respect to the Armed Forces.

### HENOCH-SCHÖNLEIN PURPURA NEPHRITIS

HSP is the commonest vasculitis of childhood with an incidence of 10–20/100 000 per year. It is a small vessel vasculitis with characteristic skin involvement of a vasculitic rash on the extensor surfaces, particularly on the lower limbs, gastrointestinal symptoms and joint manifestations. Renal involvement is usually reported in between 28 and 60% of cases. This develops within 3 months in 97% of cases but may occur years later in a small number. Features include microscopic hematuria, proteinuria, a nephrotic/nephritic picture, renal impairment and hypertension.<sup>136</sup>

The natural history is that most patients make a good recovery with the incidence of severe long-term renal morbidity/mortality being about 1–2%.<sup>137</sup> The presence of a nephrotic or nephritic picture or renal impairment is a poor prognostic indicator and these patients should be considered for renal biopsy. The severity of the histological changes is a guide to appropriate therapy.

The histological changes vary from mild mesangial proliferation to diffuse proliferative changes with crescent formation or membranoproliferative changes. Immunofluorescence shows mesangial IgA deposits and is indistinguishable from IgA nephropathy.

The treatment of HSP remains controversial. There is some evidence to suggest that steroids may prevent development of renal involvement when given early in the disease course although this has not been confirmed by recent prospective randomized, controlled<sup>138</sup> studies. There is a lack of clear data on the treatment of established nephritis. However, as with IgA nephropathy, in those with severe disease there are reports of good outcomes using intensive immunosuppression.

Children with a history of HSP nephritis should be followed up long term. Although most will not have severe long-term sequelae there is a risk of hypertension and renal impairment even in those with mild disease at onset and girls are at increased risk of hypertension in pregnancy.<sup>139</sup> Therefore at minimum an annual check of BP and urinalysis is recommended.

### MEMBRANOPROLIFERATIVE (MESANGIOCAPILLARY) GLOMERULONEPHRITIS

This condition is uncommon in children and usually presents in the second decade of life. The clinical presentation includes asymptomatic microscopic hematuria +/- proteinuria, frank hematuria, nephrotic syndrome, renal impairment and hypertension. In about one third of children hypertension and elevated creatinine are evident at presentation.

Investigations may reveal similar features to that of post-streptococcal glomerulonephritis including a low C3 in over 50% of cases and raised ASO titer levels in some. However in APSGN C3 levels return to normal in 6–8 weeks. Therefore both the persistence of a low C3 and/or persistent heavy proteinuria/impaired renal function are indicators that a renal biopsy should be performed to distinguish these conditions.

There is also an association between partial lipodystrophy, low C3 and the presence of a C3 nephritic factor (autoantibodies that bind to and stabilize the C3 convertase of the alternative or classical pathway, thus resulting in continued complement activation).

Renal biopsy identifies three distinct types of membranoproliferative glomerulonephritis:

#### Type 1 MPGN

This is the most common form with glomeruli revealing an accentuation of the lobular pattern due to a generalized increase in mesangial cells and matrix. The glomerular capillary walls appear thickened and in some areas duplicated or split due to interposition of mesangial cytoplasm and matrix between the endothelial cells and glomerular basement membrane. Crescents may be present and may be associated with a rapidly progressive glomerulonephritis. Deposition of C3 and a lesser amount of immunoglobulin may be shown on immunofluorescence. Electron microscopy confirms the presence of deposits in the subendothelial and mesangial regions.

#### Type 2 MPGN

In this type the capillary walls demonstrate irregular, ribbon-like thickening due to the dense deposits. Electron microscopy reveals extensive homogenous electron dense material in the glomerular basement membrane in the region of but distinct from the lamina densa.

#### Type 3 MPGN

This is sometimes considered a variant of type 1. There are contiguous subepithelial and subendothelial deposits associated with disruption of the basement membrane.

### Treatment and prognosis

Overall this is a chronic progressive disease with 50% of patients progressing to end-stage renal disease within 10 years of diagnosis. The outcome for type 2 appears to be worse than for types 1 or 3. In view of the rarity of the condition large randomized trials are difficult to perform. However studies have shown a probable benefit in those treated with long-term alternate-day steroids in those with MPGN types 1 and 3.<sup>139,140</sup> Treatment with steroids should probably be reserved for those with nephrotic syndrome or renal impairment. There may be a benefit in using an ACE inhibitor in those with lesser degrees of proteinuria.

### Membranoproliferative glomerulonephritis associated with systemic disease

MPGN is usually a primary kidney disease without systemic manifestations. However the features of MPGN may be seen on the renal biopsies of patients with other conditions such as HSP, SLE or polyarteritis.

MPGN features may also accompany chronic infections such as subacute bacterial endocarditis, infected ventricular-atrial shunts, syphilis, hepatitis C, hepatitis B, candidiasis and malaria. The infecting organisms usually have low virulence and the host is chronically seeded with foreign antigen. The combination with host antibodies results in complexes being deposited in the glomerular mesangium, producing mesangial proliferation and interposition. Immune deposits are subendothelial

and in the mesangium. Hence, the disease is like type I MPGN with hypocomplementemia. If elimination of the infecting agent is achieved then the lesion may heal, but with scarring and there is a possibility of progression to renal failure.

Chronic infections may also produce the pathological changes of membranous glomerulopathy, focal glomerulosclerosis and focal and segmental proliferative glomerulonephritis.

## MEMBRANOUS GLOMERULONEPHRITIS

Membranous glomerulonephritis (MGN) is the commonest cause of nephrotic syndrome in adults, but is uncommon in childhood, accounting for less than 5% of pediatric patients undergoing biopsy for nephrotic syndrome. It very rarely causes hematuria alone. Membranous glomerulonephritis is defined by the histological appearances on light microscopy of diffuse thickening of the glomerular basement membranes without significant proliferative changes. On silver staining, the continuous subepithelial deposits give a spike appearance to the glomerular basement membrane, and immunofluorescent microscopy demonstrates granular deposits of IgG and C3, which can be also identified by electron microscopy.

### Clinical features

The disease can occur at any age, but is most common in the second decade

urinalysis, or it may present with nephrotic syndrome and, less often, macroscopic hematuria. The blood pressure and C3 levels are normal.

There is a lower threshold for biopsying children who present with nephrotic syndrome over 10 years of age, because of the likelihood of finding a condition other than minimal lesion glomerulonephritis, such as MGN. In practice, unless there are other unusual features such as hypertension children may be treated with a month of daily steroids and steroid resistance is the indication for renal biopsy. Membranous glomerulonephritis may occasionally be seen in association with SLE, drug therapy, such as gold or penicillamine, syphilis, hepatitis B virus infection and some cancers.

### Treatment and prognosis

Spontaneous remission is quite common with this pathology, and the present consensus is that children who are not clinically nephrotic are at only slight risk of developing renal failure in the long term and do not require treatment. However, children with a prolonged nephrotic syndrome may have a poor prognosis and alternate-day steroid therapy has been suggested. The small numbers of patients make randomized, controlled trials very difficult to perform in children. The persistent nephrotic state is best controlled with salt restriction, diuretics, lipid-lowering drugs and ACE inhibitors and sometimes anticoagulation.

## SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a disease of immune dysregulation that affects about 1 in 2000 individuals (see also Ch. 29 on bones and joints etc.) Children represent about 15–20% of all SLE patients. It is a multisystem disease that has a wide spectrum of manifestations. Diagnosis is based on the presence of four or more of the 11 identified criteria. These include clinical features together with immunological findings of a positive ANA and as DNA and hematological abnormalities such as hemolytic anemia, leucopenia and thrombocytopenia. Lupus is rare before puberty although onset in the first year of life has been recorded. The female-to-male ratio rises from 2:1 in prepubertal children to 4.5:1 in adolescents and 8–12:1 in adults. Black and Hispanic children have a higher incidence. Black children have a greater prevalence and more severe renal and neuropsychiatric disease.

Renal involvement varies from microscopic hematuria and mild proteinuria to nephrotic syndrome, renal impairment and hypertension. Since the overall prognosis of childhood and adult SLE is closely correlated with the nature of the pathological renal lesions, it is recommended that a kidney biopsy be performed on all patients presenting with renal involvement to establish the severity of the histological changes. These

range from normal, through mesangial hypercellularity to proliferative changes (focal or diffuse) and membranous changes.

### Treatment and prognosis

Mild nonrenal lupus such as skin and joint manifestations may be managed with nonsteroidal anti-inflammatories or hydroxychloroquine. For those with moderate disease but with mild renal disease corticosteroids are used. More aggressive therapy is required for major organ involvement with renal, cardiac or central nervous system involvement. This may include high-dose methylprednisolone, mycophenolate, cyclophosphamide, immunoglobulin and more recently rituximab, a monoclonal anti-CD 20 antibody. Plasma exchange has also been used in some patients with life-threatening disease. Azathioprine has been used as a steroid sparing agent in the long term to prevent steroid toxicity.

The prognosis has improved dramatically over the past 2 decades. In 1968 the 10-year survival was reported as 20%. In the last 10 years, 5-year survival of 78–92% and 5-year kidney survival of 44–93% are reported.<sup>141</sup> Survival rates of 94% after a mean follow up of 11 years in patients with biopsy proven lupus nephritis have also been reported. Following renal transplantation allograft survival is no different but children are 1.8 times more likely to die compared with patients without SLE.

## RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerular nephritis (RPGN) is a description of the clinical course of several forms of nephritis where there is acute renal insufficiency associated with the presence of extensive crescents on the renal biopsy. Such crescents may be found in poststreptococcal, membranoproliferative, lupus and HSP nephritis, ANCA-associated vasculitis such as Wegener's granulomatosis and microscopic polyangiitis as well as the glomerulonephritis of Goodpasture disease.

After the earlier mentioned forms of glomerulonephritis have been excluded, there remains a small group of patients with so-called idiopathic rapidly progressive disease. Since the identification of ANCA the truly idiopathic groups are less common. Often there is no evidence for immunological mechanisms and the C3 level is normal. All forms of RPGN have crescents, which are found on the inside of Bowman's capsule and are composed of fibrin, proliferating epithelial cells of the capsule, basement-membrane-like material and macrophages. The stimulus for crescent formation is believed to be the deposition of fibrin in Bowman's space as a result of necrosis or disruption of the glomerular capillary wall.

Severe crescentic nephritis is associated with ARF in association with a nephritic or nephrotic syndrome. Although there have been well-documented spontaneous recoveries of renal function with post-streptococcal and HSP nephritis, about 50% of patients will progress to end-stage renal failure within weeks or months after onset.<sup>142</sup> With such a rare condition it is hard to mount a controlled trial, but some patients improve with aggressive therapy combining immunosuppressive agents with anticoagulation and plasma exchange.

## ANCA-ASSOCIATED GLOMERULONEPHRITIS

### Wegener's granulomatosis

Wegener's granulomatosis (WG) is a systemic vasculitis associated with granuloma formation. It is a distinct clinicopathological entity characterized by the classical triad of necrotizing granulomas of the upper and lower respiratory tract, a disseminated small vessel vasculitis involving arteries and veins together with a necrotizing glomerulonephritis. It has been found to be associated with the presence of c-ANCA, a typical cytoplasmic immunofluorescence pattern of antineutrophil cytoplasmic antibodies. Renal involvement is variable but may include a RPGN picture which requires intensive immunosuppression.<sup>143</sup>

### Microscopic polyangiitis

Microscopic polyangiitis is a small vessel vasculitis associated with a focal segmental necrotizing glomerulonephritis. Histologically, it is similar to WG without the evidence of granulomas. It has also been associated

with the finding of ANCA but with a different perinuclear immunofluorescence staining pattern (p-ANCA). The renal manifestations predominate and this diagnosis may include what was previously considered to be idiopathic crescentic glomerulonephritis. Immunosuppression is again the treatment.<sup>144</sup>

### GOODPASTURE SYNDROME

Goodpasture syndrome is the association of pulmonary hemorrhage, glomerulonephritis and the presence of anti-glomerular basement membrane antibodies (anti-GBM antibodies) which are typically in a continuous linear pattern along the GBM. It is one form of a rapidly progressive glomerulonephritis which is extremely rare in childhood.

Hemoptysis is the usual presenting feature and pulmonary hemorrhage may be fatal. The finding of anti-GBM antibodies in the serum support the diagnosis but this is confirmed on renal biopsy. Treatment includes intensive immunosuppression with methylprednisolone and cyclophosphamide together with plasma exchange. The prognosis is worse for those with advanced renal disease at presentation but treatment is still required to treat pulmonary hemorrhage.<sup>145</sup>

A Goodpasture-like syndrome also occurs in patients with WG and microscopic polyangiitis but the diagnosis is supported by the identification of the associated antibodies (i.e. c-ANCA or p-ANCA).

### HEREDITARY NEPHRITIS (ALPORT SYNDROME)

Hereditary nephritis is not a homogeneous entity, as the clinical expression of the disease and the mode of inheritance can vary widely between families. The classic description of Alport syndrome was of a progressive hematuric nephritis associated with sensorineural deafness and ocular abnormalities such as anterior lenticonus and cataracts. In familial cases about 80–90% are X-linked dominant, 10–20% of cases are autosomal recessive and a few are transmitted in an autosomal dominant pattern. New mutations account for up to one fifth of individuals. The most common abnormality is the inheritance of mutations in the COL4A5 gene encoding the alpha-5 (IV) collagen chain which is found on chromosome Xq26–48. Patients with an autosomal recessive form are either compound heterozygotes or have homozygous mutations in the COL4A3 or the COL4A4 gene encoding the alpha-3 (IV) or alpha-4 (IV) chain, respectively on chromosome 2q35–37.<sup>146</sup>

The condition is generally more severe in male members of the family, with most (but not all) females remaining in good health throughout life. The prognosis is best based upon the progress of other affected family members, as there appears to be a correlation between deafness, ocular abnormalities, proteinuria and chronic renal failure.

Renal biopsy in the early stages of Alport syndrome shows only focal mesangial hypercellularity. There is progressive glomerular sclerosis, tubular atrophy, interstitial inflammation and foam cells (non-specific lipid-laden tubular or interstitial cells). Immunofluorescence is unrewarding, but electron microscopy may reveal irregular thickening, thinning, splitting and layering of the basement membrane of the glomeruli, with a lattice work appearance described as 'basket weave' (Fig. 18.23). These findings are very suggestive of Alport syndrome of the classical type but may occur in patients without an abnormal family history, suggesting a new mutation.

#### Clinical features

The disease is characteristically silent during childhood, but may present as an episode of macroscopic hematuria, an incidental finding of microscopic hematuria with or without proteinuria or following family screening after an affected individual has been identified. There is progression in the second decade of life, as sclerosis proceeds, and the proteinuria becomes heavier, with hypertension and renal failure. Nephrotic syndrome can occasionally occur at presentation, or late in the disease process. There is no effective treatment but careful control of blood pressure and the use of ACE inhibitors may delay the progression

Fig. 18.23 Electron microscopy of basement membrane in a child with Alport syndrome. Lattice work appearance.

of renal failure. Dialysis and transplantation will be required as early as the second or third decade of life. Anti-glomerular basement membrane nephritis is a rare but dramatic manifestation occurring in 3–4% of Alport syndrome transplanted patients.

The deafness is initially high frequency, but is progressive and may ultimately be quite profound, especially in males. It is wise to carefully assess the hearing of children with any type of inherited nephritis. This may be of more initial importance than the renal disease.

Female carriers of mutations in the COL4A5 gene may occasionally progress to renal failure and should also be followed up particularly to monitor blood pressure and proteinuria.

Genetic counseling is an important part of the overall management.

**A pattern of painless recurrent macroscopic hematuria after infections and persistent microscopic hematuria suggests IgA nephropathy.**

*Partial lipodystrophy is associated with membranoproliferative glomerulonephritis.*

*A family history of chronic renal failure and deafness strongly suggests Alport syndrome.*

### BENIGN HEMATURIA: SPORADIC AND FAMILIAL

In any child with persistent microscopic hematuria it is important to test the urine of all first-degree family members even though there is no clear history of familial nephritis. A familial recurrent hematuria syndrome is generally inherited as an autosomal dominant trait, but recessive examples may occur. The microscopic hematuria may sometimes be accompanied by short-lived episodes of frank hematuria with mild proteinuria. However, there is usually no impairment of renal function.

The condition is generally regarded as benign (synonym: benign familial hematuria) and hence not all children have been subjected to renal biopsy. Part of the reluctance to do so is because of the absence of therapeutic measures and the lack of a history of progressive nephritis.

However, even if the biopsy is normal on light microscopy and immunofluorescence, it may be possible to demonstrate changes in the GBM on electron microscopy.<sup>147</sup> Basement membrane nephropathy has been grouped into:

1. **Group 1:** Lamellation type, with features indistinguishable from Alport syndrome.
2. **Group 2:** Extensive thinning, commonly found in children with mild microscopic hematuria (thin glomerular basement membrane disease).<sup>148</sup>
3. **Group 3:** Idiopathic hematuria, with minimal basement membrane alteration.

The long-term outcome for types 2 and 3 is still uncertain but in the absence of a positive family history is usually regarded as benign.

However, cases of renal insufficiency have been described, even with minor GBM changes and so follow-up every 1–2 years with urinalysis, blood pressure and creatinine measurements is justified. In some patients with thin basement membrane disease COL4A3 and COL4A4 mutations have also been identified suggesting that these patients may have a variant of Alport syndrome.<sup>148</sup>

Children with hematuria and proteinuria have renal parenchymal disease until proven otherwise. However, the child with asymptomatic, low-degree, isolated hematuria and a negative family history is likely to have a favorable prognosis, and a renal biopsy is not initially warranted. However, prolonged clinic supervision can generate its own anxiety and a suggested approach is shown in [Figure 18.19](#).

### FABRY DISEASE (ANDERSON–FABRY DISEASE)

Fabry disease is an X-linked disorder associated with deficiency of the enzyme alpha-galactosidase A, resulting in the intracellular accumulation of neutral glycosphingolipids with terminal alpha-linked galactosyl moieties. Fabry coined the term ‘angiokeratoma corporis diffusum’. The angiokeratomas usually appear during the second decade of life presenting as dark red macules or papules of various size.

The nephropathy of Fabry disease typically manifests as mild to moderate proteinuria, sometimes with microhematuria, and end-stage renal failure usually develops by the fourth or fifth decade of life. Fabry disease is a multisystem disorder with involvement of the heart, kidneys, skin, peripheral and central nervous systems. Enzyme replacement therapy with i.v. agalsidase beta appears to control symptoms but also potentially reverses the disease process.

### NAIL–PATELLA SYNDROME

Nail–patella syndrome (NPS) is an autosomal dominant disorder consisting of hypoplasia or absence of the patellae, dystrophic nails, dysplasia of the elbows and iliac horns, and renal disease.

The nephropathy is usually benign and includes microhematuria and mild proteinuria, which usually appear in adolescence or young adulthood. Some patients develop nephrotic syndrome and mild hypertension and are at risk of progression to end-stage renal failure. The risk of renal disease is about 10%. Mutations in the LMX1B gene on 9q34 cause nail–patella syndrome but to date there are no correlations between phenotype and genotype.<sup>149</sup>

### OTHER SYSTEMIC DISORDERS ASSOCIATED WITH GLOMERULAR DISEASE

#### Scleroderma

Scleroderma, or progressive systemic sclerosis, is a rare multi-system disorder in children. Renal involvement is unusual at the outset, but can occur with progression of the disease, and is characterized by proteinuria, hypertension and renal insufficiency. Scleroderma renal crisis occurs, with the abrupt onset of malignant hypertension and oliguric renal failure. The angiotensin-converting enzyme inhibitor, captopril, has been used successfully in its treatment.

#### Vasculitis

Vasculitis is characterized by inflammation of small, medium or large blood vessels. Classification is difficult because of the heterogeneous nature of many of these conditions and the overlapping clinical features.<sup>150</sup> A new consensus classification of childhood vasculitides has recently been developed.<sup>151</sup> Vasculitis of small vessels occurs with HSP, microscopic polyangiitis and WG.

Kawasaki disease is the second commonest vasculitis of childhood affecting the medium and large arteries. Renal disease is unusual and is generally related to vascular disease. However hematuria and proteinuria may be present and acute renal failure associated with interstitial nephritis has also been reported. Takayasu’s arteritis is not associated with glomerular disease but hypertension can be a feature and renal insufficiency may occur secondary to poor blood flow.

### Polyarteritis nodosa

This is a necrotizing vasculitis of medium-sized muscular arteries with associated aneurysm formation. There is multiple organ involvement with angiographic features of aneurysms in hepatic, renal and abdominal vessels. In contrast to microscopic polyangiitis elevated antineutrophil cytoplasmic antibodies (p-ANCA) are usually absent. The prognosis will depend upon the organ systems involved, and can be improved with the use of corticosteroid and immunosuppressive therapy such as cyclophosphamide.

### Diabetic nephropathy

Diabetic nephropathy is a leading cause of ESRF in adult patients in Western societies and accounts for 16% of end-stage renal disease in the UK. Diabetic nephropathy develops slowly over 10–15 years. Diabetes mellitus in childhood is rarely associated with overt manifestations of renal disease but microalbuminuria (an excretion of 30–300 mg/d in an adult) is reported in up to 20% of children and this may progress into overt nephropathy.

The highest long-term incidence of nephropathy is found in those who develop type 1 diabetes between the ages of 11 and 20 years. The median time between the onset of proteinuria and ESRF is 14 years, for those diagnosed under the age of 12, and 8 years for those diagnosed between the ages of 12 and 20. Mogensen<sup>152</sup> described five distinct stages of renal dysfunction: renal hypertrophy and hyperfiltration; microalbuminuria; incipient nephropathy; overt nephropathy and ESRF.

Children should commence annual screening for microalbuminuria from 3 to 5 years after the onset of diabetes or from puberty. If microalbuminuria is identified management strategies should include tighter glycemic control, ACE inhibition and management of hypertension.

### Amyloidosis

Juvenile idiopathic arthritis (JIA) has become a common cause of secondary amyloidosis in children following the eradication of tuberculosis and chronic osteomyelitis in Western countries. However, it is very rare in childhood and only occurs after many years of severe disease. Renal vein thrombosis is a well-documented complication of renal amyloidosis. Confirmation of the diagnosis requires biopsy material. Immunosuppressive agents such as busulfan may be of benefit.

### PROTEINURIA

Although proteinuria is one of the cardinal features of renal disease, and a risk factor for deterioration in most renal conditions, its isolated occurrence may be a transient finding in healthy children. Proteinuria combined with hematuria is much more significant.

In the normal individual, minimal protein is filtered, because of the charge and size selectivity of the glomerular filtration barrier (which consists of capillary endothelial cells, the GBM, and glomerular podocytes on the outside). Proteins are negatively charged and are repelled by the filtration barrier, which contains sialoproteins and proteoglycans, such as heparan sulfate, which are negatively charged. In addition, the tight collagen meshwork within the GBM, and the overlying podocytes (also known as visceral glomerular epithelial cells) with their interdigitating foot processes, act as an effective size barrier, with little protein passing through the filtration slit diaphragms. Proteinuria may result from increased glomerular permeability due to:

1. loss of the negative charges in the filtration barrier;
2. An increase in the effective pore size or number due to direct damage to components of the filtration barrier;
3. The hemodynamic effects of angiotensin II and other vasoactive amines, which may explain the mild proteinuria seen with heart failure.

Albumin (MW = 69 000) is the predominant protein lost in the urine, but globulin excretion may also be increased.

Another type of proteinuria, *tubular proteinuria*, occurs when there is increased excretion of the normally filtered low-molecular weight proteins, such as immunoglobulin light chains and  $\beta_2$ -microglobulin (MW < 50 000). Tubular proteinuria occurs when proximal tubular reabsorption is impaired, as in Fanconi syndrome, or when the production is increased to a level exceeding tubular reabsorption capacity, e.g. in multiple myeloma.

## NORMAL VALUES

Most of the filtered protein is reabsorbed, and the normal daily protein excretion in a child is < 4 mg/h/m<sup>2</sup>, or < 150 mg/24 h in an adult. Albumin accounts for about 25% of the normal protein excretion, and after severe exercise, proteinuria may increase several fold, with the albumin excretion representing up to 80% of total urinary protein. 40% of normal urinary protein is of tissue origin, and the major protein in this group is the uromucoid or Tamm–Horsfall protein, which is produced in the distal tubule.

## DETECTION

Testing for proteinuria has been simplified by the use of dipsticks, which are impregnated with a dye, tetrabromophenol blue, and change color according to the quantity of protein present. The strips detect predominantly albuminuria, but a negative dipstick does not exclude the presence in the urine of low concentrations of globulins, hemoglobin, Bence Jones protein or mucoproteins. These would be detected by 3% sulfosalicylic acid, which detects all proteins. However, dipsticks predominate in clinical practice. It is important to appreciate that false-negative results can also occur with very acid or dilute urine, whereas false-positive results may occur in the presence of highly concentrated or alkaline urine (pH > 8) along with gross hematuria, pyuria and contamination with antiseptics, such as chlorhexidine.

Dipsticks are highly sensitive and cannot accurately measure protein excretion, which is best quantified using timed (preferably 24-hour) urine collections. However, obtaining accurate 12- or 24-hour urine collections in children can be difficult to accomplish. Single voided urine samples, which relate the concentration of both the protein and creatinine in the same sample, have a high correlation with 24-hour urine excretion rates. The urine protein:creatinine ratio can be used to estimate the severity, and follow the progress, of proteinuric patients. The normal urine protein:creatinine ratio is < 20 mg/mmol in the early morning urine sample.<sup>153</sup>

## Protein selectivity index

This has usually been measured by comparing the clearances of small and large molecular weight proteins, on the basis that diseases such as glomerulonephritis, which cause severe histological change to the glomeruli, are more likely to result in the urinary loss of large plasma proteins than are diseases such as minimal change nephrotic syndrome, in which there is no obvious glomerular injury. However, there is considerable overlap in the results and the test is no longer performed routinely. It is preferable to rely on clinical features and/or the response to corticosteroids in children with nephrotic syndrome.

The causes of proteinuria are listed in [Table 18.12](#).

## INTERMITTENT PROTEINURIA

Transient proteinuria may be found in patients with high fevers in excess of 38.5°C. The mechanism is unknown and the proteinuria usually resolves as the fever abates.

Proteinuria, like hematuria, may also follow vigorous exercise and usually resolves within 48 h of rest.

Postural or *orthostatic* proteinuria is important because it is a relatively frequent cause of referral to pediatric clinics. It is suggested by finding normal protein excretion (< 20 mg/mmol) in the first morning

**Table 18.12** Causes of proteinuria

<i>Intermittent proteinuria</i>
1. Postural (orthostatic)
2. Nonpostural
a. Exercise
b. Fever
c. Anatomic abnormalities, e.g. urinary tract
d. Glomerular lesions, e.g. IgA nephropathy
e. Random finding; no known cause
<i>Persistent proteinuria</i>
1. Glomerular
a. Isolated asymptomatic proteinuria
b. Damage to glomerular basement membrane, e.g. acute or chronic glomerulonephritis
c. Loss or reduction of basement membrane anionic charge, e.g. minimal change and congenital nephrosis
d. Increased permeability in residual nephrons, e.g. chronic renal failure
2. Tubular
a. Hereditary, e.g. cystinosis, Wilson disease, Lowe syndrome, proximal tubular acidosis, galactosemia
b. Acquired, e.g. interstitial nephritis, acute tubular necrosis, post renal transplantation, pyelonephritis, vitamin D intoxication, penicillamine, heavy metal poisoning (gold, lead, mercury, etc.), analgesic abuse, drugs

urine after being supine overnight and increased protein excretion in the upright collection. Long-term follow-up has suggested that orthostatic proteinuria, as an isolated finding, is benign. These patients do not need prolonged follow-up in the clinic, if the history and examination and other urinary findings are normal. However, it is important to note that patients with glomerular disease will often have an orthostatic component to their proteinuria, so that true orthostatic proteinuria should not be diagnosed unless the urine collected in the supine position has no protein detectable by routine methods.

## PERSISTENT PROTEINURIA

In these patients, the amount of protein present in the individual samples may vary considerably, but is persistent, unless it resolves as in acute glomerulonephritis. If the proteinuria is associated with additional evidence for renal disease, e.g. microscopic hematuria, then these patients are most likely to have significant pathology in the kidney or urinary tract.

## GLOMERULAR PROTEINURIA

In the majority of cases, persistent proteinuria is of glomerular origin. The degree of proteinuria may range from > 4 mg/h/m<sup>2</sup>, to < 400 mg/h/m<sup>2</sup>, when it is usually associated with altered levels of protein in the plasma and nephrotic syndrome. Acute and chronic glomerulonephritis are believed to produce proteinuria as a result of damage to the glomerular basement membrane, which increases the permeability to plasma proteins to a degree which overwhelms the tubular absorptive mechanisms. In conditions such as minimal change or congenital nephrotic syndrome, it is usually a highly selective loss of albumin as a result of loss of the glomerular anionic charge for reasons still to be elucidated.

There has been a great deal of interest in recent years in patients who develop proteinuria with a reduced renal mass. Evidence has accumulated that the remaining nephrons, in such patients, are subject to hyperfiltration damage, which produces progressive glomerulosclerosis.<sup>154</sup> Hence several long-term studies are evaluating the use of ACE inhibitors or angiotensin II, receptor antagonists to ameliorate the progression of renal disease.

## TUBULAR PROTEINURIA

The amount of protein in the urine resulting from tubular damage is usually not as great as with glomerular disease but it has occasionally been sufficient to result in a nephrotic syndrome. Transient overflow proteinuria may occur after repeated blood or albumin infusions, and increased secretion of tubular proteins may occur with urinary tract infection or transiently in the neonatal period. Many hereditary causes of tubular proteinuria are part of a Fanconi-type syndrome.

## PERSISTENT ASYMPTOMATIC PROTEINURIA

This is defined as proteinuria, in apparently healthy children, occurring without hematuria, but persisting on repeated testing over 3 months. Significant proteinuria (Uprot/Ucr > 20 mg/mmol) is usually an indication for proceeding with further investigations. These would include urine culture, full blood count, and blood chemistry including electrolytes, urea, creatinine, albumin and an accurate measurement of glomerular filtration rate. The serological tests are performed at the same time and will include antistreptolysin O, antinuclear antibodies, immunoglobulins and complement studies. A renal tract ultrasound and plain abdominal X-ray will usually exclude any significant urinary tract pathology. A renal biopsy will only be considered in those with confirmed proteinuria or when there are other abnormal tests, such as a decreased GFR, abnormal urinary sediment, hypocomplementemia or evidence of generalized vascular disease.

## NEPHROTIC SYNDROME

The nephrotic syndrome is characterized by:

1. heavy proteinuria (> 40 mg/h/m<sup>2</sup> or protein/creatinine ratio > 200 mg/mmol);
2. hypoalbuminemia (< 25 g/L);
3. edema (Fig. 18.24).

It should be noted that this definition is distinct from a nephritic 'syndrome' (i.e. glomerulonephritis), which is defined by glomerular hematuria +/- hypertension. It is possible for a patient to be nephritic, nephritic or nephrotic/nephritic depending on the underlying cause, and the following section describes diseases that cause primarily (or solely) a nephrotic state.

The incidence of all forms of nephrotic syndrome in childhood is 2–4 per 100 000 population, but this figure will vary according to the ethnic mix of the population. For instance, the incidence amongst Asian children in two cities in the UK was reported to range from 9 to 16 per 100 000, respectively.<sup>155</sup>

The predominant pathology is minimal change disease (MCD), with contributions from other pathologies such as focal segmental glomerulosclerosis (FSGS) and MPGN. This applies only in Caucasian populations, as around the world the pathology varies. For instance, in Africa it has long been thought that 'tropical nephropathy' (malaria, HIV, hepatitis B etc.) predominates, though this has been challenged,<sup>156</sup> with schistosomiasis being responsible for the majority of the cases in South America.

Nephrotic syndrome could be subdivided into congenital, idiopathic (primary) or secondary. Many of the secondary causes have already been mentioned, and include HSP nephritis, acute post-streptococcal nephritis, connective tissue disorders (e.g. SLE), toxic causes (e.g. drugs and heavy metal poisoning), sickle-cell disease, and amyloidosis.

## IDIOPATHIC NEPHROTIC SYNDROME

Minimal change disease accounts for approximately 85% of cases presenting in childhood but only 10% of cases in adults. The other histological types of mesangial proliferative and FSGS may well represent the spectrum of a single disorder with varying histological features. There are familial cases of MCD, but these appear to be very rare in the UK. The gene locus for steroid sensitive idiopathic nephrotic syndrome appears to be distinct from the NPHS2 gene, located on chromosome 1q25 that

Fig. 18.24 17-month-old male infant with nephrotic syndrome and gross generalized edema (anasarca).

has been found to be mutated in a subset of patients with early onset autosomal recessive FSGS (see p. 584).

The cause of minimal change nephrotic syndrome (MCNS) remains unknown. It is more prevalent in families with an atopic history, and some studies have suggested an abnormality of T cell function. Although broad-spectrum immunosuppressive drugs have been used to control the disease, there is lack of evidence for classical mechanisms of immunological injury.

In minimal change disease, the glomeruli appear normal or show a minimal increase in mesangial cells and matrix. The immunofluorescence studies are negative, and electron microscopy reveals gross podocyte foot process fusion, which is a nonspecific finding in any patient with heavy proteinuria.

## Clinical features

Minimal change nephrotic syndrome is more common in boys than girls (2:1) and usually occurs between the ages of 2 and 6 years. There may be an antecedent history of an upper respiratory tract infection and, certainly, these are well known to precipitate relapses in this condition. The presenting feature is usually edema, which is first noticed around the eyes (Fig. 18.24). Since the condition is so uncommon in general practice, many children are treated for allergic conditions before the true nature of the condition is appreciated. The edema may become generalized, with swollen limbs, ascites and pleural effusions with diminishing urine output. There may be lethargy, poor appetite, mild diarrhea and, sometimes, abdominal pain.

## Investigations

The diagnosis is suggested by simple urinalysis, which will show heavy proteinuria (+++ or > 5 g/L). About 30% of patients will have transient microscopic hematuria, but gross hematuria is rare. Heavy proteinuria can be confirmed by timed urine collections or by early morning urine protein/creatinine ratio (> 200 mg/mmol). Renal function is usually normal, but there will be a low serum albumin (< 25 g/L), with raised serum cholesterol and triglyceride levels. Swabs should be taken from the throat and any skin lesions, as well as a urine culture. Overt or covert infection can be the cause of steroid resistance. Serological tests such as complement studies, an ASO titer, hepatitis B surface antigen and antinuclear factor antibodies need only be measured in patients when there is a mixed nephritic/nephrotic picture. The traditional urine protein selectivity index can be omitted, because in terms of prognosis, the response to corticosteroids is more important.

Children between the ages of 1 and 10 years are very likely to have *steroid-responsive minimal change disease* and so prednisolone therapy is usually initiated without a renal biopsy. This latter procedure is recommended *before* treatment with corticosteroids when the nephrotic syndrome occurs:

1. onset at less than 6 months of age (congenital nephrotic syndrome types);
2. evidence of a mixed nephritic/nephrotic picture with hypertension and/or low plasma C3 (pathology other than MCD more likely);

A biopsy may be *considered* in children with nephrotic syndrome and:

1. onset between 6 and 12 months of age;
2. onset over 12 years of age (other pathology may be more likely);
3. persistent hypertension, microscopic hematuria, or low plasma C3;
4. renal failure – persistent and not attributable to hypovolemia.

## Complications

Children with nephrotic syndrome still have a 1–2% mortality rate. The two major complications are infection and thrombosis.

Peritonitis is the most frequent type of infection and *Streptococcus pneumoniae* is the most common organism. Gram-negative bacteria are also encountered. The reasons for the susceptibility may be multifactorial and include decreased immunoglobulin levels, ascitic fluid acting as culture medium and immunosuppressive therapy. While on corticosteroids the clinical findings may be masked, and so any child with nephrotic syndrome and abdominal pain should be carefully evaluated in conjunction with a surgeon. Although there are instances where an unnecessary laparotomy has been carried out on a child with primary peritonitis, before the edema and nephrotic state has been recognized, there are also instances of children with nephrotic syndrome and appendicitis. In the very edematous state, penicillin prophylaxis may be considered, but antibiotics to cover Gram-negative organisms should be used for any suspected peritonitis, until the cultures and sensitivities are known. Many authors now advocate polyvalent pneumococcal vaccine when the child is in remission, but this does not appear to be fully effective, as not all the serotypes are covered.

Chickenpox and measles are major threats to the immunocompromised child. It is likely that the child has received MMR, but if not, measles and varicella immunity status should be checked as part of the routine evaluation. Zoster immune globulin should be given if there is chickenpox exposure while taking high-dose prednisolone or alkylating agents and aciclovir given promptly if the condition develops.

Nephrotic children also have a tendency to arterial and venous thrombosis. The nephrotic syndrome is a hypercoagulable state with high levels of fibrinogen, factor VIII:R:AG and alpha-2-macroglobulin with a decrease of both functional and immunological antithrombin III.<sup>158</sup> The greatest risk of thrombosis appears to be when the albumin level is very low. Children with nephrotic syndrome should be seen for prompt assessment if they have a potentially dehydrating state such as vomiting and diarrhea.

Thyroid function should be checked in all children with persistent hypoalbuminemia, as loss of thyroid binding globulin can lead to low levels of available T3 and T4.

## Treatment

Hospitalization should only be required for the initial attack, when the diagnosis can be established, treatment initiated and the response evaluated. It will also give an opportunity to educate the patient and the family in what may be a frustrating chronic illness. Good education and efficient communication should enable further problems to be assessed and treated on an outpatient basis.

Bed rest does not need to be enforced, as the child will determine their appropriate activity level.

### Dietary advice

The traditional high-protein, no-salt-intake diet should be abandoned in favor of trying to maintain the recommended daily allowances of calories and protein in a child whose appetite is likely to be markedly diminished until on steroids.<sup>159</sup> When edema is present, a no-added-salt diet is advised, with avoidance of foods known to be high in sodium, particularly snack or processed foods.

### Diuretics

A moderate fluid restriction of 750–1000 ml is advocated in the edematous state. Diuretics should be used with caution in plasma-volume-depleted nephrotic patients, as they may be predisposed to fluid and electrolyte disturbances. Thiazide diuretics have little effect. Cautious use of loop diuretics such as furosemide (frusemide) (1–2 mg/kg/24 h), in combination with an aldosterone antagonist such as spironolactone 0.5–5 mg/kg/24 h (which may take several days to act), can be used to control the edema, until there is a diuretic response to the corticosteroids. Occasionally, metolazone (0.2–0.4 mg/kg/24 h), in combination with furosemide (frusemide), may be needed to induce a diuresis, but careful biochemical monitoring is required.

If there are signs of hypovolemia, such as abdominal pain (due to a contracted plasma volume), hypertension, oliguria, low urinary sodium excretion (<10 mmol/L) or evidence of renal insufficiency, then an i.v. 4.5% albumin infusion (1 g/kg) given over 3–4 h with careful monitoring and followed by furosemide (frusemide) (1–2 mg/kg) may replenish intravascular volume. For diuretic-resistant symptomatic edema, 20% albumin infusion (1 g/kg) can be added if intravascular volume is adequate, to promote loss of peripheral fluid. Albumin infusions are both expensive and potentially hazardous, as pulmonary edema could be precipitated if the volume status has been misjudged. Since most of the infused albumin is rapidly lost in the urine, there is little place for their routine use. Mannitol (5 ml/kg of 20% solution) and furosemide (frusemide) (2 mg/kg/dose) have also been used to treat diuretic-resistant edema.<sup>160</sup>

### Corticosteroid therapy

Corticosteroid therapy has been used in childhood nephrotic syndrome since the 1950s. Of those children who present with a typical illness, 95% will respond to steroid therapy within the first 4 weeks. Nephrotic syndrome is potentially a chronic disease with about 70% of patients suffering a relapsing course and therefore being at risk of adverse effects of repeated steroid treatment.

A number of steroid regimens have been suggested. The consensus regimen proposed by the British Association for Paediatric Nephrology<sup>161</sup> was prednisolone 60 mg/m<sup>2</sup>/d until the urine was protein-free for 3 d, followed by 40 mg/m<sup>2</sup> for 4 weeks. In a national audit conducted in the UK in 1998, this was found to be associated with a high relapse rate.

The current consensus on management is shown in [Figure 18.25](#), the major change being that daily prednisolone is now given in a dose of 60 mg/m<sup>2</sup> (maximum 80 mg) for a full 28 d followed by a further month of alternate day therapy at 40 mg/m<sup>2</sup> (maximum 60 mg). The increase in the initial steroid dose acknowledges the evidence that the relapse rate is reduced with increased duration of initial therapy.<sup>162</sup> However, it falls short of the 3-month duration of initial prednisolone therapy recommended by Hodson et al<sup>163</sup> in a meta-analysis of randomized, controlled trials. Nephrologists remain concerned about the possibility of

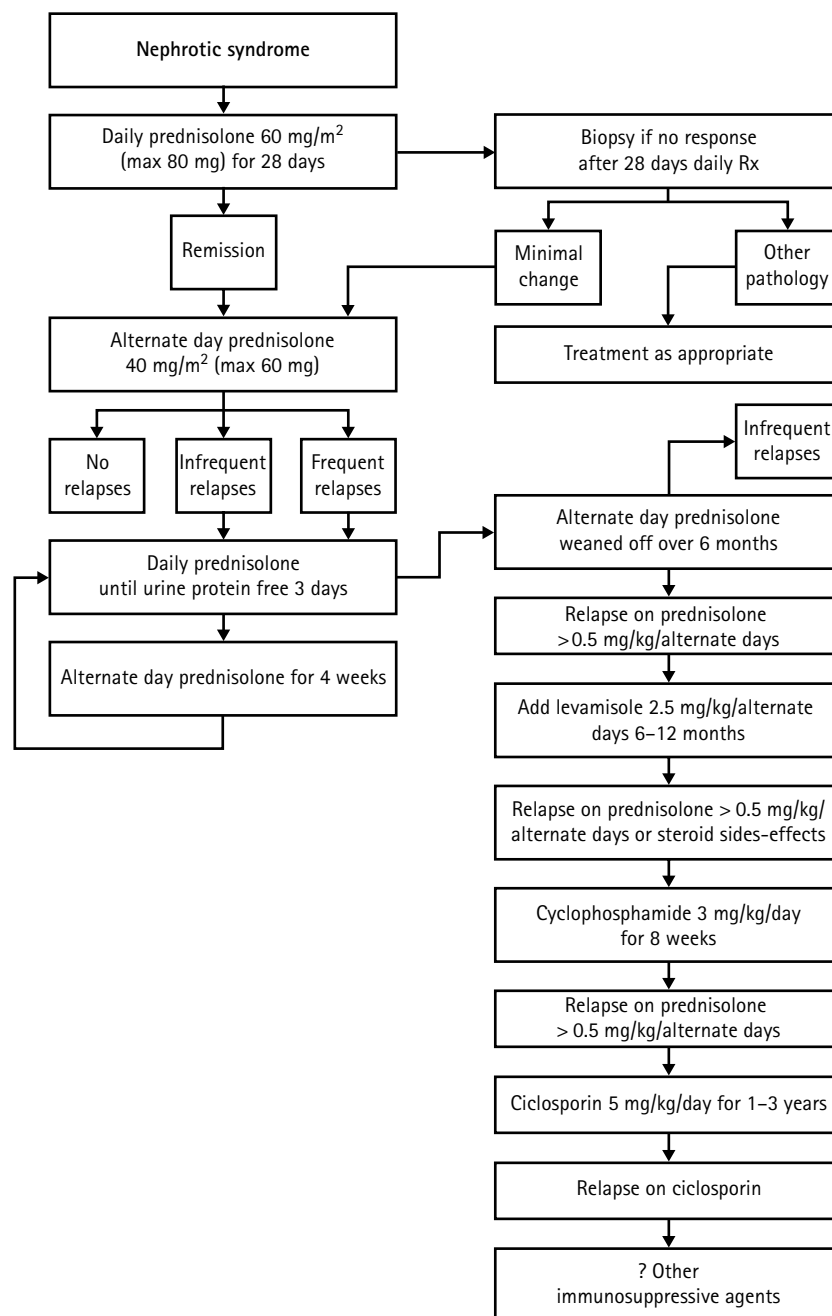

Fig. 18.25 Scheme for the management of children with nephrotic syndrome.

steroid side-effects, with this large initial dosage, and their effect on the hypothalamic pituitary axis.

Surprisingly, there is usually little gastric upset from the use of soluble prednisolone in children, and the more expensive enteric coated forms or drugs to control gastric acidity are not routinely prescribed. Children who have problems with vomiting or diarrhea should receive i.v. methylprednisolone in an equivalent dose to the oral prednisolone dosage and additional care should be taken to monitor blood pressure. It is important to exclude occult infection such as UTI as a cause of steroid resistance.

The parents should be told daily steroids may well alter the child's behavior as well as increasing the appetite. General dietary advice about avoiding excess consumption of snacks, etc. should be given. A steroid warning card should be issued, and the parents should report if the child is exposed to infections such as measles or chicken-pox, while on daily steroids. Immunization using live vaccines should

be avoided until the child has been off daily steroids for at least 3 months, but are permissible if the child is on alternate-day steroids ( $< 0.5$  mg/kg body weight/d). It should be noted that there is a reported increased risk of NS recurrence after meningococcal conjugate C vaccination. Overall, vaccines are best given when the child has been in remission for some months and inactivated, rather than live, polio should be utilized.

### Steroid-responsive patients

The family is instructed in the use of dipsticks for recording the first morning urine protein results, which should be carefully logged in a diary. This can serve as an individual record of the child's condition over a number of years.

When there is a relapse of proteinuria (3 consecutive days of heavy proteinuria [+++ or greater]), treatment may be withheld for up to 5 d (or possibly 10 if variable proteinuria) unless the child becomes

edematous. This is because some children will spontaneously remit during this period. If proteinuria persists, then remission is induced with daily steroids as before until the urine is protein free for 3 d, and then alternate-day corticosteroids are continued for 28 d. More than 75% of children with minimal change nephrotic syndrome will have at least one relapse.

### Frequent relapses or steroid dependency

If the child has two or more relapses within 6 months of initial treatment, or four or more relapses within any 12-month period (frequent relapser), then a slow weaning dose of alternate-day prednisolone may be considered, after inducing remission with daily steroids as mentioned earlier. The prednisolone may be weaned off over 6 months, and by this means steroid toxicity may be minimized.

Steroid dependency may be defined as those who relapse on two consecutive occasions as prednisolone is being decreased, or within 2 weeks of it being discontinued. If a child requires more than 0.5 mg/kg of prednisolone on alternate days to remain protein free, and particularly if there are signs of steroid toxicity, then alternative therapy should be considered. Such steroid side-effects would include stunting of growth, cataracts, obesity and behavioral changes, but alternative therapy to corticosteroids and/or the advice of a pediatric nephrologist will, preferably, have been sought before many of these side-effects are manifest. Alternative therapy consists of levamisole, cyclophosphamide, chlorambucil and ciclosporin (Fig. 18.25) which all reduce the risk of relapse in children with relapsing steroid-sensitive nephritis compared with prednisolone alone.<sup>164</sup>

### Cyclophosphamide

When cyclophosphamide was originally used in MCNS it was prescribed for 6–12 months and achieved 90% long-term remission. However, this was before gonadal toxicity was appreciated, and many young men were subsequently rendered oligo- or azoospermic. Consequently, the course of cyclophosphamide has been restricted to 8 weeks and is given after remission has been induced with daily steroids, which are then usually tapered off over 4–6 weeks. The restriction to shorter courses of 8 weeks means the remission rate has been reduced to approximately 50% at 2 years.

The potential toxic effects of bone marrow depression, hemorrhagic cystitis and mild alopecia can be minimized by close monitoring of weekly blood counts and clinic visits. Although there is no firm guarantee of future fertility, restriction of therapy to less than 16 weeks or 300 mg/kg body weight appears to be safe.<sup>165,166</sup> Nevertheless, this point needs to be discussed at length with the parents, as a prolonged remission cannot be guaranteed and there may still be long-term effects from the use of this drug. Chlorambucil does not appear to be superior to cyclophosphamide and its use has been more limited.

It was once customary to perform a renal biopsy on all nephrotic children *prior* to cyclophosphamide therapy. However, this is probably no longer justifiable if the patient is still *steroid responsive*. Even if FSGS changes are found on biopsy, the best prognostic indicator remains *steroid responsiveness*.

### Psychosocial

The current authors have found it helpful to provide the family of a child with nephrotic syndrome with an information booklet about the condition, as a great deal of anxiety can result with the clinical course of relapse and remission. In addition, the parents have benefited from attending a local parents' group, where they can discuss and share many of their anxieties.<sup>167</sup>

If a nephrotic child has been free of relapses for 5 years, then there is a strong chance of a long-term remission. However, some children may continue to relapse into adult life, and those who develop nephrosis earlier in life are likely to relapse more often.<sup>168</sup> With a decreasing relapse rate the urine tests can be performed less frequently, but the family should be cautioned to test urine at times of stress such as incidental infection.

## FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Focal segmental glomerulosclerosis (FSGS) is characterized on light microscopy by sclerosis or hyalinosis of glomeruli in a focal and segmental distribution. The involved area obliterates Bowman's space and is adherent to the capsule without epithelial cell proliferation. Epithelial foot process fusion is similar to that seen in MCD and electron microscopy should confirm the sclerosing nature of the lesion. There may be non-specific deposition of IgM and C3 in the affected segments. Tubular atrophy and interstitial fibrosis are proportional to the extent of glomerular damage.

The typical features of FSGS may be missed if the renal biopsy is too superficial, as the changes are more likely to be seen in the juxtamedullary region. FSGS usually carries with it an entirely different prognosis from minimal lesion, especially if the patient is steroid resistant. Again, the important practice point is that, if the patient responds to steroids, then whether the histology shows MCD and FSGS is generally irrelevant as long as steroid resistance does not develop. If the patient is steroid resistant, the best evidence is to use calcineurin inhibitors (ciclosporin A, or FK506) in conjunction with alternate-day steroids. Alternative immunosuppressives such as cyclophosphamide have a less consistent benefit. These agents may reduce the proteinuria sufficiently for the patient to remain edema free, with the attendant benefits.

Another mandatory investigation now becoming increasingly available is to screen for *NPHS2* mutations in any child with steroid resistance (see later), as these children will not respond to immunosuppression, and have a far smaller risk of post-transplant recurrence of disease.<sup>169–171</sup>

**Orthostatic (postural) proteinuria should be proven by finding no significant protein in the first morning compared to the afternoon sample.**

*Steroid responsiveness, not the underlying pathology, suggests a better outcome in idiopathic nephrotic syndrome.*

*Children with nephrotic syndrome are susceptible to life-threatening events such as thrombosis and infection.*

## FAMILIAL NEPHROTIC SYNDROME

An exciting development in recent years has been the elucidation of the genetic bases for many inherited cases of nephrotic syndrome. According to the molecular defect, these can present during the first year of life (congenital nephrotic syndrome), in early childhood, or in adolescence and adulthood. Congenital nephrotic syndrome was predominantly described in children of Finnish extraction (hence 'Finnish type') and is an autosomal recessive disorder. The major pathological feature is dilatation of the proximal convoluted tubules (microcystic disease), but this is very variable. The glomeruli may initially appear quite normal by light microscopy, but later show mesangial hypercellularity with an increase in matrix. Most glomeruli are immature. Both sexes are equally affected, and prematurity, with a placenta which weighs more than 25% of the infant's birth weight, is typical. Proteinuria is usually present at birth, and a frank nephrotic syndrome is usually apparent within 3 months of life. The clinical course is one of persistent edema and recurrent infections.

This condition was previously almost invariably fatal before 2 years of age. However, more aggressive feeding regimens with unilateral or bilateral nephrectomy and the appropriate management for end-stage renal disease has resulted in increasing numbers of children being successfully transplanted with normal growth and development.<sup>172</sup> Genetic counseling is very important, as antenatal diagnosis is possible by measuring the alpha-fetoprotein level in the amniotic fluid, as early as 15 weeks of gestation, or by screening for the gene mutation. The gene for the Finnish type is termed *NPHS1* and the protein product of this gene is called nephrin (see later).

Other histological types have been described in association with nephrotic syndrome in the first year of life (Table 18.13). Diffuse mesangial sclerosis is a steroid-resistant lesion with progressive loss of renal function, and renal replacement therapy may be required in the second

**Table 18.13** Causes of infantile nephrotic syndrome

Primary	a. Congenital nephrotic syndrome – NPHS1; NPHS2 mutations b. Diffuse mesangial sclerosis c. Minimal change nephrotic syndrome d. Focal segmental glomerulosclerosis e. Denys–Drash syndrome f. Nail–patella syndrome; Pierson syndrome; Galloway–Mowatt syndrome
Secondary	a. Syphilis b. Toxoplasmosis c. Cytomegalovirus d. Mercury e. Hodgkin's lymphoma or T cell malignancies

year of life. The gene defect responsible for this variant has not yet been identified. Patients with the histological appearances of minimal change NS have also been described in very young patients, and biopsy is essential, in order to predict which patients are likely or not likely to respond to a course of steroids.

In any female infant with early-onset nephrotic syndrome, chromosome analysis should be considered, as there is an association between nephrotic syndrome, pseudohermaphroditism and Wilms' tumor (Drash syndrome). Older female children with FSGS should be similarly screened, because of an association with pseudohermaphroditism and gonadal dysgenesis (Frasier syndrome).

### Molecular basis of familial nephrotic syndromes

One of the first genes identified as a cause for familial nephrotic syndrome was *NPHS1*, encoding nephrin (OMIM #602716), in the 'Finnish' type of nephrotic syndrome.<sup>173</sup> Subsequently patients have been described from many diverse populations around the world with a variety of mutations in this gene. A molecule which interacts with nephrin, called podocin (the gene is termed *NPHS2*), has been found to be mutated in congenital and early onset FSGS (OMIM #604766). In fact it is estimated that around 10–18% of children with 'acquired' FSGS in childhood have a podocin gene defect,<sup>172</sup> hence the importance of genetic screening to avoid heavy immunosuppression of children with mutations, who will be unresponsive.<sup>171</sup>

Autosomal dominant gene mutations in two familial nephrotic syndromes that present typically later in life (beyond childhood) have been identified. *ACTN4* coding for  $\alpha$ -actinin-4 was identified in patients with slowly progressive adult-onset FSGS (OMIM #604638), and the cation channel protein TRPC6 is mutated in late teenage and adult patients presenting with FSGS (OMIM #603965). Intriguingly, a signaling protein potentially in the TRPC6 pathway called phospholipase epsilon 1 (PLC $\epsilon$ 1, OMIM #608414) has been discovered to be mutated in a pedigree of early onset NS patients, some of whom responded to immunosuppression. The common link between all these proteins is that they are expressed almost exclusively in the podocyte, within the glomerulus (Table 18.14), thus emphasizing the importance of this cell in maintenance of an intact filtration barrier (Fig. 18.26).

**Fig. 18.26** Schematic representation of podocyte anatomy, showing adjacent podocyte foot processes on the glomerular basement membrane – indicating location of proteins mutated in familial nephrotic syndromes (see text for details).

### SYNDROMIC NEPHROTIC SYNDROMES

A number of syndromes present with nephrotic syndrome as a significant component. Different mutations in the *WT1* transcription factor gene (expressed in the podocyte), are responsible for Denys Drash syndrome and Frasier syndrome, respectively (see earlier, and Table 18.13). Pierson syndrome (OMIM #609049) is severe oculorenal syndrome, with early lethality, although milder nonlethal phenotypes have been reported. The mutation is in the laminin- $\beta$ 2 (*LAMB2*) gene, an essential component of the glomerular basement membrane. Microcephaly associated with congenital nephrotic syndrome, occasionally with hiatus hernia, has been described as the Galloway–Mowatt syndrome. Nail-Patella Syndrome (NPS) is characterized by developmental defects of dorsal limb structures (dysplasia of the nails, patellar aplasia or hypoplasia), nephropathy (about 22% have proteinuria), and glaucoma and is caused by heterozygous mutations in the transcription factor *LMX1B* (OMIM #161200).

### SECONDARY CAUSES OF NEPHROTIC SYNDROME

Secondary causes of infantile nephrotic syndrome are shown in Table 18.13. Syphilis can cause a membranous type of glomerular nephropathy, while cytomegalovirus and toxoplasmosis may be coincidental rather than causative agents. Mercury intoxication can cause a nephrotic syndrome, which usually responds to withdrawal of the toxic agent. Patients have been reported with lymphoma or other T-cell malignancies, and have developed MCNS.

### RENAL HYPERTENSION

#### MEASUREMENT OF BLOOD PRESSURE

The gold standard method of blood pressure measurement is with the mercury sphygmomanometer. The blood pressure should be measured with the weight of the arm supported after the child has been sitting quietly for at least 3 min using an appropriately sized cuff.<sup>174</sup> Oscillometric machines are also widely used in clinical practice. They may be preferred

**Table 18.14** Proteins expressed in the podocyte, mutated in congenital nephrotic syndromes

Mutated protein	Inheritance	Region of podocyte affected	Typical age of presentation
Nephrin	Recessive	Slit diaphragm	Infancy
Podocin	Recessive	Slit diaphragm	Infancy/early childhood
WT1	X-linked	Nuclear transcription factor	Infancy
$\alpha$ -actinin-4	Dominant	Actin cytoskeleton cross-linker	Adulthood
TRPC6	Dominant	Calcium channels	Late adolescence/adulthood
$\beta$ -laminin-2	Recessive	Anchorage to glomerular basement membrane	Childhood
PLC $\epsilon$ 1	Recessive	Cell signaling	Infancy/early childhood

for measurement of blood pressure in BP in newborns and young infants in whom auscultation is difficult.<sup>175</sup>

Since blood pressure increases with height and age the value of the blood pressure must be interpreted by comparison with normal data.<sup>175,176</sup> The trend of rising levels of blood pressure in populations as a consequence of the increasing prevalence of obesity leads to questions to about which 'normal' data is the most appropriate to use.

Ambulatory blood pressure monitoring (ABPM) can also be used to assess blood pressure in children and adolescents and provides information about the presence or absence of a normal diurnal variation. The values obtained should be compared with published normal data.<sup>177</sup> Absence of a night-time dip in blood pressure is associated with a greater risk of cardiac events in adults and is more common in children with secondary hypertension than primary hypertension. However based on the data presently available ABPM is too insensitive to allow primary hypertension to be distinguished from secondary hypertension.<sup>178</sup>

Hypertension is defined as an average systolic or diastolic BP greater than the 95th centile for age, gender and height on at least three separate occasions. Tables of normal values for blood pressure in children are presented in Chapter 21 (Cardiology). Decisions about the child's management should not be made on the basis of single measurements. The timespan over which the three measurements are taken depends on clinical circumstances. Reactive causes of hypertension for example emotion, activity or pain should be excluded.

White coat hypertension, a phenomenon well documented in adults also occurs in children. This is a phenomenon in which blood pressure that is elevated when measured in a clinical environment is normal when measured in the child's home. The significance of white coat hypertension is uncertain – there is evidence to suggest that some individuals with white coat hypertension will go on to develop essential hypertension.<sup>179</sup>

## ASSESSMENT OF THE HYPERTENSIVE CHILD

An accurate medical history and full clinical examination are essential to the evaluation of the child with elevated blood pressure. The purpose is to identify underlying causes, to detect any end-organ damage and to search for other cardiovascular risk factors.

### History

Important features in the history include the following:

- **Presenting symptoms:** headache, epistaxis, vertigo, impaired vision, abdominal pain, polyuria, muscle weakness, weight loss, palpitations, flushing, chest pain and breathlessness should be sought;
- **Previous history:** urinary tract infection, renal, cardiac or endocrine disorders and any history of neonatal intensive care should be documented;
- **Drug history:** prescribed and recreational drugs may be of relevance;
- **Family history:** hypertension, premature cardiovascular disease, diabetes and renal disease.

### Examination

Physical examination is normal in the majority of children with hypertension. However a careful examination should be undertaken. Centiles for height, weight and BMI should be documented. Particular attention should be paid to the cardiovascular system, seeking evidence of cardiomegaly and coarctation of the aorta. The blood pressure should be measured in two arms and a thigh. The child's volume status should be assessed. On abdominal examination abdominal masses and renal bruits should be sought. The examination of the CNS should include the cranial nerves and fundoscopy. Turner syndrome, Williams syndrome, neurofibromatosis, tuberose sclerosis and Cushing syndrome may all be associated with hypertension so their clinical features should be sought.<sup>180,181</sup>

If the child is symptomatic immediate referral to a specialised center and prompt treatment is indicated.<sup>176</sup>

### Investigation

The extent of the investigation is determined by the severity of the hypertension and the presenting clinical features. Initial investigation consists of urinalysis, urine culture, FBC, urea and electrolytes, creatinine, calcium, albumin and phosphate, supine renin, CXR, cardiac echo, renal USS. Plasma lipid profile and fasting glucose measurement may be indicated to evaluate co-morbidity that may contribute to overall cardiovascular risk.

Further investigation is indicated in those cases in which the blood pressure is greater than the 99th centile or clinical presentation or initial investigations suggest an underlying cause.

Urinary catecholamines, plasma aldosterone, plasma cortisol, thyroid function, DMSA or Mag 3 scan, magnetic resonance angiography, renal angiography (Fig. 18.27) with renal vein renin sampling, cerebral imaging and angiograph.<sup>176</sup>

## PREVALENCE AND CAUSES OF HYPERTENSION

The estimated prevalence of hypertension in children is 1–2%. Most studies indicate that of these approximately 70% have a detectable cause and 30% primary hypertension (Table 18.15). The most likely cause of hypertension depends on the age of the child. In all age groups secondary hypertension is most commonly due to renal disease (Table 18.16).

## TREATMENT OF CONFIRMED HYPERTENSION

The aims of treatment are to reduce blood pressure below the 95th centile and to prevent the long-term adverse effects of sustained hypertension. For children with renal disease, diabetes or evidence of target organ damage the aim should be to reduce blood pressure below the 90th centile.

The families of all hypertensive children should receive advice about lifestyle modifications that may offer benefits of reducing blood pressure. These include healthy eating to reduce excessive weight gain, reducing dietary sodium intake and taking part in regular physical activity. These measures may be sufficient to treat children with primary hypertension.

Indications for antihypertensive drug therapy include severe hypertension at presentation, secondary hypertension, evidence of target organ damage and inadequate response to lifestyle modifications. Controlling the blood pressure is important even if the etiology is not established.

There are six classes of oral antihypertensive agents for long-term treatment: diuretics, beta-blockers, ACE inhibitors and angiotensin-receptor antagonists, calcium channel blockers and alpha-blockers (Table 18.17).

In choosing an antihypertensive agent it is important to consider the child's volume status, cardiac and renal function. Diuretics and calcium channel blockers are useful agents in children with salt and water overload. It is good practise to avoid the use of ACE inhibitors in children with renal impairment until the presence or absence of renovascular disease has been evaluated. In specialized centers these drugs may occasionally be used successfully to control blood pressure in children with small vessel-renal disease. Hypertension caused by renovascular disease or phaeochromocytoma may cause increased peripheral vascular resistance and a pressure natriuresis leading to hypovolemia. Vasodilators are useful in treating these children but concomitant fluid replacement may be needed to maintain tissue perfusion and avoid precipitous falls in blood pressure. In severe heart failure beta-blockers and vasodilators may further compromise cardiac function. Diuretics or ACE inhibitors may be preferable in this situation.

The selected agent should be started at a low dose and increased gradually until blood pressure is controlled. If blood pressure control

2. Renal parenchymal disease
  - a. Scarring due to reflux nephropathy or obstructive uropathy
  - b. Acute or chronic glomerulonephritis
  - c. Hemolytic uremic syndrome
  - d. Renal dysplasia
  - e. Polycystic kidneys
3. Renovascular disease
  - a. Renal artery stenosis
  - b. Renal artery thrombosis
  - c. Renal artery aneurysm
  - d. Arteriovenous fistula
  - e. Vasculitis, e.g. polyarteritis nodosa
4. Renal tumors
  - a. Nephroblastoma
  - b. Hamartoma
  - c. Hemangiopericytoma

Table 18.17 Maintenance oral therapy for treatment of hypertension

<i>Vasodilators</i>		
Nifedipine	0.25–2 mg/kg/24 h	2 divided doses
Hydralazine	1–8 mg/kg/24 h	2–3 divided doses
Prazosin	0.05–0.4 mg/kg/24 h	2–3 divided doses
Minoxidil	200 µg–1.0 mg/kg	Single dose
<i>Beta-blockers</i>		
Propranolol	1–10 mg/kg/24 h	2–3 divided doses
Atenolol	1–4 mg/kg/24 h	Once/day if adequate renal function
<i>Diuretics</i>		
Furosemide	1–5 mg/kg/24 h	1–2 divided doses
Spironolactone	1–3 mg/kg/24 h	1–2 divided doses
<i>ACE inhibitors</i>		
Captopril	0.5–5 mg/kg/24 h	2–3 divided doses
Enalapril	0.1 mg–1 mg/kg/24 h	Single dose

is inadequate and the upper dose limit is reached or side-effects are encountered another agent from a different class is added.

The agents are often combined as follows: beta-blocker + diuretic, ACE inhibitor + diuretic, calcium channel blocker + beta-blocker, calcium channel blocker + ACE inhibitor.<sup>176</sup>

Beta-blockers have been considered the preferred first-line agent in children but data from adults indicating that ACE inhibitors are more effective in controlling blood pressure and beta-blockers are associated with a greater risk of non-insulin-dependent diabetes may lead to a change in prescribing for children.<sup>181</sup>

### Emergency treatment

Severe hypertension may cause hypertensive encephalopathy, cerebral infarction and hemorrhage, facial palsy, visual disturbance, cardiac and renal failure. These clinical situations constitute a medical emergency. Antihypertensive therapy must be introduced promptly but with intensive monitoring to produce a gradual reduction in blood pressure, allowing preservation of target organ function (Table 18.18). Every effort should be made to avoid abrupt falls in blood pressure, as these are hazardous, particularly for neurological function. The aim is to reduce the blood pressure by one third of the total desired reduction over the first 12–24 h. This is usually best achieved using i.v. infusion of short-acting antihypertensive agents in a pediatric intensive care unit. Severe hypertension should be treated with labetalol as an i.v. infusion, which will lower blood pressure in a controlled manner. I.v. alternatives include nicardipine, or nitroprusside, although with the latter cyanide levels need to be monitored after 24 h. If i.v. access is difficult, sublingual nifedipine 0.25 mg/kg has been used, but carries the risk of too rapid a fall in BP. Once the blood pressure is under control oral agents can be introduced.

### Follow-up

Regular follow-up is important in the care of children with hypertension. This is to monitor blood pressure control and adjust treatment accordingly. It also provides an opportunity to undertake surveillance for the side-effects of treatment and to look for the emergence of previously undetected causes of high blood pressure. Rarely the need for antihypertensive medication diminishes and treatment can be withdrawn.

## ACUTE RENAL FAILURE

ARF is a sudden decrease in renal function resulting in an accumulation of nitrogenous wastes and associated with fluid and electrolyte imbalance. A urine output of 300 ml/m<sup>2</sup>/24 h (or 1.0 ml/kg/h) is required to excrete the daily solute output. ARF is therefore usually associated with oliguria, although it may be associated with polyuria, particularly in the neonate.

## EPIDEMIOLOGY

The incidence of ARF in children varies according to the population studied. In the UK, data from children referred to regional nephrology units for further management, suggested an incidence of 7.5 children per million population per year.<sup>182</sup> Most of the data is from single-center

studies and as a result the etiology largely reflects the population seen at that center with considerable inter-center variations; for example in one study<sup>183</sup> those with hemolytic uremic syndrome (HUS) accounted for 45% whereas in another study those with primary renal disease including HUS was only 7%.<sup>184</sup> The more recent studies suggest an epidemiologic shift towards an increase in renal failure resulting from complications of other systemic diseases resulting from advancements in congenital heart surgery, neonatal care, bone marrow and solid organ transplantation. Aggregate data from two large single-center studies<sup>184,185</sup> showed the commonest causes to be congenital heart disease (20%), acute tubular necrosis (18%), bone marrow transplantation/malignancy (16%), nephrotoxins (13%), and sepsis (13%).<sup>186</sup>

In neonates again the incidence varies mainly because of differences in the criteria used to define renal failure and ranges from 8 to 24% of all admissions to neonatal intensive care units.<sup>187</sup> Acute renal failure is often transient and related to hypovolemia, hypotension or hypoxemia or drug nephrotoxicity and is reversible with the resolution of the underlying problems causing hypoperfusion or the suspension of certain treatments. In one study<sup>188</sup> up to 60% of severely asphyxiated infants were shown to have renal failure, but none required dialysis. Very low birthweight infants are at particular risk of developing renal failure and in one study 79% of those developing neonates in the neonatal period were under 1500 g.<sup>187</sup>

## PATHOGENESIS

### Prerenal

If renal perfusion pressure falls, renal blood flow and GFR decline but there is excretion of good-quality urine (see Table 18.19). Causes include:

1. Excess losses:
  - gastroenteritis;
  - diabetes;
  - burns;
  - ileus;
  - hemorrhage.

These children appear dehydrated with signs including sunken fontanelle, poor peripheral perfusion with wide peripheral core temperature gap, tachycardia, and hypotension.

2. Impaired cardiac output:
  - congestive heart failure;
  - pericardial tamponade;
  - sepsis/shock.

Table 18.19 Biochemical urine indices in renal failure

	Prerenal	Renal
Urine osmolality (mOsm/kg)	> 500	< 350
Urine Na (mmol/L)	< 20	> 40
U/P creatinine	> 40	< 20
U/P urea	> 15	< 5
$FeNa^+ = \frac{UNa \times PCr}{PNa \times UCr}$	< 1%	> 3%

Table 18.18 Drug therapy of hypertensive crisis

Drug	Administration	Onset of effect	Side-effects
Nifedipine	Sublingual hourly p.r.n. 0.2–0.5 mg/kg	Minutes	Headaches, tachycardia
Sodium nitroprusside	0.5–10 mcg/kg/min as infusion	Seconds/minutes	Very rapid effect, titrate dose, cyanide accumulates after 48 h of use
Labetalol	1–3 mg/kg/h	10–30 min	Postural hypotension
Hydralazine	Slow i.v. 0.1–0.5 mg/kg	10–30 min	Tachycardia, flushing, headaches
Phentolamine	0.02–0.1 mg/kg	Minutes	Use in catecholamine excess states

### 3. Hypoalbuminemic states:

- nephrotic syndrome;
- liver failure.

These children are often edematous but have intravascular volume depletion with signs including poor peripheral perfusion with wide peripheral core temperature gap and tachycardia. Blood pressure, particularly in nephrotic syndrome, is variable.

## Renal

Intrarenal causes of renal failure may be vascular, glomerular or tubular. These children are more likely to present with oliguria and signs of fluid overload, although those with tubular damage may present with polyuric renal failure. Causes include:

1. Vascular:
  - renal vein thrombosis;
  - arterial occlusion;
  - arteritis;
  - hemolytic uremic syndrome.
2. Glomerular:
  - acute glomerulonephritis.
3. Tubular:
  - nephrotoxins (especially drugs);
  - acute interstitial nephritis;
  - myoglobinuria;
  - crystal nephropathy;
  - secondary to prerenal failure.

## Postrenal

Many children with obstructive causes present acutely with infection associated with obstruction and have signs of septicemia. A poor urinary stream or a palpable bladder is highly suggestive of bladder outflow obstruction. Causes include:

- posterior urethral valves;
- pelviureteric junction obstruction;
- vesicoureteric junction obstruction;
- neuropathic bladder;
- nephrolithiasis.

## HISTORY AND EXAMINATION

Often the diagnosis may be clear, e.g. after cardiac bypass surgery, burns, or in association with multiorgan failure as in septicemia. In less obvious cases important clues in the history may include a history of diarrhea and vomiting, a poor urinary stream or exposure to drugs. Important features to note on examination include the state of hydration, blood pressure and other features including the presence of enlarged kidneys or a palpable bladder.

## INVESTIGATIONS

Initial investigations should include full biochemical indices, including renal function and acid–base status together with hematological indices, including a blood film, and in many cases a blood culture. Dipstick urinalysis for blood and protein, microscopy and culture of the urine should also be performed and in some cases urine electrolytes may be helpful in differentiating prerenal and renal failure (see Table 18.19). A renal tract ultrasound will give information on renal size and will exclude obstruction.

All other investigations ordered will depend on these initial screening results. If the ultrasound suggests bladder outflow obstruction a micturating cystogram will be necessary to demonstrate the presence of urethral valves. If the ultrasound suggests pelviureteric obstruction a percutaneous nephrostomy together with a nephrostogram (or antegrade pyelogram) will be both therapeutic and diagnostic.

If the clinical picture is that of acute glomerulonephritis then further serological investigations and a renal biopsy will help to elucidate the cause and also guide further management with respect to immunosuppressive therapy (see Glomerulonephritis section).

## MANAGEMENT

### Fluids and circulation

*Volume overload* with hypertension, raised central venous pressure and edema may be treated with a diuretic *volume depletion* with a low blood pressure, low central venous pressure and a wide peripheral core temperature gap requires resuscitation with either volume expanders, e.g. isotonic saline, or 4.5% albumin 20 ml/kg. However the observation that fluid overload is associated with increased mortality in acute renal failure in children with multi-organ dysfunction supports the recommendation of goal-directed fluid resuscitation support with less post resuscitation fluid and increased use of inotropic support together with early renal replacement therapy.<sup>189</sup>

Low-dose dopamine was commonly administered to critically ill patients because it increased renal blood flow and induced diuresis in healthy volunteers. Clinical trials<sup>190</sup> and a systematic review of the literature<sup>191</sup> have shown no significant effect on overall patient survival/outcome or delay in dialysis. Similarly diuretics have been used in patients with oliguric renal failure to improve output, but have not been shown to prevent or facilitate recovery from acute tubular necrosis, and may cause renal function to deteriorate further.<sup>192</sup>

If poor peripheral perfusion remains, i.e. a wide peripheral core temperature gap, despite an adequate circulating volume and perfusion pressure, a vasodilator, hydralazine 0.2 mg/kg, may reverse the peripheral vasoconstriction such as furosemide 1–5 mg/kg/intravenously. If there is no response dialysis is indicated.

*Maintenance fluids* should be calculated as insensible losses together with continuing losses. Daily fluid requirements are directly related to energy expended. In practice, insensible losses are calculated as approximately 400 ml/m<sup>2</sup> body surface area. Modifications are required in the presence of fever (an increase of 12% of calculated insensible losses per degree above 37.5 °C), tachypnea (an increase of 20–25%), or in neonates nursed under radiant heaters (an increase of 25%).

## Electrolyte disturbances

### Hyperkalemia

- Salbutamol (alpha-2 adrenoceptor stimulant) as the first-choice treatment.<sup>193</sup> Salbutamol can be given intravenously (4 µg/kg in 10 ml of water over 10 min) or more commonly by nebulizer (2.5 mg < 25 kg body weight or 5 mg > 25 kg body weight).
- 10% calcium gluconate 0.5 ml/kg over 5–10 min antagonizes the effect of hyperkalemia on cells and is useful for prevention, or treatment of cardiac dysrhythmias.
- 8.4% sodium bicarbonate 1–2 mmol/kg may lower serum potassium in the presence of acidosis.
- Glucose 0.5 g/kg/h with insulin 0.1 u/kg/h intravenously acts rapidly (within 1 h) to lower potassium but has been superseded by salbutamol.
- Calcium resonium 1 g/kg orally or rectally acts more slowly.
- Salbutamol, the correction of acidosis and insulin shift potassium intracellularly, and should only be regarded as temporary measures until dialysis can be established.

### Hyponatremia

Hyponatremia may be associated with neurological disturbances and convulsions particularly with values less than 120 mmol/L. This is often due to fluid overload and therefore treatment should be aimed at fluid removal. However, excess losses, particularly gastrointestinal, are associated with true sodium deficits, which should be replaced. Sodium deficit may be calculated as follows:

$$\text{mmol sodium deficit} = (140 - \text{actual serum sodium}) \times 0.6 \times \text{body weight in kg}$$

Half the deficit should be replaced in the first 24 h and the situation reviewed.

**Hypocalcemia**

Symptomatic patients may be given a bolus of 10% calcium gluconate 0.5 ml/kg intravenously over 5–10 min. Slower correction may be achieved by an infusion of 10% calcium gluconate, 0.1 mmol/calcium/kg body weight/h. The dose should be adjusted by frequent blood monitoring at least 6-hourly. Reduction of high phosphate levels may also improve plasma calcium levels.

**Hypomagnesemia**

50% magnesium sulfate 0.1 ml/kg intramuscularly.

**Acidosis**

Sodium bicarbonate 2 mmol/kg should be given intravenously as immediate treatment. The total deficit may be calculated as follows:

$$(24 - \text{the actual bicarbonate}) \times 0.6 \times \text{body weight in kg}$$

Half this amount may be given as an infusion over 4–6 h, and the acid–base status rechecked. Sodium bicarbonate needs to be given with caution, particularly in neonates and infants, as it may cause sodium, and thus fluid, overload as well as precipitating hypocalcemic symptoms.

**Hyperuricemia**

Uric acid levels are elevated in ARF and no specific treatment is usually given. Tumor lysis syndrome with grossly elevated uric acid levels can occur in the treatment of lymphomas and leukemia and a high fluid intake, allopurinol and an alkali therapy are usually employed.<sup>194</sup> However, the production of uric acid may be switched to that of xanthine and hypoxanthine, which can also cause a crystalline nephropathy. Recently rasburicase has been introduced, an agent that will oxidize uric acid to allantoin, a metabolite with 5–10-fold greater solubility than uric acid, and reduces serum uric acid levels within 4 hours of i.v. administration.

**Convulsions**

Convulsions may be due to electrolyte disturbances, uremia, hypertension, or the underlying disease such as hemolytic uremic syndrome. Many anticonvulsants tend to accumulate in renal failure. The safest emergency treatment is diazepam 0.25 mg/kg intravenously.

**Hypertension**

Hypertension may be due to fluid overload, which should be treated appropriately. Severe hypertension should be treated as an emergency as outlined in the section Renal hypertension. For sustained moderate hypertension a suitable regimen is a beta-blocker (e.g. propranolol) with or without a vasodilator (e.g. hydralazine) and/or calcium channel blocker (e.g. nifedipine).

**Nutrition**

Adequate nutrition is essential to prevent catabolism and the child should receive at least the estimated average requirement (EAR) for energy for chronological age. Energy is best provided as a combination of carbohydrate and fat, often using glucose polymers exclusively or in combination with fat emulsions. Protein intake will depend upon whether the child is being managed conservatively or is on dialysis.<sup>195</sup> Enteral feeding should be used whenever possible, although i.v. feeding may on occasions be necessary. Fluid restriction may limit the amount of nutrition that can be administered and this may be an indication to institute dialysis or increase ultrafiltration on dialysis. Specialized renal feeds often contain a high energy density and may need to be introduced gradually to prevent gastrointestinal intolerance. The protein, phosphate, sodium and potassium content of feeds need to be analyzed carefully as many are unsuitable for use in renal failure.

**Anemia**

This is inevitable in ARF but transfusion is only indicated if there are symptoms or the hemoglobin concentration is less than 6 g/dl or falling

rapidly. Caution is required in transfusing a child who is not on dialysis as hyperkalemia and fluid overload may be precipitated.

**Renal replacement therapy**

The need for renal replacement therapy will in part be guided by the anticipated prognosis for recovery. If a quick return of renal function seems likely then the child may be managed conservatively. However, if a prolonged period of oliguria seems likely it is better to dialyze earlier and be able to ensure adequate nutrition as well as maintain metabolic balance. Guidelines on the indications for dialysis may be:

1. uncontrollable fluid overload/hypertension;
2. uncontrollable acidosis;
3. symptomatic electrolyte disturbances not controlled by above measures;
4. symptomatic uremia;
5. presence of a dialyzable toxin;
6. established anuria, even if 1–5 not present, provided obstruction excluded.

Because of the complexity of the fluid and electrolyte imbalance in acute renal failure dialysis remains the definitive treatment with the mode of dialysis chosen being dependent on the patients' needs and limitations and the local resources. Good practice requires early discussion of patients with ARF with pediatric nephrology staff and transfer for investigation and management in those with rapidly deteriorating renal function.<sup>196,197</sup>

**Peritoneal dialysis**

Peritoneal dialysis is the preferred option for neonates and is particularly useful in the hemodynamically unstable patient, who may tolerate hemodialysis, or even hemofiltration, poorly.

A soft Silastic catheter may be placed surgically or a more rigid polyethylene catheter inserted percutaneously into the abdomen using a Seldinger technique, though this technique is now seldom used. Commercially available dialysis solutions containing electrolytes, and glucose as an osmotic agent, are then introduced into the abdominal cavity. The volume and duration of the cycles of fluid are adjusted according to the ultrafiltration and clearance requirements of the patient.

**Hemodialysis**

Hemodialysis may be used in patients in whom there are technical difficulties encountered in running peritoneal dialysis, for example catheter blockage or leakage. It may also be used in those children in whom peritoneal dialysis is contraindicated, for example children with intra-abdominal sepsis, major intra-abdominal pathology or following recent abdominal surgery. It is the treatment of choice for acute poisoning with nonprotein-bound drugs or metabolic derangements such as hyperammonemia where high flux filters provide the most effective rapid removal of toxins. Vascular access is usually obtained via a venous catheter inserted percutaneously into a large vessel (either subclavian or femoral vein), to permit the necessary rapid blood flow rates required. Commercially available filters and lines are available to enable hemodialysis to be undertaken even in neonates, but such children need to be managed in specialist nephrology centers where nephrology nursing expertise is available.

**Hemofiltration**

The shift towards an increasing number of children requiring renal replacement therapy for acute renal failure in association with multi-organ dysfunction, together with the production of hemofiltration machines with volumetric control has led to an increase in the use of continuous renal replacement therapy in the form of continuous arteriovenous hemofiltration (CAVH), continuous veno-venous hemofiltration (CVVH) continuous veno-venous hemodialfiltration (CVVHD). These modalities have been used even in very small infants.<sup>198</sup> All provide controlled ultrafiltration and safe removal of fluid, which is

particularly useful in unstable critically ill patients. Small molecular weight clearance (i.e. urea) has similar removal with CVVH and CVVHD but larger molecular weight clearance is enhanced by diffusive clearance (CVVHD) compared to convective clearance (CVVH).<sup>199</sup> One of the major disadvantages of continuous renal replacement therapies is the need for anti-coagulation.

## Drugs

The kidney is the major route of elimination of many drugs and their metabolites. Decreased renal function leads to both predictable and unpredictable changes in the pharmacokinetic profiles of various drugs. Many drugs will also be removed by dialysis although as peritoneal and hemodialysis remove different sized molecules, the elimination of drugs may be different with the two forms of dialysis. It is therefore essential to refer to either drug data sheets or a reference text<sup>200,201</sup> to ensure the correct dosages of drugs are administered.

## Outcome

Patient survival rates from ARF although 10–20% higher than in adults are around 30–58% with no change in recent years.<sup>184,185,189</sup> Mortality is the highest with multi-organ dysfunction syndrome and survival best in those with primary renal disease. The incidence of chronic renal failure or markers suggesting an uncertain prognosis (proteinuria, hypertension) in those surviving acute renal failure is not known<sup>202</sup> as follow-up studies are often limited and incomplete.<sup>203</sup>

## Family support

ARF is an uncommon problem in resource rich countries. When dialysis is anticipated or a biopsy is necessary the child is transferred to a designated pediatric nephrology center, which can be some distance away from the patient's home, and this adds to the family's stress. Appropriate information and psychosocial support from the center's multidisciplinary team are very necessary.

Hyperkalemia is a medical emergency if ECG changes are present

I.v. labetalol or sodium nitropruside is required for hypertensive encephalopathy but blood pressure reduction should be gradual

Patients with rapidly deteriorating renal function should be discussed early with the pediatric nephrology team

## HEMOLYTIC UREMIC SYNDROME

The hemolytic uremic syndromes (HUSs) comprise a heterogeneous group of disorders in which a triad of features, microangiopathic hemolytic anemia, thrombocytopenia and ARF occur together. The average annual incidence in the UK is 0.7 per 100 000 children,<sup>204,205</sup> which is similar that seen in North America.<sup>206</sup> HUS has many different causes.

## Epidemiology and pathogenesis

### Shiga toxin producing *E. coli*

90% of childhood HUS follows a colitis prodrome with a Shiga toxin (Stx) producing *E. coli*. The reported risk of developing HUS with toxin associated diarrhea is very variable although is probably around 5–8%.<sup>207</sup>

In Canada and the USA > 80% of cases<sup>208</sup> are associated with *E. coli* O157 and in a UK survey in children with diarrhea associated HUS 83% had *E. coli* O157, in 15% no organism was isolated and in the remaining a variety of organisms were cultured including *Campylobacter*, *Shigella*, *Salmonella*, *Rotavirus*, staphylococci, streptococci and cryptosporidia.<sup>205</sup> In Australia O157 is rare and O111 strains are more common. The reason O157 may be the most prevalent is because it possesses certain virulence factors including virulence genes.<sup>209</sup> It is also an extremely hardy organism.<sup>210</sup> There are two main toxins, Stx1 and Stx2. Strains that produce only Stx1 have the lowest risk of producing HUS and strains that produce only Stx2 have the highest risk.<sup>211</sup>

The pathogenic cascade begins with the ingestion of the *E. coli*, which causes a colitis: the inflamed colon facilitates transmural absorption of Shiga toxins and lipopolysaccharide into the circulation. These Stxs then bind to genetically determined surface expressed glycolipid (Gb3) recep-

tors on target cells. Renal tubular and glomerular Gb3 expression may be higher in infants than in adults and is one hypothesis to explain the age-related susceptibility.<sup>212</sup> This toxin-mediated injury model hypothesizes that these toxins induce pro-inflammatory cytokines that upregulate Gb3 receptors on vascular endothelial cells allowing Stx to bind and subsequently injure endothelial cells. It is injury of the vascular endothelial cell which appears to be central in the pathogenesis of HUS,<sup>213</sup> although the contributions of host immunity, toxin receptor expression and development of intravascular coagulation in the development of that injury are uncertain.

The pathogenesis of the thrombotic disturbances in HUS is complex and remains incompletely understood. Current theory favors the concept that HUS is a pro-thrombotic disturbance in which a limited form of disseminated intravascular coagulation takes place. However unlike the consumptive coagulopathies the concentration of fibrinogen is normal or elevated, and the pro-thrombin time and the partial thromboplastin time are normal or only slightly prolonged. Elevation of plasma-plasminogen activator inhibitor activity and increased levels of tissue plasminogen activator antigen and D-dimer are also characteristic.<sup>214</sup> Thrombin generation and impaired fibrinolysis have been found, even in children with Stx colitis, without signs of HUS and it has been suggested these findings even may precede the development of HUS.<sup>214,215</sup>

There is good evidence that a pro-inflammatory cytokines play an important role. TNF alpha and certain other cytokines are known to activate the p38MAP kinase cascade and in animal studies administration of an inhibitor to p38MAP prevents the thrombotic microangiopathy.<sup>216</sup> Recent evidence suggests that the action of Stx and cytokines on the vascular endothelium is followed by secondary activation of platelets and coagulation cascade. The activated platelets further bind to the Shiga toxin amplifying the pro-thrombotic state.<sup>217</sup>

Stxs also cause release of von Willebrand factor (vWf), which mediates platelet adhesion to the endothelium and promotes the formation of platelet thrombi. Raised factor VIII-related antigens, together with an abnormal multimer pattern have been shown in some patients with HUS, although it is clear that the role of vWf is not the same in HUS as in thrombotic thrombocytopenic purpura (TTP). The deficiency of vWf cleaving metalloprotease (ADAMTS 13) resulting in elevated factor VIII levels seen in TTP is not typical of HUS. Renal tissue findings, however, suggest there may be a role for Stx-mediated intrarenal vWf release in the acute nephropathy of shiga toxin associated HUS.<sup>218</sup>

Prostacyclin is produced by normal endothelial cells and is a powerful inhibitor of platelet aggregation. Its precise role in the pathogenesis of HUS remains controversial, although prostacyclin activity has been shown to be low in some patients, either due to accelerated prostacyclin degradation or to a reduction in production. Animal studies have demonstrated normal biosynthesis<sup>219</sup> and other work in animal models suggest that prostacyclin is unlikely to be central to the pathophysiology. More recently the observation in animal models that the surface expression of thrombomodulin, which is a protein that normally inhibits coagulation,<sup>220</sup> is reduced offers another speculative explanation of the pathogenesis of the coagulation abnormalities seen.

Stx-induced HUS occurs most commonly in the summer months, affects younger children and is associated with a prodromal illness, usually of bloody diarrhea. The prognosis for a full recovery in this group is excellent. Survival is > 95%, and up to 75% of children will have no long-term sequelae.

### Neuraminidase-producing organisms

Neuraminidase is an enzyme produced by a number of microorganisms, although in many it is cell bound and not released. It removes sialic acid from erythrocytes, platelets and glomeruli exposing the hidden Thomsen–Friedenreich antigen (T-cryptantigen). Anti-T, an IgM antibody present in most adult plasma, can then react with this exposed antigen leading to all the clinical manifestations of HUS. This phenomenon has been described in association with HUS in association with, most

commonly, *Streptococcus pneumoniae* but also other infections including influenza, parainfluenza, *Clostridium perfringens*, and *Bacteroides fragilis*. HUS complicating invasive pneumococcal disease is uncommon but often severe.<sup>221,222</sup> It is less common after meningitis than pulmonary disease, although that complicating meningitis has a poorer prognosis. In the largest series reported to date<sup>223</sup> 84% of children required dialysis, 12% died and 14% of the survivors developed chronic renal failure. It is anticipated that changes in immunization policies to include routine pneumococcal vaccination will alter the incidence of this condition.

### Factor H and the complement pathway

There are many reports of decreased C3 levels in children with HUS, and in some cases, this is permanent, suggesting primary complement activation. Some cases are linked to abnormalities of complement Factor H, an important regulator of the alternative complement pathway. Following the observation of Warwicker,<sup>223</sup> several studies have linked mutations in the Factor H gene with familial or sporadic HUS. Complement levels should be checked in all children with atypical HUS but interpreted with caution. Abnormal levels which return to normal can be seen in Stx-associated HUS and those with abnormalities of factor H may have normal complement levels. Factor H can be measured quantitatively although determining functional abnormalities are more difficult and at present available only in a few research laboratories. The defect in factor H can be inherited as a heterozygous or homozygous disorder and is the result of a variety of nucleotide substitutions, insertions or deletions, which makes molecular genetic diagnosis challenging<sup>224</sup> and may explain the variability in clinical expression. Reduced expression of membrane co-factor, a widely expressed trans-membrane complement regulator has also been recognized as a cause of familial HUS.<sup>225</sup> Children with factor H associated HUS tend to have hypertension early in the course of the disease, tend to relapse and have a poor prognosis.<sup>226</sup>

### Other causes

There is increasing awareness that there is a wide variety of other causes of HUS. Bone marrow transplantation is a well recognized cause and this may be aggravated by both *H. pylori* infection<sup>227</sup> and cyclosporine. A variety of other drugs,<sup>228</sup> malignant hypertension, malignancy and a wide range of infections have also been associated with the syndrome.

### Clinical features

The commonest presentation is with gastrointestinal symptoms, usually bloody diarrhea. This prodrome may last for up to 2 weeks before the onset of the triad of features comprising the syndrome. Increasing pallor and mild jaundice due to hemolysis are noted, together with decreasing urine output. Typical hematological features are then present, the blood film revealing a microangiopathic hemolytic anemia, with thrombocytopenia and the presence of fragmented red cells. Biochemical changes are indicative of renal dysfunction together with macroscopic or microscopic hematuria and variable proteinuria. There is often no correlation between the severity of the hemolysis and the renal failure. Other nonrenal features include:

#### Gastrointestinal

Colitis is a feature of the disease and it may be difficult to distinguish between the prodrome and the onset of the disease itself. Although fever is not typical of acute colitis when it is seen there is an increased likelihood of developing HUS.<sup>229</sup> The presence of abdominal pain, and the passage of blood and mucus per rectum may lead to misdiagnosis as intussusception, ulcerative colitis or even Henoch-Schönlein syndrome. The acute colitic phase is usually self-limited although rectal prolapse and intussusception can occur and in more severe cases bowel ischemia can lead to bowel perforation or colonic stenosis. Cholelithiasis has also been described as a complication.<sup>230</sup>

#### Pancreatic

Mild pancreatic involvement is common but in severe cases can lead to necrosis of the pancreas or pseudocysts. Diabetes can be a long-term

complication and is seen in the course of the disease in 1–2% of patients. Exocrine involvement is rare.

### Cardiovascular

Most of the cardiovascular manifestations are due to volume overload. However, there are reports of cardiac involvement with thrombotic microangiopathy resulting in myocarditis, cardiomyopathy and cardiac failure. This life-threatening complication has been treated with ECMO.<sup>231</sup> Hypertension is also common and seen in between 23 and 32% of cases, more commonly in the nondiarrhea-associated HUS.

### Neurological

Minor neurological disturbances of irritability, drowsiness, myoclonic jerks and tremor or ataxia are common. These may be due to metabolic derangements, or accelerated hypertension as well as a result of neurological involvement in the disease. More major neurological involvement such as coma, focal neurological deficit or decerebrate rigidity occurs less frequently although seizures may occur in up to 30% of patients.<sup>232</sup> Early regional EEG abnormalities, especially those in the occipital and temporal areas, are potentially useful in identifying those who might subsequently develop visual problems and epilepsy.<sup>233</sup> Neuroimaging typically shows basal ganglia involvement but in itself does not have a predictive value as the prognosis has been shown to be favorable even in those with severe changes.<sup>234</sup>

### Investigations

Close monitoring of renal function and full blood count are necessary and blood glucose should be checked regularly. The neutrophil count can be a useful indicator as neutrophilia indicates both the likelihood of developing HUS and the severity of HUS once it has occurred.<sup>235</sup> A high neutrophil count,  $> 20 \times 10^9$ , is associated with an adverse prognosis.<sup>236</sup> Of patients with a neutrophil count  $< 20 \times 10^9$ , 93% have a good outcome compared to 33% of those with a neutrophil count  $> 20 \times 10^9$ . Neutrophils from patients with HUS have been shown to have increased adhesion to endothelium and are able to induce endothelial injury in vitro. It is postulated that these activated neutrophils degranulate onto endothelium causing damage by local release of proteases such as elastase, which has been found to be elevated in patients with HUS.

Stool should be sent for culture, even in the absence of diarrhea and serum should also be sent to look for antibodies to *E. coli* O157 as this increases the diagnostic identification above that of stool culture alone. Latex agglutination and immunoassays are also available to detect toxin in the stool.<sup>237</sup> Complement studies should be followed by further studies on factor H if abnormal or the history atypical. Factor VIII levels and measurement of ADMTS13 should also be sent if the history is atypical. Troponin subtype cTnI,<sup>238</sup> useful in detecting myocardial injury, should be sent in children with cardiological features.

### Management

Many children with hemolytic uremic syndrome can be successfully managed with supportive therapy and careful attention to fluid balance, without the need for dialysis. However, it is essential to arrive at the diagnosis as soon as possible, as much morbidity can be induced by inappropriate fluid therapy, in patients whose renal function is compromised. Children with deteriorating renal function, oliguria/anuria or poor prognostic features should be referred early to a pediatric nephrology center. Poor prognostic features would include older children without a diarrheal prodrome, evidence of nonrenal involvement including encephalopathy or cardiomyopathy, or those children with a high neutrophil count  $> 20 \times 10^9/L$ . A prospective study of children with HUS showed that 57% of children received dialysis.<sup>204</sup>

A wide variety of treatments have been used in HUS. Anticoagulants such as heparin, prostacyclin, fibrinolytics such as streptokinase, i.v. immunoglobulin, steroids, antiplatelet agents and high doses of i.v. infusions of frusemide have all been tried but the evidence is insufficient to recommend their use.<sup>239–243</sup> None has been shown by controlled studies to affect prognosis, with the exception of the use of plasma infusion

in a multicenter study.<sup>244</sup> Unfortunately this study is disadvantaged by the inclusion of children with epidemic HUS, who would be expected to have a good prognosis, together with those with sporadic HUS, who would be expected to have a poorer prognosis. The benefits of plasma, therefore, need to be weighed against the disadvantages. Such disadvantages would include the risk of volume overload, the transmission of blood-borne viral diseases and the potential for worsening hemolysis in those patients with neuraminidase-associated HUS. Plasma exchange has also been advocated and although it has been shown to be of benefit in thrombotic thrombocytopenic purpura in both the acute illness and in patients with recurrent episodes, there are insufficient data on children with HUS. There are theoretical reasons why it may be beneficial and its use may therefore be justified in the child with a severe deteriorating course, particularly with neurological involvement. In children with factor H deficiency, plasma exchange and replacement with plasma product containing factor H seems a reasonable option in the absence of better evidence.<sup>226</sup>

The role of antibiotics in influencing the clinical course is unclear, with studies showing both an increase and a decrease in the incidence of HUS in Stx-associated infections.<sup>245,246</sup> A recent meta-analysis<sup>247</sup> suggests that the issue remains unresolved.

A number of methods of prevention are being explored and include infusion of monoclonal antibodies to Stx,<sup>248</sup> administration of Gb3 receptor analogues<sup>249</sup> inhibiting the p38MAP pathway,<sup>215</sup> immunization<sup>250</sup> and development of medications to sequester Stx in the gastrointestinal lumen and prevent absorption.<sup>251</sup>

However currently best supportive therapy with dialysis and plasma exchange where indicated remains the mainstay of treatment.

### Influencing long-term outcome

The acute mortality of HUS is around 5% in most series, although a recent survey in the UK comparing the mortality between 1985 and 1987 with that from 1999 to 2001 showed a fall in overall mortality from 5% to 2.5% between the two cohorts.<sup>205</sup> Mortality is higher in the nondiarrhea-associated HUS, and renal recovery is 88% in those with diarrhea-associated HUS compared to 56% in those with nondiarrhea-associated disease.<sup>205</sup>

Evidence of hypertension or impaired glomerular filtration rate is seen in between 11 and 25% of patients, with hypertension being more common in the nondiarrhea-associated disease and severe hypertension being particularly associated with Factor H associated HUS. Although children who remain on dialysis longer have a higher risk of long-term renal problems, the long-term sequelae cannot be reliably predicted by the acute clinical course. Persistent proteinuria is associated with a less good prognosis. A positive correlation between microalbuminuria and systolic blood pressure and a negative correlation between microalbuminuria and glomerular filtration rate<sup>252</sup> suggests that those children with albuminuria should receive longer and closer follow-up to identify occult nephropathy earlier. It has been suggested that long-term follow-up should be carried out on all children with proteinuria, hypertension, abnormal ultrasound or an impaired GFR at 1 year.<sup>253</sup> The full implications of the long-term sequelae of HUS may not yet have been realized, as a study on renal functional reserve demonstrated that all patients who had apparently made a complete recovery presented abnormalities in their renal functional reserve similar to that seen in children with a single kidney. However, the patients with HUS showed in addition an increase in microalbuminuria after a protein load, which may imply a poorer long-term prognosis.<sup>254</sup>

There is evidence that for those who develop chronic renal failure with proteinuria ACE inhibitors are useful for slowing progression due to hyperfiltration injury.<sup>255</sup> For those who develop chronic renal failure, renal transplantation is available. The prognosis for those with diarrhea-associated HUS is excellent and recurrence rate low.<sup>256</sup> For those with factor H associated HUS there is a high risk of recurrence and a potential definitive therapy that has been suggested in combined kidney–liver transplant although to date the outcomes have been poor.<sup>257</sup>

### Hemolytic uremic syndrome associated with shiga toxin producing *E. coli* is a major cause of acute renal failure in childhood.

*Atypical or familial HUS has a poorer prognosis and may be associated with mutations in Factor H associated with the alternative complement pathway.*

*Persistent proteinuria, hypertension and/or reduced GFR are poor prognostic features after any acute or chronic renal insult.*

## CHRONIC RENAL FAILURE

Data on the prevalence of chronic renal failure are uncertain, at least in part as a result of the differing definitions of the level of renal dysfunction. European data<sup>258</sup> suggest a prevalence of between 25 and 50 children per million child population with a GFR less than 25–50 ml/min/1.73 m<sup>2</sup>.

End-stage renal failure is defined as the stage at which dialysis and renal transplantation are required (Table 18.20). There is no absolute level of renal function at which this is required although in practice it is usually a GFR < 10 ml/min/1.73 m<sup>2</sup>. There are national and international renal registries for end-stage renal failure, which are important for identifying changes in incidence, treatment modalities and outcome. The European Dialysis Transplant Association (EDTA) register of children under 15 years of age accepted for renal replacement therapy each year suggested an incidence increasing from 4.6 per million child population in 1971 to 7–8 per million child population per annum in 1991.<sup>259</sup> In the UK, the national renal registry<sup>260</sup> reveals a take-on rate of under 15-year-olds is similar at 9 per million childhood population. The prevalence of renal failure rises steadily with age throughout childhood, the overall prevalence in under 15-year-olds being 51.4 per age-related population. There is however a wide ethnic variation with prevalence being twice as high in the Asian population compared to the white population. The etiology of renal failure varies also according to the child's country of origin, and age at presentation. In the UK renal dysplasia and glomerular diseases rank evenly in the UK, followed by obstructive uropathy and reflux nephropathy (Table 18.21).

Table 18.20 Stages of chronic renal failure

	GFR (ml/min/1.73 m <sup>2</sup> )	
Mild	50–75	Asymptomatic
Moderate	25–50	Metabolic abnormalities
Severe	< 25	Progressive growth failure
End-stage renal failure	< 10	Require renal replacement therapy

Table 18.21 Primary renal disease causing end-stage renal failure in 845 patients in UK<sup>89</sup>

	%
Primary renal dysplasia	23.4
Renal dysplasia	23.0
Obstructive uropathy	15.5
Reflux nephropathy	7.9
Tubulo-interstitial diseases	7.4
Congenital nephrotic syndrome	5.3
Metabolic diseases	4.8
Renovascular problems	3.7
Polycystic kidney disease	2.8
Chronic renal failure etiology unknown	2.7
Drug nephrotoxicity	2.0
Malignancy and associated disease	1.2

## CLINICAL PRESENTATION

In many children, chronic renal failure will be the end result of known progressive renal disease. More recently, antenatal diagnosis has led to detection of renal tract malformations before symptoms develop. Other children may present with signs and symptoms associated with renal failure. These may be nonspecific symptoms, including lethargy, poor appetite and nausea, together with urinary symptoms, including polyuria or enuresis.

### Growth

Growth failure is a major problem for children with chronic renal failure. The severity of the growth failure is related to the age at presentation: 50% of children with renal failure since infancy have growth failure, with a height of  $> 2$  SD below the mean height for age, in contrast to 10% of those with acquired disease. Important factors contributing to the growth failure include: acidosis, salt depletion, other biochemical abnormalities, renal osteodystrophy, and energy malnutrition. Estimation of renal function would be a routine investigation in a child presenting with unexplained growth failure.

### Renal osteodystrophy

Phosphate retention, secondary hyperparathyroidism and skeletal resistance to parathyroid hormone, intestinal malabsorption of calcium leading to hypocalcemia and altered vitamin D metabolism all contribute to the disturbances in bone and mineral metabolism associated with renal osteodystrophy. The severity of the bone disease is related to age at onset and underlying renal disease, together with the level of renal function and duration of renal failure. It is more common with the congenital and obstructive uropathies and rarely manifests clinically with a GFR of above 25 ml/min/1.73 m<sup>2</sup> although biochemical abnormalities are seen with a GFR between 50 and 80 ml/min/1.73 m<sup>2</sup>.<sup>261</sup> Symptoms may include poor growth, bone pain, skeletal deformities, and slipped epiphyses.

### Anemia

Anemia secondary to a lack of erythropoietin is also a well-recognized complication of renal failure and may be the presenting feature of the condition.

### Hypertension

Renin-dependent hypertension is the commonest cause of hypertension in childhood and may be associated with renal failure. The presentation of renal failure may therefore be with the symptoms of hypertension including headache, visual disturbances or hypertensive encephalopathy.

## MANAGEMENT

### Fluid and electrolyte therapy

Many children with congenital renal diseases, in particular dysplasia, obstructive uropathy and nephronophthisis, have poor renal concentrating capacity with polyuria and salt loss. Salt supplementation is often necessary and salt deficiency is an important cause of poor growth in these infants. Children with acquired diseases, in particular focal glomerulosclerosis and other forms of glomerulonephritis, may have salt and water retention and therefore require salt restriction. Acidosis is common and should be corrected with sodium bicarbonate.

### Infection

Urine cultures should be checked, especially in those with abnormalities of the urinary tract, as repeated infection may hasten progression of CRF.

### Renal osteodystrophy

The impairment of excretion of phosphate and the decreased renal production of 1,25-dihydroxycholecalciferol together play important roles in the development of renal osteodystrophy and secondary

hyperparathyroidism. Initially, dietary phosphate restriction may be sufficient to control hyperphosphatemia, although this can be difficult in young infants on a predominantly milk diet and the use of phosphate binders may become necessary. Calcium carbonate and calcium acetate are the most commonly used phosphate binders but the use of these may result in hypercalcemia. Noncalcium-containing phosphate binders are available although the aluminum containing compounds are best avoided in children because of the potentially neurotoxic effects.

Pharmacologic replacement, with 1-alpha-hydroxycholecalciferol, should be commenced when there are biochemical features of altered mineral metabolism or if the GFR falls below 25 ml/min/1.73 m<sup>2</sup>. The phosphate should be controlled before it is introduced as vitamin D causes an increase in phosphate absorption. If secondary hyperparathyroidism remains uncontrolled then success has been achieved with the use of the newly introduced calcimimetic agents.<sup>262</sup> There are no data on the use of these in children at present.

Data from adults has demonstrated that control of phosphate and parathyroid hormone is important not only for control of renal osteodystrophy but has important implications for long-term cardiovascular health.<sup>263,264</sup>

### Erythropoietin

The production of human erythropoietin (rhEPO), by recombinant DNA techniques, has made possible the treatment of the anemia of chronic renal failure and significantly improved the quality of life for many patients. The use of rhEPO, usually given subcutaneously, has been shown to be effective in raising the hematocrit of children with end-stage renal failure. It is also effective in predialysis patients. RhEPO may result in hypertension and changes in renal function so both of these should be monitored closely. Standards for management of anemia, mineral metabolism and various other aspects of renal failure are published in national guidelines.<sup>265,266</sup>

### Growth hormone

Short stature is a serious problem for children with chronic renal failure. Endogenous growth hormone secretion is normal, as are serum levels of insulin-like growth factors I and II. However, exogenous growth hormone has been shown to increase the height velocity in a number of conditions in which growth hormone secretion is not impaired including renal failure. Growth hormone does increase the short-term growth velocity of prepubertal children with chronic renal failure. Long-term use of growth hormone for up to 9 years is associated with persistent catch-up growth and an improvement in final height was demonstrated compared with untreated children.<sup>267</sup> However, one study<sup>268</sup> suggested that the improvement in height, obtained after a limited course of growth hormone, was maintained after discontinuation of treatment. The optimal treatment regimen of growth hormone therefore remains unknown. Of concern is that growth hormone may accelerate renal functional decline by increasing renal plasma flow and glomerular hyperfiltration and thus concerns have been expressed on the use of growth hormone post renal transplantation. However it has been shown to be effective and not associated with any increased adverse effects.<sup>269</sup> In view of the possible side-effects growth hormone use should be restricted to children who are below the third centile for height and in whom all other abnormalities such as electrolyte and acid-base balance, renal osteodystrophy and nutritional deficiencies have been corrected.

### Nutrition

General recommendations for children with chronic renal failure suggest that children should have at least the EAR for chronological age for energy, although many will need additional energy to promote growth. Protein intake should be based on the reference nutrient intake (RNI) for height age. However, individual dietary and biochemical assessment will determine requirements, as well as the stage of management.<sup>270</sup> Large reliance is placed upon nutritional supplements to achieve nutritional goals in infants and children with chronic renal failure and the assistance of an experienced pediatric dietitian is essential. In many infants

and young children the supplements are delivered either nasogastrically or via the gastrostomy route. Each child will need assessing individually, with respect to fluid and electrolyte needs, along with adequacy of micronutrient intake. These children require frequent and repeated assessments of their dietary prescriptions, if growth is to be maintained or promoted.

In adults attention has focused on dietary modifications to retard the progression of chronic renal failure. Of particular interest has been the role of restriction of dietary phosphate and protein in retarding the progression of chronic renal failure. Both the efficacy and safety of severe protein restriction in growing children requires evaluation, because of the concern regarding the effect of protein restriction on growth. The results from trials in children using protein restriction of 1 g/kg/d have shown conflicting results in the effect on GFR, although no adverse effect on growth has been demonstrated.<sup>271</sup> Compliance with dietary manipulations in childhood is often poor and in the European study on protein restriction only 76% of children adhered to their dietary prescription. Further studies are needed before such treatments are recommended for widespread clinical use in children.

## Dialysis

Dialysis does achieve satisfactory control of fluid and biochemistry, but is an incomplete form of renal replacement therapy, and is therefore considered a stepping-stone to renal transplantation in most children. The two main forms of dialysis are chronic peritoneal dialysis and hemodialysis. The choice between peritoneal dialysis and hemodialysis will depend on patient preference, geographical and practical considerations.

### Chronic peritoneal dialysis

Access to the peritoneal cavity is by way of a surgically implanted permanent Silastic catheter.<sup>272</sup> When chronic peritoneal dialysis (CPD) was first introduced, children underwent continuous ambulatory peritoneal dialysis (CAPD), where the dialysis fluid was exchanged three or four times via 'bag changes'. The advent of automated peritoneal dialysis (APD), in the 1980s, meant that children could receive most of their dialysis overnight (nocturnal intermittent peritoneal dialysis, NIPD) or mostly overnight with daytime dwell as well (continuous cycling peritoneal dialysis [CCPD]). APD is now the preferred modality in many Western countries, with the obvious benefit of freedom from daytime exchanges at school.

The disadvantages of CPD are the risk of peritonitis and other abdominal complications such as hernias.

### Hemodialysis

Hemodialysis requires adequate vascular access either via an arteriovenous fistula, or more commonly, via an indwelling vascular catheter, usually in the subclavian or jugular vein. Although the technical principles of hemodialysis are similar in adults and children, because of the challenges presented by the smaller intravascular volumes of children and the potential hemodynamic instability, together with the psychological issues it is recommended that children be treated in units with pediatric expertise. Difficulties with vascular access, including infection, are a disadvantage of the technique.

## Transplantation

Renal transplantation is the best mode of renal replacement therapy for children and adolescents.<sup>273</sup> In the UK<sup>260</sup> 76% of children with end-stage renal failure has a functioning graft. At all ages pediatric renal transplant recipients have better survival than do dialysis patients of the same age. Moreover, successful transplantation confers a degree of physiological and psychological rehabilitation not seen with any form of dialysis. Whilst most children undergo transplantation following the commencement of dialysis, in the UK about 20% of children receive transplantation prior to this (pre-emptive transplantation). Not only do results demonstrate improved growth and psychosocial development, the long-term outcome may be superior and peritoneal and hemodialysis access is preserved for future use in childhood or adult life.<sup>274,275</sup> A child is generally

considered for pre-emptive transplantation once the glomerular filtration rate (GFR) has fallen below 10–15 ml/min/1.73 m<sup>2</sup>, and dialysis is anticipated within 18–24 months and/or a significant complication of renal failure is present, for example, growth failure.

### Graft survival

Registries held by UK Transplant in the UK and the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) in North America provide good quality data on the outcomes of renal transplantation. Graft survival rates in the UK suggest 1-year graft survival of 90% for cadaveric renal transplantation, with over 93% survival for live donor grafts. Longer term follow-up results need to be interpreted with caution as treatment modalities and immunosuppressive regimens have changed considerably over the last decade but UK 5-year survival is 72% in cadaveric donors and 85% in live donors.<sup>276</sup> The use of live donor grafts between countries is very variable. In the UK currently 25% of those with grafts are from living donors whereas in North America rates of 50%<sup>277</sup> have been reported and in the Nordic countries even higher.

Graft success rates are dependent on a wide variety of factors including tissue matching, donor age, storage time of the kidney, immunosuppression regimens, previous transplantation and original and associated diseases. There was concern about outcomes in the younger renal transplant recipient, as early European and North American data tended to suggest that graft survival was lower in children less than 2 years old compared to older children. Recent reports are more encouraging.<sup>278,279</sup> A study on children developing end-stage renal failure under 2 years of age and receiving grafts at a median age of 2.6 years demonstrated a 10-year graft survival of 78%.<sup>280</sup> Results from live donation are consistently superior and comparable with other age groups.<sup>281,282</sup> There is a highly significant increased risk of graft failure associated with donors under 5 years of age.<sup>283</sup> In cadaveric transplantation there was a tendency to use young donors in young recipients and when stratified for donor age, recipient age does not seem to influence outcome and it is anticipated that policies involving not using organs from young donors in young recipients will improve the outcome of this group. More recent concern has focused on the outcome of renal transplantation in adolescents,<sup>284,285</sup> in whom long-term outcome lags significantly behind that of younger children. Poor compliance is a major contributory factor in these young people.

### Immunosuppression

All transplanted children will remain on immunosuppressive therapy with a calcineurin inhibitor, either ciclosporin or tacrolimus, usually with steroids and, in some, also azathioprine. Induction therapy with monoclonal antibodies may be used in some children and mycophenolate mofetil may be used particularly in those children with calcineurin inhibitor toxicity. In the UK national guidelines on immunosuppression therapy in children have recently been produced.<sup>286</sup> It is important to consider the side-effects of these medications, including risk of infection, hypertension, hirsutism and other cosmetic side-effects, which may influence compliance, particularly in adolescents. The long-term risks of steroids are particularly well known and there are some early encouraging reports of steroid-free immunosuppression.<sup>287</sup> With further medications being developed in future it may be possible to provide immunosuppression with greater specificity and fewer toxic effects.

### Rehabilitation

Growth is improved after renal transplantation, with a significant increase in growth velocity in prepubertal children. However, perhaps one of the most important issues when considering the quality of life following renal transplantation is the neurodevelopmental and psychological outcome.

Early reports of children with chronic renal failure, particularly those who had had renal failure since infancy, showed a worrying proportion of those children having significant developmental delay.<sup>288</sup> The etiology was felt to be multifactorial, including: poor biochemical control, inadequate nutrition, the use of aluminum-containing phosphate binders and

psychosocial factors. However, recent studies have been more encouraging, with the authors suggesting that the marked improvement in neurodevelopmental outcome was due to a shift in emphasis in renal failure management, with a more aggressive approach to nutrition and biochemical parameters.<sup>289,290</sup>

Studies on older children with renal failure have demonstrated effects on cognitive development, but despite these deficits there is no difference in grades achieved at school. Studies on the psychosocial adjustment of adult survivors of pediatric dialysis and transplant programs have shown that although the educational and employment achievements of those with renal disease are less than those of controls, two thirds of the patients leave school with qualifications and two thirds are in employment.<sup>291</sup> In conclusion, therefore, dialysis and transplantation enable the majority of children with end-stage renal failure to enter

adulthood in good physical health and well adjusted socially. However, the burden for families caring for children with renal failure, as with many other chronic illnesses is considerable. It is essential that such families have the benefits of support from an experienced multidisciplinary team which includes nursing and medical staff, dietitians, social workers, teachers, play leaders, psychologists and psychiatrists who are able to work not only in hospital but also support the families in their own communities.

*Renal dysplasia/hypoplasia and glomerulopathies are the commonest categories of conditions causing chronic renal failure (CRF) in childhood.*

*Recombinant erythropoietin by subcutaneous or i.v. injections can correct the anemia of CRE.*

*Renal transplantation is the treatment of choice for children with end-stage renal failure and is increasingly performed before dialysis is necessary.*

## INTRODUCTION

Optimum growth and development is dependent on the normal functioning of the gastrointestinal tract and of the liver. When this activity is deranged the child will develop symptoms of gastrointestinal disease and as a consequence will frequently fail to grow adequately.

The gastrointestinal tract extends from the mouth to the anus and is structurally and functionally divided into the mouth, oropharynx, esophagus, stomach, small intestine and colon (Table 19.1). Following the ingestion of food by the mouth the bolus is moved by the oropharynx into the esophagus, which acts as a conduit for the transfer of food to the stomach, where it is stored and mixed prior to its controlled passage into the small intestine. In the small intestine the food is digested and absorbed before moving on into the large intestine, where salt and water are conserved prior to excretion. This simplified view of gastrointestinal function disguises the very complex nature of the many systems which interact to give normal intestinal function.

## GASTROINTESTINAL FUNCTION

### DIGESTION

Ingested food consists almost exclusively of large macromolecules which the intestinal tract is unable to absorb without prior digestion.

**Table 19.1** The function of the gastrointestinal tract

Section of gut	Function
Mouth	Grinding of food by teeth Lubrication by salivary secretions
Oropharynx	Move food into esophagus Protect airway
Esophagus	Propulsive conduit for food Clearance of regurgitated food Prevention of reflux
Stomach	Store for food Gastric acid production Pepsin production
Small intestine	Digestion of food Absorption of food Immune tolerance
Terminal ileum	Absorption of vitamin B <sub>12</sub> Absorption of bile salts
Pancreas	Digestive enzyme production Bicarbonate production
Colon	Reabsorption of luminal fluid Storage and excretion of feces

Complex carbohydrates are broken down into their component monosaccharides; fats, with the help of the emulsifying activity of bile salts, are digested to free fatty acids and monoacylglycerol and proteins are dismantled into dipeptides and amino acids. The digestive enzymes act mainly within the lumen of the stomach and small intestine although the process is completed for carbohydrate by small intestinal brush border disaccharidases.

### TRANSPORT

Discrete transport processes are present within the epithelial cells of the intestinal tract to promote the absorption of nutrients, salts and water by some cells and the excretion of salt and water by others. Many of these processes are dependent on the electrochemical gradient across the cell wall created by the Na<sup>+</sup>/K<sup>+</sup> ATPase ion pump. This generates a low Na<sup>+</sup> concentration and a negative charge within epithelial cells, which facilitate the movement of specific ions and solutes through transmembrane proteins which traverse the lipophilic cell membrane.

### MOTILITY

The movement of food along the gut is integrated with, and related to, the function of each section of the intestine. The rate of emptying of nutrients from the stomach is closely controlled to prevent overloading of the small intestine. Specific patterns of fasting motor activity have developed in the small intestine to clear the lumen of food debris after meals and highly developed control mechanisms are present to facilitate the controlled emptying of the distal colon and rectum at the time of defecation.

### IMMUNITY

The gastrointestinal tract serves as the interface between ingested elements from the external environment and the internal milieu of the individual. By a combination of immunological and non-immunological mechanisms the entry of noxious substances such as bacteria, viruses and undigested food protein is prevented. The development of tolerance to the foreign proteins of commonly ingested food is vital to the normal functioning of the gut.

### ENDOCRINE

The gastrointestinal tract is a major endocrine organ and many regulatory peptides with endocrine, paracrine and neurocrine functions are released along the length of the intestine. The function of many of these peptides is poorly understood, although it is clear that they have an important role in modulating intestinal secretion, growth and motor function.

A more detailed description of the anatomy and physiology of the intestinal tract<sup>1</sup> is given in subsequent sections of this chapter.

## NATURE OF GASTROINTESTINAL DISEASE

Normal intestinal function requires the combined action of each of the functional systems described earlier and if any one should break down intestinal function will be compromised. An understanding of the basic physiology of these systems is important when interpreting symptoms of gastrointestinal disease and planning the rational investigation of these problems.

Diarrheal disease will develop if, as a consequence of maldigestion or active secretion, there is an increased effluent of fluid passing into the colon from the small intestine or if the absorptive capacity of the colon is compromised by disease.<sup>2</sup> Loss of normal intestinal motility will result in the development of symptoms of obstruction and where a defect of mucosal immunity is present recurrent enteric infection is likely to occur. Damage to the digestive or absorptive capacity of the small intestine will result in failure of the patient to grow adequately.

## THE MOUTH

The mouth is responsible for the grinding of food into small fragments, through the voluntary action of the tongue and jaw, prior to its passage into the esophagus. In addition, the fragments are mixed with salivary secretions, which help lubricate the food and initiate digestion, through the action of salivary amylase and lingual lipase. Any disease of the mouth which makes feeding painful or compromises the normal process of deglutition is likely to lead to difficulties with feeding.

While most oral lesions are the result of local disease, both gastrointestinal and systemic disease may result in abnormalities within the mouth.<sup>3</sup> It is therefore important to look closely at the mouth in all children undergoing physical examination.

## THE LIPS

Unilateral or bilateral clefts of the upper lip are among the most common of congenital malformations and are frequently found in combination with a cleft of the palate (see Ch. 37). Dryness of the lips with cracking may be due to mouth breathing, and fissure formation at the angle of the mouth may result from chronic drooling in children with swallowing disorders. Nutritional deficiencies of iron, zinc and riboflavin may all produce an angular stomatitis.

Edema of the lips may occur as part of an immediate hypersensitivity reaction following the direct contact of the lips with a sensitized protein or as part of the systemic response in anaphylaxis. Intermittent swelling of the lips due to chronic granulomatous infiltration is seen in orofacial granulomatous disease, a condition associated with Crohn's disease in some patients. Exacerbation may be brought on by dietary triggers.<sup>4</sup> Cobblestone ulceration of the buccal mucosa may be seen in Crohn's disease.

## THE ORAL MUCOSA

Ulceration to the buccal mucosa occurs most commonly in healthy individuals as a result of recurrent aphthae. These may be precipitated by local trauma and heal spontaneously within 2 weeks. More persistent ulcers may occur in chronically debilitated patients, children with poor dental hygiene and as mentioned earlier in inflammatory bowel disease (IBD). Extensive ulceration of the oral mucosa in association with lesions on the perineum are seen in Stevens–Johnson syndrome and less commonly in Behçet syndrome.

Abnormal pigmentation may be seen in Addison disease and Albright syndrome; in Peutz–Jeghers syndrome there is freckling of the lips and buccal mucosa and in lead, mercury and bismuth poisoning pigmented lines are sometimes seen near the dental margin of the gums. Koplik's spots are characteristically present in measles, palatal petechiae may be seen in rubella and oral vesicles in chickenpox can make feeding very uncomfortable.

The most common infections involving the mucosa are herpes stomatitis and thrush. Primary herpes infection occurs most commonly

in children between the ages of 1 and 3 years and presents with pyrexia, lymphadenopathy and the eruption of vesicular lesions on the buccal mucosa, lips and on the skin below the mouth. The vesicles burst, forming painful ulcers, making the ingestion of solids and liquids very uncomfortable. Although the condition is self-limiting, with a course of 7–10 d, this may be shortened by treatment with oral aciclovir.

Oral candidiasis or thrush commonly occurs in young babies who become infected in the neonatal period but may also develop in patients on broad-spectrum antibiotics, inhaled steroids or in patients who are immunosuppressed. Gut carriage may also lead to infection of the nappin area. Treatment is with a topical antifungal such as nystatin. Oral nystatin should also be given where gut carriage is likely to be a source of reinfection.

## THE GUMS

Infection of the gums in children most commonly results from poor oral hygiene and leads to inflammation of the free margin of the gingiva. Hypertrophy of the gums is a common side-effect of phenytoin or cyclosporine treatment and may also be rarely seen in Langerhans' cell histiocytosis (see Ch. 24). Bleeding of the gums may be secondary to local infection but will also occur in children with bleeding diatheses and in nutritionally compromised patients who are vitamin C deficient.

## THE TONGUE

Macroglossia occurs in hypothyroidism, as part of generalized visceral enlargement in Beckwith syndrome and in glycogen storage disease type II. A normal-sized tongue may appear to be enlarged if the oral cavity is small as in children with Down syndrome. The tongue can also be enlarged by a lymphangioma or a hemangioma and a mass in the region of the foramen cecum may be due to a lingual thyroid.

The surface of the tongue becomes coated in children with poor oral hygiene and in patients with dehydration. In scarlet fever the tongue is first white and coated and then becomes red, hence the name 'strawberry tongue'. In familial dysautonomia the tongue is smooth due to the absence of papillae and in congenital familial telangiectasia the vascular abnormality may be clearly seen. The focal loss of papillae leads to the so-called 'geographical tongue', a benign self-limiting condition.

## THE TEETH

The primary dentition usually erupts at about 6 months but in hypothyroidism, hypopituitarism, rickets, congenital syphilis and cleidocranial dysostosis this can be delayed. Premature shedding of these teeth is likely to occur in hypophosphatasia and in mercury poisoning. The enamel of the teeth will become hypoplastic as a result of such insults as prematurity, kernicterus, vitamin D deficiency and from congenital infections such as rubella and syphilis. Similarly the shape of the teeth may be abnormal as a consequence of congenital infection (notched incisors in congenital syphilis) or in ectodermal dysplasias, where the teeth may be peg shaped.

A black staining of the teeth can occur with oral iron, a brown discoloration occurs with congenital defects of enamel and dentine, in congenital porphyria the teeth are a purplish brown and in neonatal unconjugated hyperbilirubinemia a green staining may be left. The administration of tetracycline to a mother after the fourth month of pregnancy or to the infant in the first year of life will result in yellow discoloration of the primary dentition and administration up to the age of 7 years will affect the permanent dentition.

## THE SALIVARY GLANDS

With the exception of mumps, inflammation or enlargement of the salivary gland is uncommon in childhood. Acute bacterial parotitis may occur in the neonate or debilitated child and is characterized by

a unilateral swollen tender parotid gland. Infection with *Staphylococcus aureus* is generally responsible and treatment with flucloxacillin is required.

Recurrent parotitis either uni- or bilateral may occur where the symptoms are generally mild and not associated with systemic upset.<sup>5</sup> Treatment with parotid massage and stimulants of salivary flow such as chewing gum along with oral penicillin are generally helpful. The condition is self-limiting and generally resolves by puberty. Less commonly, recurrent pain and infection may be precipitated by salivary stones.

## THE ESOPHAGUS

### STRUCTURE AND FUNCTION

The esophagus is a long, narrow muscular tube which connects the oropharynx and stomach providing a conduit for the passage of food. The lumen of the esophagus is lined by a stratified squamous epithelium and is encircled by an inner circular and an outer longitudinal layer of muscle. The muscle of the upper third of the esophagus is striated and is dependent on extrinsic innervation from the vagus nerve while the muscle in the lower third is smooth muscle and is under the influence of both intrinsic and extrinsic controls. The muscle of the middle third forms a transitional zone. Two high pressure zones are found along the length of the esophagus, one at the proximal end forms the upper esophageal sphincter and the other at the distal end forms the lower esophageal sphincter.

### Deglutition

After food has been chewed and mixed with saliva a bolus of food is isolated and pushed back, between the tongue and the hard palate, towards the pharynx at the same time as the soft palate is raised to close off the nasopharynx. As the food enters the oropharynx an involuntary reflex is initiated whose afferent limb is transmitted along the glossopharyngeal nerve and the superior laryngeal branch of the vagal nerve to the medulla. Efferent impulses from the facial, glossopharyngeal, vagus, accessory and hypoglossal nerves result in contraction of the pharyngeal muscles and relaxation of the upper esophageal sphincter with movement of the bolus of food onward into the upper esophagus. Entry of food into the larynx is prevented by cessation of respiration, elevation of the larynx and closure of the glottis.

Given the very complicated nature of this reflex and its reliance on many cranial nerve nuclei within the brainstem it is perhaps not surprising that central nervous system disorders which result in the development of bulbar or pseudobulbar palsies will disturb the swallowing reflex; similarly any anatomical disorder of the pharyngeal apparatus (i.e. Pierre Robin or cleft palate) will disrupt normal feeding (Table 19.2). Disordered deglutition is also likely to result in the nasopharyngeal regurgitation of food and the aspiration of ingested food into the lungs. This reflex develops in the neonate at approximately 34 weeks' gestation.

Oromotor coordination develops throughout the first year of life to accommodate the many food consistencies and textures experienced by the child after weaning. If inappropriate foods are given, which fail to match the child's oromotor development, feeding may become difficult and lead to the development of behavioral problems at meal times.

### Esophageal peristalsis

During primary peristaltic activity pressure waves of 50–80 mmHg (7–11 kPa) propagate down the esophagus, pushing the bolus of food at a velocity of 2–5 cm/s. A marked reduction in magnitude and propagation velocity of this activity is seen in cerebral palsied children with severe gastroesophageal reflux. Secondary peristaltic activity which develops in response to distension of the esophagus and plays an important role in clearing regurgitated gastric contents back into the stomach is also compromised in children with neurological disease. Tertiary peristaltic activity occurs spontaneously and may be responsible for the pain induced by esophageal spasm.

Table 19.2 A list of the causes of dysphagia

1. Anatomical abnormalities
  - a. Cleft palate
  - b. Micrognathia (Pierre Robin)
  - c. Macroglossia
  - d. Cysts, tumors and diverticula of the pharynx
  - e. Esophageal atresia
  - f. Esophageal stricture
    - (i) Anastomotic
    - (ii) Corrosive
    - (iii) Reflux esophagitis
  - g. Esophageal compression
    - (i) Aortic arch anomaly
    - (ii) Mediastinal tumor
    - (iii) Esophageal duplication
2. Neuromuscular
  - a. Prematurity
  - b. Cerebral palsy of any type
  - c. Bulbar or pseudobulbar palsies
  - d. Isolated cranial nerve paralysis or agenesis
  - e. Familial dysautonomia (Riley-Day syndrome)
  - f. Achalasia
  - g. Esophageal dysmotility (i.e. spasm)
  - h. Myasthenia gravis or dystrophica myotonica
3. Inflammatory/trauma
  - a. Stomatitis
  - b. Acute tonsillopharyngitis
  - c. Esophagitis
    - (i) Reflux
    - (ii) Eosinophilic esophagitis
    - (iii) Corrosive
    - (iv) Infective (i.e. *Candida*)
  - d. Foreign body
4. Behavioral
  - a. Rumination
  - b. Globus hystericus

### Lower esophageal sphincter

The lower esophageal sphincter is a zone of raised pressure (20 mmHg; 3 kPa), just proximal to the gastroesophageal junction which has a central role in the control of the reflux of gastric contents into the esophagus.<sup>6</sup>

The effectiveness of the lower esophageal sphincter as an antireflux barrier depends also on a number of anatomical factors which assist the sphincteric smooth muscle. A length of intra-abdominal esophagus potentiates the high pressure zone of the sphincter; the acute angle between the esophagus and fundus of the stomach forms a flap valve which closes as the intragastric pressure rises and the crura of the diaphragm press on the lower esophagus. These mechanisms are illustrated in Figure 19.1. Loss of the normal anatomy of the gastroesophageal

Fig. 19.1 The factors contributing to the normal function of the lower esophageal sphincter.

junction as occurs in patients with sliding hiatus hernias severely disrupts these mechanisms and increases the likelihood of gastroesophageal reflux.

## DYSPHAGIA

### Diagnosis

The diagnosis of dysphagia can be made by taking a detailed clinical history and by careful observation of the child feeding. Nasal regurgitation of liquids in the absence of vomiting is suggestive of nasopharyngeal reflux and coughing and choking during feeding is very suggestive of aspiration into the larynx. As a consequence the child may develop recurrent chest infections due to aspiration or, because of the difficulty in ingesting an adequate calorie intake, the child may fail to thrive.

Many of the anatomical abnormalities will be obvious on inspection (Table 19.2) and most neuromuscular disorders will be associated with other neurological sequelae such as cerebral palsy. Assessment of feeding and swallowing by a speech therapist will give insight into the level of oromotor coordination; video fluoroscopy (except esophageal atresia) will define the degree of pharyngeal coordination during swallowing and the motility of the esophagus and will determine whether aspiration or nasopharyngeal regurgitation has occurred. A chest X-ray will show signs of aspiration pneumonia or mediastinal space occupation and laryngoscopy and esophagoscopy will allow direct visualization of any motor incoordination, foreign bodies or strictures that may be present.

### Treatment

The management of dysphagia depends very much on the underlying cause. Thickening of liquids or giving solids as a puree are often found to be easier and also safer to swallow than liquids alone. Great care and attention is needed with feeding technique but in some patients the airway has to be protected by instituting nasogastric or gastrostomy feeding. Neuromuscular disorders of swallowing are also frequently associated with severe gastroesophageal reflux and in conditions such as cerebral palsy and familial dysautonomia an antireflux procedure such as a Nissen fundoplication is frequently required in addition to a gastrostomy.

## GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux is the passive regurgitation of gastric contents into the esophagus and should not be confused with vomiting, which is an active process and requires the contraction of the diaphragm and abdominal muscles to initiate the event.<sup>7</sup> Gastroesophageal reflux will result if there is incompetence of the sphincteric mechanisms at the gastroesophageal junction or if raised intragastric or intra-abdominal pressures are able to overcome this mechanism. It is clear that the lower esophageal sphincter is poorly developed in the very young infant and that the formation of a sliding hiatus hernia severely limits the competence of the sphincter. Similarly in conditions where gastric emptying is delayed or in chronic respiratory diseases such as cystic fibrosis, where coughing increases intra-abdominal pressure, gastroesophageal reflux is exacerbated. In atopic children, dietary protein intolerance may be a significant factor in the development of reflux symptoms.<sup>8</sup>

With prolonged ambulatory recordings of intraesophageal pH (Fig. 19.2) it has become clear that gastroesophageal reflux is a physiological phenomenon which occurs in most children for between 1% and 5% of any 24 h period, with the majority occurring in the postprandial periods. Whether gastroesophageal reflux is deemed to be trivial or pathological is dependent on many factors of which the parents' perception of the problem, the absolute level of reflux and the development of any complicating sequelae are important. It has been shown that in normal individuals reflux most commonly occurs as the child is swallowing and the lower esophageal sphincter is relaxing to allow the passage of food into the stomach. During these brief 'unguarded moments' ingested food and acid pass into the lower esophagus, where a secondary peristaltic

Fig. 19.2 (a) A solid state 24 h pH recorder with recording electrode. (b) A trace from a 24 h pH recording showing prolonged reflux episodes (pH < 4) after feeds. The time is shown on the horizontal axis.

wave promptly clears the food back into the stomach. If, however, esophageal peristalsis is deranged the contact time of gastric acid on the esophageal mucosa will be prolonged. In a patient with very severe reflux, spontaneous relaxations of the lower esophageal sphincter occur throughout the day, leading to many more 'unguarded moments'. The most troublesome reflux occurs in patients with cerebral palsy or previous esophageal surgery where disordered innervation of the esophagus leads to increased spontaneous relaxation of the sphincter and poor peristaltic clearing mechanisms.<sup>9</sup>

### Clinical features

The passive regurgitation of milk occurs in up to half of newborn babies and is accepted by most mothers as being a normal feature of infancy. With time the problem steadily improves and with the introduction of solids and the development of a more upright posture the problem clears in almost all cases. Problems, however, develop where the mother is inexperienced or stressed and has difficulty coping with the problem or where complications such as esophagitis, aspiration or failure to thrive occur.<sup>10</sup>

In most children with reflux the volume of milk which is lost with each regurgitation is insignificant but in some children the intake is severely compromised and as a consequence weight gain is poor. With the prolonged contact of gastric acid on the esophageal mucosa an esophagitis may develop. This may present clinically as blood in the vomit or more insidiously with the development of anemia or stricture. Older children may complain of heartburn with reflux while smaller infants may develop feeding difficulties due to esophageal discomfort.

Aspiration in cerebral palsied children is very common, due to an inability to protect the upper airway from food during both swallowing and regurgitation. When considering the differential diagnosis for children with recurrent cough or respiratory tract infections, gastroesophageal reflux must be included. Aspiration is thought to be a cause of 'near-miss episodes' and in some circumstances may present with the sudden death of the infant. A bizarre presentation of gastroesophageal reflux has been described (Sandifer syndrome) where reflux episodes are associated with dystonic movements of the neck.<sup>11</sup> The clinical clue is that these episodes occur after meals and it has been postulated that stimulation of vagal afferents by the falling esophageal pH results in reflex stimulation of the spinal accessory nerve with the resulting contraction of the sternomastoid.

Although most children with reflux present in the first year of life there are some who present later with symptoms of heartburn or vomiting and a small group who though apparently symptom free through most of their lives present with a peptic stricture of the esophagus (Fig. 19.3). Chronic irritation by acid reflux may lead to replacement of the esophageal mucosa with a columnar epithelium (Barret's esophagus). This metaplastic change can lead to increased risk of adenocarcinoma in later life. There is also the occasional child who will present outwith the first 2 years of life with the precipitous development of severe gastroesophageal reflux in whom detailed investigation may reveal the presence of a posterior fossa tumor.

In children with reflux there may also be longer term behavioral sequelae which can frequently lead to major management problems. Some children are reluctant to eat, particularly solids, and as a consequence feeding problems develop which may last long after the reflux has apparently cleared. Other children who find it easy to reflux are able to regurgitate at will and use this as a powerful attention-seeking tool. A small number of children develop the ability to ruminate, a condition which is generally associated with prolonged periods of reflux.

## Diagnosis

In the majority of cases the diagnosis is made clinically from the history of effortless vomiting occurring after meals and no further investigations are required. The family history is often positive in children with severe reflux who do not have neurological disease. Where the clinical picture is unclear or where symptoms suggest a more severe problem,

Fig. 19.3 (a) (left) A barium meal showing gross gastroesophageal reflux. (b) (right) A lateral view of the esophagus showing a peptic stricture with proximal dilatation.

further investigation is required. Unfortunately no single investigation provides all the information which is required. A 24 h pH study will quantify the degree of acid reflux (Fig. 19.2); a barium meal will tell if there is a hiatus hernia or more distal obstruction (i.e. malrotation) but it has poor sensitivity and frequently misses short reflux episodes. If esophagitis is suspected an endoscopy is required and a full blood count may show evidence of anemia secondary to blood loss. The presence of fat-laden macrophages in the sputum may help in the detection of aspiration. A fuller discussion of esophageal investigations is given later in this section.<sup>12,13</sup>

## Treatment (Table 19.3)

Although it is possible to differentiate between physiological and pathological reflux by using 24-hour pH studies, it is likely that in most children treatment decisions will be determined largely on clinical grounds. In an otherwise well baby who is growing adequately and who is free of any complicating features it is likely that the condition will follow a benign course and will resolve spontaneously. The mother should be reassured and advised of simple measures to help with the problem. If the infant is being overfed this should be stopped and if over 3 months of age the introduction of solids should be encouraged. There is generally no need to alter the child's feed but where there is a strong family history of atopy or signs of eczema the introduction of a hypoallergenic feed may be indicated. In addition a small but significant number of children who fail to respond to medical treatment improve dramatically with dietary exclusion. Some of these children will have eosinophilic oesophagitis (see p 607). As the consistency of the feed seems to influence the degree of reflux, thickening agents are found to be helpful in many babies. Alginate compounds are sometimes also found to relieve symptoms.

Traditionally it was advised that children with reflux should be kept sitting upright in a chair but it is likely that this may increase intra-abdominal pressure and exacerbate the problem. Babies should sleep in the supine position to reduce the risk of sudden infant death syndrome.

Where these simple measures fail to reduce reflux, the use of prokinetic agents should be considered. Domperidone and metoclopramide can be used but the former is not licensed to treat reflux in children and the latter can be associated with extrapyramidal side-effects. Additionally domperidone may cause prolongation of the QTc, as has previously been reported with cisapride, and as such a pretreatment electrocardiogram should be considered. They both act by increasing the rate of gastric emptying and it has been postulated that they also increase the lower esophageal sphincter pressure. They do, however, have to be taken continuously to be effective.

Table 19.3 Treatment for children with gastroesophageal reflux (see text for details)

Clinical condition	Treatment
Very mild reflux	Mother reassured Simple feeding advice
Mild reflux	Thickened feeds
Moderate reflux	Prokinetic drugs (consider risk versus benefit)
Reflux with esophagitis	Add histamine 2 blockers Proton pump inhibitor
Severe reflux	Consider continuous nasogastric tube feeding in children less than 1 year as an alternative to fundoplication
Failure of medical treatment	Fundoplication
Esophagitis with stricture	Fundoplication with dilation (Consider a trial of exclusion diet if there is an atopic history)

In patients with crying, irritability or persistent discomfort due to esophagitis, measures to control gastric acid output are required. Histamine 2 (H2) blocking drugs such as ranitidine, or proton pump inhibitors such as omeprazole, will raise the pH of the regurgitated food and seem to help in the healing of esophagitis. In the screaming baby the empirical trial of a H2 blocking drug can be successful, and be a helpful diagnostic test to confirm reflux as the cause of the child's discomfort. It is, however, unclear how long and in what dose this treatment should be continued as suitable controlled trials have yet to be carried out. Antacids have no place in the long-term treatment of esophagitis as the amount required to adequately alkalize the gastric juices would be likely to lead to salt overload. Their occasional use may be helpful in the older symptomatic child with heartburn.

In young children with reflux there is an expectation that spontaneous clinical improvement is likely up to about 18 months of age. Continuous nasogastric feeding significantly reduces the amount of reflux and in some children with severe symptoms, may be preferable to fundoplication. Although this treatment needs a high degree of motivation from the parents it may adequately control symptoms until the child spontaneously improves.

Where medical management, including a trial of exclusion diet, fails to control complications and gastroesophageal reflux persists, a surgical antireflux procedure is indicated. Where stricture formation has already occurred this should be combined with dilatation of the stricture. It is important that an experienced pediatric surgeon carries out these procedures as the operation may be complicated by retching or gas bloat syndromes. Careful preoperative assessment of patients is required to try and minimize subsequent complications.<sup>14</sup>

A suggested plan of treatment for patients with gastroesophageal reflux is shown in Table 19.3.

## EOSINOPHILIC ESOPHAGITIS

Eosinophilic esophagitis is a condition that has only been recognized in children over the last 10–20 years and in adults for an even shorter time.<sup>15</sup> These children present with many of the symptoms of gastroesophageal reflux such as vomiting, nausea and abdominal pain but fail to respond to conventional medical treatment for reflux. Diagnosis is made by esophageal biopsy which frequently shows small macroscopic white 'candida-like' patches. Microscopically the biopsies show more than 20 eosinophils per high power field. If left untreated, this can lead to symptoms of dysphagia with the eventual development of esophageal stricture.

The cause is thought to be due to food allergens such as milk, soya, egg and wheat although in some patients respiratory allergies such as pollen have been implicated. IgE, radioallergen sorbent testing (RAST) and skin prick measurement is generally unhelpful as the allergic reactions which may involve all layers of the esophagus are not IgE mediated.

Exclusion diets based on liquid amino acid feeds have been shown to be successful in treating this condition but in all but the youngest patients the feed needs to be given by nasogastric tube. Other treatments such as steroid administration, sodium chromoglycate or leucotriene receptor antagonists have all been tried with varying degrees of success.

The natural history of this condition remains unclear and until this is clarified and high-quality treatment trials are carried out, the best management for this condition will be open to debate.

## ACHALASIA

Achalasia of the cardia results from a failure of the lower end of the esophagus to relax with swallowing, resulting in the development of dysphagia, aspiration, retrosternal discomfort and weight loss. This functional obstruction is caused by neurodegenerative changes in the enteric nerves of the lower end of the esophagus.

The condition is very uncommon in childhood and may be confused with gastroesophageal reflux or peptic stricture in young children and

anorexia nervosa in older children. An autosomal recessive form called the triple A syndrome occurs when achalasia is associated with Addisonism (hypoadrenalism), alacrima and in some patients neurological deterioration.

The diagnosis is confirmed by the barium swallow appearance of esophageal dilatation with a funnel-shaped narrowing at the lower end and by esophageal manometry which demonstrates disturbed peristaltic activity in the body with increased basal tone and failure of relaxation of the lower esophageal sphincter.

The condition is generally progressive and is treated either by pneumatic dilatation of the lower esophageal sphincter or by Heller's cardiomyotomy.<sup>16</sup> Dilatation procedures frequently have to be repeated more than once and effective treatment of achalasia may lead to the development of gastroesophageal reflux. For this reason in the long term a myotomy and fundoplication procedure is frequently also necessary.

## ESOPHAGEAL INVESTIGATIONS

A number of esophageal investigations are available but unfortunately no single test is likely to give all the information that is required to resolve a clinical problem. Each test gives information on a specific aspect of esophageal structure or function and it is necessary for tests to be combined for an overall picture to be obtained (Table 19.4).

### Barium studies

Traditionally the barium swallow has been the investigation of choice in children with gastroesophageal reflux. While it is true that contrast studies give good information on the anatomy of the esophagus and the gastroesophageal junction it is a very insensitive test for reflux and the mucosal changes of esophagitis will only show if they are well advanced (see Fig. 19.3). Video studies are useful in detecting abnormalities of swallowing and motility disturbances of the body of the esophagus. It is important that screening is continued until contrast has passed into the jejunum as abnormalities of gastric emptying or malrotation will otherwise be missed.

### Gastroesophageal scintigraphy

Scintiscanning using technetium-99m (<sup>99m</sup>Tc)-labeled milk has been shown to be more sensitive in detecting reflux than barium studies and with prolonged scans gastric emptying can be measured and bronchial aspiration of the milk can be detected. The method, however, requires the patient to remain still for up to 30 min on a gamma camera and gives very little anatomical information.

### Esophageal manometry

This technique is presently available in only a few pediatric centers and its clinical uses are limited to the diagnosis of the less common conditions such as achalasia and esophageal spasm. The measurement of

Table 19.4 Investigations of esophageal structure and function

Test	Uses
Barium studies	Define anatomy of upper GI tract
Scintiscanning	For the detection of reflux and aspiration (not as sensitive as pH studies)
Manometry	Detect achalasia or esophageal spasm
pH monitoring	Most sensitive test for acid reflux
Esophagoscopy	Detect esophagitis and allows mucosal biopsy
Trial of NG feeding	Unmasked reflux in patients with poor oral intake

GI, gastrointestinal; NG, nasogastric

lower esophageal sphincter pressure is a very insensitive indicator of gastroesophageal reflux.

### Esophageal pH monitoring

The prolonged ambulatory recording of esophageal pH using catheter-mounted electrodes is a very sensitive means of quantifying acid gastroesophageal reflux (Fig. 19.2). Modern computerized systems allow the length of time and the number of episodes of acid reflux to be measured and their division between awake, asleep, postprandial and fasting periods can be derived. Unfortunately it fails to detect non-acid reflux and with the realization that up to 50% of reflux in some patients may be non-acid, the potential limitations of this investigation are becoming clear. Newer impedance techniques when combined with pH measurement should hopefully help overcome this problem as all liquids refluxed are detected.

### Esophagoscopy

If significant reflux is found or peptic or eosinophilic esophagitis is suspected it is important that an esophagoscopy is carried out. This is the only method which allows accurate assessment of esophagitis both visually and histologically and mucosal inflammation can be detected at a very early stage long before any radiological changes are found. With modern pediatric endoscopes the procedure can be carried out as a day case under sedation or a short general anesthetic.

### Trial of nasogastric tube feeding

The assessment of children with cerebral palsy is often compromised by the fact that their oral intake is significantly reduced and reflux may not be seen during barium studies. The passage of a nasogastric tube and the administration of appropriate feed volumes often unmasks symptoms of reflux and facilitates the administration of contrast during barium studies.

## THE STOMACH AND DUODENUM

### STRUCTURE AND FUNCTION

The stomach is a J-shaped organ which lies obliquely across the midline in the upper abdomen. It is covered by an inner oblique, middle circular and outer longitudinal layer of smooth muscle and is lined by a columnar epithelium which is indented with gastric pits. The muscular layer is thickened at the pylorus, which acts as a valve to control the rate of emptying from the stomach. The columnar epithelium produces mucus, which forms a protective layer over the mucosa. The pits in the antrum, body and distal fundus are short and contain the parietal cells which produce hydrochloric acid and intrinsic factor, the chief cells which synthesize and secrete pepsinogen, endocrine cells and mucus-producing cells which are located at the neck of the glands. The pyloric glands which also contain endocrine cells are more tortuous and secrete large amounts of mucus.

### Gastric motility

Following the ingestion of food, the body and fundus distend greatly and act as a reservoir for the storage of food. In contrast the antrum is a more muscular organ which, working in concert with the pylorus, produces propulsive, segmenting and retrograde activity to break the food down into small, easily digested pieces.

Liquids generally empty very rapidly from the stomach with the rate being determined by the pressure gradient across the pylorus. A typical half emptying time for a drink of orange squash is 15 min. Solids in contrast empty much more slowly with a half emptying time being more typically between 90 and 120 min. The rate of emptying is very closely controlled by mechanoreceptors in the antrum and chemoreceptors in the duodenum which feed back to the gastric smooth muscle to limit the rate of emptying. As a consequence of this a homogenized meal will empty more rapidly than a solid meal and a low energy meal will empty faster than a more energy-dense meal. The rate of emptying is also inhibited by the presence of undigested fat in the ileum and

by distension of the rectum due to fecal loading. The nongastrointestinal factors which influence gastric emptying are discussed further in the section on vomiting.

### Digestion

Pepsinogen is released from zymogen granules in the chief cells of the gastric glands in response to the ingestion of food. Under the influence of hydrochloric acid and then by the autocatalytic action of free pepsin the active pepsin is formed. This enzyme has a pH optimum of 1.0–1.5 and initiates proteolysis in the stomach by hydrolyzing peptide bonds at the amino groups of aromatic or acidic amino acids.

It is also likely that triglyceride hydrolysis starts in the stomach with the activation of the acid-stable lingual lipase and possibly also by the action of gastric lipase. In the preterm infant, because of the very low activity of pancreatic lipase it is likely that this mechanism is of some importance.

### Gastric acid production

Hydrochloric acid is actively secreted by the parietal cells of the gastric glands maintaining the pH of the stomach at approximately 1. The rate of acid production is modulated by circulating levels of the gut hormone gastrin, which is produced by G cells within the antrum of the stomach. The acid environment of the stomach has an important defensive role against ingested pathogens and as mentioned earlier provides the optimal environment for activity of the gastric digestive enzymes. The low pH facilitates the absorption of inorganic iron by preventing its precipitation. Excessive acid production, however, is likely to lead to an increasing incidence of duodenal ulceration.

The parietal cells are also responsible for the secretion of the glycoprotein intrinsic factor which stabilizes vitamin B<sub>12</sub> during intestinal transit and binds to specific receptors in the terminal ileum prior to absorption. In autoimmune gastritis where the parietal cells are destroyed, hydrochloric acid and intrinsic factor production cease, resulting in achlorhydria and vitamin B<sub>12</sub> deficiency.

## GASTRITIS

### Acute gastritis

Acute inflammation of the stomach may arise from conditions as diverse as irritation from nonsteroidal anti-inflammatory drugs (NSAIDs), chemical ingestion or the duodeno gastric reflux of bile. Many of these conditions are self-limiting and may resolve spontaneously if the insult is removed. If the cause of the mucosal irritation persists the gastritis may become chronic and in the case of continued NSAID ingestion, may proceed to peptic ulceration.

### Chronic gastritis

There are two main forms of chronic gastritis: atrophic and non-atrophic. The former is usually associated with autoimmune disease and leads to loss of glandular tissue with resulting achlorhydria and loss of intrinsic factor production. This condition is very rare in childhood.

Non-atrophic gastritis is most commonly caused by *Helicobacter pylori* although less common causes include Crohn's disease and eosinophilic gastroenteritis.<sup>17</sup> Diagnosis is made by histological examination of mucosal biopsies from the antrum, incisura and body of the stomach. The Sydney classification of gastritis has been devised primarily for adults but it is likely that the general principles also apply to children. In *H. pylori* infection, the gastric antrum frequently has a nodular appearance and histologically acute infection is associated with an increase in intraepithelial neutrophils which progresses to chronic inflammatory changes with an associated increase in lymphoid follicles.

## PEPTIC ULCERATION

### Acute ulcers

Peptic ulceration can occur acutely in response to stress or the administration of ulcerogenic drugs. Stress ulcers can occur in either the

stomach or duodenum and are most common in the neonatal period in response to birth asphyxia or respiratory distress but they can also occur in later childhood following severe burns, meningitis or other major stresses. In patients receiving NSAIDs for conditions such as juvenile arthritis or corticosteroids for severe asthma or IBD, acute ulcers can also occur. It is unlikely that *H. pylori* plays a significant role in acute ulceration.

A stress ulcer is likely to present with intestinal bleeding or acute pain and should be treated with an H<sub>2</sub> blocker or proton pump inhibitor but where perforation occurs, surgery is required. In situations where stress ulceration is likely, prophylaxis with gastroprotective drugs should be considered.

### Chronic ulcers

Chronic peptic ulceration occurs most commonly in children over the age of 5 years but unlike acute ulcers, which affect the stomach and duodenum equally, chronic ulcers occur 10 times more frequently in the duodenum. As in adulthood there is very frequently a family history of peptic ulcer disease with a slight (3:2) male to female preponderance.

In many older children the classical ulcer symptoms of localized epigastric discomfort, nocturnal waking and relief of symptoms with food or antacids are present. However, in younger children more non-specific symptoms such as vague abdominal pain, vomiting and nausea may make the diagnosis less clear. Some children may present with an occult anemia or more acutely with a hematemesis or melena. Because of the vague nature of many of these symptoms it is very important to differentiate between peptic ulcer disease and the far more common 'non-organic' recurrent abdominal pain of childhood. The presence of epigastric pain, nocturnal waking, a progressive worsening of symptoms, an iron deficiency blood picture or a family history should alert the practitioner to the possibility of duodenal ulceration.

While the diagnosis can be made on a barium meal, carried out by an experienced radiologist, the relatively poor sensitivity of this test (50%) means that where a peptic ulcer is suspected upper gastrointestinal endoscopy should be the investigation of first choice. In addition to visualizing the ulcer, endoscopy allows the practitioner to look for *H. pylori* infection in mucosal biopsies.<sup>18</sup> Although the measurement of gastric acid output is a very insensitive way of diagnosing peptic ulcer disease, in the rare situation where multiple ulcers refractory to treatment are present it is important to measure fasting serum gastrin and basal and stimulated gastric acid output levels to exclude the possibility of a gastrin-secreting pancreatic tumor (Zollinger–Ellison syndrome).

### Treatment

Much of the advice for treatment of peptic ulceration has been extrapolated from the adult experience as clinical trials in children have been limited by the small number of patients and by ethical constraints. It is likely, however, that a similar condition exists in both groups of patients as the clinical experience of therapeutic regimens is similar in each.

The treatment of chronic peptic ulcer disease is primarily aimed at reducing excess gastric acid production and eradicating *H. pylori* infection, which is invariably present. A 6-week course of treatment with acid suppressive therapy will provide symptomatic relief of dyspeptic symptoms within 1–2 weeks in most patients and by the end of the 6-week course the ulcers will have healed in over 80% of patients. Recurrence of ulcer symptoms is likely to develop unless attempts are made to eradicate *H. pylori* and a course of triple therapy using one of the regimens outlined in the section on anti-*Helicobacter* therapy, is indicated at the time of initial treatment. If symptoms recur after treatment it is likely that the *H. pylori* has not been completely eradicated.

### HELICOBACTER PYLORI

Since the identification of *H. pylori* in the mucosa of the gastric antrum there has been an explosion of interest in the role of this small spiral

organism and its causal relationship to gastritis, duodenal ulcer, recurrent abdominal pain, lymphoproliferative disorders and gastric cancer.

While *H. pylori* is undoubtedly a causal factor in the pathogenesis of peptic ulcer disease in both children and adults, the presence of infection only leads to active disease in 10% of the population. Up to half of the world's population is infected with *H. pylori*, the majority of whom will have no recognizable disease. Similarly in children the presence of an active gastritis may not lead to the development of any symptoms and the priority when investigating a child is to determine the cause of their symptoms and not whether they are or are not infected with *H. pylori*. Our present understanding remains incomplete and many questions remain unanswered. There have however been consensus statements in recent years from both Europe and North America which begin to answer questions such as, who should be screened for infection, how they should be tested, and who should be treated and what is the optimal method of eradicating *H. pylori*?<sup>18,19</sup> (see Table 19.5).

### Pathogenesis

This organism is recognized as the most important cause of non-auto-immune gastritis in both children and adults. It may colonize either the antrum of the stomach, leading to increased acid production, or the body of the stomach, where inflammation may lead to the development of an atrophic gastritis. Normal duodenal mucosa is not colonized unless gastric metaplasia has developed. *H. pylori* lies deep within the mucus layer which covers the gastric mucosa and through the action of the enzyme urease, which produces ammonia and the release of cytotoxins, the underlying mucosa becomes damaged and inflamed. During endoscopy a nodular inflammation of the antrum may be seen and hypertrophy of the gastric mucosal folds has been reported.

### Epidemiology

*H. pylori* is acquired in early childhood and, once infected, children are likely to remain colonized, despite the mounting of a host response, for the rest of their life unless they are inadvertently treated with antibiotics. The incidence of *H. pylori* infection in industrialized countries is approximately 0.5% of the susceptible population per year compared to a rate of 3–10% in developing countries. Spread occurs through close physical contact either by oral–oral or fecal–oral routes with the prevalence increasing where there is social deprivation or institutionalization.

### Diagnosis of *Helicobacter pylori* Biopsy and histopathology

Endoscopy and biopsy is the most reliable method for diagnosing infection. Multiple biopsies from the antrum, incisura and body of the stomach allow the location and severity of inflammation to be defined and the presence of small spiral organisms on specially stained tissue

**Table 19.5** Agreed points from consensus statements on *Helicobacter pylori*

1. The aim of diagnosis is to find the cause of the symptoms rather than the presence of *H. pylori*
2. Testing all children and treating those positive for *H. pylori* is not recommended
3. Antibody tests of blood, serum or saliva are not recommended
4. Upper GI endoscopy and biopsy is the best test for a child with chronic upper abdominal pain or suspected peptic ulcer disease
5. A child diagnosed with peptic ulcer disease by barium study should undergo endoscopy if symptoms recur
6. The urea breath test is not a satisfactory alternative to endoscopy for *H. pylori* diagnosis because of the wide differential diagnosis. It can be used for confirming success of treatment
7. Screening for *H. pylori* in asymptomatic individuals is not indicated
8. Treatment should be given when *H. pylori* is causing active disease (i.e. duodenal ulcer). When it is present without associated disease (i.e. asymptomatic child) the need for treatment should be discussed with the parents

sections confirms the presence of infection. In patients with infection that is resistant to treatment, biopsy allows culture and antimicrobial sensitivity to be determined.

The advantages of high sensitivity and specificity and the ability to examine the esophagus and duodenum at the same time have to be balanced against the invasiveness, availability and cost of the procedure.

### Rapid urease (CLO) test

A single gastric biopsy is placed in the well of a CLO test slide. If *H. pylori* is present, its urease activity will cleave urea to produce ammonia, which will turn the pH indicator red if left at room temperature for 24 h. This test gives indirect evidence of infection but cannot be relied upon in isolation to make a diagnosis.

### Serology

This test is based on the detection of specific IgG to *H. pylori* in serum samples. The tests are cheap and relatively easy to set up. In children however the humoral immune response to infection may be slow to develop and this test is most unreliable in children under 5 years. The accuracy of serum-based kits in symptomatic patients is between 60% and 70%. These tests cannot be used to confirm eradication after treatment as antibodies may remain positive for many months despite successful therapy. The recent consensus reports do not recommend the use of serological testing as the primary means of diagnosing *H. pylori* infection.

Tests using salivary antibodies are not presently recommended but stool tests for *H. pylori* antigens appear a little more promising.

### C<sup>13</sup> urea breath test

This non-invasive test involves the patient taking a small oral dose of C<sup>13</sup>-enriched urea following a test meal which delays gastric emptying.<sup>20</sup> If *H. pylori* is present within the stomach the urea is cleaved, releasing C<sup>13</sup>-enriched CO<sub>2</sub>, which is then exhaled in the breath. By collecting two breath samples, one before and the other 30 min after taking the oral urea, a rise in C<sup>13</sup> levels in the breath signifies infection. This test has a sensitivity of 95% and a specificity of almost 100%. The sensitivity is reduced if antibiotics or acid suppressing drugs are not discontinued for 1 month prior to the test. The breath collection may also be technically difficult in young children.

The primary role of breath testing is confirming successful eradication after a course of treatment.

### Symptoms

It is likely that the majority of children infected with this organism have no symptoms but, conversely, in children with evidence of chronic peptic ulceration, *H. pylori* is likely to have an important role in its pathogenesis. Why the majority of children has no symptoms and only a small minority develops peptic disease remains unclear. It is not possible to differentiate infected from non-infected patients on the basis of history alone and in infected patients only those with proven ulceration responded well to eradication therapy. This would suggest that *H. pylori* gastritis does not in isolation cause symptoms.

It was initially thought that *H. pylori* infection might be a significant cause of recurrent abdominal pain in childhood. While 5–17% of such children may be infected, it has been found that 5–29% of children without pain also had evidence of infection. It is therefore quite clear that this infection is not a significant factor in children with recurrent

abdominal pain and current recommendations are that such children should not be screened for infection.

## Treatment

### Who to treat?

Eradication therapy is recommended where *H. pylori* infection and symptoms due to that infection are both present.<sup>21–23</sup> However because infection with *H. pylori* is so common many children in whom infection is found will either be asymptomatic or will have symptoms not directly attributable to the infection. In this latter group the decision to treat is less clear-cut as it may not be of any benefit to the child and may carry the risk of side-effects from treatment.

Treatment is indicated for children with *H. pylori* infection and gastric or duodenal ulcer. In the rare patient with mucosa-associated lymphoid tissue (MALT) lymphoma or atrophic gastritis with intestinal metaplasia eradication therapy is also indicated.

Many children with *H. pylori* infection have evidence of gastritis without either gastric or duodenal ulceration. Under such circumstances treatment is unlikely to benefit the child. There is at present no convincing evidence that eradication therapy will reduce the risk of later peptic ulceration, adenocarcinoma or lymphoma. The clinician should discuss the pros and cons of treatment with the child and his/her parents before making a decision on whether to treat or not.

At present there is no evidence that children with recurrent abdominal pain or asymptomatic children benefit from eradication therapy.

### Drug therapy

No properly controlled trials of *H. pylori* eradication therapy in children have been carried out and most of the available information is extrapolated from adult studies. A number of factors however are clear. Firstly the most important determinant of the success of therapy is compliance with treatment and secondly it is recommended that three medications are given twice daily for 1–2 weeks. The use of one or two medicines is likely to be ineffective and will increase the risk of drug resistance developing. The recommended first-line treatment for *H. pylori* eradication is given in Table 19.6.<sup>19</sup> It is suggested that successful eradication is confirmed by C<sup>13</sup> breath testing and where reinfection occurs the use of alternative antibiotics such as tetracycline (over 12 years) or bismuth salts should be considered.

## UPPER GASTROINTESTINAL BLEEDING

Bleeding from the upper gastrointestinal tract may present either as a hematemesis or melena depending on the site and severity of the bleeding. In the majority of cases the bleeding has little hemodynamic effect but major bleeds warrant urgent treatment. It is important, however, when taking a history to be sure that the child has in fact passed blood. The swallowing of bloodstained liquor, sucking on a cracked nipple, a recent nose bleed and the recent ingestion of beetroot can all mimic an intestinal hemorrhage.<sup>24,25</sup>

### Diagnosis

The most likely cause for a bleed can be determined from the age of the child and by searching for clues from the history and examination. A history of previous gastrointestinal symptoms, recent drug ingestion, umbilical catheterization as a neonate, stigmata of chronic liver disease or a bleeding diathesis, or evidence of subcutaneous or cutaneous hemangioma should be sought (Table 19.7). In children with forceful

Table 19.6 Recommended first-line eradication therapy for *Helicobacter pylori* in children. Gold et al 2000<sup>19</sup>

Medication	Dose
Omeprazole (or equivalent proton pump inhibitor)	1 mg/kg/day up to 20 mg twice a day
Give two } amoxicillin	50 mg/kg/d up to 1 g twice a day
of three } metronidazole	20 mg/kg/d up to 500 mg twice a day
antibiotics } clarithromycin	15 mg/kg/day up to 500 mg twice a day
Treatment should be as a twice-daily regimen (to aid compliance) for 7–14 d.	

**Table 19.7** Causes of upper gastrointestinal bleeding

vomiting due to gastroenteritis, Mallory–Weiss tears are the likely cause if specks of blood are present in the vomitus.

A full blood count will give an indication of the duration and severity of the bleed but may be misleading in the acute situation. A clotting screen will define the nature of any bleeding disorder that may be present. Direct visualization of the upper gastrointestinal tract by endoscopy should be carried out within 24 h of the bleed or whenever the patient is hemodynamically stable. This investigation will allow the detection of esophagitis, esophageal varices, gastric and duodenal ulcers and vascular malformations of the intestine proximal to the third part of the duodenum. If bleeding persists and these initial investigations are negative, a small bowel meal should be carried out and if negative a capsule endoscopy should be considered.<sup>26</sup> The direct visualization afforded by this technique is ideal for the detection of polyps, ulcers and vascular malformations. If bleeding persists and no cause can be found a laparotomy may be indicated.

At times it can be very difficult to distinguish between upper and lower tract bleeding and it is suggested that this section is read in conjunction with the section on rectal bleeding (see p. 638).

## Treatment

The initial treatment of the shocked patient is resuscitation, ensuring the patient has a secure airway and is breathing adequately with maintenance of the circulation by the rapid infusion of 10–30 ml/kg initially of saline and then whole blood when available. Any bleeding diathesis should be corrected and attempts should be made to define the underlying cause. If varices are found the patient should be treated by a team experienced with this type of problem. A description of the management of a variceal bleed is given in the section on liver disease (see p. 651). Most patients stop bleeding with simple medical management, and treatment should be aimed at the underlying cause of the bleeding.

## VOMITING

Vomiting is a very common symptom of disease in childhood and should not be confused with the regurgitation of food, which occurs in conditions such as gastroesophageal reflux. The vomiting reflex is the body's response to noxious stimuli, which may reside within the gastrointestinal tract or result from some systemic disturbance and act directly or indirectly on the 'vomiting center' in the area postrema of the brainstem. The act of vomiting can be divided into three phases. In the pre-ejection phase the patient feels nauseous, looks pale, salivates and through the action of visceral efferent nerves develops a tachycardia with relaxation of the proximal stomach. This is followed by a period of retching and

then, with synchronous contractions of the intra-abdominal muscles and diaphragm with an open glottis, upper esophageal sphincter and mouth, the contents of the stomach are ejected.

In the neonate, vomiting may be the first symptom of an intestinal obstruction, although any infection, metabolic disturbance or cerebral insult may present in an identical manner. The presence of bile in the vomit would suggest an obstruction distal to the duodenum. As the child becomes older the range of conditions causing obstructive and metabolic problems will change and in addition dietary indiscretions or intolerances may develop. The possibility of idiopathic hypertrophic pyloric stenosis should be considered in any baby of 1–4 months of age who develops projectile vomiting. In the older child drugs taken either accidentally or therapeutically may result in vomiting. A history of recurrent episodes of severe vomiting punctuated by asymptomatic periods should alert the practitioner to the possibility of cyclical vomiting. The symptoms of vomiting and diarrhea are frequently combined during enteric infections and it is likely that on a worldwide scale this is the most common cause of vomiting.

## Diagnosis

A good history and examination will often give strong pointers to the most likely cause for the vomiting. A pyloric tumor or the mass of an intussusception may be palpable on abdominal examination. In some patients, particularly the very young, clues may be few and far between and it must also be remembered that the differential diagnosis varies greatly depending on the age of the patient and on whether any associated features such as diarrhea are present (Table 19.8).

An erect and supine abdominal X-ray will show multiple air–fluid levels in intestinal obstruction but it must also be remembered that a

**Table 19.8** Causes of vomiting in infancy

Cause	First week of life	After first week
Alimentary tract	Duodenal atresia	Malrotation/volvulus
	Jejunal atresia	Hirschsprung disease
	Malrotation/volvulus	Intussusception
	Duplication of bowel	Strangulated hernia
	Diaphragmatic hernia	Pyloric stenosis
	Meconium ileus	Functional obstruction
	Hirschsprung disease	Peptic ulceration
	Anal atresia	Appendicitis
	Functional obstruction	Bezoar Crohn's disease
Metabolic	Galactosemia	Organic acidemia
	Organic acidemia	Hyperammonemia
	Hyperammonemia	Hypoadrenalism
	Hypercalcemia	Diabetic ketoacidosis
	Hypoadrenalism	Drug intoxication Reye syndrome Uremia

		Septicemia
Cerebral	Birth trauma Hydrocephalus	Head injury
		Cerebral tumor
		Encephalitis
		Increased intracranial pressure
Others		Motion sickness Cyclical vomiting

functional obstruction due either to some intrinsic abnormality of the gut or to the toxic effect of sepsis or metabolic derangement may also give a similar picture. Barium contrast studies will define the nature of surgical causes of vomiting which are not clear from plain films. Where appropriate, detailed infection and metabolic screens should be carried out and signs of raised intracranial pressure should be sought. The serum electrolytes will give information on the extent of the vomiting and may even, as in the case of hypochloremic hypokalemic alkalosis of pyloric stenosis, give clues to the underlying cause.

If a non-organic cause for the vomiting is suspected or if a behavioral element is thought to be present, referral to a psychiatrist or psychologist for a diagnostic assessment should be considered.

### Treatment

The treatment should be aimed at the resuscitation of the patient in the first instance and then more specifically at the underlying cause of the vomiting. Electrolyte losses should be corrected with i.v. fluids and oral fluids should be stopped. If vomiting persists a nasogastric tube should be passed and where an obstructive lesion seems likely a pediatric surgeon should be consulted. As an adjunct to the treatment of the underlying problem, antiemetic drugs may be useful in modifying the emetic response. Given the wide variety of stimuli which can produce vomiting and the varying mode of actions of these drugs it is perhaps not surprising that these agents are not universally effective.

### INFANTILE HYPERTROPHIC PYLORIC STENOSIS

Pyloric stenosis develops in approximately 3 per 1000 live births with a male-to-female preponderance of 4:1. The cause of the condition is unclear although a reduced number of cases occur in babies with blood group A and there is also a strong familial pattern of inheritance. A thickening of the pyloric muscle results in gastric outlet obstruction with resulting vomiting.<sup>27</sup>

Symptoms of projectile vomiting occurring 10–20 min after a feed, develop between the second and fourth week of life, although they can occasionally occur either sooner or at up to 4 months of age. With progressive vomiting the infants lose weight and may eventually become dehydrated and alkalotic. On clinical examination gastric peristaltic activity may be seen, and palpation of the right upper quadrant of the abdomen during a test feed will reveal the pyloric tumor in most cases. If the mass cannot be felt diagnosis can be aided by a barium meal, which will show a narrow elongated pyloric canal or by ultrasound, which should also define the mass.

The initial management of the patient after the diagnosis has been confirmed is i.v. rehydration and correction of any acid–base disturbance. The patient should then undergo a Ramstedt's pyloromyotomy where the pyloric muscle is split down to the mucosa. Oral feeds can be restarted 24 h after surgery (see Ch. 37).

Other surgical causes of vomiting are discussed more fully in Chapter 38.

### CYCLICAL VOMITING

Cyclical vomiting is defined as three or more periods of intense nausea and unremitting vomiting with intervening periods free of symptoms in a child without metabolic, gastrointestinal or central nervous system disease.<sup>28,29</sup> The attacks, which can occur as frequently as once a week in some children and as infrequently as every 6 months in others, are generally preceded by a prodromal phase when the child is pale and withdrawn with the attack lasting anything from 12–72 h. The vomiting may also be associated with features of the periodic syndrome such as abdominal pain or headache.

The vomiting may be exacerbated by the child's desire to drink large amounts of fluid; persistent vomiting can lead to Mallory–Weiss tears, dehydration, electrolyte imbalance and eventually coma. It is frequently difficult to define the factors which precipitate each attack but a careful history may reveal stress factors, the most common being marital

conflicts and school-based problems. The children require a full blood count, the measurement of serum electrolytes and a urine culture. Where symptoms persist or bilious vomiting occurs, a contrast study should be done to exclude malrotation. It is important also to exclude raised intracranial pressure as a cause of the vomiting. Rare metabolic problems such as medium chain acyl CoA dehydrogenase deficiency (MCAD) or ornithine transcarbamylase deficiency in girls need to be considered and excluded. In a small number of children an intercurrent viral infection may appear to initiate the episode.

If left untreated the majority of children will grow out of the problem but this may take many years. In others, headache may become a prominent feature and a picture of migraine may develop later. If stress factors have been revealed from the history, psychological therapy may be of benefit in preventing further attacks while in those with migrainous features, dietary exclusion of cheese, chocolate, caffeine or citrus fruits should be considered. During acute attacks the child may require hospital admission for i.v. fluids. The 5 hydroxy tryptophan three (5HT<sub>3</sub>) antagonist ondansetron given with a benzodiazepine such as lorazepam may be helpful in shortening the length of attacks. I.v. dexamethasone may potentiate this effect. Good control of the raised blood pressure associated with this condition is also required.

### FOREIGN BODIES

Children between the ages of 1 and 4 are particularly liable to swallow foreign bodies. The majority of these cause very few problems and simply pass straight through the intestine but long pointed objects such as fish bones or needles can become lodged in the pharynx, esophagus or occasionally in the duodenal loop. If the foreign body becomes lodged in a high position, coughing and choking may occur but frequently there may be no initial symptoms. Perforation of the mucosa will result in the development of a mediastinitis or peritonitis and where a battery becomes lodged a caustic stricture or mucosal erosion may develop.

### Bezoar

The repeated ingestion of hair or paper or fibers from clothing or blankets can result in the formation of a large non-opaque foreign body in the stomach. These masses can grow to quite a large size but frequently there are very few symptoms other than vague abdominal pain or halitosis. The bezoar may be felt by abdominal palpation or outlined on a contrast study where the barium adheres to the fibrous mass.

### Treatment

Small foreign bodies without sharp edges should be left to pass through the intestine. If they do not appear within 72 h a plain X-ray should be taken to check on their position. Sharp foreign bodies should be removed endoscopically under direct vision. If endoscopic removal from the stomach is not possible a laparotomy will be required.

### GASTRIC INVESTIGATIONS

#### Barium studies

In patients with chronic nausea and vomiting a barium meal will define the anatomy of the stomach and detect the presence of a hiatus hernia, reflux, if it occurs during the examination, malrotation or any space occupation due to a bezoar. Although duodenal ulcers may be detected, endoscopy is the investigation of choice where a mucosal lesion is suspected.

#### Gastroscopy

Fiberoptic endoscopy is the preferred investigation for detecting duodenal or gastric ulcers or the antral gastritis associated with *H. pylori* infection. The method can be used in infants of all ages allowing histological and microbiological confirmation of the suspected diagnoses.

## THE SMALL INTESTINE

### STRUCTURE OF THE SMALL INTESTINE

In man the small intestine occupies the major length of the gastrointestinal tract and is the major organ of digestion and absorption. In the adult the small intestine varies in length from 3 to 5 m depending on the state of contraction, while in the term infant the length is probably nearer 1.5 m. The small intestine is divided into the duodenum, which extends from the pylorus to the duodenal–jejunal flexure at the ligament of Treitz, and the remaining small intestine is arbitrarily divided into the jejunum and ileum, which represent the proximal two fifths and distal three fifths, respectively.

In cross-section the structure of the small intestine is grossly similar throughout. The inner circular lumen is lined by a highly convoluted mucosa which exposes a large surface area for the absorption of nutrients. Underneath the surface epithelium lies the submucosa, which in turn is encircled by the muscularis, which comprises an inner circular and an outer longitudinal layer. The outermost layer is the serosa, which is in continuity with the peritoneum. The mesentery of the small intestine is inserted diagonally across the posterior abdominal wall from the ligament of Treitz to the cecum. When this mesentery is shortened by malrotation of the small intestine it becomes unstable and is liable to twist.

### Mucosa

The mucosa consists of the surface epithelium and the lamina propria. The mucosal surface is covered by villi which project into the lumen and greatly increase the surface area and by the crypts of Lieberkühn, which lie between the villi and form a depression in the mucosa (Fig. 19.4). In the jejunum the villous:crypt ratio is 3:1 but this decreases more distally to 1–2:1 in the ileum. Underneath the surface epithelium lies the lamina propria, which contains a connective tissue core for the villi along with the vascular, lymphatic and neural networks which serve the nutrient and transport needs of the surface epithelium.<sup>30</sup>

### The surface epithelium

The crypts and villi should be thought of as the functional unit of the surface epithelium. The crypts contain paneth, goblet, endocrine and undifferentiated cell types. Goblet cells which lie on the lateral wall of the crypts produce large amounts of protective mucus and the endocrine cells, which are neuroectodermal in origin, synthesize and secrete gastrointestinal hormones. Rapidly dividing undifferentiated cells migrate up the length of the crypts and on to the villi, where they transform into

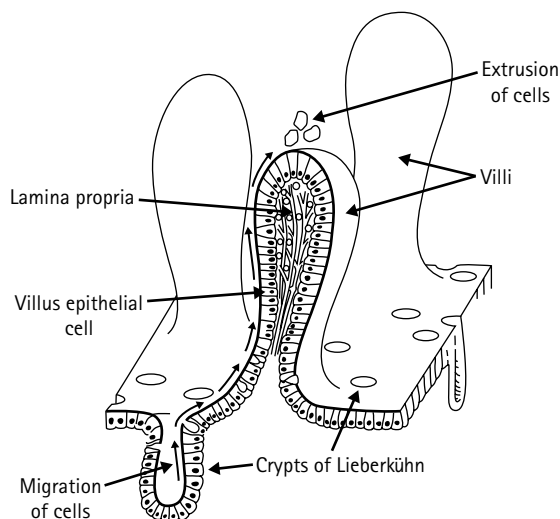

Fig. 19.4 A diagrammatic view of the surface of the small intestine. (Reproduced from *Harries' Paediatric Gastroenterology*<sup>30</sup> by kind permission of the publisher.)

mature villus cells (Fig. 19.4). The rate of division of these cells and their speed of migration is under the control of the trophic effect of enteral nutrients and a number of gut hormones. When enteral nutrients are removed as a result of starvation or the prolonged use of parenteral nutrition (PN), mucosal hypoplasia results while during the adaptation process that follows small intestinal resection, the rate of cell turnover increases resulting in mucosal hypertrophy and increased villous length.

As the epithelial cells reach the villous tip they degenerate and fall off into the lumen. This rapid turnover of the villous epithelium takes between 4 and 6 days and explains both why the intestinal mucosa is on the one hand very susceptible to the toxic effects of ionizing radiation and chemotherapeutic drugs and why on the other its rate of repair and recovery from serious insult can be very rapid. The enterocytes have a well-developed brush border which further increases the surface area of the mucosa to luminal nutrients and supports the enzymes responsible for the final digestion of nutrients prior to absorption.

The cells in the crypts play an important role in the secretion of water and electrolytes into the lumen in contrast to the villous cells, which largely absorb water, electrolytes and nutrients. In health the small intestine is a net absorber of water but in situations where the villous structure is damaged (i.e. celiac disease) or where mucosal inflammation stimulates the activity of the secretory crypt cells (i.e. Crohn's disease) this situation is reversed, leading to active mucosal secretion. A similar situation occurs in rotavirus gastroenteritis, where the rapid turnover of regenerative cells results in villi populated with immature cells which have yet to develop significant absorptive capacity.

### The muscularis

The motor activity of the small intestine is provided by the inner circular and outer longitudinal muscle layers which are present along the whole length of the small intestine. Nerve fibers freely travel between these layers with extension distally onto the mucosa and proximally through afferent and efferent fibers which project both to and from the brainstem and cerebral cortex.

## DIGESTION

### Digestion of carbohydrates

Starch, the main form of ingested carbohydrate, is a mixture of long chains of glucose units linked at the alpha-1,4 position (amylose), and shorter chains of alpha-1,4-linked glucose units connected by alpha-1,6 links to give a branched structure (amylopectin). As the intestine is only able to absorb monosaccharide units these large molecules require digestion by hydrolytic enzymes.

This digestion takes place in two steps: the first, occurring within the lumen of the gut, breaks the starch into oligosaccharides and the second, which occurs on the brush border of the small intestine, further digests these carbohydrates to their component monosaccharides. The luminal digestion is carried out by amylase from the salivary glands and the pancreas, which hydrolyzes alpha-1,4 bonds, breaking the amylose into maltose (two glucose units) and maltotriose, and amylopectin into limit dextrins with on average eight glucose units and one or more alpha-1,6 branching points. In the adult approximately 15% of duodenal amylase activity is salivary in origin but in the newborn infant, where pancreatic exocrine function is very poorly developed, this may increase to 50%.

Dietary disaccharides and the products of amylase digestion are further hydrolyzed by the enzymes of the enterocyte brush border membrane. These include the alpha-glucosidases sucrase, isomaltase, maltase and trehalase, the latter having no functional significance in the human. The beta-galactosidase lactase is also present. The substrate and product of each of these enzymes is outlined in Table 19.9. These enzymes are all high molecular weight glycoproteins which are synthesized in the endoplasmic reticulum, processed in the Golgi and inserted into the plasma membrane. The sucrase and isomaltase activities originate from a large molecule which is synthesized in continuity

**Table 19.9** Carbohydrate digestion by the brush border

Enzyme	Substrate	Product
