#### **Note**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Authors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

# Preface

---

One of the most important developments in the 21<sup>st</sup> century has been the acknowledgment that clinical practice should be embedded where possible in a sound evidence base. The editors of this new edition of *Forfar & Arneil's Textbook of Pediatrics* continue to set contributors the challenging task of ensuring that the statements and recommendations made are based on the most robust clinical research available. The objective assessment of evidence and the formulation of secure recommendations from the evidence are gathering pace. In Child Health the evidence base, with the possible exception of disciplines such as oncology and neonatology, is not as comprehensive or as well defined as we would wish. This edition of *Forfar & Arneil* continues to flag up the most important evidence sources for the content of each chapter. The whole book has been revised and updated and the chapter authors and editors again incorporate where possible secure evidence of therapy, diagnosis, etiology and prognosis. This evidence is incorporated into the individual chapters and in the chapter reference list is starred for easy reference. We believe that the result is the most comprehensive evidence-based general textbook of pediatrics available. Our ability to access best evidence has been greatly enhanced by the rapid advances of information technology and electronic

publishing and consequently another important new feature for this edition is a website of the text in which references listed in PUBMED can be accessed via the internet. We would like to acknowledge the outstanding contributions of the many individual authors and our chapter editors, without whom this ambitious project would not have been possible. It has been a great privilege to work with them. We would also like to thank our own secretaries for their unstinting help (Elaine Forbes, Flora Buthlay, Collette Lorne and Stella Taylor) and of course our respective families for sharing the burden with us.

As with previous editions the book is produced by the Elsevier Organization. There have been many highly professional people involved. We hope that this new 7th edition with its expanded formal evidence base will be well received by you, the reader, and become as trusted a friend and guide as have previous editions.

Evidence-based child health	6		

### INTRODUCTION

Evidence-based pediatrics and child health has been defined as 'the integration of clinical information obtained from a patient, with the best evidence available from clinical research and experience and the application of this knowledge to the prevention, diagnosis or management of disease in that child'.<sup>1</sup> This definition has been adapted from an earlier one by Sackett and colleagues<sup>2</sup> who have consistently argued that there is an art to medicine, as well as objective scientific knowledge, and that both are essential to the clinical encounter. Within the classical clinical method, as taught in medical schools and beyond, the diagnostic approach starts with a history, leads on to a clinical examination and utilizes, if required, special investigations. In the process of history taking, the clinician integrates the case specific features of the patient's own story with their accumulated case expertise. For example, the differential diagnosis and mode of history taking in two children presenting with cough will be very different, if in one, it is elicited that she has experienced fever and night sweats and is recently returned from India, and in the other, recurrent wheeze and hay fever are accompanying symptoms. In taking a history, one constantly updates the differential diagnoses and redirects one's questioning as each new item of information is elicited. Indeed, it is this ability to take a history in a directive and efficient manner that distinguishes the experienced clinician from the new clinical student.

Sackett and colleagues have long argued that the clinical examination should be studied rigorously to establish which features are predictive of specific diagnoses. For example, they have reviewed studies that evaluated the accuracy of signs recommended for use in the diagnosis of chronic obstructive pulmonary disease.<sup>3</sup> They found that for all the signs reviewed, the sensitivity, specificity and likelihood ratios varied considerably between studies, and were far short of what would be required for an ideal diagnostic test.<sup>3</sup>

It is only the final part of the diagnostic process, the use of special investigations, for which there are many studies which meet established criteria for valid assessment of clinical evidence.<sup>2</sup> Conventionally, diagnostic tests are judged by their sensitivity (proportion of patients with the target disorder who have positive tests) and specificity (proportion of patients without the target disorder who have negative tests). More useful than sensitivity or specificity in understanding the performance of a test is the likelihood ratio which can be regarded as a summary of sensitivity and specificity (although it can also be used to summarize the performance of tests which have many categories where sensitivity and specificity are unhelpful). For example, suppose you are assessing a child with failure to thrive and malabsorption. You might estimate on the basis of the clinical picture that the probability of the child having celiac disease is around 10%. You might feel that this probability is too low to

justify suggesting to the parents that the child should undergo a small intestinal biopsy but also too high to allow you to dismiss the possibility. You wish to know whether a test which measures antiendomysial antibodies in the serum will, if positive, mean that the diagnosis is sufficiently likely to make the biopsy worth doing or, if negative, decrease the probability to a level where you can reasonably discount the diagnosis.

A publication from 13 European Centres has evaluated both serum antitissue transglutaminase IgA (IgA-TTG) antigliadin antibodies and serum IgA antiendomysial antibodies (IgA-EMA) and compared them with findings of subtotal or severe partial villous atrophy with crypt hyperplasia on small intestinal biopsy (the reference standard).<sup>4</sup> The blood samples were taken no more than 60 days before and not after the small intestinal biopsy, and were independently reviewed by two investigators, who had no knowledge of the diagnosis. So it appeared that the reference standard was applied independently of the diagnostic tests being evaluated and the reference standard was applied objectively to all patients. It is not clear from the paper whether the diagnostic tests were evaluated in an appropriate spectrum of patients or whether all patients with a possible diagnosis of celiac disease underwent small intestinal biopsy, regardless of the results of the blood tests. However, the sensitivities of IgA-TTG and IgA-EMA in the detection of celiac disease were 94% and 89%, with specificities of 99% and 98% respectively.

The likelihood ratio is the ratio of the probability of the test result in patients with the disease to the probability of the test result in patients without the disease. It enables an updated 'post-test' probability to be calculated from the pretest probability, using the results of appropriate studies. The likelihood ratio associated with a positive test result can be calculated from the sensitivity and specificity as follows:

$$LR+ = \text{sensitivity}/(1 - \text{specificity})$$

The equation which relates post-test odds to pre-test odds, using the likelihood ratio is:

$$\text{Post-test odds} = \text{pretest odds} \times \text{likelihood ratio}$$

From the example of IgA-TTG provided above, the study we have found would suggest the following:

$$LR+ = 94\%/1\%, \text{ or } 94$$

and for IgA-EMA:

$$LR+ = 89\%/2\% \text{ or } 44.5$$

If this is applied to the estimated pretest probability, provided in the example above, of 10%, or odds of 1:9, a positive test result for IgA-TTG will convert these pretest odds to a post-test odds of 94:9, or a post-test probability of 91%. The equivalent calculation for IgA-EMA is a post-test odds of 44.5:9 or 83%. Most clinicians would consider that a small

intestinal biopsy should be performed in a child with these probabilities of having celiac disease.

What should the clinician do, though, if the test is negative? The likelihood ratio of a negative test result can be calculated as follows:

$$LR- = (1 - \text{sensitivity})/\text{specificity}$$

For our example, with IgA-TTG this is:

$$LR- = 6\%/99\% \text{ or } 0.06$$

and for IgA-EMA:

$$11\%/98\% \text{ or } 0.11$$

So a negative test result for IgA-TTG and IgA-EMA will convert our pretest odds of 1:9 or 10% to a post-test probability of around 0.7% and 1.2% respectively. Most clinicians would not perform intestinal biopsies in a child with the probabilities of having celiac disease.

What this example shows is that it is not only how a test works that is important in interpreting the result but also the initial likelihood of disease in the child who has the test. Imagine if you did a test for IgA-TTG on a completely well child where the probability of having celiac disease is very low (perhaps less than 0.1%). If the test was negative the likelihood of the child having celiac disease would be vanishingly small but even a positive test would mean only about an 8.5% chance that she had the condition. Using this approach to thinking about diagnostic tests lets you plan the rational use of tests and minimizes the chance of being led astray by false positive or false negative results.

For those familiar with statistical methods, it will be evident that the concept of likelihood ratios has been adopted from the Bayesian approach to statistical inference. The first step in any Bayesian analysis is to establish a prior probability distribution for the value of interest (e.g. probability of a child having a diagnosis of gluten sensitive enteropathy). The clinical evidence is then used to update the prior distribution to a posterior distribution using Bayes theorem. This is analogous to the intuitive process in clinical history taking, where the probabilities of having one of a number of different diagnoses are updated as each new piece of information is elicited. In an evidence-based medicine approach, we start with a prior view about whether, for example, a drug treatment will improve clinical outcomes for an individual patient. This view may be informed by knowledge of pathophysiology and pharmacology, the patient's preferences, cost of therapy and so on. This prior view is then updated by the results of a randomized controlled trial of the drug treatment, in a group of patients similar to our patient, which shows clear improvement in the outcomes we consider important. This evidence is integrated with our prior beliefs, to enable a clinical decision to be made. Many have argued that the natural statistical framework for evidence-based medicine is a Bayesian approach to decision making,<sup>5</sup> both for the individual patient and for health policy.<sup>6</sup>

In an article entitled 'Narrative-based medicine in an evidence-based world',<sup>7</sup> Greenhalgh quotes a scenario, referred to as 'Dr Jenkins' hunch', which goes as follows: 'I got a call from a mother who said that her little girl had had diarrhea and was behaving strangely. I knew the family well and was sufficiently concerned to break off my Monday morning surgery and visit immediately.' Dr Jenkins' subsequent actions resulted in the child recovering from meningococcal septicemia. To many this may seem like a fortunate fluke, and indeed meningococcal septicemia presents rarely in primary care. No guideline could have reliably prompted Dr Jenkins' action. However the doctor was integrating his clinical intuition (mothers rarely use the word 'strangely' to describe their children's behavior), his acquaintance with the family (known to be sensible and uncomplaining), with current best evidence (prognosis of meningococcal septicemia, with and without early administration of parenteral penicillin) to take a course of action which saved a child's life. Greenhalgh rejects the notion that the 'narrative of illness experience' and the 'intuitive and subjective' aspects of clinical method run counter to evidence-based medicine.<sup>7</sup> In making clinical decisions, either informally, by integrating new evidence with our prior views, or formally, by using Bayesian analysis, the framework exists to ensure that clinical evidence can play an explicit part in the process.

## THE PRACTICE OF EVIDENCE-BASED MEDICINE

Traditionally there are four basic steps described in this approach. The first is to frame a clinically relevant question and to focus it in a way which can be answered. This is not as trivial a step as it may at first appear. The key elements of a well framed question include a description of:

1. the patient or population;
2. the intervention or exposure;
3. the comparison intervention or exposure (if relevant); and
4. the clinical outcome(s) of interest.

Such an approach can be applied whether the issue is one of diagnosis, prognosis or therapy.

For example, let us consider the following scenario. You are the clinical director of a pediatrics department in a large district hospital. An audit has demonstrated that among children who attend the pediatric clinics with a diagnosis of asthma, there appears to be a high rate of attendances at the accident and emergency department and admissions to hospital. You are interested in interventions which may improve the management of children with asthma and prevent exacerbations severe enough to require A&E attendances and admissions. It was suggested by one of your colleagues that to achieve this, the department should invest in an asthma nurse specialist, who would initiate asthma self-management programs and education programs for all children who attended outpatient clinics with asthma. The resource to provide this service has to compete with other priorities for the department and so you need to know whether or not it might be effective. To investigate this further you formulate the following question: 'in children with asthma, who attend hospital outpatients (population), does a program of education and self-management, delivered by an asthma nurse specialist (intervention), compared with no such program (comparison intervention), reduce the risk of attendances with acute asthma at the accident and emergency department and admissions to hospital (outcome)?'

Having defined the question, the second step is to undertake a comprehensive review of the best available clinical evidence. This is likely to involve searching electronic databases (e.g. Medline, EMBASE, CINAHL and *The Cochrane Library*). The development of search strategies for these databases often involves the expertise of information scientists who can adjust the search strategy to maximize finding all relevant studies (which increases sensitivity), but at the expense of identifying many irrelevant articles (decrease specificity).

Having retrieved all potentially relevant articles which address the question, the third step is to critically appraise them. Tools have been developed to appraise studies evaluating diagnostic tests, prognostic markers, treatments, adverse effects and systematic overviews.<sup>2</sup> In the example provided above, you will have been searching for studies which are used to evaluate the effectiveness of treatments. There are many different study designs which may address this type of question. A hierarchy of such study designs for questions about treatment effectiveness has been developed with the most rigorous at the top and the least rigorous at the bottom (Fig. 1.1). The primary research study, which is considered to be the gold standard in assessing treatments, is the randomized controlled trial. The key element in this design is that the allocation of patients to the treatment group or to the comparison group is

Systematic Review of Randomized Controlled Trials

done randomly, and thus the observed differences between the treatment and the comparison group(s) will be due to the experimental treatment alone rather than to biases which may be introduced by patient characteristics, physician preferences, etc. However, even given this robust study design, the methodological quality of randomized controlled trials may be subject to biases in other ways and these can be evaluated appropriately using checklists.<sup>2</sup>

The fourth step, which is to apply the evidence in clinical practice, is the point at which clinical expertise and patient values are integrated with the best available external evidence. To do this, clinicians need to ask two questions concerning the evidence that they have appraised. The first is 'is this evidence sufficiently robust for me to be confident in its application?' and the second is 'is this study applicable to the patient (or population) about whose care I am deciding?'

Practitioners of evidence-based medicine have long argued that it should not be conducted from ivory towers, by individuals who have little patient contact. If it is to be applicable it needs to be practiced by all clinicians, not least because the questions or question posed need to be relevant to routine practice. However, as will be apparent from the brief description above, the second and third steps of this approach can be very laborious. This has led to the development of a number of shortcuts which will enable the clinician to move easily from step one to step four. To be reliable, such shortcuts must use rigorous methods. One of the most attractive and reliable of these tools is the development of systematic reviews. As will be seen from Table 1.1, the systematic review is now regarded by many as the most rigorous study design for providing information about treatments. The term *systematic* or *scientific* review is used to distinguish them from more *traditional* or *narrative* type reviews of topic areas conducted by experts in the field.

## SYSTEMATIC REVIEWS

Narrative reviews have become a regular feature of many medical journals. Such reviews may be very informative, lively and interesting and are usually well illustrated. They are popular because clinicians are busy and have limited time to try and assimilate all primary research which is relevant in a particular area. However, if judged as scientific work which provides summaries of the evidence, which can be used to guide diagnosis or treatment, they are very subject to bias and are therefore unreliable.

These deficiencies led to the concept of systematic reviews, which should adopt a rigorous scientific methodology to eliminate systematic bias or random error, as would be expected of investigators undertaking primary clinical research. The methodology for systematic reviews is outlined in Table 1.1. First the reviewer needs to state the hypothesis that they wish to investigate and then prospectively define a comprehensive search strategy to identify all potentially relevant studies. This

**Table 1.1** How to conduct a systematic review

1. State objectives and hypotheses
2. Outline eligibility criteria, stating types of study, types of participant, types of intervention and outcomes to be examined
3. Perform a comprehensive search of all relevant sources for potentially eligible studies
4. Examine the studies to decide eligibility (if possible with two independent reviewers)
5. Construct a table describing the characteristics of the included studies
6. Assess methodological quality of included studies (if possible with two independent reviewers)
7. Extract data (with a second investigator if possible), with involvement of investigators if necessary
8. Analyze results of included studies, using statistical synthesis of data (meta-analysis), if appropriate
9. Prepare a report of review, stating aims, materials and methods and describing results and conclusions

Courtesy of Craig JV, Smyth RL. Evidence based practice manual for nurses. Edinburgh: Churchill Livingstone, 2002.

strategy will almost certainly include searching electronic databases but may involve other methods such as those designed to access unpublished studies, to ensure that the studies accessed are representative of all the research conducted in a particular area. The protocol for the review should state prospectively what studies will be considered eligible for inclusion, defined according to study design, type of participant, intervention, (or exposure) and comparison intervention or exposure. The outcomes of interest are stated prospectively. The protocol should also state how the quality of the included studies will be assessed.

Having determined which studies are to be included and assessed them for methodological quality, the reviewer then extracts the relevant data and analyzes it. This may involve statistical methods such as meta-analysis. This enables the data from a number of different studies to be aggregated so that a pooled effect size can be estimated. There are many examples where individual studies, usually because they are too small, fail to show that an intervention is either beneficial or harmful. By combining the results from all potentially relevant studies, such benefit or harm has been clearly demonstrated. This enables questions to be answered such as 'does this treatment have a beneficial effect?' and also 'what is the size of the effect?'

There now exists a database of systematic reviews of randomized controlled trials of interventions across the whole range of health care. This is found in *The Cochrane Library*,<sup>8</sup> which, at the time of writing (Disk Issue 4, 2006), contains 2905 systematic reviews. These reviews have been prepared by the Cochrane Collaboration, an international body dedicated to producing systematic reviews of the effects of health care using randomized controlled trials as the primary study design. *The Cochrane Library* is produced as a CD-ROM, is updated quarterly and is accessible on the Internet <http://www.cochrane.org/> This means that systematic reviews can also be updated to take account of new knowledge.

For the question described above, 'in children with asthma, who attend hospital outpatients (population), does a program of education and self-management, delivered by an asthma nurse specialist (intervention), compared with no such review (comparison intervention), reduce the risk of attendances with acute asthma at the accident and emergency department and admissions to hospital (outcome)?', a Cochrane review, entitled, 'Educational interventions for asthma in children'<sup>9</sup> addresses this question. It is a systematic review of randomized controlled trials, which included children, aged 2–18 years. Studies which assessed any educational interventions targeted to children or adolescents (and/or their parents) designed to teach self-management strategies related to prevention, attack management, or social skills using any instructional strategy or combination of strategies (problem-solving, role-playing, videotapes, computer assisted instruction, booklets, etc.) presented either individually or in group sessions were included in the review. The outcomes assessed in the included studies were health care utilization outcomes, which were the main interest in our scenario, but also physiological measures, morbidity and functional status and self-perception. A number of the studies included self-management programs delivered by a specialist nurse and a high proportion of the studies took place in an outpatient setting. For the outcomes of interest in this scenario, A&E attendances and hospital admissions, 12 trials reported A&E department visits as an outcome and when the results of these trials were pooled, self-management education programs were associated with a reduction in this outcome (standardized mean difference  $-0.21$ , 95% confidence intervals  $-0.33$  to  $-0.09$ ). However, when the results, for hospital admissions, of the eight trials which reported this outcome were pooled, there was no significant benefit of educational interventions (standardized mean difference  $-0.08$ , 95% CI  $-0.21$  to  $0.05$ ). Self-management and education was associated with improvements in lung function, days of school absence and days of restricted activity. All of this information will help informed decision-making in planning the delivery of care for children with asthma in an outpatient hospital setting.

Although well conducted systematic reviews are regarded as being at the top of the hierarchy of study designs to evaluate the effectiveness of treatments, they can be misused or be badly conducted. Therefore systematic reviews need also to be appraised and there are checklists

available for doing this. Jadad et al,<sup>10</sup> for example, have published an evaluation of reviews and meta-analyses of treatments used in asthma. Of the 50 reviews that they considered, 40 were found to have serious methodological flaws. Included within these 40 were six reviews funded by the pharmaceutical industry. All but one of these six reviews had results and conclusions that favored the intervention related to the company which sponsored the review. Reassuringly they found that Cochrane Reviews had higher overall quality scores than reviews published in other scientific journals. The Cochrane Collaboration has made strenuous efforts to ensure that its methodology reduces bias to a minimum and has also guarded against biases which may be introduced by authors with conflicts of interest, e.g. significant support from the pharmaceutical industry. This methodology and the external appraisal by individuals such as Jadad provide reassurance that systematic reviews produced by the Cochrane Collaboration are reliable sources of information for the clinician.

## EVIDENCE-BASED CHILD HEALTH

The evidence-based medicine movement was initially advanced by practitioners of internal medicine, but, more recently, pediatricians have become leading proponents. The scope of a number of Cochrane Collaborative Reviews Groups (such as the Cystic Fibrosis and Genetic Disorders Group) covers areas that deal mainly with illnesses of childhood. In addition, there is a Cochrane Child Health Field which has the goal of supporting the production of child-focused, clinically relevant, methodologically rigorous systematic reviews. However, one feature that this discipline of evidence-based health care has highlighted is that when children's health is compared to adult health care, research questions in children may have been addressed either not at all or by small, poorly designed studies.<sup>11</sup> This was the case when all randomized trials published during a 15-year period in a specialist pediatric journal were examined. In this review sample sizes were found to be generally small and only a small proportion of studies were multicenter.<sup>12</sup> Subspecialty areas within pediatrics have also been reviewed, such as cystic fibrosis,<sup>13</sup> pediatric rheumatology<sup>14</sup> and community pediatrics,<sup>15</sup> and the conclusions about the volume and quality of the research have been similar. The 6th edition of Forfar & Arneil was the first to ask contributors to be more explicit about the evidence that they cite and led to contributors expressing some frustration at the lack of level 1 evidence available for them to access in many different disease areas.

There are a number of reasons why it is more difficult to undertake clinical trials and other rigorous studies in children than in adults. There are obvious ethical dilemmas. For example, research on a new therapy is often conducted first in adults before studies are undertaken in children. However, if data from a study of a therapy in adults show a clear advantage for a drug over placebo, does equipoise still exist and is it ethical to repeat such a study in children? Such ethical dilemmas need to be considered clearly and dispassionately by individuals who are advocates for the interests of children. However, there are many examples of therapies which have different effects depending on the stage of the disease process or the age of the patient, including, for example, the sedative effects of phenobarbital in adults, but its frequent association with hyperactivity in children.

There are other practical problems. Generally the proportions of children affected by chronic diseases are smaller than in adults, and even for common childhood diseases such as asthma, the condition may be more heterogeneous than in adults and diagnostic criteria less precise. Outcome measures which have been developed and validated in adults, such as quality of life measures, are unlikely to be appropriate or feasible for young children and infants.

These difficulties have meant that pediatricians, wishing to practice evidence-based child health, have relatively little high quality evidence on which to base their decisions. However, there are encouraging signs that as well as identifying the deficiencies in the evidence, initiatives are being made to promote research that will meet these needs. For example, the Food and Drug Administration in the USA mandated in 1997

that new drugs brought to the market should be tested in children unless there were compelling reasons not to do so. In the European Union, the European Regulation on medicinal products for pediatric uses, which became law in early 2007, provides a system of requirements and incentives for pharmaceutical companies to agree a pediatric investigation plan for all new drugs which may have an indication in children. There is a provision, within the Regulation, for a European research network, of existing national and European networks, investigators and centres, with expertise in conducting clinical studies with children. In the UK, the Medicines for Children Research Network was established in 2005, with substantial government funding.<sup>16</sup>

## HOW TEXTBOOKS ENSURE THAT THEY ARE EVIDENCE BASED

Most manuals written for evidence-based practitioners do not consider textbooks to be a valuable source of information. Sackett et al<sup>2</sup> in the relevant section in their textbook *Evidence-based Medicine* state 'we begin with textbooks only to dismiss them' later stating 'while we may find some useful information in textbooks about the pathophysiology of clinical problems it is best not to use them for establishing the cause, diagnosis, prognosis, prevention or treatment of a disorder'. Part of the problem is that the material published in textbooks is written some time (often some years) before the book is published. Thus textbooks rapidly become out of date. Publishers have realized this and are trying to address this with strategies such as providing regular electronic updates more frequently than the published paper editions.

However, some textbooks have been found not to include information which is current at the time they are written. *The Oxford Textbook of Medicine* has been criticized for including a statement in its 2nd edition concerning the clinical benefits of thrombolysis for patients who had had a myocardial infarction, which stated that these benefits had not been established. This statement was made some years after this therapy had been shown, in a systematic review of randomized controlled trials, to reduce the risk of premature death after myocardial infarction.<sup>17</sup> By way of further illustration Jefferson<sup>18</sup> described his experience in conducting a Cochrane Review of the effects of cholera vaccine. Although much of the data available for this review concerned older, killed whole cell cholera vaccine, the reviewers were aware that the killed whole cell vaccine had been discouraged as it had become widely accepted that it had a low efficacy and short duration of effect, required multiple doses and was less effective in children under 5 than in adults. However, the systematic review found that the efficacy of the vaccine compared with placebo was over 50% in both the first 7 months and in the first year and just under 50% in the second year and that most of the trials achieved this efficacy using a single dose. Vaccine efficacy in the first year was also as great in children under 5 as in older people. The reviewers concluded that the level and duration of efficacy of the killed whole cell cholera vaccine had been underestimated in the literature and that the incidence of adverse effects had been overestimated. A further survey of journal editors and authors of reviews of cholera vaccines concluded that many narrative reviews had been written using the so called 'desk drawer method'. This involved including the evidence that was known to reviewers, but not assembling it or evaluating it systematically. Now that nearly 3000 Cochrane Reviews and 479 462 controlled trials of interventions are available on *The Cochrane Library*, there can be no excuse for the reviewer, or indeed textbook writer, not to consult *The Cochrane Library* when considering treatments for the condition or conditions they are writing about.

Many textbooks now contain the term 'evidence-based' within their title. These fall into two groups. Firstly the manuals that aim to instruct the clinician on how to practice evidence-based medicine and secondly textbooks which purport to present evidence-based information which has been synthesized in a rigorous manner and presented in an easily accessible format. Such textbooks include *Evidence-based Pediatrics and Child Health*<sup>19</sup> and *Clinical Evidence*.<sup>20</sup> *Clinical Evidence*, which states at the outset that it is 'not a textbook of medicine', is rather a handbook, or

a reference guide, of topics of wide general interest in health care. In the 'Compendium of evidence', at the start of the book, the methods used are clearly presented. However, its question and answer presentation, limitation to interventions and incomplete coverage of all subjects within its scope make it rather different from a textbook such as this one. *Evidence-based Pediatrics and Child Health* describes itself as a 'melding of a textbook of evidence-based medicine and a clinical pediatric text addressing common conditions'. The first section of this book provides readers with the skills needed to practice evidence-based child health, while the second and third sections address common pediatric conditions. Again the format is in a question and answer framework, with illustration by scenarios. Within the second and third sections, only those specific questions for which evidence is available are considered and as a consequence much of clinical pediatrics is not discussed.

A large and complete textbook of pediatrics such as this one needs to provide a detailed consideration of all aspects of a condition, not just diagnosis, prognosis, prevention and treatment (which are more amenable to evidence-based approaches). Moyer and Elliott<sup>1</sup> refer to two sorts of questions which may be used by the reader in trying to elicit information about a topic, including background information such as: what is Cornelia de Lange syndrome, how commonly is tracheoesophageal fistula associated with esophageal atresia and what is meant by the term apoptosis? These are distinguished from 'foreground' questions relating to, for example, benefits or adverse effects of therapy. Textbooks therefore need to consider the definition, pathophysiology and clinical presentation of conditions as well as diagnosis, prognosis, prevention or treatment of the disorder.

In considering how textbook writers put this information together in a readable format it is helpful to consider how this process has evolved over decades or even centuries. Bristowe in the preface to the 1876 first edition of his *Theory and Practice of Medicine*<sup>21</sup> states his primary aim as 'to give in a readable form as much information as I could within a limited

space'. He describes his practice of 'in every case to read the subject up carefully; to compare the knowledge thus acquired or renewed with the results of my own experience, in those cases in which I had any experience; and then, having taken a more or less definite view of the whole subject and while my mind was still full of it, and its details, to write as clear and as comprehensive an account as I was capable of'. He states that this method of procedure will partly explain 'the prevailing absence of notes, quotations and references to authorities'. This textbook, which ran to over 1000 pages, was written entirely by Bristowe and contained no references. Indeed it was unusual for textbooks to contain more than a few references per chapter until the middle of the twentieth century. The method used by Bristowe is similar to that used by many authors today, and the depth of the individual's experience contributes to the richness of the narrative and thus its readability.

So whilst retaining these traditional methods for the provision of background information we have, however, asked all authors to search for and use the best available evidence when presenting 'foreground' information. The methods that we have used to do this will be discussed in the next section.

### CLINICAL EVIDENCE WITHIN THE 7TH EDITION OF FORFAR & ARNEIL

For the 6th and 7th editions of Forfar & Arneil the editors gave specific instructions to contributors to ensure that their contributions were as evidence-based as possible. The contributors were asked to identify, where possible, 'level 1 evidence'. This system of grading evidence and recommendations was chosen because it is widely used and has been developed over the last 20 years. The table which contributors were asked to use (Table 1.2) is available on the Website of the Oxford Centre for Evidence-based Medicine (<http://cebm.jr2.ox.ac.uk>).<sup>22</sup> This

Table 1.2 Oxford Centre for Evidence-Based Medicine levels of evidence (December 2006)

Level	Therapy/prevention, etiology/harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
1a	SR (with homogeneity*) of RCTs	SR (with homogeneity*) of inception cohort studies; CDR <sup>†</sup> validated in different populations	SR (with homogeneity*) of level 1 diagnostic studies; CDR <sup>†</sup> with 1b studies from different clinical centers	SR (with homogeneity*) of prospective cohort studies	SR (with homogeneity*) of level 1 economic studies
1b	Individual RCT (with narrow confidence interval <sup>‡</sup> )	Individual inception cohort study with ≥80% follow-up; CDR <sup>†</sup> validated in a single population	Validating** cohort study with good <sup>+++</sup> reference standards; or CDR <sup>†</sup> tested within one clinical center	Prospective cohort study with good follow-up <sup>****</sup>	Analysis based on clinically sensible costs or alternatives; systematic review(s) of the evidence; and including multiway sensitivity analyses
1c	All or none <sup>§</sup>	All or none case-series	Absolute SpPins and SnNouts <sup>††</sup>	All or none case-series	Absolute better-value or worse-value analyses <sup>†††</sup>

Level	Therapy/prevention, etiology/harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
2c	'Outcomes' research; ecological studies	'Outcomes' research		Ecological studies	Audit or outcomes research
3a	SR (with homogeneity*) of case-control studies		SR (with homogeneity*) of level 3b and better studies	SR (with homogeneity*) of level 3b and better studies	SR (with homogeneity*) of level 3b and better studies
3b	Individual case-control study		Non-consecutive study; or without consistently applied reference standards	Non-consecutive cohort study, or very limited population	Analysis based on limited alternatives or costs, poor quality estimates of data, but including sensitivity analyses incorporating clinically sensible variations
4	Case-series (and poor quality cohort and case-control studies <sup>§§</sup> )	Case-series (and poor quality prognostic cohort studies <sup>***</sup> )	Case-control study, poor or non-independent reference standard	Case-series or superseded reference standards	Analysis with no sensitivity analysis
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'

Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes, Martin Dawes since November 1998.

Notes – Users can add a minus-sign '-' to denote the level that fails to provide a conclusive answer because of:

- EITHER a single result with a wide confidence interval (such that, for example, an ARR in an RCT is not statistically significant but whose confidence intervals fail to exclude clinically important benefit or harm)

- OR a systematic review with troublesome (and statistically significant) heterogeneity.

- Such evidence is inconclusive, and therefore can only generate Grade D recommendations.

\*By homogeneity we mean a systematic review that is free of worrisome variations (heterogeneity) in the directions and degrees of results between individual studies. Not all systematic reviews with statistically significant heterogeneity need be worrisome, and not all worrisome heterogeneity need be statistically significant. As noted above, studies displaying worrisome heterogeneity should be tagged with a '-' at the end of their designated level.

†Clinical Decision Rule (these are algorithms or scoring systems which lead to a prognostic estimation or a diagnostic category).

‡See note #2 for advice on how to understand, rate and use trials or other studies with wide confidence intervals.

§Met when *all* patients died before the treatment became available, but some now survive on it; or when some patients died before the treatment became available, but *none* now die on it.

§§By poor quality *cohort* study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both exposed and non-exposed individuals and/or failed to identify or appropriately control known confounders and/or failed to carry out a sufficiently long and complete follow-up of patients. By poor quality *case-control* study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both cases and controls and/or failed to identify or appropriately control known confounders.

§§§Split-sample validation is achieved by collecting all the information in a single tranche, then artificially dividing this into 'derivation' and 'validation' samples.

†† An 'Absolute SpPin' is a diagnostic finding whose Specificity is so high that a Positive result rules-in the diagnosis. An 'Absolute SnNout' is a diagnostic finding whose Sensitivity is so high that a Negative result rules-out the diagnosis.

††† Good reference standards are independent of the test, and applied blindly or objectively to all patients. Poor reference standards are haphazardly applied, but still independent of the test. Use of a non-independent reference standard (where the 'test' is included in the 'reference', or where the 'testing' affects the 'reference') implies a level 4 study.

†††† Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and equally or more expensive.

\*\*Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using a regression analysis) to find which factors are 'significant'.

\*\*\* By poor quality prognostic cohort study we mean one in which sampling was biased in favor of patients who already had the target outcome, or the measurement of outcomes was accomplished in <80% of study patients, or outcomes were determined in an unblinded, non-objective way, or there was no correction for confounding factors.

\*\*\*\* Good follow-up in a differential diagnosis study is >80%, with adequate time for alternative diagnoses to emerge (e.g. 1–6 months acute, 1–5 years chronic).

RCT, randomized controlled trial; SR, systematic review.

Grades of recommendation:

A. Consistent level 1 studies

B. Consistent level 2 or 3 studies *or* extrapolations from level 1 studies

C. Level 4 studies *or* extrapolations from level 2 or 3 studies

D. Level 5 evidence *or* troublingly inconsistent or inconclusive studies of any level

'Extrapolations' are where data are used in a situation which has potentially clinically important differences from the original study situation.

type of approach has been used in other evidence-based textbooks.<sup>23</sup> The editors appreciated that in a number of areas there may not be level 1 evidence available, but to distinguish this category of evidence from the remainder, authors were asked to identify references to level 1 evidence with an asterisk (\*). This approach may be considered inadequate by some evidence-based proponents but was felt to be an important step in ensuring that the standard of information available from this textbook was as high as possible. The grading system used has some problems and a number of these are acknowledged (<http://cebm.jr2.ox.ac.uk>). For example, definitions of homogeneity (with respect to systematic reviews) and narrow confidence intervals (with respect to randomized controlled trials) are open to considerable interpretation and may not adequately distinguish high quality studies from those of poor quality. It is also important to realize that this particular 'hierarchy of evidence' applies only to questions about the effectiveness of interventions – other types of questions need different research approaches.

## SUMMARY

Clinical decision making is a complex process. Evidence-based medicine proponents endorse the importance of clinical expertise, which uses narrative skills to integrate the information provided by the clinical method. In practicing evidence-based medicine, clinicians integrate this information with that provided by sound clinical research. When tensions arise in this approach, it is usually because the narrative/intuitive paradigm has been discarded and decision making is predicated on the 'evidence' alone. Systematic reviews are the result of rigorous research, using methodology which is designed to reduce bias. As such they can provide reliable summaries of evidence. This methodology has been most comprehensively developed for systematic reviews of randomized controlled trials, but is being developed for other study designs. By searching databases of systematic reviews, such as those contained within *The Cochrane Library*, the clinician can obtain high quality evidence rapidly and reliably and enhance his/her clinical practice.

## INTRODUCTION

Children under 15 comprise about one third of the world population, with three quarters living in less developed countries. Children's health varies enormously across the world. In 2003 the under-5 mortality rate was 6 per 1000 in industrialized countries but 175 per 1000 in sub-Saharan Africa.<sup>1</sup>

Understanding the patterns of health and disease is important in planning health and social policies and in monitoring change over time. It is important to recognize the limitations of the data that are available. If the statistics are to be useful for comparing between areas and over time, effective systems must be in place to collect the data and there must be consistency of definitions. In many parts of the world, such systems are rudimentary, although considerable progress has been made in ensuring agreed definitions at least for the principal measures of birth and mortality. The World Health Organization is an excellent source of regularly updated health data which can be accessed on their website<sup>1</sup> and this chapter draws heavily on these data and can be assumed to be the source where no other reference is given.

This chapter will review the patterns of mortality and morbidity amongst children and examine the major determinants of health at a population level. These patterns vary widely between countries. This chapter will discuss mainly the extremes, with data drawn from the rich industrialized nations and the poorest nations, largely in sub-Saharan Africa. Many countries will of course have rates of mortality and patterns of disease lying between these extremes.

In describing the health of children at a population level we are usually forced to rely on measures of mortality or morbidity. Measures of health rather than disease are philosophically attractive but have proved problematic in practice. Although a number of tools have been developed to measure quality of life in childhood their application at a population level has been limited and they have mainly proved useful in clinical trials or in the investigation of the effects of specific conditions.

## MORTALITY RATES

### DEFINITIONS

Any infant who breathes, has a heart beat or pulsation of the umbilical cord is defined as a 'live birth', irrespective of gestation or the duration of the signs of life. It seems likely that at least some very premature infants

who fulfill this definition are not in fact registered as live births and that, as the frontiers of neonatal intensive care have been pushed back over time, this proportion has changed. In the UK a stillbirth is defined now as being 'a child born at 24 or more weeks post conception who shows no signs of life', although, up until 1992, the definition required that they were born at least 28 weeks' post conception.

The definitions of the various perinatal, neonatal and infant mortality rates (IMRs) are shown graphically in [Figure 2.1](#). The denominator for the stillbirth and perinatal mortality rates is the number of still and live births while that for the other rates is the number of live births.

The under-5 mortality rate, widely used, particularly in poorer countries, is defined as the annual number of deaths in children under 5 years of age per 1000 live births. Age-specific death rates are the number of deaths in an age group per 1000 individuals in that age group.

## PATTERNS OF MORTALITY

There have been dramatic changes in life expectancy in developed countries over the last century. In 1901, the average life expectancy for women in the UK was 48 years, but by 2004 it was 81 years. Life expectancy for men in the UK, although lower than for women, at 76 years, has also risen greatly<sup>2</sup> (except where specifically referenced, UK data are from the Office of National Statistics, whose website gives access to an enormous range of current and historical data). Although death rates at all ages have declined, much of this change has been due to the rapid decrease in deaths in childhood, particularly in the first half of the century. Changes in death rates during childhood over time for England and Wales are shown in [Figure 2.2](#).<sup>2</sup>

In Tanzania by contrast the life expectancy for women in 2004 was 49 and for men, 47. Much of the difference in life expectancy between the UK and Tanzania is driven by differences in childhood mortality, particularly mortality under the age of 5. The probability of dying between 15 and 60 years of age per 1000 population was 102 in the UK and 5.5 times higher (552 per 1000) in Tanzania. However, the under-5 mortality rate in the UK in 2004 was 6 per 1000 live births and 126 in Tanzania, 21 times higher. All these figures are for males, rates for females showing similar patterns but lower absolute rates. Not only are the relative differences larger in childhood but each childhood death contributes more to the total years of life lost and hence the life expectancy figures.

Not only are absolute mortality rates higher in poorer countries but the pattern of change over time is also different. Globally the under-5

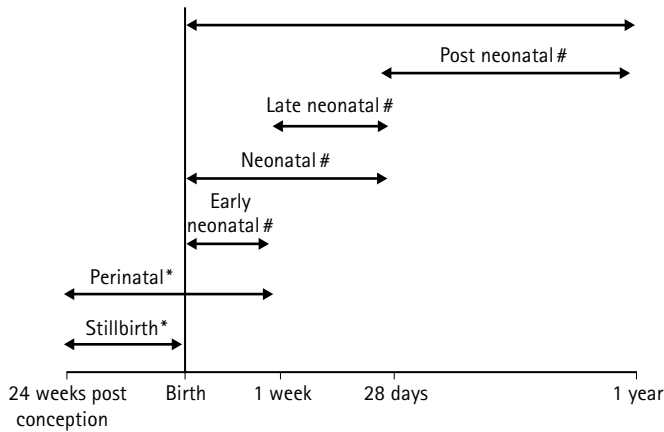

Fig. 2.1 Definitions of mortality rates in the neonatal period and infancy.

Fig. 2.2 Death rates in children in England and Wales over time.<sup>2</sup>

mortality rate fell from 198 in 1000 in 1960 to 80 in 1000 in 2003. This hides a huge variation in the rate of decline, with the least progress generally being made in countries which started with the highest rates. In 93 countries containing 40% of the world's population, < 5 mortality is declining fast, in 51 (48% of the population) progress is slow and in the remaining 43 (12% of the population), mostly clustered in sub-Saharan Africa, rates are stagnant or rising (Table 2.1).

Table 2.1 Changes in under-5 and infant mortality rates per 1000 live births over time by region<sup>1</sup>

Region	Under-5 mortality rate		Infant mortality rate	
	1960	2003	1960	2003
Industrialized nations	39	6	32	5
Developing countries	224	87	142	60
Least developed countries	278	155	127	54
Sub-Saharan Africa*	278	175	165	104
World	198	80	127	54

\*Most countries in sub-Saharan Africa are included within the category 'least developed countries' but the region is shown separately to emphasize the slow rate of improvement.

### MORTALITY IN POOR COUNTRIES

The burden of mortality in children in poor countries is extraordinary. In sub-Saharan Africa some 10% of infants die in the first year of life (compared to around 0.5% in Europe) and over 15% before their 5th birthday. The proportions of deaths related to major causal groups is shown in Figure 2.3 for under-5s in Africa and in western Europe<sup>3</sup>. Nearly three quarters of these deaths are due to six causes: (1) pneumonia (19%), (2) diarrhea (18%), (3) neonatal sepsis or (4) pneumonia (10%), (5) preterm delivery (10%) or (6) asphyxia at birth (8%). It is estimated that undernutrition is an underlying cause in over 50% of deaths in under-5-year-olds.

The first year of life is the most dangerous period of childhood and globally 40% of under-5 deaths occur in the neonatal period. The proportion is lower in Africa (26%) because of the higher burden of deaths in the post-neonatal period, although the neonatal death rates are highest here. As in the resource rich world, the consequences of prematurity and low birth weight are important causes of neonatal deaths in resource limited countries but infections (including neonatal tetanus) are also important (Fig. 2.4).<sup>3</sup> The high risks related to underlying poverty are exacerbated by the lack of services. In Africa only 40% of women deliver with skilled care and in South Asia less than 30%.<sup>4</sup>

Communicable diseases are responsible for around half of the under-5 deaths in the world and nearly two thirds in Africa. Malaria is particularly important in Africa with 94% of all malaria deaths occurring in this region. A similar picture is seen with deaths from human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) where 89% of deaths are in Africa although this picture is likely to change as the prevalence of the infection rises in poor countries of Southeast Asia. The deaths of over 400 000 children per year due to measles is depressing considering the availability of a cheap and effective vaccine which

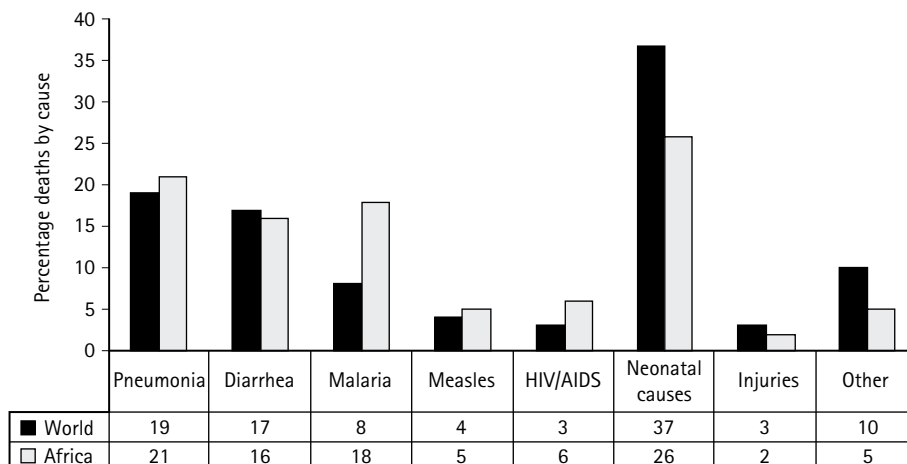

Fig. 2.3 Percentage of deaths of under-5-year-olds by cause in the world and in Africa 2000-2003.<sup>3</sup>

Fig. 2.4 Percentage of neonatal deaths by cause in Africa and western Europe 2000–2003.<sup>3</sup>

Table 2.2 Proportion < 5 deaths by cause in the 42 countries in which 90% of all < 5 deaths occur which are potentially preventable<sup>5</sup>

Disease or condition	% total deaths	% preventable
Diarrhea	22	88
Pneumonia	21	65
Malaria	9	91
HIV/AIDS	3	48
Measles	1	100
Neonatal disorders	33	55

has virtually eliminated deaths from this condition in countries with high vaccine coverage.

The vast bulk of these deaths are related directly or indirectly to poverty. Knowledge already exists about effective interventions for both treatment and prevention, which could substantially reduce this burden. It has been estimated that about two thirds of these deaths could be prevented by a small number of key interventions of proven effectiveness which could feasibly be introduced in low-income countries (Table 2.2).<sup>5</sup> The interventions considered are relatively cheap and simple including measures such as the use of oral rehydration fluid in diarrhea, insecticide treated materials for the prevention of malaria, antibiotics for neonatal sepsis and pneumonia and encouragement of high rates of breast-feeding.

### CHILDHOOD MORTALITY IN THE INDUSTRIALIZED WORLD

Of all deaths in childhood in the UK (ages 0–14), 73% occur within the first year of life, 50% within the first month and 38% within the first week (Fig. 2.5).<sup>2</sup> The decline in the rate of stillbirths and infant mortality in England and Wales is shown in Figure 2.6. The rates for stillbirth after 1992 are not strictly comparable because of the change in definition mentioned earlier. The decline in infant mortality reflects declines in both neonatal and post-neonatal mortality rates.

In the neonatal period, a substantial proportion of deaths are related to congenital anomalies and prematurity (Fig. 2.4). Congenital anomalies are an important cause of death in the neonatal period although the birth prevalence of many anomalies appears to have declined, particularly that of anomalies of the central nervous system. While part of this decline appears to relate to the widespread introduction of screening for neural tube defects in pregnancy there has also been a substantial decline in incidence, possibly related to changes in diet or the use of periconceptual folate supplements.

Congenital anomalies remain an important cause of death after the neonatal period, accounting for 22% of all deaths between 1 month and 1 year of age in England and Wales in 2005. As with older children,

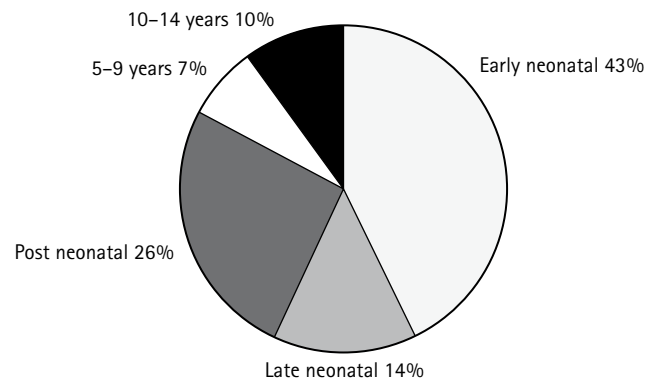

Fig. 2.5 Proportion of deaths in childhood by age of occurrence (England and Wales 2005).<sup>2</sup>

Fig. 2.6 Changes in stillbirth and infant mortality rates over time (England and Wales).<sup>2</sup> \* Per 100 live births. \*\* Per 100 live and stillbirths.

injuries and poisoning are responsible for a significant number of deaths in the first year of life, but in this age group, the much higher rates of death from other conditions mean that they are responsible for a relatively small proportion of all deaths.

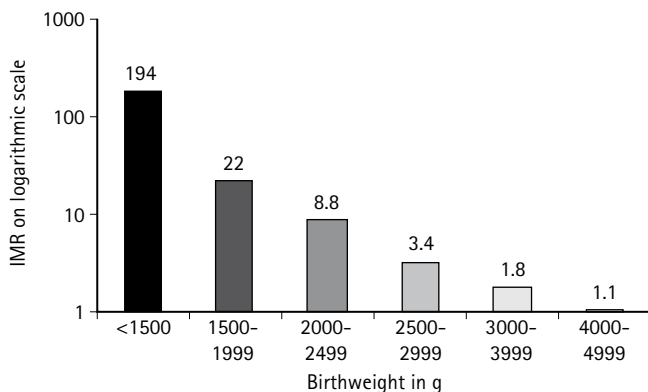

Even within the industrialized world there are substantial variations in IMRs (Table 2.3)<sup>1</sup>. While there is an obvious relationship between mortality rates and wealth there are some surprising anomalies. For example, the USA has an IMR more than twice that of Sweden. To some extent, this appears to reflect differences in IMRs in different population groups within the same country. In the USA, in 2002, the IMR for infants born to non-Hispanic black mothers was 2.4 times higher than

**Table 2.3** Infant mortality rates in some selected industrialized countries (2002)<sup>1</sup>

Country	IMR (per 1000 live births)
Sweden	3.3
Norway	3.5
Austria	4.1
France	4.1
Germany	4.2
Italy	4.5
The Netherlands	5.1
Ireland	5.1
UK	5.2
Canada	5.4
New Zealand	5.6
United States	7.0

in non-Hispanic white, and different states reported IMRs ranging from 5.0 in New Hampshire to 11.3 in the District of Columbia.<sup>6</sup>

Birth weight, reflecting both gestation and intrauterine growth, is the strongest predictor of the risk of death in the first year of life (Fig. 2.7). In large part, differences in mortality between, for instance, Sweden and the UK and between different ethnic groups in the USA are accounted for by differences in the birth weight distribution. The proportion of babies by birth weight group in England and Wales in 2004 is shown in Figure 2.8. In recent decades there has been a small overall increase in mean birth weight in many industrialized countries, largely accounted for by an increase in the proportion of babies born weighing more than 3500g. There has also, however, been an increase in the proportion of babies born weighing less than 2500g, in the USA from 6.7% of live-born infants in 1984 to 8.1% in 2003. This partly reflects increasing numbers of twins and higher order births, which in the USA now comprise over 3% of all births.<sup>6</sup>

**Fig. 2.7** Infant mortality rate (IMR) by birth weight (England and Wales 2004).<sup>2</sup>

**Fig. 2.8** Proportion of live births by birth weight in grams, England and Wales (2004).<sup>2</sup>

The risk of death drops rapidly after the first year of life; in the UK to around 21 per 100 000 children aged 1-4 and to 9 per 100 000 aged 5-14 compared to a risk of death in the first year of life of 520 per 100 000 live births. Death rates then begin to rise again after the age of 15, particularly in boys and largely as a result of the increasing risk of injuries.<sup>2</sup>

As shown in Figure 2.2, the risk of death from all causes in childhood has been falling throughout the last 50 years. Rates of death from unintentional injury in children have also fallen, but injury and poisoning still remain responsible for the greatest proportion of deaths in older children. Table 2.4 compares the most common attributable causes of death in children aged 1-14 in 1955, 1985 and 2005, in England and Wales. Very similar patterns are seen in the USA<sup>6</sup> although unintentional injury rates are higher than in England and Wales and homicide is a more important cause of death in children. In 2000 in the USA, homicide accounted for some 5.8% of deaths in children aged 1-14 compared to 2.0% in England and Wales.<sup>1</sup> Amongst adolescents aged 15-19 in the USA in 2003, accidents were responsible for 49.7% of deaths, homicide for 13.9% and suicide for 10.9%.<sup>6</sup> In both the UK and USA the risks of non-intentional and intentional injuries are substantially higher in boys than in girls.

## MORBIDITY IN CHILDHOOD

Morbidity data are more difficult to obtain, especially in poorer countries, and to interpret than mortality data, which are generally easily available and reasonably reliable. However such data are essential if a picture of the health of the population can be built up.

## HEALTH SERVICE USE

Children are heavy users of health services and routine service data can provide useful information about patterns of morbidity. A number of different sources of health service data are available in the UK, some

**Table 2.4** Percentage deaths age 1-14 by leading causes in order of frequency in 1955, 1985 and 2005 in England and Wales<sup>2</sup>

1955		1985		2005	
Category	%	Category	%	Category	%
Injury and poisoning	25.0	Injury and poisoning	33.6	Injury and poisoning	20.5
Respiratory disease*	13.0	Congenital anomalies	15.3	Malignant disease	20.0
Malignant disease	11.7	Malignant disease	14.0	Diseases of the CNS	13.9
Infectious disease	9.4	Diseases of the CNS	9.4	Congenital anomalies	11.3
Congenital anomalies	8.7	Respiratory disease	6.2	Respiratory disease*	8.1
Diseases of the GIT	4.1	Infectious diseases	4.0	CVS disease	6.6

derived directly from the use of services and some from special surveys such as the annual 'General Household Survey', which includes self-reported health and use of services.<sup>7</sup> Somewhat confusingly, these often cover different components or combinations of components of the UK. All these routine data have to be interpreted with some caution. Changes in admission rates over time for instance may reflect changes in classification either by health professionals or those who code the data, changes in thresholds for admission or real changes in incidence.

Admission of children to hospital is relatively common. In the UK, in 2002, around 11% of 0–4-year-olds and 4% of 5–15-year-olds reported being admitted to hospital at least once in the previous year.<sup>7</sup> There has been a steady decline in both the proportion and the average length of stay in hospital over time. The two most important reasons for admission in 5–14-year-olds are respiratory conditions, (including asthma), and injuries, each accounting for about 16% of admissions.

Children are also frequent visitors to Accident and Emergency departments and to general practitioners (GPs).<sup>7</sup> More than 11% of British children report going to an Accident and Emergency department over a 3-month period. Those under 5 visit a GP on average seven times per year and those between 5 and 15, three times per year. Data collected in Scotland suggest that the commonest reasons for these GP visits are upper respiratory tract infections, otitis media, coughs, sore throats and other minor conditions.

### CHRONIC DISEASE AND DISABILITY

Data on chronic disease and disability are relatively poor, even in countries with highly developed health systems. In the UK, special studies generally have to be relied upon for this information. Unfortunately there are often problems with the representativeness of the samples and with the quality of the definitions used.

The General Household Survey, mentioned earlier, asks a representative group of people in the UK to report on their own and their children's health. One of the questions asks whether they have a long-standing illness and whether it limits their activities. In 2002, the parents of 20% of boys and 17% girls aged 0–14 said that their child had a longstanding illness and 7% said that this limited their child's activities.<sup>7</sup>

Reliable information on the prevalence of disability in childhood, except for the prevalence of a few well-defined conditions such as Down syndrome, is particularly difficult to find. Such information may also be difficult to interpret, as children's functional abilities form a continuum, and the point at which the child is labeled as 'disabled' is arbitrary. A national survey in the UK, published in 1989, reported 3% of 0–15-year-olds were perceived by their parent as disabled.<sup>8</sup> Clearly such reports depend on the definitions used, the way the data are collected and the population, leading to widely varying estimates. In 1994<sup>9</sup> Boyle et al reported that 17% of US children had developmental disabilities while in 2006<sup>10</sup> Blanchard et al suggested that the figure was 5%. Using multiple methods of ascertainment a study based in Atlanta (roughly 50000 births/year) has reported on the prevalence of four specific developmental disabilities (Table 2.5).<sup>11</sup>

**Table 2.5** Prevalence of selected developmental disabilities in Atlanta (2000)<sup>11</sup>

	Prevalence /1000 children
'Mental retardation'*	12.0
Mild	8.7
Moderate, severe or profound	3.3
Cerebral palsy	3.1
Hearing loss (> 40 dB)	1.2
Visual impairment (20/70 or worse corrected)	1.2

\* In Europe the term more commonly used is 'learning disability'. Mental retardation was defined here as IQ <70 (mild = IQ 50–70, moderate/profound = IQ <50).

Estimates of the prevalence of cerebral palsy, the most common form of serious physical disability in childhood, are available from a number of countries. Most recent studies in industrialized countries report rates of cerebral palsy between 2 and 3 per 1000 infants surviving the neonatal period. There is conflicting evidence about trends over time. In the UK, one study reported a change between 1964–1968 and 1989–1993 from 1.68 to 2.45/1000 neonatal survivors.<sup>12</sup> A report combining data from five UK registers of cerebral palsy seems to suggest that rates rose during the late 1970s and then flattened thereafter but is unclear about the extent to which this represents changes in ascertainment.<sup>13</sup> The rate in babies born weighing > 2500 g has remained virtually constant over this period while one large study has reported that in western Europe the rate in very low birth weight babies (< 1500 g) fell from 60.6/1000 live births in 1980 to 39.5/1000 in 1996.<sup>14</sup> There have also been increases in the lifespan of children with cerebral palsy, which will further increase the overall prevalence of cerebral palsy in the population.

The life expectancy of children with a number of other chronic conditions has also increased in the developed world, which is again likely to raise the prevalence of such conditions in the population. A survey carried out in one health district in the UK attempted to ascertain what proportion of children suffer from nonmalignant 'life-threatening' conditions.<sup>15</sup> These were defined as conditions as a result of which the child had at least a 50% likelihood of dying before the age of 40 and included conditions such as cystic fibrosis, chronic renal failure and conditions causing central nervous system degeneration. The overall prevalence among children aged 0–19 was 1.2/1000, suggesting a large burden on families and services.

Mental health problems are extremely common in children and adolescents. A large population survey carried out in Great Britain in 2004 of children aged 5–16 reported that 9.6% had a mental disorder (based on ICD 10 diagnostic criteria).<sup>16</sup> The prevalence rises with age and rates are generally higher in boys than girls except for emotional disorders (Table 2.6). Even apparently milder psychological problems such as behavioral difficulties which would not fulfill the criteria for a mental disorder in young children can have profound effects on the quality of families' lives.

### Disabling conditions in poor countries

The prevalence of disabling conditions in children is believed to be disproportionately high in poorer countries although the sources of high-quality data are few.<sup>17</sup> Mung'ala-Odera et al<sup>18</sup> reported that 61 of 1000 6–9-year-old children in one rural area in Kenya had moderate to severe neurological impairment (Table 2.7). The authors point to the relatively low prevalence of cerebral palsy in their population and suggest that this is likely to be related to a high mortality rate in these children in poor communities. The higher rates seen in girls than boys in this study are surprising and unexplained. A study of intellectual disability in children of the same age group in rural South Africa (defined as IQ < 80, mild 56–80, severe < 55) reported the more commonly observed excess in males who were 1.5 times as likely to be affected.<sup>19</sup> The overall reported prevalence was 35.6 of 1000 (mild 29.1 of 1000, severe 6.4 of 1000).

Poverty leads to poor nutrition, recurrent illness and inevitably deficient care as families struggle to survive. In addition to the more obvious

**Table 2.6** Percentage of children with a mental disorder by age and gender in Great Britain in 2004<sup>16</sup>

Disorder	5–10 years		11–15 years	
	Boys	Girls	Boys	Girls
Emotional disorder	2.2	2.5	3.9	6.0
Conduct disorder	6.9	2.8	8.8	5.1
Hyperkinetic disorder	2.7	0.4	2.6	0.3
Autistic spectrum disorder	1.9	0.1	1.0	0.5
Any disorder	10.2	5.1	13.1	10.2

**Table 2.7** Estimated prevalence of moderate to severe neurological impairment in 6–9-year-olds in rural Kenya per 1000 children<sup>18</sup>

Impairment	Boys	Girls	Total
Epilepsy	37	45	41
Cognitive impairment	27	36	31
Hearing impairment	12	15	14
Motor impairment	5	4	5
Visual impairment	2	2	2
Any impairment	52	79	61

severe forms of disability this poverty of environment means that children fail to reach their developmental potential. Grantham-Macgregor et al estimate that more than 200 million children under the age of 5 fail to reach their potential in cognitive development as a result of poverty.<sup>20</sup> This has serious economic and social consequences for them as individuals and for the societies in which they live.

### POPULATION DETERMINANTS OF CHILD HEALTH

The health of an individual is determined by a complex interaction between genetic factors, health behaviors and environmental influences.

#### AGE AND SEX STRUCTURE OF THE POPULATION

Between the ages of 5 and 15 the risk of death and severe illness is at its lowest, before rising again. Death rates are higher in boys than girls at all ages in both poor and rich countries (Fig. 2.9 shows the rates by age and gender for England and Wales). The magnitude of the difference varies with age, in the UK rising from around 25% higher in boys from birth until the age of 15 and then becoming more than twice as great in adolescence and early adulthood. Much of this increasing discrepancy between the sexes is due to the much higher rates of unintentional injuries in males, particularly later in childhood and adolescence. The death rates from all injuries and poisoning (which includes the small numbers of deaths due to intentional injuries) in the UK are shown in Figure 2.10, broken down by age and gender.

#### GENETIC FACTORS

At an individual level there is no doubt that genetic factors play an important role in determining health status. At a population level however, there is little evidence that they have a significant effect on overall health. The genetic differences between human subpopulations are in fact small and it appears that differences in health are largely accounted for

**Fig. 2.9** Death rates per 1000 by age and gender in England and Wales (2005).<sup>2</sup>

**Fig. 2.10** Death rates from injury and poisoning per 100 000 by age and gender in England and Wales (2004).<sup>2</sup>

by environmental and behavioral differences. Clearly there are differences between populations in the frequency of some specific single gene disorders – for instance, sickle cell disease is uncommon in northern Europeans and cystic fibrosis is uncommon in Africans – but these contribute relatively little to the health experience on a population level. In other words, an individual’s genetic makeup is important in determining their risk of ill health within a particular subpopulation who share common experiences, but not in explaining the differences between these subpopulations. This is borne out by numerous studies of immigrant populations, which suggest that the longer they spend in a new country and the more they adopt the lifestyle of that country, the more nearly their health experience comes to resemble that of the native population. Most differences that continue to exist between immigrant groups and the native population can be explained on the basis of either behavioral or socioeconomic factors.

#### BIRTH WEIGHT AND GESTATION

Birth weight, reflecting both gestation and intrauterine growth, is a powerful predictor of mortality (Fig. 2.7) and morbidity (e.g. cerebral palsy, Fig. 2.11)<sup>21</sup> in childhood. Globally 60–80% of neonatal deaths occur in low birth weight infants. In recent years it has been recognized that the effects of suboptimal birth weight may persist throughout life, with links being demonstrated between birth weight and cardiovascular and respiratory disease in adulthood. It appears that these adverse effects have a nearly linear relationship with birth weight rather than simply being associated with the lower extreme of the birth weight distribution.

Many of the determinants of both prematurity and poor intrauterine growth remain to be elucidated, although some specific conditions such as pre-eclamptic toxemia are important in individuals. Poor intrauterine

**Fig. 2.11** Prevalence of cerebral palsy by birth weight in Europe.<sup>21</sup>

growth is associated with smoking during pregnancy and with socio-economic deprivation. Diet has often been suggested as a possible cause of intrauterine growth retardation but good evidence for this is lacking, except for the effects of extreme malnutrition.

**PHYSICAL ENVIRONMENT**

While some specific environmental hazards have been clearly identified, the links between others such as damp, overcrowded housing or atmospheric pollution and ill health have been difficult to determine. Many of these, possibly disadvantageous, conditions tend to occur in combination with each other and with socioeconomic disadvantage, making it difficult to disentangle their effects. Many pollutants in the environment or in food are so widespread that investigation is difficult. It is also possible that it is the interactions between such pollutants that are important, which further complicates attempts to quantify their effects. It could be argued that, in these circumstances, it may be appropriate to accept lower levels of evidence before proceeding to action, sometimes referred to as the precautionary principle, than would generally be required for reaching conclusions about causal links.

**SOCIAL FACTORS**

Socioeconomic status (SES) is a powerful predictor of health outcome within all societies. Within poor countries, this is unsurprising, given that SES is linked to the availability of basic necessities including food and shelter. What is perhaps remarkable is that the link remains strong even in rich industrialized countries. What may seem equally surprising is that the differences exist, not simply between the poorest members of society and the rest of the population, but, for many important health outcomes, there is something approaching a linear relationship between SES and adverse outcome.

How best to measure SES in childhood remains a source of debate. It is clearly a complicated concept and it seems likely that different aspects of disadvantage will be important for different health outcomes. In the UK, SES has traditionally been measured using an occupational classification. This scheme, first employed around the beginning of the twentieth century, assigned all occupations to six (originally five) groups based on a notion of a hierarchy of status. In 2001 this system was replaced by a new eight-group classification, the National Statistics Socio-economic Classification. Other classifications have been developed based on factors such as maternal education, income, access to material goods such as motor cars or telephones, type of housing and the nature of the area in which the family lives. Although the strength of the association between SES and a particular outcome may vary according to the measure used, the direction of effect is virtually always the same.

The effects of SES are observable from the beginnings of life, with a strong relationship between birth weight and SES. Figure 2.12 shows

the proportion of infants born weighing less than 2500 g in SES deciles in one region of the UK (based on the characteristics of the small area in which they live).<sup>22</sup> Perhaps even more striking is the proportion of infants born weighing more than 3500 g (regarded as being an optimum birth weight) in different SES deciles (Fig. 2.13). In both figures there is a clear gradient across the different social groups. The magnitude of this effect is illustrated by the fact that this study reported that, if the whole population had the risk seen in the richest 10%, this would avoid 30% of all births below 2500 g and 32% of births below 1500 g.

In the UK in 1994–1999 the difference in life expectancy at birth between children in the 10% of most deprived areas in the UK and those in the richest 10% was 6 years for boys and 3.2 years for girls.<sup>2</sup>

The differences in infant mortality across social classes are shown in Figure 2.14. Particularly marked differences are seen in mortality from injuries and poisoning between social groups (Fig. 2.15).<sup>23</sup>

Similar differences are seen for most measures of morbidity, where figures are available, with large differences being shown between social groups for the risk of admission to hospital, for severe respiratory infections and for mental disorders (Table 2.8).<sup>16</sup> Finally, SES in early childhood strongly predicts the likelihood of educational achievement, which in turn predicts later job opportunities and income.

SES can of course not be said to directly cause ill health, but rather acts as a marker for various adverse circumstances and behaviors, which are the proximal causes for health outcomes. There is growing evidence that these circumstances cumulate over the life course and that the longer a child spends in adverse social circumstances, the greater the risk of poor health outcome.

**HEALTH BEHAVIORS**

There is considerable evidence of the deleterious effects of a number of health behaviors by parents and children on the health of children. Smoking by parents, and by children, in particular, is a major cause of many adverse outcomes including intrauterine growth retardation, sudden infant death syndrome and respiratory disease. At least in the UK and USA, smoking is much more common amongst people in poorer social circumstances and is likely to be one of the mechanisms through which SES has its effects on children’s health. This close relationship between SES and smoking does, however, hamper efforts to estimate the magnitude of the effect of smoking per se as its effects may be confounded by other adverse circumstances.

Harmful effects of poor diet and lack of exercise in childhood have also been suggested. Very large increases in the proportion of children who are overweight or obese have been reported in the UK and USA. Between 1994 and 2004 in the UK the proportion of 11–15-year-old boys who were obese rose from 14% to 24% and of 11–15-year-old girls from 15% to 26%.<sup>24</sup> As there is substantial tracking between fatness in childhood and adulthood, this may have important implications for

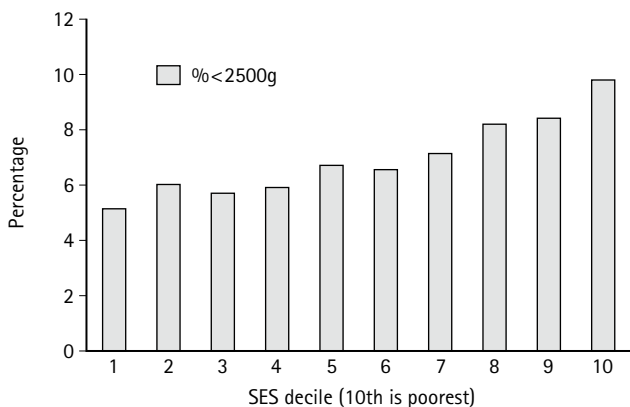

Fig. 2.12 Percentage of births < 2500 g by SES decile in the West Midlands, UK.<sup>22</sup>

Table 2.8 Percentage of children aged 5–16 with a mental disorder by gender and weekly household income in Great Britain, 2004<sup>16</sup>

Household income	Boys	Girls
< £100	18.4	13.4
£100–199	13.9	13.0
£200–299	17.8	11.5
£300–399	14.8	9.8
£400–499	10.2	6.8
£500–599	10.6	7.1
£600–770	6.0	3.7
>£770	6.7	3.9

the risk of cardiovascular disease and type 2 diabetes in later life. It has been suggested that these increases are likely to reflect declining levels of physical activity and the increasing consumption of convenience foods, although clear etiological evidence is lacking.

### HEALTH SERVICES

Until recent years there has been surprisingly little evidence that health services are an important determinant of children’s health in richer

countries. The obvious exceptions are immunization and public health measures such as the provision of safe water supplies. Even for vaccine-preventable diseases, much of the decline in mortality in these countries preceded the introduction of immunization. It is nonetheless true that immunization has been associated with dramatic declines in deaths from measles, polio, meningococcal disease and other conditions which were major causes of deaths into recent times.

It is clear that the major determinants of child health lie outside the realm of curative services and are related to social and environmental factors. However, in rich societies, the rates of mortality have fallen to very low levels and the importance of the effective management of relatively uncommon conditions has become proportionately more important in determining mortality rates. For instance, the widespread use of antenatal steroids in women in preterm labor and of surfactant in premature infants has led to substantial declines in mortality from idiopathic respiratory distress syndrome in neonates. Similarly, as malignant disease accounts for an increasing proportion of childhood deaths, improvements in cure rates due to medical management can have significant effects on childhood mortality rates.

As discussed earlier, simple interventions by health services have the potential to significantly reduce deaths and morbidity in the poorest communities in the world. The difficulty has been in trying to introduce such services in the face of a shortage of resources and often weak governmental structures which are not always responsive to the needs of the poorest members of society. The ‘inverse care law’<sup>25</sup> was first described in the UK in the 1970s and suggested that ‘The availability of good medical care tends to vary inversely with the needs of the population served.’ Unfortunately this law still applies between countries and between population groups, within even the poorest. For instance, in sub-Saharan Africa and Southeast Asia, amongst the 20% of richest women 86% have skilled care at the birth of their children compared to only 14% amongst the poorest 20%.<sup>4</sup>

While health services can significantly ameliorate the consequences of many diseases they can also lead to an increased prevalence of children with significant morbidity. Some of the children who are saved from death may survive with significant morbidity and may be kept alive for long periods in spite of their disabilities. It is important that clinicians recognize both the importance of factors outside their control in determining children’s health and the potential societal consequences of advances in technology.

Vertical, parallel or horizontal services?	23		

### BACKGROUND

In 1978 in Almaty Kazakstan (then Alma-Ata) a meeting on primary health care was jointly sponsored by the United Nations Children's Fund and the World Health Organization (WHO) and attended by representatives from many countries.<sup>1</sup> A call was made for 'health for all'. Nearly 30 years on 'health for all' is still more hope than substance.<sup>2</sup> In 1990 The Millennium Development Goals were defined.<sup>3</sup> Amongst the goals are to improve the health of both mothers and children; to reduce under 5s child mortality rate by two thirds, and maternal mortality by three quarters by 2015. At current rates these goals will not be achieved until 2165 in sub-Saharan Africa.<sup>4</sup> In 2003 the Bellagio child survival group (named after the place that the meeting was held) report<sup>5</sup> was published in which representatives of the donor communities and health services of resource constrained areas described children's health in various parts of the world and suggested that with the present state of knowledge and relatively little financial investment, 60% of the deaths in children under 5 years of age could be averted. In research too, the World Health Forum describes a 90/10 divide in which only 10% of research funding goes to poorer parts of the world where 90% of the people live.<sup>6</sup>

Why is the health divide so wide, and increasing, between well resourced countries and those which are financially constrained? The problems are complex.

### THE PHILOSOPHY OF CARE

In the 1970s primary health was promoted as the way forward to reach the poorest and most difficult to access (often rural) population. This service was to deploy community health workers (CHWs), traditional birth attendants (TBAs) and mid-level health staff such as nurses and clinical officers. However primary care has been understood variously, as the central pivot for health systems, as a mere extension of services to underserved areas, or even as a rather second class service for the poor.<sup>7</sup> The first definition requires social, structural and financial investment, the other definitions diminish the value of primary care.

Funding for primary care has been inconsistent in part because it is not easy to establish clear indicators of achievements and failures and without these, financial systems do not function.<sup>8</sup> Primary health care is often seen as an emergency response to health disasters by international donors rather than the bedrock of health care delivery. But in the second Disease Control Priorities in Developing Countries report, it is argued that 90% of the health care demand is potentially addressable by primary care.<sup>9</sup> Historically most health services have been built and powered from the top down. Centrally made decisions have trickled down to primary services in the community. Urban health in resource poor countries is nearer to the health model taught in most traditional medical schools, with emphasis placed on specialization and hospital care.

The large hospitals were built, managed and staffed like those in developed countries. This tended to lead to excellent care for the politically powerful urban few, at the neglect of the rural poor. Medical students were, and are given bedside teaching which emphasizes diagnostic acumen and knowledge of diseases, but teaches little about health care delivery – for instance why did this particular child get admitted, by whom, when and why? Why were others not admitted? In the 1970s the pendulum of donor funding tipped towards primary health care and it gradually improved. The use of traditional birth attendants and village community health workers was encouraged. Acceptance has not been universal, with some reports arguing that skilled care at delivery made the difference in maternal survival with the result that the unskilled cadre of health workers fell into some disrepute.<sup>10,11</sup> More recently there are many examples of the value of the CHW. They have helped improve community uptake of health services, decreasing neonatal mortality in India, and in many countries successfully run immunization services and health promotion schemes.<sup>12-14</sup> They work best when included as part of the health service and not made to feel outsiders, or second best.<sup>15</sup> A health service needs all levels of service to be effective. It is recognized that the larger hospitals have been neglected, and as these are teaching centers and service the community, there is an important swing back to seeing their improvement as equally important.

## HUMAN RESOURCES

Health services are directed by policy and finance but are driven and sustained by people. In the 2006 World Health Report, the WHO highlights the crisis in human resources for health.<sup>16</sup> The central importance of human resources to health means that this issue deserves high international priority.<sup>17</sup> To achieve the Millennium Development Goals – which are wider than child and maternal health – Africa alone will need a further 1 million health personnel, and the global need is an extra 4 million health workers.<sup>18</sup> The ratio of health carers (nurses, doctors, midwives) to population is 10 times greater in Europe than in Africa, and yet maternal, neonatal and infant mortality are directly related to the skilled staff:patient ratio.<sup>19</sup>

The need for skilled health carers is at crisis point in much of sub-Saharan Africa and efforts are being redoubled to train as well as to deploy CHWs where possible. In Asia CHWs have worked with great effect. For instance, in the 2005 earthquakes of Pakistan 8000 female health workers were mobilized from the affected areas to assist in the camps and villages. In India there are plans to train 300 000 more CHWs while in Thailand 60 000 village health workers were trained to support 600 000 voluntary health workers; who in turn looked after 20 children each.<sup>20</sup> It has been suggested that a ratio of one full-time paid CHW to 500 people and one to 10–20 for local volunteers is the correct requirement.<sup>20</sup>

In poorly resourced settings we tend to think of resources as material needs – equipment, drugs, good buildings, transport, communications – all of which are necessary and important and which may be scarce or in poor shape. The health care team is made up of a group of people with varying backgrounds, training, skills and expectations. Each person in the team has a much bigger task in terms of quantity and breadth than their counterparts in a well-resourced system. This team may consist of a clinical officer (akin to a nurse practitioner), nurses/midwives, health care auxiliaries and health surveillance assistants. If there is a doctor he/she will be expected to lead this team.

## WHAT IS EXPECTED OF THE CHILD HEALTH DOCTOR?

In such circumstances the doctor must be the leader, a teacher, a supervisor and an advocate. He/she needs to think creatively about how to deploy staff, to prioritize both their time and that of others, and to stimulate, enthuse and lead 'from the front'. In child health, whatever their own clinical interests and preferences they need to see the wider context of the health service and ensure that the team's efforts reflect the needs and demands of the community they serve.

Many doctors trained in poorly resourced countries have stayed to serve their communities for little financial or career rewards. For very many others the offers of specialization, security and financial gain have attracted them to resource rich countries.<sup>21–23</sup> There is much to be gained from medical exchanges, extra specialist training, sabbaticals and cross-fertilization of ideas but if these encourage a drain from settings of need to places of plenty; then the loss to poor communities is very great indeed.<sup>24</sup>

Government services struggle to implement health care with too few trained staff. Skill mix has become increasingly important; nurses and clinical officers have taken on many of the jobs that traditionally have been carried out by doctors, nurse auxiliaries work under the supervision of trained nurses and Health Surveillance Assistants play key roles in health promotion, disease prevention and monitoring in the community. Voluntary or paid community health workers, elected by the village community assist with bed net provision, simple treatments and health promotion. Nurses have had many tasks put upon them in the antenatal clinics beyond the monitoring of a woman's pregnancy (e.g. human immunodeficiency virus [HIV] prevention, malaria prophylaxis, nutrition teaching, advice about breast feeding, tetanus immunization, STI treatment and prevention). Similarly in

the Under Fives Clinics a nurse is being asked to weigh and measure the height of a child, assess development, encourage exclusive breastfeeding for 6 months, give immunizations, give vitamin A, nutritional advice, malaria prophylaxis, co-trimoxazole prophylaxis for HIV-infected infants and children. Many of these duties can be done, and are done by less skilled but dedicated and trained staff. The World Health Report of 2006 urges health services and health training institutions to re-look at task allocations within both the professional and voluntary cadres.<sup>16</sup>

## HEALTH CARE FINANCING

As the cost of and demand for health care has risen various ways of cost sharing have been tried. The Bamako Initiative of 1987 was an attempt to improve primary care and user fees were suggested as a key component to make improvements sustainable.<sup>25</sup> By raising revenue it was hoped that the quality of care, coverage and drug availability would improve without the need for persistent external inputs. User fees have been successful in some countries (Benin, Senegal, Burkino Faso) but not in others and in some places have been withdrawn as they were seen as a barrier to the poorest people accessing care.<sup>26</sup> They seem to help when they are part of a care package that includes insurance and good exemption schemes. Some countries (e.g. Sri Lanka) have continued successfully to provide free health at point of care while others such as Bolivia intend to provide a similar service backed up by insurance.<sup>27</sup> The World Health Report 2005 'Making every mother and child count'<sup>28</sup> rejects user fees and argues that social insurance or tax-based responses are superior.

## DRUG SUPPLY – THE PHARMACEUTICAL PIPELINE

In 1975–1997, of 1325 new drugs which came on to the market only 11 were for tropical infections.<sup>29</sup> WHO has compiled an essential drugs list (329 drugs and 559 formulations) to help focus drug provision on basic needs.<sup>30</sup> Many governments have central medical stores through which bulk medical buys are made but worldwide 30% of people lack access to essential drugs. This varies from 26% in most of SE Asia, to 47% in Sub-Saharan Africa (SSA) and 65% in India.<sup>31</sup> UNICEF provides 40% of the global demand for vaccinations and the Global Alliance for Vaccines and Immunisation (GAVI) and the Global Fund have been very effective and active in providing a wider range of immunizations for national EPI programs as well as treatments for TB, malaria and HIV, respectively.<sup>31–33</sup>

Good will donations are sent to many hospitals without any clear understanding of the pharmaceutical needs or controls of a country. Lavy et al<sup>34</sup> gave advice to help potential donors and the WHO has come up with standards to which donated drugs must conform.<sup>35</sup> In some villages drug revolving schemes have been established whereby a responsible villager is chosen by the community to be custodian of a few simple medicines which he/she dispenses at cost and thus recovers the monies to buy replacement medicines.<sup>36,37</sup>

## NATIONAL HEALTH PROGRAMS

Programs require substantial funding which is heavily dependent on donor provision.<sup>38</sup> Donors have, over the years, channeled funds in a variety of different ways – vertical programs, parallel programs, single disease-focused initiatives, funds targeted to one sector of the population such as reproductive health or primary care. National health services have been molded to meet the requirements of individual donor states or programs. More recently a sector-wide approach (SWAps)<sup>39</sup> has been introduced in which donors 'basket' (put together) funds and give them to a Ministry of Health to deliver a predetermined health program based on an assessment of needs called the Essential National Package of Health Services.<sup>40</sup>

## HEALTH DELIVERY AND THE REFERRAL CHAIN

Health services are divided into different levels of care delivery. It is essential to provide care as near to the home as possible, but that care must be supported by a tiered system that provides support for the tier below and receives support and refers to the tier above. There must be a seamless continuum of care within which there is free and good communication at and between all tiers and appropriate use of each level of care.

### THE HEALTH CENTER

At village level, health centers or mobile health clinics provide simple first-line curative treatment, immunizations and health promotion and do uncomplicated deliveries. These are ideally run by a nurse, midwife and medical assistant and Community Health Workers supervised and supported by staff from the local district hospital. These interventions collectively reduce many risk factors for ill health.

### THE DISTRICT HOSPITAL

The district hospital provides first level referral care and is often staffed by clinical officers and nurses, with or without a doctor. Such a hospital will typically have about 200 beds and serve a wide catchment area. This service can be provided relatively cheaply and is reported to cost about \$9/d in Kenya, \$12 in Bangladesh.<sup>41</sup> District hospitals will refer their difficult cases to the regional or tertiary referral hospital.

This level of care is termed the first-level referral and plays a significant role in the quality of service a population can expect to receive. English et al reported on the indifferent quality of care first-level referral hospitals give in Kenya when staff members are demoralized and unsupported and equipment and structures are neglected.<sup>42</sup>

### THE TERTIARY HOSPITAL

The tertiary hospital or regional hospital will have staff in at least the main specialties of medicine, pediatrics, surgery, obstetrics and gynecology. They are in large towns or cities and may serve as the city district hospital. They are also the teaching units for different medical and nursing cadres. Staff members of these large hospitals visit district hospitals to teach and help with problem cases. Many of these hospitals were built in the 1950s or 1960s and, when policy focused on primary care, were neglected. It is now recognized that these hospitals are where future health staff are trained and are a vital link in the continuum of care for patients.<sup>16</sup> The public's views of the quality of a national health service is colored by the care seen to be provided in its tertiary institutions.

## VERTICAL, PARALLEL OR HORIZONTAL SERVICES?

Vertical programs may offer an effective response to address specific issues but there is a danger that programs may conflict with each other or may undermine the provision of primary health care. Maternal and child health (MCH) are interdependent but in some programs (Safe Motherhood for instance) the baby got little mention, and in some child initiatives the importance of the mother's health is unemphasized.<sup>43</sup> Of the 10 million children who die every year, the vast majority in resource constrained areas, 4 million are neonatal deaths.<sup>44</sup> Half a million mothers die every year in childbirth, which imperils infant survival and leaves many orphans, whose health and well being will inevitably suffer.<sup>45</sup> There are over 12 million orphans in Africa.<sup>46,47</sup>

In Tanzania to avoid vertical programs and strengthen subnational health systems the Tanzanian Essential Health Interventions Project (TEHIP) was started in 1997.<sup>48</sup> After 5 years the mix, quality, use and coverage of health services improved and there was a 40% reduction in under-fives mortality. This initiative cost \$1 per person and the fund-

ing was obtained through the SWaps financing system. District health management teams set their own priorities and integrated health informatics into the plan. This experience suggests that investing in the health system can work but that it takes time. In addition to a burden of disease analysis consideration of cost effectiveness, budgeting, management, team building, mapping, transport, and communications were all necessary. Even then the effect was only seen after 5 years.<sup>49,50</sup>

## INFORMATION, SURVEILLANCE AND RESEARCH

Comprehensive health management information is important to measure quality and coverage of health services. Poor data often leads to poor decision making and ultimately poor quality of care.<sup>51</sup> In many countries data is collected in too many different and uncoordinated ways and there is lack of access to information and to information research.<sup>52-54</sup> The importance of data and the need to rapidly cycle results back to the health care units so as to influence day-to-day decision making has become clear.<sup>55</sup>

Detailed country-specific epidemiological data will be available for each country from WHO so that a national health service can tailor its efforts, prioritize its needs and set goals for itself.<sup>16</sup>

## HIGH-IMPACT HEALTH INTERVENTIONS

Some relatively simple interventions influence the health of many. Examples are immunization programs, vitamin A supplementation, zinc supplementation, infant care, simple treatments, bednet provision, improving care at first level referral hospitals and the integration of health care through the Integrated Management of Childhood Illnesses (IMCI).<sup>56-58</sup>

Improving inpatient care in referral hospitals and especially emergency care can make an immediate difference to inpatient morbidity and mortality. In Blantyre, improving triage and emergency care by teaching and implementing the WHO Emergency Triage Assessment and Treatment (ETAT) has led to a reduction in inpatient mortality from 11-18% to 6-8%.<sup>59,60</sup> Prophylactic co-trimoxazole for HIV-infected children, anti-retroviral therapy for children (and their parents) who have reached a clinical- or laboratory-based stage of the disease needing therapy, TB diagnosis and treatments gain from vertically managed programs which are not mutually exclusive and are imbedded in the health care system.

Clear consideration of evidence is important as not all apparently sensible interventions have proved as successful. For instance the blanket provision of iron and folic acid to preschool children in a highly malarial area in East Africa proved detrimental to health and outcome.<sup>61</sup>

## SYNDROMIC MANAGEMENT OF DISEASES

Where patients are many and staff are few, supported by little or no laboratory services, a syndromic approach to the diagnosis and management of particular types of infection has been taken. A diagnosis is made on a brief history and the presence of a few key symptoms or signs. For instance in sexually transmitted diseases an appropriate history and findings elicits a treatment which covers all the common treatable bacterial causes. This leads to overtreatment but simplifies the management of large numbers of patients by relatively few staff. Clinicians are taught this approach and national programs rationalize the availability of appropriate drugs for the level of health service.

IMCI is an integrated approach to the care of children which uses flow diagrams and simple pattern recognition in signs and symptoms to treat children.<sup>62</sup> IMCI strategy has three main components:

1. to improve case management skills of health carers using locally adapted clinical guidelines that do not focus on a single diagnosis but rather on selected signs and symptoms which guide rational treatment
2. to provide support through the provision of appropriate therapies and referral chains

3. to see the child in the context of the family and the clinical context with the acute event used to provide not only immediate curative treatment but also attention to nutrition, immunization, counseling and other health needs.

In Tanzania this is reported to have led to 13% reduction in cost of care and better outcomes.<sup>63</sup> A recent re-analysis of this data to include the quality of care given showed that the cost of using IMCI was \$4.02/person per annum compared with \$25.70 without IMCI.<sup>64</sup>

### EXPANDED PROGRAM FOR IMMUNIZATION (EPI)

Immunization remains one of the most cost-effective approaches to health care but the coverage varies greatly from country to country and even between rural and urban areas. The least accessible children who are the most vulnerable in society receive least protection.

EPI programs include periodically giving vitamin A supplements to children. The included vaccines vary. While some countries (e.g. Malawi) have achieved high rates of uptake and include pentavalent vaccines (DPT/Hib/HepB – diphtheria, pertussis, tetanus, *Haemophilus influenzae*, hepatitis B) most countries of sub-Saharan Africa are still using DPT. Pentavalent vaccine raises the cost of vaccination tenfold and can only be sustained with external funding such as from GAVI.<sup>65</sup>

### HIV/AIDS – PREVENTION, DIAGNOSIS PROPHYLAXIS AND TREATMENT

Many high-burden countries with HIV/AIDS are struggling to provide for the needs of people who are living with AIDS with high proportions of the population needing care. Fixed combination drugs (FDCs) are now available and provided through the global fund, but every affected country needs a national program with registration procedures, protocols, training, stock control, prescribing controls and monitoring. The human resources required and logistical implications are huge. Children are expected to form about 10% of the total number of people on anti-retroviral therapy (ART) and their access to therapy has been slower than that of adults. In Malawi they are 5% of the total number on ART.<sup>66</sup> Reasons for this have been difficulty in deciding how to provide suitable doses for children with a limited variety of FDC tablets available and none of them child friendly tablets. Other difficulties include the inability to confirm a diagnosis below the age of 15 months if only HIV antibody testing is available and complex issues surrounding advice about infant feeding. What advice is best for babies whose chances of acquiring HIV infection with breast-feeding are about 14–42%,<sup>67</sup> but whose chances of dying of gastroenteritis in a poor family if bottle fed are much greater?<sup>68</sup> A Zambian study of co-trimoxazole (CoT) prophylaxis for children with HIV showed a decrease in mortality.<sup>69</sup> This has meant that CoT is recommended to all children (and adults) with HIV infection and HIV-exposed infants. The logistics for this provision are challenging.

### PALLIATIVE CARE

Holistic care of a child and family is incomplete without palliative care, a stark reality with the HIV/AIDS epidemic. There is a steady increase in awareness of its value and national palliative care programs have started, training courses are available and oral morphine is available in some countries.<sup>70–72</sup> Hospital-based and home-based care must liaise to try to provide medical, moral, emotional and spiritual support to the children and their families who approach the end of the children's lives.<sup>73</sup> Palliative care supports the families involved and is also a great support to staff who may feel helpless when faced by the obvious needs of these families.

### TB TREATMENT PROGRAMS

National TB programs have served as models for the HIV/AIDS programs. National TB drug policies, protocols, supervision and monitoring are helping to provide treatment for the increased number of TB

cases with the onset of the HIV/AIDS epidemic. National control of the TB treatments also reduces the risk of poor prescribing leading to the emergence of resistant TB. The directly observed therapy (DOTs) campaign helps reduce poor compliance.<sup>74</sup>

Both TB and HIV/AIDS are well served by vertical national programs.

### MALNUTRITION

Poor nutrition directly affects 5.6 million deaths every year in children under 5 years old. In the developing world 25% of all children (about 146 million children) are underweight, which remains unchanged since 1999. Half these children are in Bangladesh, India and Pakistan, where 45% of the children under 5 years of age are malnourished. It is particularly evident in places of rapid population growth, in areas of conflict, or with high HIV prevalence, drought or poor agricultural productivity. Diarrhea and poor feeding habits are confounding and causative factors and it is of concern that children who do not catch up with growth in the first 2 years of life may have continuing cognitive problems. Regular vitamin A supplementation and micronutrients help prevent some of the diarrheal diseases that lead to malnutrition.<sup>75</sup>

Malnourished children need either supplementary feeding or therapeutic feeding. This is done in a phased manner so that calorie intake and protein load are increased over a few days and high loads introduced once diarrhea and edema have started to resolve and appetite increase. This is especially important in severe kwashiorkor. Supplementary feeding is for moderately malnourished children and is provided as a nutritious porridge flour or a ready-to-use therapeutic feed (RUTF) such as plumpynut – a peanut-based high-energy food.<sup>62,76–78</sup> It is vital to support nutrition in all areas of health care as malnutrition has a detrimental effect on every aspect of health outcomes.

### TRAINING

Training is required at many levels. University-trained doctors and nurses are needed for leadership roles and in the referral hospitals but they tend to stay in urban areas. Their training is costly and once qualified their expectations of resources and rewards are high. They are not enough to provide for a country's health needs. Other cadres of staff must be trained for different tiers of the health service. Medical assistants, clinical officers, patient attendants and community workers are trained to provide many of these services. For instance, in Malawi clinical officers receive 4 years of training, which includes 1 year's internship making them able to deal with common illness and emergencies.

### DILEMMAS AND CONSTRAINTS

The means with which to meet large unresolved problems are limited. There is a dilemma in trying to provide good-quality service – service which includes kindness, courtesy and explanations – in quantity and for little cost. Rural primary health care workers in Zambia, 40% of whom worked without a doctor, identified transport, knowledge, traditional beliefs, social stigma, poorly trained health staff, poor access to drugs and user fees as barriers to good health service provision. Lack of human resources is a major problem and requires lateral and creative thinking in job allocations.

Concentrating on infectious diseases, the HIV/AIDS epidemic, TB and malaria has distracted concern from chronic medical conditions such as renal disease, hypertension, cardiac disorders and has meant that trauma has been seriously neglected. Road traffic accidents are rising in increasingly urban societies, often against a background of poor town planning, poor driving ability, poor traffic control and unsafe vehicles. Emergency care has not gained priority and is not recognized as such in many health services. Triage, resuscitation, stabilization and initial good clinical management of all acute pediatric illness will prevent many deaths and much morbidity. Reduction in hospital costs and manpower use would be considerable.

## SUMMARY

Health delivery is a big subject and in this chapter a broad brush has been used to give a picture of common health themes in many countries in poorer parts of the world. The fine details are place and person specific but training, feedback of outcome, praise, constructive criticism, commitment and faithful service of members of the health team are essential to fill in the details of the picture. Without these the picture

remains blurred and unfocused. It is these potent, small, personal efforts of people at the heart of the service that give it life and clarifies the picture. They identify real needs and sustain changes that really matter. Creative thinking and great ingenuity go into local health care to provide what on the surface may not look possible.

It is to these often unrewarded and unrecognized people that this chapter is respectfully dedicated.

### DETERMINANTS OF CHILD HEALTH

(see also Ch. 2)

Any child's health, development, and welfare reflect the interaction of various factors including:

- the individual's genetic endowment;
- environmental factors including aspects of the direct physical environment such as housing and 'behavioral' factors such as nutrition;
- the quality of interpersonal relationships, particularly with the child's primary caregiver;
- the wider social, political, and economic circumstances the child is living in;
- the availability of health care.

The health of the child's mother is also an important factor in determining the health of the child, whether this is, for example, in ensuring proper antenatal care of mothers with diabetes or treating and supporting mothers with psychiatric problems or alcohol addiction.

The impact of this complex web of determinants of health is reflected in the marked socioeconomic inequalities that exist in child health.<sup>1</sup> These inequalities are seen both between countries of the resource rich and developing worlds and also within individual countries.<sup>2</sup> Even within resource rich countries, almost all indicators of child health show a marked social gradient, with children living in disadvantaged circumstances having poorer health.<sup>3</sup> In Scotland, for example, children from the most deprived areas are more than twice as likely to die compared to children from the most affluent areas (Fig. 4.1) with some specific health problems showing particularly marked inequalities (Ch. 2).

### CONTRIBUTION OF HEALTH SERVICES TO IMPROVING CHILD HEALTH

As many of the factors that influence child health are modifiable, there is considerable scope for improving children's health and reducing inequalities in child health. It is clear, however, that much of the activity required to bring about this improvement lies outwith the remit of traditional health services. The profound impact of political action, economic progress, improved education and social change on child health is shown by falling morbidity and mortality long before antibiotics, vaccines and high-technology medicine became available (Fig. 4.2). Thus

improving child health has been considered to involve 'placing the health of children and their families in its full social, political and economic context' and to be 'the responsibility of decision makers in all organizations in all sectors of the economy'.<sup>4</sup>

Nevertheless, the organization and provision of health services can and should make a substantial contribution to improving child health.<sup>5</sup> This is acknowledged in the UN Convention on the Rights of the Child, which places a clear responsibility on the State to provide access to preventive care (article 24).<sup>6</sup> The remainder of this chapter will therefore concentrate on the actions that can be taken principally by health services to promote child health and development and prevent childhood illness and handicap, and will be considered from the perspective of health professionals working in pediatric services.

In order to maximize their potential to improve child health, health services should meet certain key criteria. Services should be:

- universal, i.e. accessible to all members of the population;
- comprehensive, i.e. focused on health promotion and disease prevention as well as curative care;
- integrated with other services that impact on the well-being of children, in particular social services and education;
- responsive to the health needs of the population;
- centered on the individual health needs of children and their families;
- evidence based and of high clinical quality.

In addition, services should be provided with the aim of reducing inequalities in health. This may mean that additional steps are taken to ensure very high coverage of essential immunizations in all sections of the population or that particularly vulnerable children (such as those in families of asylum seekers or travelers, those from economically deprived areas, or 'looked after' children) require additional special services to ensure they receive adequate preventive care. The capacity to monitor the contribution of health services to improving child health and reducing health inequalities on an ongoing basis is also important.

It is clear from the above that a focus on health promotion and disease prevention should pervade the day-to-day practice of all health professionals who work with children. This will require skilled teamwork in working with children and their families, other health workers, and colleagues outside the health services such as teachers and social workers.

## HEALTH PROMOTION AND DISEASE PREVENTION

Health promotion is usually thought of broadly as encompassing all activities aiming to improve health and hence incorporates specific disease prevention activities along with broader health education and lobbying for socioeconomic change.<sup>7,8</sup>

Disease prevention is commonly categorized into primary, secondary, and tertiary prevention.<sup>9</sup> Primary prevention aims to reduce the incidence of disease by controlling causes or risk factors. Examples of primary prevention interventions include vaccination against measles, the use of condoms to prevent human immunodeficiency virus (HIV) infection, antenatal folate supplementation, and fluoridation of drinking water.

Secondary prevention aims to reduce the prevalence of disease through early diagnosis and treatment that either leads to a cure or to a reduction in the more serious consequences of disease. Examples of secondary prevention interventions include screening for hypothyroidism in neonates to permit early replacement of deficient thyroxine and prevention of the disabilities of cretinism, and otoacoustic emission screening for hearing loss in neonates to improve outcomes for deaf children. The term 'secondary prevention' can also be applied to the termination of pregnancy to avoid the birth of a fetus with a recognized severe impairment.

Tertiary prevention aims to reduce the progress or complications of established disease, thus limiting its impact. It consists of measures to reduce impairments and disabilities from the disease or injury and so minimize any handicap which may result. For example, tertiary prevention through the rehabilitation of children with polio can enable them to take part in daily social life and bring about a great improvement in the well-being of these children.

## CHILD HEALTH ADVOCACY

In addition to improving child health and reducing inequalities through a focus on health promotion and disease prevention in their day-to-day clinical practice, pediatricians are well placed to make a valuable contribution to child health advocacy.<sup>10</sup> This is advocacy that strives to promote action within society that addresses the broader determinants of child health (e.g. socioeconomic circumstances, quality of the environment, housing, nutrition and education).

Child health advocacy often begins with an individual child or family and then may extend into local, regional or even national public health action. It involves taking action to promote health beyond treatment of a medical condition. This action can be taken as an individual or collectively. Specific steps in individual pediatrician advocacy have been described by Waterston and Tonniges<sup>11</sup> as:

- identifying a preventable problem in one child;
- helping that child overcome the problem;
- drawing conclusions in relation to the factors that led to the problem in the first place;

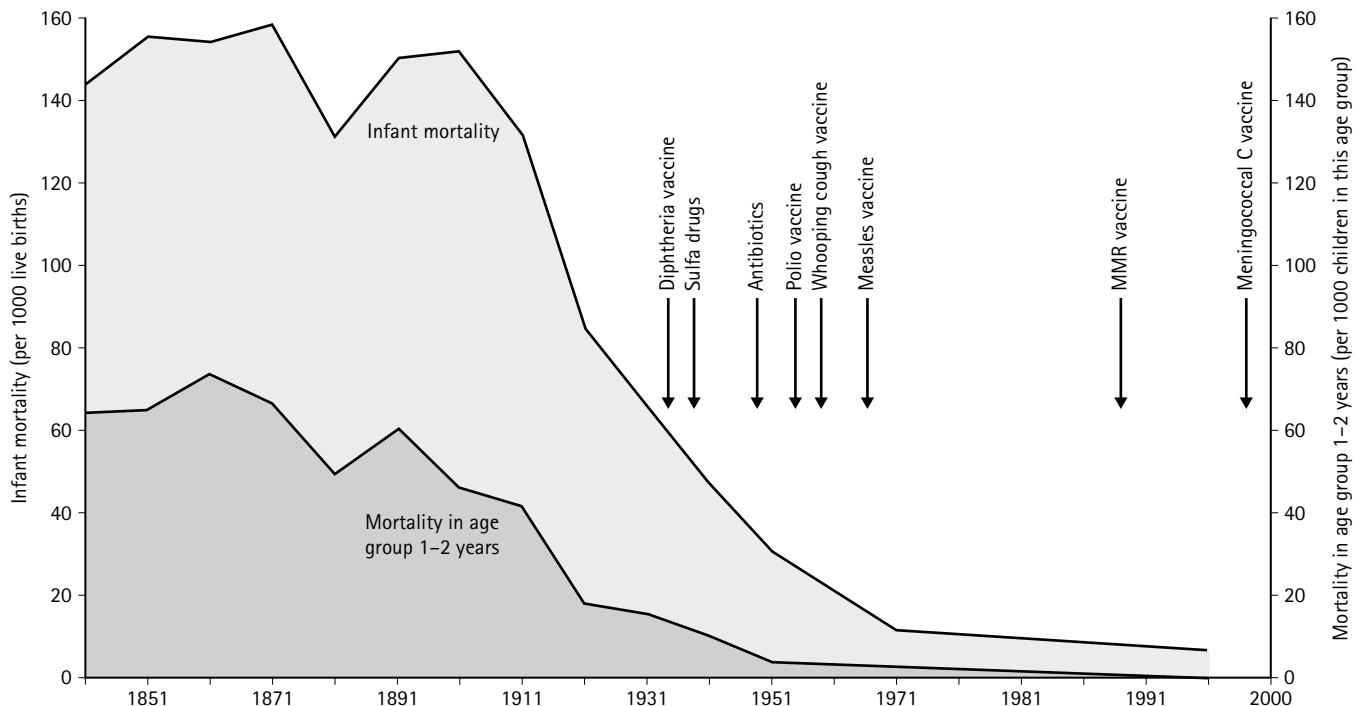

Fig. 4.2 Infant mortality in England and Wales and important developments in medicine.

- identifying the means to tackle these factors;
- influencing government or policy makers to change or reform the system that fostered these factors or introduce appropriate legislation.

Waterston gives as an example of such individual advocacy the work of Hugh Jackson, who cared for a child who died of an accidental drug overdose and whose later action led to the development of legislation requiring the use of childproof medication.<sup>11</sup> Collaborative action of pediatricians and other professionals involved in child health can advocate effectively against the tobacco industry, the motor industry, or baby milk manufacturers.

## A LIFE COURSE APPROACH TO DISEASE PREVENTION

In this section we provide an overview of effective measures to prevent disease and improve health in childhood. In later sections we go on to consider three preventive interventions in more detail, specifically support for parenting, child health screening and surveillance, and immunization. We concentrate on measures of relevance in the developed world, as preventive actions relevant to promoting child health in developing countries are presented in Chapter 3.

Table 4.1 presents effective disease prevention measures for each stage of childhood using a 'life course' framework. Over recent decades there has been a general resurgence of interest in the life course approach to health that emphasizes the long-term health implications of the fetal and early childhood environment.<sup>12-14</sup> It is now widely accepted that exposure to adverse environments in early life can irreversibly program higher risk of certain diseases, in particular hypertension, diabetes and ischemic heart disease, later in life.<sup>15-18</sup> Thus some of the preventive actions presented here may not only lead to improvement in child health but also represent effective interventions against some of the common diseases of public health importance in the adult population.

Some of the preventive interventions presented in Table 4.1 come under the remit of the UK universal child health promotion program that is mainly delivered by midwives, health visitors and the school health service with support from GPs and specialist pediatricians (see later section on Child health screening and surveillance) however knowledge of all of the interventions listed is relevant to the day-to-day practice of pediatrics. The centrality of preventive work to pediatrics is reflected in the fact that many of the interventions presented in Table 4.1 are discussed in other chapters of this book. For this reason we have cross-referenced other chapters in addition to providing references to the evidence base for many of the interventions listed.

### PREVENTION BEFORE CONCEPTION AND DURING PREGNANCY

Genetic factors in either parent, the present and past health of the mother, her age, her habits (e.g. smoking, alcohol), the frequency of her pregnancies, her previous immunizations (e.g. rubella and tetanus) and her social class are all factors which can potentially influence the health of her infant before it is conceived, and control or elimination of adverse factors will play an important part in prevention. A mother's own birth weight and growth through childhood and general nutrition during adulthood and pregnancy are being increasingly recognized as important determinants of her child's fetal growth patterns and hence subsequent risk of chronic diseases.<sup>15-18</sup> This developing understanding of 'biological programming' demonstrates the importance of focusing on health promotion for women and young children in order to break intergenerational cycles of poor health. It also shows how complex disease prevention interventions can be, for example it is not yet clear how best to optimize maternal nutrition.<sup>19</sup>

The effects of a pregnant woman's smoking or alcohol consumption on her fetus are now well recognized and demand preventive action.<sup>20</sup> Smoking can lead to intrauterine growth retardation, certain congenital anomalies, fetal loss, and preterm delivery.<sup>21-23</sup> In addition, smoking

during and after pregnancy has emerged as a major risk factor for sudden infant death syndrome (SIDS) in studies carried out after the widespread recommendations on infant sleeping position led to a reduction in the number of infants found dead in the prone position.<sup>24-26</sup> Reduction of smoking levels in the population requires coordinated action including increasing the cost of tobacco, banning advertising, and restricting the places where people are allowed to smoke.<sup>27</sup> At the individual level effective interventions to help people to stop smoking are available. Pregnant women can benefit from smoking cessation counseling and nicotine replacement therapy, and maternity services should ensure all pregnant smokers have access to specialist stop smoking care.<sup>19,28</sup>

Well-organized antenatal care makes a vital contribution to maternal and child health. In the UK, current recommendations suggest that routine antenatal care for healthy women should include provision of health information along with the offer of screening for anemia, red cell alloantibodies, syphilis, hepatitis B and HIV infection, immunity to rubella, asymptomatic bacteriuria, pre-eclampsia, Down syndrome, structural anomalies, and fetal growth.<sup>20</sup> Women with particular risk factors may require additional antenatal care, for example individuals with a family history of a genetic disorder may benefit from genetic testing. Over recent years there have been major advances in the understanding of the molecular basis of medical disorders and in the development of new techniques to identify genes associated with disease. Most of the genes for the more common inherited (single gene or 'Mendelian') disorders have now been identified (see Chapter 14). This in turn often makes prenatal detection and genetic counseling possible.<sup>29-31</sup> In conjunction with this there have been advances in prenatal diagnostic techniques, for example using amniocentesis or chorionic villous sampling. Secondary prevention by termination of pregnancy has therefore become more widely practiced.

In early pregnancy the avoidance of various teratogens is an important preventive measure. The following drugs and chemicals have been found to be associated with fetal defects: diphenylhydantoin (phenytoin), trimethadione, paramethadione, valproic acid, carbamazepine, thioureas, carbimazole, methimazole, isotretinoin, vitamin A, etretinate, thalidomide, warfarin, methotrexate, corticosteroids, androgens, progestins, diethylstilbestrol, iodine, lithium, mercury and chlorobiphenyls. A number of other drugs and chemicals have featured in retrospective studies or case reports but associations with fetal defects have not been confirmed by subsequent investigations (see Stevenson<sup>32</sup> for a further discussion). Exposure to abdominal X-rays should be avoided, but there is no evidence that ultrasound examinations are harmful to the fetus.

### PREVENTION IN NEONATAL PERIOD

Good intrapartum obstetric care and subsequent effective monitoring, investigation and treatment of the many disorders from which the newborn infant may suffer are important preventive measures. Such disorders include asphyxia, birth injury, low birth weight and hyperbilirubinemia. Neonatal screening procedures are discussed in the section on Child health surveillance and screening.

The promotion of breast-feeding is a crucial preventive measure. Breast-feeding reduces the risk of necrotizing enterocolitis, diarrheal disease, lower respiratory infections, otitis media, and other serious neonatal infections.<sup>33,34</sup> It also appears to reduce the risk of childhood obesity, probably through better development of appetite control.<sup>35</sup> Recent evidence has further linked lack of breast-feeding with poorer intellectual development, possibly due to the lack of certain long chain fatty acids, essential for normal brain development, in most breast milk substitutes, although it is difficult to totally exclude the possibility of confounding from these studies.<sup>36,37</sup> Frequent breast-feeds given over a prolonged period also significantly reduce fertility and increase the birth interval, with indirect benefits to both mother and infant.<sup>38</sup>

WHO and UNICEF are coordinating a global initiative (the Baby Friendly Hospital Initiative) to promote breast-feeding and to improve health service support for breast-feeding mothers.<sup>39,40</sup> Hospital routines

Table 4.1 Effective preventive interventions across childhood

Intervention	Health benefits	Relevant section in Forfar and Arneil	Additional evidence (reference number)
<i>Preconception through to infancy</i>			
Adequate nutrition	Adequate maternal nutrition promotes a healthy pattern of fetal growth and avoids 'biological programming' of higher chronic disease risk for child throughout its life		15–19
Avoidance of smoking	Avoidance of maternal smoking reduces the risk of intrauterine growth retardation, preterm delivery, and SIDS	Ch. 6 (SIDS)	19, 21–28
<i>Preconception</i>			
Adequate folic acid intake	Reduced risk of neural tube defects	Ch. 22	116–120
Rubella immunization	Reduced risk of congenital rubella syndrome	Ch. 28	121–123
<i>In pregnancy</i>			
General antenatal care	Avoidance of preventable morbidity, e.g. maternal anemia		20
Antenatal screening, e.g. for Down syndrome	Prevention of disability through optimal management of pregnancy, delivery and child, or termination of affected pregnancies	Ch. 11	124–126
Adequate folic acid intake	Reduced risk of neural tube defects	Ch. 22	116–120
Moderate alcohol intake	Prevention of fetal alcohol syndrome		127–129
Avoidance of teratogens, e.g. drugs, infections, and radiation	Reduced risk of congenital anomalies		32
Anti D immunoglobulin if Rhesus negative	Prevention of Rhesus alloimmunization	Ch. 11	130, 131
Steroids for women at risk of preterm delivery	Reduced risk of respiratory distress syndrome in neonate	Ch. 12	132
<i>In the perinatal/neonatal period</i>			
General intrapartum and neonatal care	Prevention of birth injury, kernicterus, and infections including those that are health care associated, e.g. MRSA	Ch. 12	133, 134
Neonatal screening, e.g. physical examination, heel prick blood test, and hearing screening	Prevention of disability through, for example, management of congenital hip dislocation, PKU and hearing impairment	Ch. 12	135, 136
Breast-feeding	Reduced risk of necrotizing enterocolitis, gastrointestinal and respiratory infections, otitis media, and childhood obesity; increased child spacing and reduced risk of breast cancer for mother	Ch. 13	33–53
Vitamin K	Prevention of hemorrhagic disease of the newborn	Ch. 12	54–58
Interventions including medication, immunization, and management of labor and infant feeding	Avoidance of vertical transmission of infection e.g. HIV and hepatitis B	Ch. 27 (HIV)	59, 60
<i>In infancy and childhood</i>			
General clinical care	Prevention of a range of illness and disability through prompt and effective diagnosis, treatment, and rehabilitation		
Screening and child health surveillance	Prevention of disability associated with, for example, vision and hearing problems	Chs 7 (developmental delay), 31 (vision), and 32 (hearing)	135
Fostering of positive relationship between child and primary caregiver	Prevention of mental health problems, development of personal resilience, and increased chance of healthy behavior choices in later life		See support for parenting
Sleeping on back and avoiding overheating	Reduced risk of SIDS	Ch. 6	61–68
Immunization	Reduced risk of a range of infectious diseases and their sequelae	Ch. 28	See Immunization
Appropriate weaning	Reduced risk of iron deficiency, dental decay, and childhood obesity	Ch. 13	69–75, 79–81
Tooth brushing and fluoride provision	Reduced risk of dental decay	Ch. 13	76–78

Table 4.1—cont'd

Intervention	Health benefits	Relevant section in Forfar and Arneil	Additional evidence (reference number)
Safety promotion interventions, e.g. car seats, smoke alarms, safe toys	Reduced risk of accidental injury	Ch. 6	82–87
Adequate exercise	Reduced risk of childhood obesity	Ch. 5	88–91
Detection and treatment of child abuse	Reduced impact of abuse on mental and physical health		92–94
<i>In adolescence</i>			
Accessible health services	Opportunities for health promotion and disease prevention through positive interaction between health professionals and adolescents	Ch. 35	
Avoidance of development of unhealthy behaviors, e.g. smoking, unsafe alcohol intake, inadequate exercise, and use of illegal drugs	Reduced immediate adverse impact on health and prevention of establishment of damaging behavior patterns	Chs 16 (nutrition) and 35	27, 95–101, 107–111
Sexual health promotion including sex and relationships education and accessible contraceptive and GUM (Genito-urinary medicine) services	Reduced risk of unwanted teenage pregnancy and sexually transmitted infections	Ch. 35	102–105

and practices can discourage women from breast-feeding or make it difficult for them to do so successfully<sup>41,42</sup> hence good practice guidelines have been developed for maternity hospitals.<sup>43</sup> Key features of good practice include 'rooming in', i.e. allowing mother and babies to remain together, supporting skin-to-skin contact and the first breast-feed soon after birth, encouraging subsequent feeding on demand, and education of staff and mothers to promote good positioning and attachment of the baby.<sup>44–48</sup>

Improving hospital practices and staff skills in line with these guidelines has been shown to improve breast-feeding rates across all ethnic and socio-economic groups.<sup>49–52</sup> Policy statements on breast-feeding by pediatric associations have been used to raise awareness amongst pediatric staff of the need to promote breast-feeding, to promote good practice and to advocate for inclusion of breast-feeding topics in the undergraduate medical and nursing curricula and in postgraduate courses for pediatricians, obstetricians, general practitioners, midwives and maternal and child health nurses.<sup>53</sup>

Vitamin K should be given to all babies at birth to prevent the rare but serious disorder hemorrhagic disease of the newborn (HDN).<sup>54</sup> Vitamin K administered either as one intramuscular injection shortly after birth or as multiple oral doses (with more doses required for breast-fed babies) over the first few weeks of life is effective at preventing early, classic, and late HDN.<sup>55</sup> As compliance is higher and costs are lower with the IM route, that is the regimen that is usually preferred. This was questioned following the publication of one case-control study in 1992 that reported an association between administration of vitamin K via the intramuscular route to neonates and the subsequent development of childhood leukemia.<sup>56</sup> Later studies and systematic reviews have failed to replicate this finding however, and the consensus view is now that IM vitamin K does not increase the risk of cancer.<sup>57,58</sup> Current advice from the Department of Health for England states that all babies should be offered vitamin K but does not state which regimen should be followed.

The risks of HIV transmission are now better understood, leading to guidelines for the management of HIV-positive mothers to reduce vertical transmission of infection.<sup>59</sup> Key interventions include universal antenatal screening of mothers for HIV infection, antiretroviral therapy for those found to be infected along with elective Caesarian sec-

tion delivery and avoidance of breast-feeding in areas where it is safe to do so.<sup>60</sup>

## PREVENTION IN INFANCY AND EARLY CHILDHOOD

In infancy and early childhood curative medicine can have an important preventive role. Early diagnosis and effective treatment of diseases such as meningitis, pneumonia, otitis media, osteomyelitis and patent ductus arteriosus can prevent chronic illness or permanent handicap in some children following these conditions. The contribution of screening, of positive relationships between children and their primary caregivers, and of immunization to improving child health is discussed later in the sections on Child health screening and surveillance, Support for parenting, and Immunization, respectively.

Proven effective interventions to reduce the risk of SIDS include putting babies to sleep on their backs, avoiding overheating by attention to environmental temperature, not over wrapping the baby and not covering its head, and avoiding exposure to environmental tobacco smoke in the home.<sup>61–64</sup> Areas that are still under debate include the contribution of co-sleeping, i.e. babies sleeping with their parents in the bed and the use of pacifiers ('dummies')<sup>65–68</sup> (See Ch. 6 for a full discussion).

An appropriate weaning diet progressing on to a healthy diet throughout childhood is fundamental to child health. Dietary guidelines have been published by many authorities.<sup>69,70</sup> These combine concerns about achieving recommended daily intakes of selected essential nutrients with the need to reduce risks of chronic diseases of adulthood which are partly attributed to diet. Dental decay in childhood is a significant health problem.<sup>71,72</sup> Ensuring children's diets are low in free sugars, and in particular in sugary foods and drinks taken as snacks at regular intervals through the day, helps to reduce the incidence of decay.<sup>73–75</sup> In addition there is good evidence that twice daily tooth brushing with toothpaste containing 1000 p.p.m. fluoride from as soon as the primary teeth erupt is effective at preventing decay.<sup>76</sup> Fluoridation of the public water supply has also been shown to reduce decay and represents a highly clinically and cost-effective public health measure but is not routine within the UK at present.<sup>77,78</sup>

Care should be taken to ensure that children's diets provide adequate sources of available iron. Recent studies in the UK have shown

a prevalence of iron deficiency anemia of up to 25% in young children, with particularly high rates in some ethnic minority communities.<sup>79</sup> Effects on mental and motor development can be reversed if treatment is prompt.<sup>80</sup> All premature babies should receive iron supplements. The Department of Health for England currently recommends that all children receive vitamin A, C, and D drops between ages 1 and 5 years (from 6 months for breast-fed infants).<sup>81</sup> Children should also receive iodine supplements where specific deficiency is endemic.

Accidents cause nearly half of all deaths at ages 1–19 years in the UK.<sup>82,83</sup> The cause of the accidents, and therefore the preventive action, varies with the age of the child. Important preventive measures of proven effectiveness include: area wide urban safety measures; traffic speed restrictions; child car restraints; cycle helmet wearing; road safety education; child-proof containers for drugs; and home safety devices such as stair gates and fire alarms. The use of safe playground apparatus and surfaces, the use of age-appropriate toys, and the proper supervision of children near water are also important.<sup>84,85</sup> Evidence also exists on effective ways to deliver safety promotion interventions, such as through targeted health visiting and provision of subsidized safety equipment to households at risk of home-based accidents.<sup>86,87</sup>

The health benefits of physical activity are less well defined for children than for adults. Nevertheless, there is some evidence to show that adequate physical activity in childhood helps to reduce the numbers of overweight and obese children and improve well-being and self-esteem, biological cardiovascular disease risk factors, and skeletal health.<sup>88</sup> Importantly also there is clear tracking of behaviors between childhood and adulthood, hence active children are more likely to become active adults and thus gain health benefits.<sup>89</sup> Current recommendations suggest that children should achieve at least 1 h of moderate physical activity a day. There is limited evidence available on measures to increase physical activity levels among children, although restricting television and computer viewing and developing holistic programs of health promotion with schools are likely to be important.<sup>90,91</sup>

All health professionals in contact with children should be alert to the possibility of child abuse, particularly in cases of repeated multiple or unusual trauma or burns, or in children with developmental delay.<sup>92</sup> Prompt recognition can prevent future abuse and can identify the need for counseling or specific treatment.<sup>93,94</sup>

## PREVENTION IN LATER CHILDHOOD AND ADOLESCENCE

The prevention of poor diet, inactivity, obesity, smoking, unsafe alcohol use, abuse of drugs and related substances, unplanned and unwanted teenage pregnancy, sexually transmitted diseases including HIV, family breakdown, and child abuse and neglect is particularly challenging. Considerable medical, social, economic and, in the view of some, spiritual or moral resources are required to meet these challenges. Owing to the very close correlation between unhealthy behavior patterns in late childhood and in adulthood, prevention in childhood could make a major contribution to improving future adult health as well as the health of children.

The health risks of smoking are well recognized. The Scottish Schools Adolescent Lifestyle and Substance Use Survey (SALSUS) 2004 found that 5% of boys and 7% of girls aged 13 years were regular (i.e. at least one cigarette a week) smokers, increasing to 14% of boys and 24% of girls aged 15 years.<sup>95</sup> There is evidence of effectiveness for a variety of interventions designed to reduce the uptake of smoking among young people, including school-based health promotion programs, increasing the unit price of cigarettes, working with retailers to reduce sale of cigarettes to children, and mass media campaigns.<sup>27</sup> In addition young people who are established smokers can benefit from specialist smoking cessation support.<sup>27,96</sup> Health professionals should routinely ask about smoking in older children and their

parents, and provide advice and help where necessary on stopping smoking. Parents who cannot stop smoking should be encouraged not to smoke in the house or in front of their children. Health services should actively support any effective and appropriate action against the promotion of cigarettes and tobacco.<sup>97</sup>

Alcohol consumption among young people, in particular young girls, has increased markedly over recent years. In 2004 SALSUS found that 20% of boys and girls aged 13 years had had an alcoholic drink in the week prior to the survey compared to 40% of boys and 46% of girls aged 15 years.<sup>95</sup> Concern over alcohol use in adolescents is based not only on related health problems (e.g. one third of all accidental deaths in 16–19-year-olds are associated with alcohol) but also on drunkenness and its related social problems. Whilst there is evidence for effective interventions to reverse established unsafe drinking, there is very little evidence available on preventing alcohol misuse among young people.<sup>98–100</sup>

Experimentation with illegal drugs is common among adolescents. In 2004 SALSUS found that 11% of 13-year-olds and 31% of 15-year-olds had used drugs in the year preceding the survey, with cannabis being by far the most commonly used substance (results for boys and girls are very similar).<sup>95</sup> There is evidence that intensive interactive school-based health promotion programs can be effective in increasing knowledge about drugs and reducing or delaying the onset of drug use although direct effects on drug use can be small and short lived.<sup>101</sup>

Levels of unsafe sexual activity are worryingly high among young people. Rates of sexually transmitted infections (STIs), particularly *Chlamydia*, have increased dramatically over recent years.<sup>102</sup> In addition approximately 1% of girls aged 14–15 years in the UK conceive each year and over half of these pregnancies result in abortion.<sup>103</sup> Teenage motherhood leads to poor health outcomes for both the mother and child and contributes to intergenerational cycles of ill health.<sup>104</sup> There is evidence that well-organized family or school-based programs incorporating personal development, sex and relationships education, and accessible contraceptive and genitourinary medicine services do work in reducing unsafe sex, STIs, and teenage pregnancy.<sup>105,106</sup> Conversely there is evidence that health promotion programs that rely solely on promoting abstinence from sexual activity do not work.<sup>105</sup>

The dramatic increase in numbers of those overweight and obese among all age groups including children in Western societies over recent years is a major public health concern. The Health Survey for England found that in 2004 13% of boys aged 11–15 years were overweight and an additional 24% were obese: 19% of girls of the same age were overweight and an additional 26% were obese.<sup>107</sup> There is debate as to the precise cause of increasing levels of obesity in children but it is likely that increased consumption of high fat, energy dense foods and reduced levels of physical activity both contribute.<sup>108</sup> It is of note that levels of physical activity decline markedly in teenage years so that only one half of young men aged 16–24 years and one third of young women undertake recommended levels physical activity.<sup>109</sup> There is evidence that school-based holistic programs incorporating curricular material, nutrition education, modification of school meals and tuck shops, and physical activity promotion can prevent the development of obesity, particularly in girls.<sup>110</sup> There is also some evidence regarding effective interventions to promote weight loss in obese children although maintenance of reduced weight can be challenging.<sup>110,111</sup>

The above discussion shows the importance of holistic health promotion for young people to prevent the establishment of health damaging patterns of behavior and also the importance of the school environment in health promotion for young people. Health promotion for young people should reinforce negative views of unhealthy behaviors and promote positive views of health and of healthy behaviors such as emphasizing nonsmoking as the norm. Action needs to involve not only a wide range of health, education and social work professionals but also relevant voluntary agencies and young people themselves through peer projects, and requires to be part of an overall strategy involving both national and local action. Action can be taken in a stepped fashion with:

- broad messages or action aimed at the general population at low risk (e.g. warnings about binge drinking or the use of recreational drugs at parties);
- more focused messages or action for subgroups at higher risk;
- individual action and support for young people who are, for example, dependent on substances and at greatest risk to themselves and their community.<sup>112</sup>

Health professionals who care for children should maintain a high level of awareness and know where and how to seek assistance when faced with these problems. Integrated school health services could include diagnostic, treatment and health counseling services. These services operate most successfully when they are fully integrated with other community and hospital health and related social services.<sup>113</sup> An international network of 'health promoting schools' has developed this model further by harnessing a wide variety of school policies to promote child health within schools, for example by providing affordable and tasty healthy food options and promoting a healthy diet, by ensuring there are sufficient opportunities for physical activity such as through organized sports, adopting and enforcing no-smoking policies and making the school environment safer and more attractive.<sup>114,115</sup> In all these areas there is an increasing recognition of the need to adopt evidence-based action based on systematic reviews of randomized controlled trials or other evidence of effectiveness of interventions.

## SUPPORT FOR PARENTING

Over recent years there has been an increasing focus on the role of parenting as a determinant of child and adult mental and physical health. Key features of 'good' parenting include consistent parental sensitivity and responsiveness to a child's needs along with positive communication, secure boundaries and positive discipline, and parental example.<sup>137</sup> It is therefore far more than just the absence of neglect or abuse. Good parenting is not culture dependent although specific child rearing practices vary widely between cultures.<sup>138</sup> Good parenting facilitates the initial establishment of secure attachment between an infant and its primary caregiver, usually its mother, and uses this as a stepping stone for broader positive relationships and increasing independence through the toddler years.<sup>137</sup>

Babies are highly social from birth and the quality of the social relationships they experience, in particular the provision of responsive care, influences the development of neural pathways regulating response to stressful stimuli, emotional arousal, attention, memory, and learning.<sup>139</sup> In practice, therefore, parenting has been shown to influence children's cognitive capacity, language development, school performance, ability to form positive social relationships, risk of health damaging behaviors, and risk of involvement in criminal activity, although clearly parenting is not the only determinant of these broad outcomes.<sup>139-141</sup>

Whilst almost all parents want the best for their children and work hard to provide that, unhelpful parenting is common across all sectors of society. The stresses associated with material and social deprivation make achieving good parenting even more difficult, and hence unhelpful parenting contributes to health inequalities.<sup>142</sup> Conversely, positive parenting has a marked protective effect on children who are living under stressful and disadvantaged circumstances and can ameliorate the adverse health consequences of social inequalities.<sup>138</sup>

There is reasonably robust evidence now available that specific support for parenting is both clinically and cost effective. In general terms two types of programs to facilitate helpful parenting are available: infant mental health programs and parenting education and support programs.<sup>142,143</sup> Infant mental health programs are based on attachment theory and generally aim to develop parental understanding, sensitivity and responsiveness to infants' needs. The programs can include elements of counseling, role play, video feedback, cognitive behavioral work, and baby massage. Parenting education and support programs can be based on either social learning theory or emotional literacy the-

ory. The former focuses more on positive discipline and improving child behavior whereas the latter focuses more on improving parent-child relationships. In practice most programs encompass elements of both approaches.

Infant mental health programs are intensive – to be most effective they should involve weekly sessions for the first 6 months of a baby's life. They can be provided either on a one-to-one basis, for example through a home visiting program, or to groups of mothers in community-based centers.<sup>142,144</sup> Parenting education and support programs should involve weekly sessions for around 3 months. They are most effective when provided in a group setting to parents of children aged up to 3 years.<sup>142,145</sup> Programs that meet these standards have been shown to improve attachment, the emotional and behavioral adjustment of young children, child language development, and maternal mental health.<sup>142,146-149</sup> Within the UK, infant mental health programs are uncommon but parenting programs for older children are becoming more widespread. They are often provided by nongovernmental organizations, however, and are not always well integrated with mainstream NHS services. The UK Royal College of Pediatrics and Child Health has recommended that a range of parenting programs should be universally available for expectant mothers through to parents of children aged 3, with scope to target the most intensive support to families most in need.<sup>137</sup> The UK system of universal health visiting for pre-school-age children provides a good setting for helping parents access available support.

Another issue closely aligned to that of helpful parenting is non-parental care for pre-school children. As more mothers of young children undertake paid work, so the requirement for nonparental care increases. The type of nonparental care used varies widely and includes informal care from friends and extended family, care from a nanny or professional childminder, and day center or nursery-based care. Nonparental care should mirror the attributes of helpful parenting and for older pre-school children should encompass high-quality early education. There is considerable evidence, mainly from the USA, that children provided with this kind of care develop better behavioral adjustment, improved school performance, and lower involvement in juvenile crime.<sup>150,151</sup> The availability of affordable, high-quality nonparental care for pre-school children remains a major issue in many countries.

The importance of parenting and provision of nonparental care to child health and development is being increasingly recognized in UK policy, for example in the English National Service Framework for Children, Young People, and Maternity Services (Standard 2: Supporting Parenting)<sup>136</sup> and the UK-wide Sure Start programme.<sup>152</sup> In general, pediatricians have a key role in being aware of the evidence on these topics, supporting the development of effective services in their local areas, and advocating on these issues more broadly.

## CHILD HEALTH SCREENING AND SURVEILLANCE

In the UK, child health screening programs and surveillance of children's growth and development are delivered in a coordinated way within the broad child health promotion (CHP) program that is offered to all children. The CHP program also comprises the nationally agreed immunization schedule, delivery of effective health promotion advice, provision of support for parenting including advice on issues such as infant sleeping and child behavior, and identification of at-risk children and contribution to child protection procedures. Specific recommendations about the content of the program, based on a critical consideration of the published literature, are periodically published by the Royal College of Pediatrics and Child Health.<sup>135</sup> In addition the UK National Screening Committee publishes advice on screening programs.<sup>153</sup> These recommendations are then usually adopted into health policy such as the National Service Framework for Children, Young People and Maternity Services in England<sup>136</sup> and equivalent guidance for Scotland.<sup>154</sup> The current UK recommended

**Table 4.2** Screening and surveillance procedures recommended for all children as part of the UK child health promotion program

Age	Intervention
Newborn	Weight and head circumference Physical examination with particular emphasis on eyes, heart, and hips
5–6d	Newborn blood spot screening test for phenylketonuria, congenital hypothyroidism, cystic fibrosis, and sickle cell disease
Within first week	Newborn hearing screening using automated otoacoustic emissions
6–8 weeks	Weight and head circumference Physical examination with particular emphasis on eyes, heart, and hips
3 months	Weight
4 months	Weight
4–5 years	Screening for visual impairment by an orthoptist
School entry	Height and weight Screening for hearing loss by sweep test

Adapted from *Health for all children*, 4th ed.<sup>135</sup>

screening and surveillance procedures for children are summarized in [Table 4.2](#).

Although the core content of the child health promotion program is decided centrally, the detailed decisions about how different elements of the program should be delivered remain a local responsibility. In practice a wide range of professionals are involved in delivering the program, including health visitors, school nurses, GPs, and pediatricians. It is important therefore that a local child health promotion program has clear leadership, identified responsibilities, and agreed lines of accountability.<sup>155</sup> A multi-agency steering group should oversee the development and implementation of local policies including detailed guidance on how the program should be delivered, staff training requirements, standards and monitoring, and use of information from the program for epidemiological purposes. Personal child health records should be made available to all families and their use by both families and health staff encouraged.<sup>156</sup> It is important to note the distinction between formal child health screening programs and surveillance or monitoring of child health. Screening comprises offering a test to all members of a defined population (such as all newborn babies) in order to identify those at higher risk of a particular disease or condition so that they can be offered further tests to confirm the diagnosis and then treatment or care to improve their outcome.<sup>157,158</sup> Screening is therefore a risk stratification process and the result of a screening test is not in itself sufficient to diagnose disease. All screening tests result in some false positives (healthy people who screen positive) and false negatives (people who have the disease of interest but screen negative). The administration of a screening test can also cause direct harm, for example by generating anxiety or causing direct complications such as a baby getting an infection following the heel prick required for blood spot testing. In addition screening programs are very resource intensive to set up and maintain. A careful consideration of the balance of potential benefits and harms of any proposed screening program is therefore required before a program is introduced,<sup>159,160</sup> and participation in any existing program should be on the basis of informed consent – parents should understand that a negative screening test is not a guarantee of health.

The UK National Screening Committee is responsible for reviewing the evidence for existing or proposed screening programs and recommending whether or not they should be provided. The Committee has

established criteria for good screening programs which focus on the condition being screened for, the screening test, subsequent diagnostic and treatment options available, and the feasibility of providing the program as a whole.<sup>157</sup> All the formal screening programs included in the recommended child health promotion program, such as the newborn blood spot test for phenylketonuria, have been endorsed by the National Screening Committee. Screening is intuitively attractive and there is often considerable pressure from both health professionals and the public to provide screening for which there is little robust evidence of benefits outweighing harms. For example there is currently interest in screening newborn babies for medium chain acyl CoA dehydrogenase deficiency (MCADD) using Tandem Mass Spectrometry however the National Screening Committee has advised that this should not be provided outwith the confines of a randomized, controlled trial at present.<sup>161</sup>

Historically, child health promotion programs have incorporated a large element of child health surveillance or monitoring in addition to the provision of formal screening tests. Child health surveillance mainly comprises repeated assessment of a child's growth and development in order to detect abnormalities early. This type of surveillance is not formal screening and in general there is limited evidence of its clinical benefit.<sup>162</sup> Children with serious problems are usually identified by other means, for example by parents or nursery/playgroup workers raising concerns, and there is limited clinical value in detecting minor developmental delay of uncertain significance.<sup>163</sup> Surveillance may well be highly valued by parents and health care professionals however as a way of structuring contact with families, identifying vulnerable children, and providing opportunities for health promotion and reassurance.

The latest recommendations for the UK child health promotion program have moved away from formal assessment of pre-school children's growth and physical and social development at multiple fixed ages and instead suggest a more risk-based approach.<sup>135</sup> In Scotland all children will be allocated to varying levels of support at their 6–8-week check.<sup>154</sup> Whatever level of contact is agreed between health visitors and families with young children it is important that all parents are provided with information on the normal range of development and have ready access to experienced professionals at any point if they have concerns about their child. Professionals also need to take parental concerns seriously, avoid repeated unjustified reassurance, and have clear local policies for onward prompt referral of children who may have problems.

The UK Education Acts of 1981 and 1993 require health authorities to inform education departments of children who have developmental or other medical problems and who may therefore have special educational needs.<sup>164</sup> A full assessment of the child is then made and a statement of special educational needs produced. This system involves the parents of the child in the assessment and focuses on the needs of the child rather than on categorization of the child by diagnostic labeling. These children often require medical support and this is usually best provided by a multidisciplinary team such as those found in child development centers or 'district handicap teams'. The aim of these procedures is tertiary prevention – to limit the handicap which can result from specific impairments by early recognition of the child's medical and educational needs and then appropriate intervention.

## IMMUNIZATION

### IMPORTANCE AND EFFICACY OF IMMUNIZATION IN THE PREVENTION OF DISEASE

Immunity to a specific infectious disease can be acquired through natural infection or immunization.<sup>165,166</sup> Immunization can involve the administration of injected antibodies to generate passive immunity or the administration of a vaccine to generate active immunity. Passive immunization produces immediate protection which lasts for some

weeks or months until the donated antibodies are broken down or used up by the individual. Active immunization stimulates the vaccine recipient's immune system to produce antibody and/or cell-mediated immunity and triggers immunological memory hence produces long-lasting protection.

The immediate goal of active immunization is to prevent disease in individuals, but the ultimate goal is to eliminate or even eradicate a communicable disease. Herd immunity exists if the number of people in a community who have active immunity against an infection that is spread from person to person exceeds a critical level.<sup>167</sup> Above this, susceptible individuals are unlikely to contact someone with the infection. In this way transmission falls or stops without universal immunity. Immunization is a simple, effective, and economic form of control for many infectious diseases.<sup>168</sup> The efficacy of immunization depends on the epidemiology of the pathogen, the vaccine available, the biological and social response of individuals, and the health service infrastructure for delivering the immunization.

## VACCINES: PRESENT AND FUTURE

A vaccine is an antigen, originally derived from or similar to a bacterium or virus, used for active immunization. Vaccines may comprise live attenuated organisms, killed ('inactivated') organisms, isolated components of organisms (usually cell wall proteins or polysaccharides), or attenuated toxins ('toxoids').<sup>169,170</sup>

A live attenuated vaccine is one which produces active immunity by causing a mild 'infection'. A virulent organism is weakened, usually by multiple subcultures in unfavorable conditions, so that it produces an antigenic response without the serious consequences of a wild organism infection. Examples include the measles, mumps, and rubella components of the MMR vaccine. Cross-reacting organisms are another type of live vaccine that causes the body to produce a defense against the virulent strain. The bacillus Calmette–Guérin (BCG) vaccine is an example of this. A killed or inactivated vaccine is prepared from virulent organisms inactivated by heat, phenol, formaldehyde or some other means. Classical pertussis vaccine is an example of a whole-cell killed vaccine.

Component vaccines use parts of organisms as antigens. Examples of protein component vaccines include the newer acellular pertussis vaccines and influenza and hepatitis B vaccines. Examples of polysaccharide component vaccines include *Haemophilus influenzae* type b (Hib), meningococcal C, and pneumococcal vaccines. The response to polysaccharide vaccines is incomplete and unreliable and consequently these may be conjugated with other protein antigens to improve their immunogenicity.<sup>171–173</sup> An example is the linkage of Hib polysaccharide with tetanus and diphtheria toxoids to produce a vaccine conjugate capable of stimulating T cells and thus eliciting immunological memory.<sup>174</sup> Toxoid vaccines are used to protect against organisms such as diphtheria and tetanus, which cause damage through the release of toxins when they infect humans. Diphtheria and tetanus toxoid vaccines produce antibodies which inactivate the toxins and hence prevent the serious clinical consequences of infection but they do not kill the bacteria.

Live attenuated vaccines usually produce a lasting immune response after one dose. Multiple dose schedules incorporating an initial vaccination followed by booster doses may however be used to compensate for vaccine failures. No vaccine is 100% efficacious and some vaccine recipients will fail to generate clinically significant immunity following vaccination, for example around 10% of children fail to generate immunity following a single measles vaccine.<sup>175</sup> Multiple dose schedules therefore allow a second chance for children who missed their first dose for whatever reason or who received it but failed to respond. All types of nonlive vaccines usually require a course of initial vaccinations followed by later booster doses to generate and maintain adequate immunity. Nonlive vaccines may also be adsorbed onto adjuvant compounds such as aluminium hydroxide to increase their immunogenicity and reduce the risk of vaccine failure.

Despite major advances in vaccine development, major inequalities still exist in the delivery of vaccines to children around the world

and large numbers of children continue to die from vaccine-preventable infections.<sup>176,177</sup> The Global Alliance for Vaccines and Immunization (GAVI) and the associated Vaccine Fund were established in 1999 to address these inequalities.<sup>178</sup> GAVI is an alliance between the World Health Organization, UNICEF, the World Bank, the Bill and Melinda Gates Foundation, governments, nongovernmental organizations, academia, and the vaccine industry. GAVI supports poor countries to develop sustainable immunization services and also fosters research of benefit to children in the developing world, for example research developing combined vaccines that do not require storage at cold temperatures or parenteral administration.<sup>179</sup> The development of combined vaccines, i.e. vaccines that provide protection against more than one disease, is also an issue for the industrialized world with more vaccines being adopted into childhood immunization schedules as new vaccines are developed. Combined vaccines are not simple to develop as subtle interactions that impact on the immunogenicity of the component parts can occur.<sup>180</sup>

## ADVERSE REACTIONS AND CONTRAINDICATIONS TO IMMUNIZATION

In general, most of the routine vaccines recommended in national immunization schedules can safely be given to most children, and no child should be denied vaccination without serious thought about the consequences, both for the individual child and the community.<sup>181</sup> Like all medicines, however, vaccines can cause adverse reactions and the risks of these should be clearly explained to parents and set against the risks of natural infection in the absence of vaccination.

Adverse reactions following immunization may be due to faulty administration, inherent properties of the vaccines, or co-incidental.<sup>182</sup> Faulty administration may involve incorrect storage, reconstitution, or injection of vaccines. Co-incidental 'reactions' are those that are not directly linked to vaccination and would have occurred anyway but are linked in time to vaccination. They are important as they can be incorrectly interpreted as a direct consequence of vaccination and undermine professional and parental confidence. Adverse reactions that are due to the inherent properties of vaccines can be classified as local or generalized and they can be predictable or idiosyncratic. Local reactions comprise varying degrees of pain, swelling, and redness at the injection site, which is usually short-lived. Predictable generalized reactions include fever and rash. Unpredictable idiosyncratic reactions include anaphylaxis, idiopathic thrombocytopenic purpura (ITP), and hypotonic-hyporesponsive episodes (HHEs).<sup>183</sup> The range and timing of reactions varies between specific vaccines (Table 4.3).

As serious adverse reactions are rare following vaccination it is difficult to obtain precise estimates of their frequency. It is clear, however, that the risk of adverse reactions is always substantially lower than the risk of serious complications following natural infection, for example:<sup>184</sup>

**Table 4.3** Common adverse events following vaccination

Vaccine	Adverse event	Timing
DTaP/IPV/Hib*	Local reaction**, fever, crying and irritability, loss of appetite	Within 48 h
Meningococcal C	As above plus headache in older children	Within 48 h
MMR	Measles – mild fever, rash	6–10 d
	Mumps – mild fever, swollen parotid glands	18–21 d
	Rubella – mild fever, rash, joint pain in adults	7–21 d

\*DTaP/IPV/Hib is diphtheria–tetanus–pertussis, inactivated polio, and *H. influenzae* type b;

\*\*Local reactions comprise pain, swelling, and redness at the injection site.

Adapted from Immunisation Against Infectious Disease.<sup>182</sup>

- Acute encephalitis occurs in approximately 1 in 1000 cases of measles versus < 1 in 1 000 000 recipients of MMR;
- Meningitis occurs in 1 in 10 cases of mumps versus 1 in 50 000–1 000 000 recipients of MMR;
- ITP occurs in 1 in 3000 cases of rubella versus < 1 in 30 000 recipients of MMR.

Despite this, in industrialized countries parents and professionals tend to overestimate the risks of vaccination and underestimate the risks of natural infection;<sup>185</sup> this is partly because successful vaccination programs ensure that cases of natural infection are rare and therefore may not be perceived as a real threat. In addition, people are generally far less willing to accept risk associated with medicines given to healthy children than treatments given to children who are already unwell.

There are relatively few genuine contraindications to vaccination and most children could and should receive the complete immunization schedule.<sup>181,186</sup> In practice, however, parents and professionals often withhold vaccination unnecessarily<sup>187,188</sup> (see Table 4.4 for a list of false contraindications to vaccination). Vaccination should be postponed for children who are acutely unwell, for example with a febrile illness, or who have an evolving neurological condition of uncertain diagnosis and/or prognosis.<sup>189</sup> This is primarily so that co-incidental symptoms are not incorrectly ascribed to the vaccination. A previous proven anaphylactic reaction to a specific vaccine or one of its components absolutely contraindicates further doses. The additional risks associated with live vaccines mean they are also relatively contraindicated for pregnant women and patients with significant immunosuppression, for example due to chemotherapy, post-transplant immunosuppression, or HIV infection. In the UK definitive advice on genuine contraindications to specific vaccines is available in the 'Green Book' (Immunization against infectious disease available on the Department of Health website<sup>190</sup>). Even when a list of specific contraindications is available, it can be difficult to interpret this for children with very complex problems and needs. Specialist advice should be sought before withholding vaccination from children with special needs as they are likely to be highly vulnerable to

**Table 4.4** Situations which are *not* absolute contraindications to immunization

1	Prematurity
2	Under a certain weight
3	History of jaundice after birth
4	Breast-feeding
5	Mild self-limiting illness without fever, e.g. common cold
6	Asthma, eczema, or hay fever
7	Stable medical problems such as cardiac or renal disease
8	Stable neurological conditions, e.g. cerebral palsy or Down syndrome
9	Personal history of febrile convulsions or epilepsy
10	Treatment with antibiotics or topical or inhaled steroids
11	Recent or imminent surgery or general anesthesia
12	Previous history of the disease being vaccinated against (except for BCG)
13	Unknown immunization history
14	Over the age recommended in the routine immunization schedule
15	Contact with an infectious disease
16	Child's mother or other household member being pregnant
17	Close contact with immunosuppression
18	Family history of any adverse reactions following immunization
19	Family history of febrile convulsions or epilepsy

Note that although these situations are not absolute contraindications to immunization in some circumstances they may warrant additional precautions. Adapted from Immunisation Against Infectious Disease.<sup>189</sup>

the serious consequences of natural infections and hence have much to gain from vaccination.

## IMMUNIZATION SCHEDULES

Immunization schedules are the basic framework for the delivery of immunizations to individuals and the community. No one schedule is applicable to all countries and communities of the world and national programs undergo frequent change in response to changing epidemiology of infection and the development of new vaccine products. The basic aim of an immunization schedule is to reach the majority of children before they become at risk of natural infection. Which vaccines are included and the ages at which they are delivered depends on the age-specific risks of disease, response to vaccines, risks of complications, potential interference from maternal antibody, cost of vaccine and health service infrastructure. The schedule should also be simple so that it can be remembered by staff and parents and should fit in with other aspects of health care such as the child health promotion program. In addition to providing comprehensive coverage of the core national immunization schedule, immunization services also need to be flexible enough to accommodate the needs of children traveling to different countries.<sup>191</sup> Small children now travel with their parents to every corner of the globe. Such visits may expose children to infectious diseases no longer endemic in Europe and North America and to conditions which, although preventable, are not normally covered in a routine immunization program. As the disease incidence and health regulations are constantly changing, up-to-date advice should be sought from appropriate authorities. Basic preventive measures should always be observed, in particular careful food hygiene and protection from insects which transmit infections.

The timing of the first routine immunizations is a compromise between the developing maturity of the infant's immune system and the risk of infection from virulent organisms.<sup>192</sup> Very young infants may not mount an adequate immune response to some vaccines and they also have residual maternal transplacental immunoglobulin G (IgG) that both offers some protection against natural infection and may interfere with the immune response to vaccination.<sup>193</sup> The level of protection provided to infants by maternal IgG varies between organisms, for example it is poor for pertussis but more complete for measles.

Three current immunization schedules (for the UK, the USA and that recommended for developing countries by the WHO) are set out in Table 4.5. The current UK schedule completes primary immunization by 6 months of age, minimizing the number of drop-outs. Recent changes to the UK immunization schedule include:

- the change from live oral polio vaccine to injected inactivated polio vaccine to eliminate the risk of vaccine-associated paralytic polio in 2004;<sup>194</sup>
- the change from whole-cell to acellular pertussis vaccines to reduce the risk of adverse reactions in 2004;<sup>194</sup>
- withdrawal of BCG for children aged 10–14 years and implementation of enhanced neonatal BCG immunization for at-risk infants in 2005;<sup>195</sup>
- introduction of pneumococcal conjugate vaccine for infants in 2006;<sup>196</sup>
- introduction of a booster dose of Hib vaccine in the second year of life in 2006.<sup>196</sup>

## DEVELOPING COUNTRY SCHEDULES

In developing countries booster immunization schedules present financial and logistic problems so the main emphasis is on primary immunization as part of basic health care.<sup>197</sup> The priority for the WHO is to deliver the primary immunization series to over 90% of infants and thus reduce the burden of these diseases.<sup>198</sup> Low birth

**Table 4.5** A comparison of three immunization schedules recommended for use in the UK, USA, and developing countries (the World Health Organization Expanded Program on Immunization recommendations) as at July 2006

Age	UK <sup>201</sup>	USA <sup>202</sup>	Developing countries (WHO EPI) <sup>197</sup>
Birth/neonatal period	BCG if higher risk Hep B if higher risk	Hep B	BCG Hep B (Scheme A for areas with high perinatal transmission) OPV if polio endemic
1 month	Hep B if higher risk	Hep B (can be given any time from 1 to 2 months)	
6 weeks			OPV DTP Hep B (Schemes A and B) Hib
2 months	DTaP/IPV/Hib PCV Hep B if higher risk	DTaP IPV Hib PCV	
10 weeks			OPV DTP Hib Hep B (Scheme B for areas with moderate perinatal transmission)
3 months	DTaP/IPV/Hib MenC		
14 weeks			OPV DTP Hep B (Schemes A and B) Hib
4 months	DTaP/IPV/Hib PCV MenC	DTaP IPV Hib PCV	
6 months		DTaP PCV Hep B (6–18 months) IPV (6–18 months) Annual influenza vaccine (6–23 months, 2 doses in first year)	
9 months			Measles Yellow fever if YF endemic
12 months	Hib MenC Hep B if higher risk	Hib (12–15 months) MMR (12–15 months) PCV (12–15 months) Varicella (12–18 months) Hepatitis A (12–23 months, 2 doses separated by ≥ 6 months)	
13 months	MMR PCV		
15–18 months Pre-school/school entry	dTaP/IPV (3½–5 years) MMR (3½–5 years)	DTaP DTaP (4–6 years) IPV (4–6 years) MMR (4–6 years)	
11–12 years		dTaP	
13–18 years	Td/IPV	Men A, C, W135, and Y	

BCG, bacillus Calmette–Guérin; Hep B, hepatitis B; DTP, diphtheria, tetanus and whole cell pertussis; DTaP, diphtheria, tetanus and acellular pertussis; dTaP, low dose diphtheria, tetanus and acellular pertussis; Td, tetanus and low dose diphtheria; OPV, oral polio vaccine; IPV, inactivated polio vaccine; Hib: *H. influenzae* type b; PCV, pneumococcal conjugate vaccine; Men C, Meningococcal C conjugate vaccine; MMR, measles, mumps and rubella; Men A, C, W135, Y: quadrivalent meningococcal vaccine.

weight infants, whether due to premature birth or intrauterine growth retardation, or both, should generally be immunized with the same schedule as for normal weight, full-term infants.<sup>189</sup> In addition to the standard WHO schedule, other vaccines are available and recommended for use in specific geographic areas, for exam-

ple Japanese encephalitis and pigbel vaccines. Others like Hib may not yet be affordable in some developing countries. This is a striking example of global inequity in child health care – the children at lowest risk of Hib disease receive immunization whilst the children at highest risk have no access to immunization, resulting in hundreds

of thousands of child deaths each year.<sup>199</sup> Access to Hib vaccination is being specifically addressed by GAVI.<sup>178</sup> Mass immunization campaigns are an integral part of the global polio eradication strategy; they are now also recommended by WHO for use in measles elimination programs.<sup>200</sup> They can have a dramatic impact as the first phase of an elimination strategy, especially where health infrastructure is limited. Such campaigns should not be isolated events, but part of a long-term strategy.

In conclusion, immunization schedules should be epidemiologically relevant, immunologically effective, operationally feasible and socially acceptable. At a global level child health advocacy (see earlier) is required to promote equitable access to essential vaccines for all children in the world since immunization (with WHO Expanded Program of Immunization vaccines) represents a highly cost-effective child health promotion strategy in all world populations.

## IMMUNIZATION COVERAGE

As previously mentioned, stark inequalities in access to vaccination exist within and between countries, with children living in disadvantaged circumstances having considerably lower uptake. The reasons for these inequalities are complex but ultimately they reduce population immunization coverage, prevent achievement of herd immunity, and increase the chance of continuing or re-emerging epidemics of infectious disease. Another major threat to immunization coverage is an unfounded lack of professional and parental confidence in the safety and effectiveness of immunization.<sup>187,188,203-206</sup> In industrialized countries this usually reflects exaggerated or erroneous fears of adverse reactions, often following media scares. In developing countries this can reflect false beliefs about infectious disease and immunization. Problems in maintaining an adequate supply of vaccine and new developments leading to frequent changes to immunization schedules also impede high coverage.

Developing and delivering an effective vaccination policy is challenging for any country. Issues to consider include having comprehensive documented policies/guidelines, clear lines of responsibility, ensuring an adequate and safe vaccine supply chain, ensuring professionals delivering vaccination are adequately trained and supported, and fostering confidence in and engagement with the immunization program. Many of these issues have been clearly set out by the World Health Organization in *Immunization in Practice: A Practical Resource Guide for Health Workers*.<sup>207</sup>

Interventions to increase vaccination coverage can be patient, provider, or system orientated. Examples of interventions of proven effectiveness include:<sup>208-212</sup>

- robust patient call–recall and reminder systems;
- provider prompt systems (for example computer ‘pop-ups’ that flag when a child attending any health care setting is overdue vaccinations);
- multifaceted education programs for professionals and parents;
- generally increasing the accessibility of immunization (including providing accessible immunization clinics and making immunization available in other settings such as hospital outpatients and Accident and Emergency departments);
- ensuring vaccination providers receive regular assessment of and feedback on their performance relative to vaccination targets;
- integrating immunization into general mother and child health programs;
- ensuring parents and providers do not incur costs associated with vaccination.

Making complete vaccination a requirement for children to enter child-care or school is effective in increasing coverage and is used in some countries. This approach has not been adopted in the UK due to the potentially damaging consequences of overriding parental choice.<sup>213</sup> Ensuring the availability of high-quality information on the target pop-

ulation that would benefit from vaccination is also important in developing effective recall systems and monitoring performance. Achieving and maintaining high vaccination coverage is an important effective measure to reduce health inequalities.<sup>214-216</sup>

## SPECIFIC IMMUNIZATIONS

This section provides information on selected vaccine preventable diseases that have been the subject of recent debate in the UK or internationally.

### *Haemophilus influenzae type b (Hib)*

*Haemophilus influenzae* type b causes a range of invasive infections including meningitis, epiglottitis, septicemia, septic arthritis, and cellulitis. It predominantly affects young children aged up to 4 years, with peak incidence at 10–11 months. Prior to immunization, Hib was the commonest cause of bacterial meningitis in pre-school-age children and around 1 in 600 children in the UK had an invasive Hib infection before their 5th birthday.<sup>174</sup>

Routine vaccination against Hib at 2, 3, and 4 months of age using a polysaccharide conjugate vaccine was introduced in the UK in 1992 alongside a ‘catch up’ campaign offering immunization to all children aged up to 4 years. The vaccination program was initially very successful with invasive Hib infections falling to very low levels.<sup>217</sup> From 1998, however, the enhanced surveillance program put in place to monitor the effect of vaccination noted a gradual increase in Hib disease.<sup>218</sup> This led to a further ‘catch up’ campaign in 2003<sup>219</sup> and the adoption of a routine booster at the age of 12 months into the UK immunization schedule in 2006.<sup>196</sup>

The resurgence in Hib disease was predominantly due to the use of a particular combined DTaP-Hib (acellular pertussis) vaccine and the accelerated schedule used in the UK.<sup>220,221</sup> When Hib vaccination was first introduced it was given as a separate injection but from 1996 it was given as a combined DTP-Hib (whole-cell pertussis) vaccine to minimize the number of injections given to infants. In 1999 there was a shortage of the DTP-Hib vaccine hence a switch to using DTaP-Hib (trivalent acellular pertussis) was made. This combined vaccine was known to result in lower Hib antibody titers but the effect was not thought to be clinically significant due to immunological memory. Experience showed however that the combined vaccine when given according to the accelerated schedule used in the UK did lead to lower protection and allowed the disease to re-emerge. The switch back to DTP-Hib vaccine (and subsequently DTaP-Hib with pentavalent acellular pertussis) and catch up campaign in 2003 was successful in reversing the re-emergence of Hib disease and the introduction of a booster dose should ensure that no further re-emergence occurs. The experience of Hib vaccination in the UK highlights the vital importance of robust surveillance mechanisms to monitor the long-term impact of vaccination on disease epidemiology.

Conjugate Hib vaccination was introduced in other developed countries around the same time as in the UK and has generally been very effective in reducing the incidence of Hib disease.<sup>222</sup> The problem of disease re-emergence has not been an issue in other countries that use different combination vaccines, more spaced out primary immunization courses, and/or routine booster doses of Hib vaccine in the second year of life. As previously discussed, access to Hib vaccine in developing countries is very limited despite high disease burdens and introducing sustainable Hib vaccination is a major focus of the work of GAVI.<sup>178,199</sup>

### Poliomyelitis

Polio virus infections may be asymptomatic or, less commonly, cause mild febrile illness, aseptic meningitis, or acute flaccid paralysis. Polio infection was common in the UK prior to vaccination, with frequent large-scale outbreaks. Routine childhood immunization was implemented in 1956 initially with injected polio vaccine (IPV) and sub-

sequently with oral polio vaccine (OPV) from 1962. The vaccination program was highly successful with the last case of wild polio infection acquired in the UK occurring in 1984. Since then 1 or 2 cases of paralytic polio have occurred in the UK per year, mainly vaccine-associated paralytic polio (VAPP) with occasional imported cases of wild polio.<sup>223</sup>

The World Health Assembly passed a resolution aiming for global eradication of polio in 1988 and the WHO and partners have subsequently been working towards this goal.<sup>224</sup> The target of globally interrupted transmission by the end of 2004 was not achieved, however by mid 2006 only four countries in the world still have endemic polio (Nigeria, India, Pakistan, and Afghanistan), with by far the majority of transmission occurring in Nigeria.<sup>225</sup> The relatively slow progress towards eradication in Nigeria reflects loss of confidence in the vaccination program by local leaders in 2003.<sup>226</sup>

As progress towards global eradication is made the benefits of continuing to use OPV become less clear.<sup>194,223,227–230</sup> Both OPV and IPV provide good individual protection against polio. OPV has additional benefits however in that vaccine recipients can excrete and hence transmit vaccine strain virus thus benefiting their contacts. OPV also stimulates the production of local immunity in the gastrointestinal tract as well as systemic immunity and hence reduces the risk of excretion of wild type polio virus. OPV virus strains do retain the ability to revert to virulent forms however and approximately 1 in 1 million OPV recipients develops VAPP. In areas of low population immunity OPV-derived virus can also cause outbreaks of paralytic disease. Nevertheless, the WHO continues to recommend that OPV should be used until global eradication is achieved, then there should be a coordinated switch worldwide to IPV before eventually ceasing all polio vaccination. Despite this, because of the reducing risk of imported cases of wild polio and the ongoing risk of VAPP, many resource rich countries are moving from OPV to IPV in their routine childhood schedules. The USA switched to IPV in 2000<sup>231</sup> and the UK followed suit in 2004.<sup>194</sup>

### Tuberculosis and the bacillus Calmette–Guérin

Tuberculosis (TB) remains a major killer worldwide with approximately one third of the world's population infected with *Mycobacterium tuberculosis* and approximately 2 million TB deaths occurring annually.<sup>232</sup> Rates of TB have increased in some areas of the world over recent years, for example in sub-Saharan Africa due to the HIV epidemic and the former Soviet Union due to economic and health care infrastructure collapse. In 1993 the WHO declared TB a 'global emergency'. In the UK TB has changed from a common disease affecting all sections of society in the 1950s to a relatively uncommon disease primarily affecting certain population subgroups, specifically immigrants from areas of high endemicity and indigenous people suffering from homelessness or alcohol problems.<sup>233</sup>

Routine BCG immunization for 14-year-olds was implemented in the UK in the 1950s to combat the high incidence of disease in young adults. In the 1960s this was supplemented by a targeted neonatal immunization program for children of immigrants from areas of high endemicity.<sup>233</sup> In 2005 the adolescent program was stopped and an enhanced targeted neonatal immunization program was adopted focusing on immunizing neonates living in areas of the UK with an annual TB incidence of = 40 per 100 000 population or with family links to other countries with a similarly high incidence.<sup>195</sup> This change in policy reflected the changing epidemiology of TB in the UK and also growing evidence of the relative effectiveness of BCG vaccine.<sup>234</sup> BCG is around 70–80% effective in protecting children from severe disseminated primary disease such as military TB or TB meningitis however it has questionable effectiveness against pulmonary disease in children or reactivated disease in adults.<sup>233</sup>

BCG, a live attenuated strain of *Mycobacterium bovis*, is currently the only vaccine available against TB however a major international effort to develop better TB vaccines is currently underway.<sup>235,236</sup> Vaccines that are more effective at preventing primary disease in children are required as are vaccines that prevent the reactivation of latent infection and thera-

peutic vaccines that boost the effectiveness of treatment for active disease. Recombinant BCG or other organisms that overexpress particular *M. tuberculosis* antigens and heterologous vaccines have been developed and promising candidates are currently undergoing Phase I human trials. TB control currently focuses on active case finding and effective treatment, and concurrent HIV control, as BCG alone also does not have a significant impact on TB incidence due to its minimal effect on open pulmonary disease. It is hoped that new vaccines will contribute more to TB control.

### Pneumococcus

*Streptococcus pneumoniae* causes a range of infections collectively known as pneumococcal disease including sinusitis, otitis media, pneumonia, bacteremia, and meningitis.<sup>237</sup> There are around 100 types of encapsulated pneumococci capable of causing disease in humans, although the substantial majority of infections are currently caused by 10 types. Pneumococcal infections occur in all age groups but the peak incidence is in young children and the elderly. Following the introduction of Hib vaccination, pneumococcal disease has become the commonest cause of invasive bacterial infection in young children.

Two types of vaccines are available against pneumococcal disease: polysaccharide vaccine (active against 23 serotypes) and conjugated polysaccharide vaccines (active against 7–11 serotypes). The polysaccharide vaccine is poorly immunogenic in children aged less than 2 years who are most at risk of disease, however the conjugate vaccine is effective in children from the age of 2 months.<sup>238,239</sup> One major randomized, controlled trial conducted in the USA showed pneumococcal conjugate vaccine (PCV7) given at 2, 4, 6, and 12–15 months was effective in preventing > 90% of invasive disease (bacteremia and meningitis) caused by the serotypes included in the vaccine in children aged up to 2 years. It was less effective against pneumonia and otitis media however, reducing all clinical diagnoses of pneumonia by 11% (but all diagnoses confirmed by consolidation seen on chest X-ray by 73%) and reducing clinical diagnoses of otitis media by 7%.<sup>240,241</sup>

By mid-2006, 13 countries worldwide had implemented or were planning to implement routine pneumococcal conjugate vaccination. Routine immunization of infants with PCV was implemented in the USA in 2000,<sup>242</sup> although vaccine shortages initially meant that many children received suboptimal schedules.<sup>239</sup> Enhanced surveillance of pneumococcal disease in selected areas of the USA nevertheless showed there was a 94% reduction in vaccine type invasive pneumococcal disease (IPD) in children aged under 5 during the post-vaccination period 2001–2003 compared to the pre-vaccination period of 1998–1999.<sup>243,244</sup> Over the same period there was a 75% reduction in all (vaccine and nonvaccine type) IPD in children aged under 5 years and a 30% reduction in all IPD in all age groups. The rate of invasive disease caused by penicillin nonsusceptible strains of pneumococcus also declined considerably following implementation of vaccination.<sup>245</sup> Modeling suggested that while vaccination was highly effective in preventing IPD in vaccine recipients, more cases of IPD were actually prevented in members of the general population who had not received the vaccine through the vaccine's effects on nasal carriage of the pneumococcus among young children, who are the main reservoir of infection. The enhanced surveillance did identify some replacement disease effect, i.e. disease due to nonvaccine type pneumococci did increase somewhat, although not enough to counteract the reduction of vaccine-type disease. Replacement disease is potentially a serious concern with pneumococcus due to the large number of serotypes capable of causing disease in humans and this demonstrates the paramount importance of ongoing surveillance.

The decision to introduce routine childhood immunization with PCV in the UK was taken in early 2006<sup>196</sup> although to date vaccine supply and funding issues have caused delays in implementation of the policy. There is currently very limited access to PCV in the developing world despite a heavy disease burden, and working towards increased access to PCV, along with rotavirus and meningococcal A and C vaccines, has been identified as a priority by GAVI.<sup>246</sup>

## Child protection

*Alison Kemp, Sabine Maguire*

Background	45	Visceral injury	49
Historical perspective	45	Fabricated and induced illness	50
Prevalence	45	Poisoning	50
Child protection process	46	Child sexual abuse	50
Clinical assessment of suspected child abuse	46	Assessment and investigation of suspected child sexual abuse	51
Physical abuse	46	Emotional abuse	51
Bruising	47	Neglect	52
Fractures	47	Effects of domestic violence on children	52
Burns	47	Adult mental health, substance abuse and child protection	53
Bites and oral injuries	49	Protecting the child	53
Intracranial and spinal injury	49		

### BACKGROUND

Identification of suspected abuse, prevention and the protection of children from abuse remain key priorities for all professional agencies who work with children. Four categories of child abuse are defined: physical, emotional, sexual abuse and neglect. The nature of what constitutes child abuse varies over time and between different cultures and ethnic groups.

### HISTORICAL PERSPECTIVE

In 1895 the NSPCC described neglected children as 'miserable, vermin infested, filthy, shivering, ragged, nigh naked, pale, puny, limp, feeble, faint, dizzy, famished and dying' and those who were physically abused were battered with 'boots, crockery, pans, shovels, straps, ropes, thongs, pokers, fire and boiling water'.<sup>1</sup> The clinical consequences of physical child abuse were first described in the medical literature by Tardieu in 1860.<sup>2</sup> Caffey<sup>3</sup> (1946) and Silverman<sup>4</sup> (1953), described multiple fractures and subdural hematoma and suggested that they resulted from intentional trauma and not organic disease, as commonly thought. In a seminal paper on the 'battered child' in 1961 Henry Kempe<sup>5</sup> drew attention to the US problem of physical abuse, probably the first time that the issue started to gain acceptance in clinical circles.

Tardieu was also the first to describe child sexual abuse in his 1860 publication of a population study of rape in France. He stated that 80% of some 11 500 cases involved children. Following his death at the end of the century there was vociferous denial of child sexual abuse and the condition was not recognized. It was not until the beginning of 1980s that the condition was widely accepted and recognized.

Child care and parenting practices have however improved over the past century. In the UK a number of important laws came into force: in the latter part of the 19th century the Factories Acts, Coal Mines Acts and Chimney Sweeps Acts were introduced to protect children from harmful occupations while the First Children Act was introduced in 1908 at the same time as the establishment of the Juvenile Courts. The legal framework, cultural practices, tolerance and protective strategies for children vary widely between countries. At least 12 European countries have reformed their legislation to effectively ban the physical

punishment of children. In England and Wales however the law permits 'reasonable chastisement' in the form of physical punishment, allowing mild smacking.

### PREVALENCE

It is difficult to identify an accurate prevalence figure for child abuse. Children are abused behind 'closed doors' and only a proportion of cases are reported so there are no accurate statistics to define the extent of the problem.

In the UK, the Child Protection Register contains confidential details of children who are identified by the authorities as being at continuing risk of abuse and have a child protection plan. In 2005 the register included 32 000 children (out of a total under-16 population of roughly 10 million) under the categories of physical abuse (37%), neglect (32%), sexual abuse (26%), emotional abuse (13%) and multiple categories (9%). The UK-based National Society for Prevention of Cruelty to Children (NSPCC) completed a child maltreatment study in 2000, updated in 2002, which recorded the childhood experiences of 3000 young adults.<sup>6</sup> This study reported that:

- 7% of children experience serious physical harm from their carers during childhood.
- 1% of children under 16 years old experience sexual abuse by a carer and 3% by another relative; 11% by people other than relatives who are known to them and 5% by a stranger or someone that they had just met
- 6% of children experienced serious absence of care
- 6% experienced frequent and serious emotional abuse.

Children with disability are 3–4 times more likely to suffer from all types of abuse than nondisabled children.<sup>7</sup> It is estimated that 1–2 children die in the UK every week as a result of child abuse<sup>8</sup> and every year 400 will sustain permanent disability. Currently it is estimated that 79 000 children are looked after by local authorities in the UK.<sup>9</sup>

Child abuse is often an ongoing process rather than a one-off event. Studies quote significant recurrence rates in children who have been abused and are returned to the abusing carer.<sup>10</sup> This is particularly true for the youngest age group, where child abuse is most prevalent and most serious in terms of long-term morbidity and mortality. It can be argued

therefore that those in this age group have the greatest potential as far as prevention is concerned and justify early diagnosis and intervention.

Child abuse occurs in one form or another in all walks of life, however certain risk factors for abusive families are recognized. The strongest include: a history of previous abuse or neglect to the child or siblings, mental health problems in the carer, parental conflict or domestic violence. Weaker risk factors identified are when parents themselves were abused in childhood, parental stress, alcohol or substance abuse, a lack of social support and where the family is already in contact with social services. However in a significant number of children who are abused, there are none of these risk factors.<sup>11</sup>

## CHILD PROTECTION PROCESS

Legislation governing child protection varies in different countries but in most, clear processes are laid out and it is the duty of all clinicians dealing with children to understand their roles in the process. In the UK, the current definitions of child abuse and child protection legislation are set out in Children Act 1989 (revised in 2004). The Act introduces the concept of significant harm as a threshold that, once breached, justifies intervention in family life to secure the best interests of the child. It establishes the principles that the welfare of the child must be the paramount consideration and that agencies must co-operate in the interests of the child to identify abuse and protect a child from further harm. The court must take the wishes of the child into consideration when making an order and ensure that the child's best interests are met. Every effort should be made to retain the family unit and the law sets out clear parental rights, duties, powers and responsibilities when caring for their child.

According to Section 47 of the Children Act, the local authority has the 'duty to investigate... if they have reasonable cause to suspect that a child who lives, or is found, in their area is suffering, or likely to suffer, significant harm.' This process involves a number of agencies including Local Authority social work and education teams, health professionals from primary care and child health teams based in the community and hospital trusts, police and family and criminal lawyers. The roles of the professionals involved and how they work together as a team are set out in Working Together.<sup>12</sup>

Pediatricians are primarily involved in the clinical assessment process and may call upon a wider team of clinical disciplines to inform an investigation within the Framework of Assessment of Children in Need and their families.<sup>13</sup>

Within each UK health organization a designated doctor and nurse take a strategic professional lead on the health service contribution to safeguarding children. All pediatricians must have the skills in the recognition of abuse, and be familiar with the procedures to be followed if abuse and/or neglect are suspected. They may be involved in difficult diagnostic situations, differentiating abuse from nonabuse and those who specialize in child protection may undertake forensic medical examinations. Pediatricians will be required to provide reports for case conferences, statements for the police, reports for civil and criminal proceedings, to appear as witnesses and to give oral evidence.

All health professionals who work with children must be able to recognize the signs of child abuse. They should be aware of the local child protection procedures and know how to contact those who have a responsibility for assessment or the named professionals for advice and support. They should receive the training and supervision needed to recognize and act upon child welfare concerns, and to respond to their needs.

Anyone who works with children may suspect child abuse and should refer their concerns to the appropriate person (the social services department in the UK). Within the health service these children may first present in Primary Care, Accident and Emergency departments, as an inpatient or to any number of health professionals during a routine investigation or procedure. However, most referrals for investigation come to the clinician via Social Services, who have received the referral from education, a member of the public, a fellow social worker or mem-

ber of health services who is working in the community. If any clinician becomes concerned that a child is being abused, they should ensure that their suspicions are investigated and that an appropriate referral is made.

## CLINICAL ASSESSMENT OF SUSPECTED CHILD ABUSE

When abuse is suspected, the majority of children will require a clinical assessment by a senior pediatrician (or member of the child and adolescent mental health team if emotional abuse is suspected). The clinician will be expected to take a detailed history and perform a full examination of the child detailing relevant clinical findings. Relevant investigations will be dictated by the nature of the abuse and presentation. Consideration must be given to an assessment of any siblings thought to be at risk. The examining clinician will be expected to make a clinical diagnosis, to present their findings in strategy meetings and case conferences, and to write detailed evidence-based statements for the police and reports for the relevant multidisciplinary discussion meetings. They may also be invited to Court hearings as professional witnesses.

The diagnostic process differs from other clinical areas where there may be a single confirmatory test. In this field the clinician must perform a thorough assessment and piece all of the information together to come to a decision based on a balance of probability that abuse has occurred or not. The risks of making an incorrect diagnosis are great. It is equally damaging to a family to wrongly diagnose abuse as it is when the diagnosis is missed.

## PHYSICAL ABUSE

Physical abuse may involve hitting, shaking, throwing, poisoning, burning, scalding, drowning, suffocating, or otherwise causing physical harm to a child. Physical harm may also be caused when a parent or carer fabricates the symptoms of, or deliberately induces illness in a child who they are looking after.<sup>12</sup> The challenge for clinicians is to distinguish intentional from unintentional injuries which are common in childhood (Table 5.1).

Some features may help to make this distinction, such as:

- a history that is incompatible with the child's developmental stage (e.g. an explanation that a 6-week-old sustained their fracture by rolling off the bed). It is rare that a parent offers a full description of an abusive injury. They may be in denial, genuinely ignorant of the causal events, blame the presentation on others or propose irrelevant events as explanations;
- a history which changes as it is told to different clinicians or over time;

**Table 5.1** Features that warrant investigation to exclude abuse in a child where there is no explicit and developmentally plausible explanation

- 
- Bruising in a nonmobile child, particularly to the hands, back or areas away from bony prominences
  - Rib fractures in the absence of underlying bone disease, major trauma or birth injury
  - Nonsupracondylar fractures of the humerus, without clear trauma
  - Femoral fractures in the nonmobile child without specific trauma
  - Hemorrhagic retinopathy in a child with intracranial hemorrhage, and no history of high-impact trauma.
  - Contact burns leaving a clearly demarcated imprint, particularly on back/shoulders/buttocks, without clear history
  - Immersion scalds with clear upper limits, involving lower limbs with or without buttock/perineal involvement
  - Unexplained oral injuries including trauma to teeth (involve dentist in interpretation)
  - An adult bite on a child
-

- an inappropriate parental response, e.g. failure to seek medical attention for a 3-month-old who has not been using their leg for 5 d;
- history of repeated attendance with traumatic injuries which are poorly explained;
- history of an unlikely child response, e.g. a child with a scald who is said to have shown no sign of pain.

## BRUISING

'Of all the physically abusive injuries that children sustain, bruising is by far the commonest'.<sup>14</sup> While no single injury is diagnostic of abuse in itself, certain patterns of bruising are found in accidental childhood injuries, and these are quite different from those found in abused children. Accidental bruising is very closely correlated with a child's independent mobility,<sup>15</sup> with bruising occurring in less than 1% of infants who are not yet crawling, rising to 17% of those who are cruising around the furniture, and 52% of those who are walking. Similarly the number of bruises increases with increasing mobility, from 1 to 5 in the children who are cruising, but up to 27 per child when they are walking.<sup>16</sup> However, even when bruising is as common as this, the location tends to be over the front of the body and bony prominences in more than 90% of infants.<sup>15,17</sup> Once children reach the age of 5 years, 90% have bruises. However, across all ages, certain sites are very rarely bruised, these include the back, buttocks, forearm, face, ears, abdomen or hip, upper arm, posterior leg, foot or hands. Indeed in children less than 2 years old, accidental bruising to the hands is hardly ever recorded in the scientific literature.<sup>16</sup> Contrary to popular belief, both boys and girls sustain the same amount of accidental bruising.<sup>16</sup>

In contrast, children who have been abused tend to have larger and more numerous bruises (up to 44 per child),<sup>18</sup> and these occur in quite different locations. The head is the commonest site for intentional bruises, and other sites commonly bruised are the ear, face, neck, trunk, buttocks and arms.<sup>16</sup> Bruises may occur in clusters, or show the negative or positive imprint of the weapon with which they were struck.<sup>19,20</sup> It is important to remember however, that although bruising is the commonest finding in fatally abused infants, fractures and serious intracranial injury may occur without any external bruising.<sup>21</sup> There is some evidence to suggest that the presence of petechiae around a bruise occurs more commonly in abuse than in accidental injuries.<sup>22</sup>

It is frequently stated that bruises of different ages are indicative of abuse however there is no published evidence to validate the aging of bruises with the naked eye.<sup>23</sup> Most people would estimate the age of a bruise by its color, but this will vary depending on the depth, location, skin color etc. of the bruised area. In addition, it is clear that we all perceive color differently, both in vivo and in photographs, and as such this becomes an unreliable indicator.<sup>24</sup> Considerable research is ongoing into other methods of estimating the age of a bruise at the bedside, but none are validated for clinical practice yet.<sup>25</sup> Clearly before deciding that a pattern of bruising is consistent with abuse, it is important to exclude other causes such as coagulation disorders, sepsis, Henoch-Schönlein purpura, idiopathic thrombocytopenic purpura, connective tissue disorders, drugs, striae, artefactual marks, or photosensitive dermatitis. When documenting bruises, it is important to record the location and dimensions of all of the bruises and to take clinical photographs with a measuring device included.

## FRACTURES

Eighty percent of abusive fractures occur in children less than 18 months of age, in contrast to 85% of accidental fractures which occur in children older than 5 years.<sup>26</sup> Abusive fractures are consistent with a severe assault on the child. However, fractures are common accidental injuries, with up to 64% of boys and 40% of girls sustaining a fracture by their fifteenth birthday.<sup>27</sup> Diagnosing abusive fractures requires a careful history of the alleged accident, taking into account the weight of the child, the height fallen from and the surface on which they landed, as well as ensuring that the history offered is consistent with the child's develop-

mental ability, e.g. could they have climbed onto the surface described? It is important to establish whether there could be an underlying bony abnormality such as osteoporosis associated with prematurity, chronic disease or drugs, congenital bone fragility such as osteogenesis imperfecta, infection or mineral deficiency or whether the fracture in question could have been the result of a birth injury. Having excluded such causes, the following fracture patterns warrant investigation for possible abuse:<sup>28</sup>

- rib fractures, particularly in children less than 3 years old;
- multiple fractures, particularly if they show different stages of healing;
- long bone fractures in children who are not independently mobile;
- metaphyseal fractures of the femur in particular;
- spinal fractures without an adequate explanation;
- pelvic fractures where there is no history of massive trauma.

Rib fractures, in the absence of underlying bony abnormalities, birth injury or major trauma, have the highest specificity for abuse of any physical injury.<sup>29</sup> Abusive rib fractures are frequently multiple, predominantly anterior or posterior, in contrast to accidental fractures, which are commonly lateral.<sup>30</sup> Some children who present collapsed, may have undergone cardiopulmonary resuscitation (CPR), raising the question as to whether this has caused the rib fractures. CPR is an extremely rare cause of rib fractures in children, but when they do occur, they are anterior and may be multiple.<sup>31</sup>

Long bone fractures are recorded in abuse; the commonest site is in the shaft of the bone, especially in the premobile child.<sup>32</sup> Certain fracture types usually reflect accidental injuries, specifically supra-condylar humeral fractures, which are seen after falls in the increasingly mobile toddler.<sup>33</sup> Metaphyseal fractures although difficult to see radiologically are reported more commonly in abuse than non-abuse<sup>26</sup> and post-mortem studies suggest that they are underdiagnosed on radiology.<sup>34</sup>

Skull fractures also occur in abuse, but are difficult to distinguish from accidental fractures. They are the commonest fractures in any child less than 1 year of age.<sup>35</sup> There is some evidence that complex or multiple/bilateral fractures or those that cross suture lines are commoner in abuse.<sup>36,37</sup> However, the commonest abusive and accidental fracture overall is a linear parietal fracture.<sup>35</sup> It is important to remember that any bone in the body may be fractured as a consequence of physical abuse.

As many abusive fractures may be occult, particularly rib fractures, which have a very high specificity for abuse, it is essential to look carefully.<sup>38</sup> It is recommended that all children less than 2 years with suspected physical abuse undergo a full skeletal survey (SS), including oblique views of the ribs.<sup>39</sup> If there is any remaining doubt as to whether fractures may be present or not, and the skeletal survey is negative, either a radionuclide bone scan may be performed or the child could be recalled for a repeat SS in 11–14 d, as each option will enhance the sensitivity of the original investigation in detecting abusive fractures.<sup>40</sup> In addition, repeat SS may help in clarifying ambiguous findings or dating the fractures present, although this can only be done in broad time frames in terms of weeks rather than days.<sup>41</sup>

## BURNS

In common with head injury, abusive burns carry a high morbidity and mortality. Scalds are the commonest intentional burn injury.<sup>42</sup> A child can sustain a full-thickness burn in 1 s at a liquid temperature of 60°C, and the maximum household water temperature in the UK is 60°C, although in the USA it is 48.8°C. It is estimated that 2–35% of scalds in children are due to abuse.<sup>43,44</sup> There are certain differences however between intentional and unintentional scalds, which relate to the mechanism and agent causing the burn, and the pattern and distribution of the burn (Figs 5.1 and 5.2). Accidental scalds are predominantly caused by non-tap water, e.g. hot drinks or cooking liquids, that are usually pulled down by the child over himself.<sup>45–47</sup> The pattern of these burns is usually asymmetrical with irregular margins and burn depth. It typically involves the upper body, i.e. head, face, neck and trunk or

Fig. 5.1 A typical intentional scald showing clear upper margins, involving the buttocks, perineum and both lower limbs. (Printed with permission from Mr Tom Potokar, Consultant Plastic Surgeon, Welsh Centre for Burns and Plastic Surgery, Morriston Hospital, Swansea)

asymmetric involvement of the upper limbs. Children can sustain accidental hot water scalds when they turn on a hot tap, which will typically cause a flowing water scald over the lower or upper limbs, which again is asymmetric.<sup>48</sup>

In contrast, intentional scalds are caused most commonly by immersing the child in extremely hot water. The burns have clearly defined upper limits, tend to be symmetrical, and involve upper or lower limbs with or without scalds to the perineum or buttocks.<sup>45,46,49,50</sup> There may be skinfold sparing, e.g. of the popliteal area if the child drew their legs up, or central sparing of the buttocks, if they were pressed firmly against the surface of the bath, which has a cooler temperature than the water (doughnut ring pattern).<sup>45,51</sup> There may be additional important features found in the history or on examination of the intentionally scalded child, including: an associated unrelated injury, fractures, numerous prior accidental injuries or previous abuse, a quiet or withdrawn child or a history of domestic violence. Many intentional scalds are attributed to siblings, or appear to occur following a trigger such as soiling or enuresis, or misbehavior by the child.

The triage tool shown in Table 5.2 may help clinicians to classify children with scalds into those who are at high, intermediate and low risk of having an injury that was intentionally inflicted.

Fig. 5.2 A typical accidental scald, a spill injury showing irregular margins and burn depth, involving face, neck, and upper trunk. (Printed with permission from Mr Tom Potokar Consultant Plastic Surgeon, Welsh Centre for Burns and Plastic Surgery, Morriston Hospital, Swansea)

Table 5.2 Triage tool for identifying intentional scalds in children

Intentional scald must be excluded	Intentional scald should be considered	Intentional scald unlikely
<b>Physical features</b> <b>Mechanism:</b> Immersion	<b>Physical features</b>	<b>Physical features</b> <b>Mechanism:</b> Spill injury Flowing water injury
<b>Agent:</b> Hot tap water		<b>Agent:</b> Non-tap water (hot beverage)
<b>Pattern:</b> Clear upper limits Scald symmetry (extremities)	<b>Pattern:</b> Uniform scald depth Skin fold sparing Central sparing buttocks	<b>Pattern:</b> Irregular margin and burn depth Lack stocking distribution
<b>Distribution:</b> Isolated scald buttock/perineum +/- lower extremities Isolated scald lower extremities	<b>Distribution:</b> Glove and stocking distribution 1 limb glove/stocking	<b>Distribution:</b> Asymmetric involvement lower limbs Head, neck and trunk or face and upper body
<b>Clinical features:</b> Associated unrelated injury History incompatible with examination findings Old fractures	<b>Clinical features:</b> Previous burn injury Neglect/faltering growth History inconsistent with assessed development	
<b>Historical/social features:</b> Passive, introverted, fearful child Previous abuse Domestic violence Numerous prior accidental injuries Sibling blamed for scald	<b>Historical/social features:</b> Trigger, such as: Soiling / enuresis/misbehavior Differing historical accounts Lack of parental concern Unrelated adult presenting child Child known to social services	

Contact burns may also be inflicted; examples include a child held against a hot stove, or 'branded' with an iron etc. The severity of the burn will depend on the heat of the object and the contact time. In some instances there may be a delay in presenting for medical attention. This could be interpreted as neglectful, but may simply reflect the fact that the carers have underestimated the severity of the burn initially. It is difficult to be certain if there has been delay in presentation, as there are no studies to validate how you would age a burn clinically. Clearly however, contact burns are usually deep, and as such may leave permanent scarring if appropriate treatment is not sought early.

Cigarette burns may occur accidentally, or may be inflicted. It is thought that if an infant or toddler brushes against a cigarette, they will withdraw immediately and this will either leave no mark, or an elliptical one with reddening and possible scattered small circular burns from the hot ash. An intentional cigarette burn however, although poorly defined in the literature, presents as a deep crater-like circular burn with the deepest part of the burn located in the center and corresponding to the hottest part of the cigarette end.<sup>52,53</sup>

Other burns such as chemical burns and flame burns have also been described, however a careful history is required to distinguish accidental causes. For example, a toddler was referred with suspicious burns when he sustained an accidental chemical burn as batteries had leaked onto his car seat and burned his buttocks.<sup>54</sup> Some conditions can mimic burns, particularly phytophototoxic reactions such as occur when the

skin is exposed to a plant chemical, such as hogweed, and then sunlight.<sup>55</sup> These may appear to have occurred 'spontaneously' and often have an unusual pattern or location, so need a very careful history. In addition, certain cultural practices, such as moxibustion, where a herb, moxa, is burnt over an area of the body where there is illness, and similarly cupping or coining, may leave patterned burns or marks over the back.<sup>56,57</sup> Although these are inflicted injuries, they are not malicious in intent, and it is important to be aware of them.

## BITES AND ORAL INJURIES

Injuries to the lips, such as bruising or lacerations are the commonest oral injuries sustained in abuse, but in themselves may not be specific. Abusive trauma to the mouth includes dental fractures, intrusions and extrusions, forced dental extractions by parents as a punishment, lacerations to the gums and foreign body insertion to the pharynx.<sup>58</sup> A torn labial frenum, the thin fold of mucosa between the lip and the alveolar margin, has long been held to be pathognomonic of physical abuse, but it is documented to occur accidentally in children. When an abusive torn frenum has been described in the scientific literature, the children are predominantly less than 4 years old, and the majority have suffered fatal abusive injuries, such as intra-cranial or intra-abdominal injuries. A torn frenum may result from intubation attempts,<sup>59</sup> and dentists commonly see young children who have accidentally torn the labial frenum by falling against a hard surface, or being hit in the mouth accidentally. When this occurs, there usually appears to be considerable bleeding, as the blood mixes with saliva, making this injury one that parents should be able to recall. A torn frenum in isolation is not diagnostic of abuse, but clearly if it occurs in a nonmobile child, there needs to be an explicit explanation.

Children are commonly bitten, but many of these are animal bites or children biting one another. However, if an adult bites a child this is an assault, and of all the physical injuries that children may sustain abusively, bites are the only one that may enable the detection of the perpetrator by use of forensic odontology or retrieval of DNA.<sup>60</sup> A dog bite is usually V shaped and dogs usually tear flesh, in contrast to a human, who will compress flesh when biting. A human bite leaves an oval or circular mark, measuring 2–5 cm, with or without central bruising.<sup>61</sup> As a general rule it is estimated that if the intercanine distance of the bite is 2.5–3.0 cm it is caused by a child or small adult, and if 3.0–5.0 cm it is caused by an adult. If you suspect a child has been bitten, it is essential to obtain good-quality clinical photographs, with a right-angled measuring device, and if the bite is on a curved surface, e.g. the arm, then obtain one photograph in each plane. Serial photographs may be beneficial. In order to confirm if this is an abusive bite, and possibly identify the perpetrator, it is essential to seek a forensic orthodontic opinion as early as possible.<sup>62</sup>

## INTRACRANIAL AND SPINAL INJURY

Abusive head injury is the most serious form of physical abuse and carries a high morbidity and mortality. One third of children who suffer this form of abuse will die and a further third will suffer from long-term disability from central neurological damage.<sup>63</sup> The condition is seen most commonly in babies under 6 months old, where the estimated incidence is 35/100 000 children per year.

Abusive head injury may be caused by a direct blow to the head, or shaking, or a combination of the two. If the child has been subjected to a shaking injury, they may also suffer contusion of the spinal cord, either in the cervical or lumbar region, due to extreme hyperflexion and hyperextension.

The clinical presentation of these infants varies. The child who has suffered from extreme hyperextension whiplash-type injury may present in a moribund state. Those with significant intracranial injury are likely to be encephalopathic with altered levels of consciousness and present with a combination of apnea, seizures, vomiting and shock. More chronic symptoms of general malaise are recognized in children

Fig. 5.3 Hemorrhagic retinopathy.

who sustain subdural hemorrhage with minimal damage to the brain itself. Thorough clinical examination and investigations reveal mixed associated signs which may include associated intentional injuries, co-existent fractures of ribs or long bones, hemorrhagic retinopathy (Fig. 5.3), anemia, subdural hematomas and intracerebral damage.<sup>64</sup>

The subdural hemorrhages are generally small and may be bilateral or multiple. They can be located in the interhemispheric fissure, lie along the falx or in the posterior fossa. If these children have suffered an impact injury as well as shaking, they may have a variety of additional injuries, including bruising and swelling to the head, subgaleal, or rarely extradural hemorrhage, with or without a skull fracture.

In the small number of cases who have a nonencephalopathic presentation, there may be variable combinations of subdural hemorrhages, some of which may be old at presentation. There may or may not be associated fractures of varying ages. In chronic cases, signs of raised intracranial pressure may be present, but additional findings such as hemorrhagic retinopathy may no longer be apparent. It is possible that the diagnosis is missed in these children as the clinical presentation is very similar to many childhood illnesses at this age.

It is important to have a high level of suspicion for this condition in infants with unexplained encephalopathy or other signs that suggest physical abuse. If the diagnosis is suspected, neuroimaging should be performed. Computerized tomography (CT) is widely available and currently recommended as the first-line investigation. A CT scan will show fresh bleeding and localize bleeding to the subdural or subarachnoid space. The addition of magnetic resonance imaging (MRI) may yield more information about subdural bleeds in sites not easily visualized on CT and delineate the precise pattern of intracerebral injury. Consideration should also be given to imaging the spine to exclude associated damage.<sup>65</sup> A further MRI study at approximately 3 months may yield further information as to the level of damage that has been caused, which may be relevant to clinical prognosis.

When taking a history, it is vital to obtain a detailed account of any alleged injury, e.g. if it was a fall, the height, surface of impact etc. Full fundoscopy by an ophthalmologist using indirect ophthalmology techniques should be performed to exclude hemorrhagic retinopathy often evident at the periphery of the retina. In a child less than 2 years of age, a skeletal survey is mandatory and will need to include a skull X-ray, as CT scanning may miss skull fractures.<sup>66</sup>

It is important to consider other causes of intracranial hemorrhage in infants, including coagulopathy, sepsis, and metabolic abnormalities such as glutaric aciduria type 1.<sup>67</sup>

## VISCERAL INJURY

Abusive visceral injury, predominantly within the abdominal cavity, is rare, but can be fatal. It occurs most commonly in children under 3 years of age. It is important to remember that it is rarely accompanied by abdominal wall bruising.<sup>68</sup> The liver is the commonest solid organ to be injured with tears or rupture, and the duodenum is often involved. The child may present with shock/severe abdominal pain or sepsis. There may be evidence of bowel rupture, and in a number of cases

co-existent head injury may be present. Investigations should include liver enzymes, amylase and full blood count (FBC). CT scanning is the most sensitive investigation to define details of injury. Other visceral injuries include pharyngeal, esophageal or cardiac rupture.

## FABRICATED AND INDUCED ILLNESS

The terminology, fabricated or induced illness (FII) has replaced 'Munchausen syndrome by proxy'. The diagnosis refers to a form of abuse where the carer presents the child to the doctor with a false story of illness with or without fabricated or induced physical signs. The condition is rare and the estimated annual incidence in the UK is 0.5 per 100 000 children under 16 years of age and for children under 1 year 2.8 per 100 000. The outcome is serious with an estimated mortality rate of 10% and morbidity of 50%.<sup>69,70</sup>

The clinical picture may be induced by poisoning, smothering, simulation of clinical signs or interference with medical records. The perpetrator is generally the mother who is motivated by attention-seeking behavior and a form of satisfaction gained by assuming the sick role through their child. Many of the children have atypical presentations of illness which fail to resolve and they are often subjected to prolonged medical investigations which compound the attention seeking and increase the suffering.

The condition occurs mostly in young children and making the diagnosis is challenging and time consuming, and often involves an experienced pediatrician who can spot idiosyncratic issues. Factors that should alert the clinician to the condition include:

- signs that only occur in the presence of the perpetrator and disappear in their absence;
- the illness may have an unpredictable pattern and fail to respond to conventional treatment;
- the child may be seen by multiple specialists and receive many repeat investigations;
- there may be a history of unexplained death in siblings.

The diagnostic approach involves confirming symptoms and patterns of illness with other family members and the primary care team and making a detailed chronological history of events. All possible clinical causes of symptoms and signs must be considered and excluded. A trial period of observation away from the suspected perpetrator may give valuable information.

At the point in the process when the balance of probability suggests FII, the risks to the child must be considered. If the child is at risk of immediate, significant harm, social services and the police must be informed. In other cases where it is important to collect the evidence to support the diagnosis the clinician should work with the multi-agency strategy group to plan the investigation and communication strategy with parents. Careful consideration must be given to information sharing with parents or carers and should be avoided if it is likely to put the child at increased risk of harm; adequate plans must be in place for protection of the child before doing so.

Smothering is recognized as a form of child abuse and may present as alleged recurrent apneic or cyanotic attacks, recurrent seizures, an acute life-threatening event or a child who has died. This form of abuse generally occurs in infants under the age of a year. It is rare but life threatening. External signs may include facial petechiae, particularly around the eyes and conjunctiva or nasal bleeding; equally there may be none. Evidence of metabolic acidosis, hypocalcemia transient coagulation abnormalities, lymphocytosis or encephalopathic features on EEG may confirm a significant smothering event.

When this form of abuse is suspected as part of a fabricated or induced illness profile, covert video surveillance of child and carer may help to confirm or exclude the diagnosis.<sup>71</sup> This investigation is rarely used in current practice and has caused significant controversy in terms of potential invasion of civil liberties. In the UK this investigation must be sanctioned by senior health service management and the ultimate decision rests with the chief constable of the local police force.<sup>70</sup> The investigation must be conducted according to the Regulation of Investigatory

Powers Act 2000, the main purpose of which is to ensure that investigatory powers are used in accordance with human rights.<sup>72</sup>

## POISONING

Non-accidental poisoning can be seen in FII but not exclusively. It has a different profile to accidental poisoning, which is frequently seen in toddlers and preschool children. In the latter, the history is generally of a child that has been found to have ingested tablets or a domestic product. There may be evidence of an opened container and the accompanying adult can recount where the poison was kept and how the child could have accessed it. The carer will seek medical advice appropriately. The child rarely ingests much of the agent and is therefore generally asymptomatic with the exception of caustic agents, which may cause superficial oral and facial burns. Accidental poisoning is unusual in children under the age of 12 months who do not have the necessary levels of independent mobility or manual dexterity to access the poison. Deliberate self-abuse with large quantities of medication is seen in the adolescent age group.

In contrast deliberate poisoning often presents when a child has unusual symptoms and poisoning is diagnosed on clinical evaluation. The child may present acutely or with chronic indolent symptoms. Proposed explanations of accidental ingestion may be presented only when it is evident that significant quantities of drugs have been ingested and there are inconsistencies in the story given.

The commonest poisons used in intentional poisoning include prescribed medication for a family member, particularly anticonvulsants, tranquilizers, analgesics or antidepressants. Salt, iron, laxative, emetics, insulin and water poisoning are also reported. Motivations for poisoning include punitive acts, fabrication of illness or when children are included in the drug abusing activities of the parents. If poisoning is considered the clinician should identify possible agents from family prescription history and symptomatology and consult with the toxicology laboratory as to which investigatory samples are appropriate. If ingestion of a poison is confirmed, careful consultation with parents is required. There may be explanations other than intentional poisoning that explain findings. These include misguided attempts by carers to treat childhood ailments, incorrect dosage regimens or the use of alternative therapies.<sup>69</sup>

## CHILD SEXUAL ABUSE

'Sexual abuse involves forcing or enticing a child or young person to take part in sexual activities, including prostitution whether or not the child is aware of what is happening. The activities may involve physical contact, including penetrative (e.g. rape, buggery or oral sex) or nonpenetrative acts. They may include noncontact activities, such as involving children in looking at, or in the production of, pornographic material or watching, sexual activities, or encouraging children to behave in sexually inappropriate ways'.<sup>73</sup>

These children may be of any age, sex or social background. The most common referrals however are girls who disclose the abuse to a trusted friend or adult. Disclosures are frequently historical and refer to ongoing abuse over a period of time. Victims may have been sworn to secrecy or threatened with reprisals and are therefore reluctant to disclose. They may only become aware that their experiences are abusive after sexual health education in the school setting. False allegations do occur but are rare and raise concerns as to whether the sexual awareness of the child is age appropriate.

The abusers are usually known to the child and are commonly male members of the household, however female abusers are recognized and female carers can be complicit in the abuse when they know what is going on but avoid intervening or protecting the child.

Sexual abuse may be associated with inappropriate sexualized behavior or sexual knowledge with respect to the child's age. Secondary effects include emotional and behavioral problems, enuresis, vaginal discharge, bleeding, or irritation, encopresis and rectal bleeding. These presentations may elicit concerns about sexual abuse, especially when

associated with other worrying features, but each is associated with other clinical conditions so careful evaluation is essential.

## ASSESSMENT AND INVESTIGATION OF SUSPECTED CHILD SEXUAL ABUSE

The objectives of the child protection clinical assessment are: to identify conditions that require treatment, to identify any injuries or forensic signs that support the allegations, to reassure and address the concerns of the child and family and to offer counseling or future support when needed.

Any history of sexual abuse should be taken sensitively and in consultation with the agencies involved. The clinician should be fully informed of any disclosure made to the police or social worker and consider whether it is appropriate for the child or carer to repeat a description of events, which can be extremely emotive. Repetition causes upset and potential contamination of forensic evidence that may be used in the child protection process or court. However the clinician must ensure that they have the full picture on which to base their clinical evaluation.

When the sexual abuse arises from physical contact, genital, anal or oral abuse may be involved. An examination therefore needs to be thorough and appropriate in the context of the allegation made. It is unlikely that children who have been fondled will sustain genital injury however those who have suffered penetrative abuse may have clinical signs especially if they are examined soon after the abusive event. The examination should be an integral part of a full paediatric examination to exclude other health needs and associated injury or infection. Such an assessment needs to be performed by a senior child health practitioner with expertise in the field.

Current paediatric assessment recommends a minimally invasive examination using a colposcope and providing video or photo-documentation. Small swabs are taken for sexually transmitted disease and forensic sampling. The nature and purpose of the examination and potential use of information for evidential or clinical teaching purposes must be clearly explained to the attending parent and child and detailed informed consent should be sought.

Examination should be undertaken as soon as possible after disclosure, especially if the disclosure is acute when it is more likely that signs or forensic evidence of abuse may be detected. The examination should be carefully planned with the appropriate personnel in place. Repeated examination should be avoided as far as possible but may be necessary to ensure healing or to firmly exclude infection. Forensic medical examinations are best conducted jointly between a paediatrician and trained forensic medical examiner.

Microbiology investigations after alleged penetrative sexual abuse include appropriate genital and anal swabs for *Chlamydia*, gonorrhoea, and *Trichomonas vaginalis*. Serology for syphilis, herpes simplex types 1 or 2, hepatitis or human immunodeficiency virus (HIV) must be duly considered and biopsy of any anogenital warts.<sup>74</sup> Pregnancy should be excluded in the post pubertal female. Any evident infection must be managed appropriately and emergency contraception prescribed when there are risks of pregnancy.

Examination findings rarely provide diagnostic evidence of abuse and there are frequently no signs of injury when a child is examined, especially when this takes place some time after the most recent abusive episode. The examiner needs to be aware of the normal anatomical variants of the hymen and how it changes with puberty before they can distinguish abnormality.<sup>75</sup>

Findings that strongly support child sexual abuse (CSA) are semen or DNA from the alleged perpetrator on or within the genitalia or anus or pregnancy in the victim. These findings reach diagnostic significance in the pre-pubertal child who cannot be considered to have given informed consent. In the adolescent, although sexual intercourse is illegal, consensual sexual activity is now more commonly seen within relationships. Levels of force, coercion and consent need to be considered as part of the final diagnosis.

Acute genital or anal abrasions, lacerations, bleeding or bruising seen soon after an acute episode of vaginal penetration, support the diagnosis of CSA. Plausible explanations however may include an accidental straddle injury where there may be injury to the more external genital structures.

Supportive signs of previous penetrative sexual abuse include healed hymeneal lacerations through the entire hymeneal rim, often extending into the vagina (variously described in the literature as complete transsections or deep clefts of the hymen). These are commonly located in the posterior part of the hymen. The significance of thinning of the hymeneal margins or partial clefts is less clear.

The diameter of the hymen is not currently thought to be relevant and may vary considerably according to the age of the child, position of examination, level of relaxation or whether the child is anesthetized.

Vaginal discharge should be swabbed for bacteriology. Nonspecific discharge is common in prepubertal girls but confirmed sexually transmitted infection (STI) is supportive of CSA, especially when it can be shown to be present in the perpetrator. It is important to exclude and treat these infections to prevent long-term morbidity.

All symptoms and signs need to be carefully considered in the context of the history and presentation of the child. The timing of onset of the symptoms may be of relevance and note should be taken of any previous examination findings that may have changed.

Labial fusion is seen in girls who have not been sexually abused as are urethral prolapse, lichen sclerosus, vaginal/perianal *Streptococcus*, seborrhea/eczema, perianal swelling, erythema, tenderness and prolapse, although they can coexist with CSA.

Boys may be sexually abused and frequently suffer from anal abuse. However traumatic injury to the male genitalia should also be carefully excluded. Signs of anal abuse seen when the child is examined soon after the abuse includes anal fissures that may extend to the perianal region, perianal swelling, erythema and sometimes venous pooling. In cases examined some time after the event anal scars and tags may be seen in up to one third of cases. In addition, reflex anal dilatation and venous congestion are reported. Children may have no abnormal signs or a combination of those listed earlier. When these physical signs are seen in association with a disclosure of anal abuse, they support the child's statement. However these signs may also occur variously in constipation, inflammatory bowel disease etc. and must be assessed in the full clinical context of the child's presentation signs and symptomatology.<sup>76</sup>

Sexual abuse from exploitation, witnessing sexual acts and pedophilia perpetrated over the internet opens up newer and complex risks to children. The consequences include psychological damage, risk of stalking, child trafficking and trading in pedophilic images. Challenges to prevention, diagnosis and management are vast. A recent international criminal investigation, 'Operation Orr' exposed a pedophilic pornographic website with over 75 000 paying subscribers worldwide.

## EMOTIONAL ABUSE

Emotional abuse is defined as the persistent emotional ill-treatment of a child such as to cause severe and persistent adverse effects on the child's emotional development. It may involve conveying to children that they are worthless or unloved, inadequate, or valued only insofar as they meet the needs of another person. It may feature age or developmentally inappropriate expectations being imposed on children. These may include interactions that are beyond the child's developmental capability, as well as overprotection and limitation of exploration and learning or preventing the child participating in normal social interaction. It may involve seeing or hearing the ill treatment of another, causing children to feel frightened or in danger, or the exploitation or corruption of children. Some level of emotional abuse is involved in all types of ill-treatment of a child, though it may occur alone.<sup>12</sup>

Emotional maltreatment is increasingly recognized in conjunction with other forms of abuse. Emotional abuse is not an event but arises out of the relationship between carer and child. The earliest years of a child's life are the most important in terms of emotional stability

and nurturing to secure their emotional wellbeing for the future. Attachment theory proposes that attachment is essential to human survival and relies upon infants emitting signals to the carer that elicit responses and in turn draws the child–carer pair together and secures ‘attachment.’ In maltreatment, carers who do not respond or respond inappropriately to the child are likely to produce children who are insecure or anxious in their attachments to them.<sup>77</sup> The consequences of this type of abuse in early years can be longstanding.

Emotional abuse can be confirmed in the observation of the interaction between carer and child or reflected in a carer’s persistent criticism or negativity about the child. The victim may be singled out from siblings and exposed to an emotionally damaging relationship with one or both parents or a teacher or other adult. A child may be emotionally damaged by: omission, a failure to provide consistent care-giving and encouragement to foster stability; or commission, deliberate verbal harassment, ridicule, shame and threatening their emotional well-being.

An emotionally abusive relationship is pervasive and results in actual harm to the child. Five categories of emotional ill treatment are recognized. These may be mixed and occur to a varying degree:<sup>78</sup>

1. *Lack of interaction*: for one reason or another, carers fail to interact with their children. They may be preoccupied with their own needs through work, chronic or mental illness or substance abuse. They may also fail to respond to the child’s overtures for attention.
2. *Criticism and rejection*: the carers may constantly criticize, scapegoat or ridicule the child and reject their need for affection, reassurance or conversation.
3. *Unrealistic expectations*: where the child is expected to take on roles, responsibilities or behaviors that exceed their developmental age or are overprotected and excluded from peer interaction.
4. *Projected roles*: the child is used as a vehicle to fight adult battles or a pawn in marital strife, to fulfill adult ambitions or to take on a sick role in fabricated or induced illness.
5. *Socialization*: where the child is encouraged to partake in criminal or anti-social activities or prevented from peer group social interaction or school attendance.

Parental risk factors include mental health problems, domestic violence and substance abuse.

Diagnosis requires joint assessment with the clinical psychologist and/or child and adolescent mental health team. Signs in the child include manifestations of poor functioning in terms of emotional stability, behavior, social skills, educational achievement as well as physical manifestations. The young emotionally damaged child may have an abnormal reaction to parental separation either expressed by indifference or an extreme response. They may present as unhappy children with a flat affect, depressed, frightened, anxious or withdrawn. Young children may assume habitual rocking or self-soothing behavior whilst those in the older age group may self-harm and display low self-esteem. Behavioral manifestations include attention seeking for favorable or unfavorable response, oppositional defiance, antisocial or delinquent behavior. Developmental consequences include poor school achievement or developmental delay in infants and toddlers and secondary physical symptoms include poor growth, non-organic abdominal pain or headache, encopresis or secondary enuresis. Long-term emotional–behavioral consequences include poor social relationships with peers, isolation or aggression.

## NEGLECT

‘Neglect is the persistent failure to meet a child’s basic physical and/or psychological needs, likely to result in the serious impairment of the child’s health or development. Neglect may occur during pregnancy as a result of maternal substance abuse. It may involve a parent or carer failing to provide adequate food, clothing, shelter including exclusion from home or abandonment; failing to protect a child from physical harm or danger; failure to ensure adequate supervision including the use of inadequate care-takers; or failure to ensure access to appropriate medical care or treatment. It may also include neglect of, or unresponsiveness to, a child’s basic emotional needs.’<sup>73</sup>

The definition is broad and the clinical presentation may include physical symptoms, developmental delay, illness and disease or psychological damage. A pediatrician needs to be aware of the causative events that lead to the child’s clinical presentation before suspecting neglect.

Neglect may be intentional, where carers put their needs above those of the children or when their children are a low priority. In these circumstances emotional abuse is frequently associated. Factors that contribute may include domestic violence, substance abuse, mental health issues and parents who were themselves neglected. However in many cases it is seen in families where carers are suffering from health issues, mental stresses or have learning difficulties or disabilities and are unable to respond appropriately to the child’s needs. The risks to the child in these circumstances may be transient and resolve with parental support.

Failure to meet a child’s basic physical or psychological needs may include failure of carers to provide adequate nutrition which may result in a child with faltering growth or nutritional deficiencies. The provision of inappropriate food may result in dental caries and obesity from sugary drinks or a persistent diet of junk food. Faltering growth may arise from diets high in fiber and low in calorific content where parents impose their own weight-watching dietary practices on the child inappropriately. The levels of knowledge of carers need to be assessed in these circumstances and a judgment of omission versus commission should be made. In cases of genuine ignorance or where there is transient parental inadequacy, the situation often resolves with simple intervention. Diagnosis often relies upon a short period of admission when organic causes of weight loss can be excluded and weight gain witnessed once the child is returned to a normal diet.

Failing to meet a child’s psychological needs includes failure to provide the emotional support that the child needs or to provide social interaction. This form of neglect results in many of the symptoms of emotional abuse, speech and language impairment and delay in the development of social skills.

Inadequate supervision includes the failure to protect a child from physical hazards, inappropriate contact with unsuitable people, leaving children with inappropriate carers or on their own. Failure to supervise can result in frequent injuries and visits to Accident and Emergency departments. The injuries often have the same profile as accidental injuries but are numerous and the antecedent events reflect the neglectful attention to prevention, the provision of a safe environment and appropriate adult supervision.

Medical neglect can arise when carers fail to take their children for medical assessment when they are unwell or to provide essential care or treatment. This problem may manifest as poor vaccination uptake, poor control of a chronic medical condition that is dependent upon medication or late presentation with illness. A judgment must be made as to when the threshold of significant harm has been breached and what factors influenced the carer’s decisions to determine the degree of negligence involved.

Neglect may occur in any social setting but is more common in the socially deprived. It is important to distinguish failure to provide for a child through poverty, learning impairment or ignorance from a pervasive pattern of negligent parenting. The two scenarios require a different interventional approach.

## EFFECTS OF DOMESTIC VIOLENCE ON CHILDREN

Domestic violence describes an ongoing abusive relationship between partners in an intimate relationship, whether the violence is physical, sexual, emotional or financial. Domestic violence and child abuse often co-exist.<sup>79</sup> Most domestic violence is perpetrated by men against women, and members of their family. In up to 75% of cases, children witness this violence.<sup>80</sup> The children themselves may develop a wide range of consequences, including depression, aggression, anxiety, post-traumatic stress disorder and behavioral problems. Sadly over the long term there is evidence for intergenerational transmission of violence. This is believed to occur as a consequence of sex-role stereotypes and the acceptance of

violence against women.<sup>81</sup> Clearly the women who are victims of ongoing domestic abuse may themselves be unable to parent effectively or protect their children. It is important therefore to explore the possibility of domestic violence in history taking, while considering confidentiality. If the clinician is made aware of such domestic violence, they must ensure the welfare of the child first and foremost and offer support to the victim, including practical information regarding refugees, Women's Aid etc., and contribute to inter-agency processes.

## ADULT MENTAL HEALTH, SUBSTANCE ABUSE AND CHILD PROTECTION

Parental mental health problems can have a significant bearing on children's welfare. 31% of children on the child protection register for emotional abuse have parents with mental health problems.<sup>82</sup> Adults have a one in four lifetime chance of experiencing mental health problems so the potential for problems in children is significant. Clearly not all children whose parents experience mental health problems will be affected by it, but it is important to be aware of this as a risk factor and include relevant questions in history taking. Clearly if the parent/carer is severely incapacitated by their own health problems, the child may end up as 'carer', placing a significant burden on them. It is important that the adult and children's services work together, to ensure recognition of the risks and problems experienced by parents and children.

Parental dependence on alcohol or drugs can severely impair their ability to parent effectively. This may compromise a child's health, development, and welfare at all stages from conception onwards. The dependence on alcohol or other drugs becomes a central issue when procuring such substances becomes the parents' prime objective, rendering their care of their child secondary. The influence on the child may include neglect, financial difficulties as a result of supporting their addiction, a failure on the part of the parent to recognize or place the child's need

first, poor attendance at school, or recurrent episodes of injuries or abuse. It is vital that the pediatrician ensures that the child's needs are maintained as paramount and that there is effective collaboration with the other services including the drug and alcohol services.

## PROTECTING THE CHILD

The UN Convention on the Rights of the Child sets out the provisions that must be realized for children worldwide to develop their full potential free from hunger, want, neglect and abuse. The Convention was developed in 1989 and recognizes the fundamental rights of children to protection from economic exploitation, harmful work, sexual exploitation and abuse, physical or mental violence. Despite near universal signature or ratification by world states, UNICEF recognizes the massive violation of children's rights in terms of their unequal access to education and legal systems; their levels of poverty, homelessness, abuse, neglect and preventable disease; their exposure and involvement in armed conflict, child trafficking, and their exploitation at every level. UNICEF has established child protection programs that include international advocacy through the mechanism of human rights, the inclusion of child protection issues in national development plans, law and community-based approaches.

On an individual level, successful child protection relies upon adequate resources and good lines of communication between the agencies and individuals involved. Identifying a suspicious bruise on an infant's face and recognizing that it may be the hallmark of a pervasively abusive household may provide the only chance for that child to be protected from an abusive future. Clinicians have an obligation to be vigilant and investigate the possibility of child abuse when suspected. Local authorities and associated agencies have an obligation to support and work with families to protect children from abuse and to contribute to the wider prevention agenda.

### POISONING IN CHILDHOOD

Poisoning in children may be accidental, non-accidental, and iatrogenic or, in older children, deliberate.

#### ACCIDENTAL CHILD POISONING

##### Epidemiology

Accidental poisoning is predominantly seen in children under the age of 5 years but older children may be involved if they are developmentally delayed. The peak age is between 1 and 4 years. More boys than girls take poisons accidentally. Some children die from poisoning each year, but the number of deaths has fallen over recent years, probably because of better treatment and because of the child-resistant container (CRC) regulations. There are also less tricyclic antidepressants prescribed. Though the numbers of deaths are few, many more children are admitted to hospital for treatment and observation and even more present to hospital Accident and Emergency (A & E) departments. Many of these are sent home directly because they have taken relatively nontoxic substances.

##### Substances taken

Children may take a variety of substances accidentally. These are conveniently divided into medicines (prescribed and nonprescribed), household products and plants. The majority of children who take poisons do not have serious symptoms. Medicines may be of low toxicity, e.g. the oral contraceptive pill or antibiotics; intermediate toxicity, which may cause symptoms in young children; or potential high toxicity. Many of the household products children take may be relatively nontoxic,

but a few such as caustic soda, soldering flux and paint stripper may cause serious harm. The commonest household product that children take is white spirit and turpentine substitute. About 10% of these children have patchy chest X-ray changes. In developing countries paraffin (kerosene) poisoning is a particular problem as it is used as a cooking fuel and is often kept in open containers. These incidents are common in poor social circumstances and in summer and are probably largely related to thirst. Kerosene may cause serious aspiration pneumonitis and death.

A child may eat a poisonous plant accidentally or a group may sample a plant, such as laburnum, together. Most plants are relatively nontoxic, e.g. cotoneaster, rowan or sweet pea. However, some such as arum lily, deadly nightshade or yew can cause serious symptoms.

##### Etiology

Perhaps surprisingly, the availability of poisons does not appear to be a major factor in accidental child poisoning. There is evidence that family psychosocial stress and behavioral problems, such as hyperactivity, predispose towards child poisoning<sup>1</sup> and these family and personality findings have importance for the prevention of child poisoning.

##### Preventing child poisoning

###### Education

A campaign in Birmingham, UK, to publicize accidental child poisoning and to encourage the return of medicines concluded that 'publicity, storage and destruction of unwanted medicines have little preventive value'. A New Zealand study evaluated placing 'Mr Yuk' stickers on poisons together with a campaign to prevent child poisoning. No reduction in poisoning admissions was found. The link between acci-

dental child poisoning and family psychosocial stress and hyperactivity make it unlikely on theoretical grounds that education will be effective. Families under stress will be unlikely to remember safety propaganda.

### *Child-resistant containers*

CRCs were first suggested in 1959 by Dr Jay Arena in Durham, North Carolina. These containers were evaluated in a community in the US by Scherz<sup>2</sup> and found to be successful. They were then introduced into the US for aspirin preparations, with successful results. Following this work in the US, child-resistant closures were introduced by regulation in 1976 in the UK for junior aspirin and paracetamol preparations. This resulted in a fall in admissions of children under 5 years with salicylate poisoning.<sup>3</sup> In 1978 CRCs were introduced by regulation for adult aspirin and paracetamol tablets. Child-resistant containers or packaging are now a professional requirement by the Royal Pharmaceutical Society and are regulated for a number of household products (e.g. white spirit and turpentine substitute).

### *Other methods of preventing child poisoning*

Lockable medicine cupboards have been suggested for the prevention of child poisoning. On theoretical grounds they are unlikely to be effective as parents under stress are less likely to remember to put their medicines away or lock the cabinets. Making household products unpalatable with bitter chemical agents (e.g. Bitrex – denatonium bromide)<sup>4</sup> is a possible preventive measure to child poisoning. Serious accidental poisoning might also be prevented by a reduction in the prescribing of toxic drugs. This has been done for barbiturates and tricyclics and might also be done for quinine and vaporizing solutions.

## DELIBERATE SELF-POISONING IN OLDER CHILDREN

A number of older children take poisons deliberately. They may take medications as a response to an emotional crisis (mainly adolescent girls) or ingest excess alcohol (predominantly adolescent boys). They form one end of an age spectrum of overdose in adults.

## NON-ACCIDENTAL POISONING

The recognition of non-accidental poisoning as an extended syndrome of child abuse was made in 1976. These children are deliberately poisoned by their parents and may present with bizarre or unusual symptoms rather than poisoning directly. A number of medicines or household products may be given to children including salt in feeds to babies. These cases probably form part of the syndrome of factitious illness in childhood.

## TREATMENT OF CHILD POISONING

### Management of accidental poisoning in childhood

#### *General*

The majority of children who present to hospital after accidental poisoning do not have serious symptoms. There are nevertheless a few children who have taken a significant poison and who are potentially ill or are ill. We should clearly like to prevent unnecessary admissions to hospital whilst maintaining safety. A way round this dilemma is to classify the substance the child has taken into one of four categories: low toxicity, uncertain toxicity, intermediate toxicity or potential high toxicity. After classification children can be either sent home, observed in the A & E department or admitted for observation or treatment. **The Poisons Information Center should be contacted if there is any doubt about the toxicity of a substance a child has taken or the treatment that is needed.** A list of some of the poisons commonly taken accidentally by children is shown in [Table 6.1](#).

Older children who have taken poisons deliberately and cases of iatrogenic poisoning and non-accidental poisoning should all be admitted to hospital.

The parents of all children who present with accidental poisoning should be given advice regarding the storage of medicines and household

products. The health visitor should be contacted in all cases, remembering that family psychosocial stress is often linked with accidental poisoning in childhood. There may be specific problems, which need medical or social help.

### *Emptying the stomach*

It used to be standard practice to empty the stomach in cases of accidental poisoning in childhood. This has come under review and emesis using ipecacuanha pediatric mixture (ipecac) is now not used.<sup>5</sup> Gastric lavage was largely abandoned some years ago. It may be needed in certain cases, such as iron poisoning, for substances to be instilled into the stomach. The stomach should never be emptied in cases of hydrocarbon ingestion, such as paraffin or white spirit, or with corrosive substances such as caustic soda.

### *Activated charcoal*

Activated charcoal is being increasingly used in the management of childhood poisoning. Activated charcoal absorbs toxic materials in the gut by offering alternative binding sites. Its routine use is limited by its poor acceptance by children. Activated charcoal may not be effective more than 1 h after ingestion.<sup>6</sup> Two preparations are available: Medicoal 5 g sachets and Carbomix 50 g. Activated charcoal has been used for a variety of drugs including aspirin, carbamazepine, digoxin, mefenamic acid, phenobarbital, phenytoin, quinine and theophylline. It is particularly useful in tricyclic antidepressant poisoning.

### *Accidental poisoning with substances of low toxicity*

Children who have taken substances of low toxicity can be allowed home after assessment. Their parents should be given advice regarding storage of medicines and the general practitioner should be contacted. If there is doubt over what substance has been taken, a child should be admitted for observation.

### *Accidental poisoning where there is uncertainty of toxicity*

If there is any doubt about the toxicity of a substance a child may have taken, the Poison Information Center should be contacted day or night:

London – Guy's Hospital Tel. 0207 407 7600 or 0207 635 9191  
 Edinburgh – Royal Infirmary Tel. 0131 536 1000  
 Cardiff – Llandough Hospital Tel. 02920 709901  
 Belfast – Royal Victoria Infirmary Tel. 01232 240503

Some children arrive in hospital having taken unknown tablets or household products. Often research with the pharmacist will help. If there is doubt the child should be admitted for observation.

### *Intermediate toxicity*

Children who have taken substances of intermediate toxicity accidentally should be observed for a period in hospital (usually up to 6 h) until the practitioner can be confident that significant symptoms are not going to occur. This observation can be undertaken in many cases in an A & E department which has a section for children or for short periods in the pediatric ward or day unit. If there are adverse factors, particularly social factors, children should be admitted to hospital for longer periods.

### *Accidental poisoning with potentially toxic substances*

Children who have taken substances of potential toxicity should be admitted to hospital for observation and treatment.

### *Treatment of individual poisons*

[Table 6.1](#) shows the toxicity of the substances which are most frequently taken accidentally by children under 5.

## Deliberate poisoning in older children

Deliberate poisoning in older children should be treated differently from accidental poisoning in younger children. These children form one end of the age spectrum of overdose in adults and such children are more likely to take significant amounts of poison. Substances that

Table 6.1 Guide to toxicity of substances taken in accidental child poisoning

<b>Low toxicity</b>	<i>Plants</i>
<i>Medicines</i>	Berberis
Antibiotics (except ciprofloxacin, sulfasalazine and chloramphenicol)	Fuchsia
Antacids	Holly
Calamine	Pyracantha
Oral contraceptives	<b>Potentially toxic</b>
Vitamin preparations which do not contain iron	<i>Medicines</i>
Zinc oxide creams	Benzodiazepines
<i>Household products</i>	Carbamazepine
Chalks and crayons	Codeine-containing cough medicines
Emulsion paints and water paints	Clonidine
Fabric softeners	Digoxin
Plant food and fertilizers	Diphenoxylate (Lomotil)
Silica gel	Hyoscine
Toothpaste	Iron
Wallpaper paste	Mefenamic acid (Ponstan)
Washing powder (except dishwasher powder)	Metoclopramide
<i>Plants</i>	Mianserin (Bolvidon)
Begonia	Paracetamol tablets
Cacti	Phenytoin
Cotoneaster	Quinine
Cyclamen	Salicylates
Honeysuckle	Theophyllines
Mahonia	Tricyclic antidepressants (including dothiepin and amitriptyline)
Rowan	<i>Household products</i>
Spider plant	Acids
Sweet pea	Alcoholic beverages
<b>Intermediate toxicity</b>	Alkalis
<i>Medicines</i>	Bottle-sterilizing tablets
Cough medicines (most)	Camphor and camphorated oil
Fluoride	Carbon monoxide
Ibuprofen	Cetrimide
Laxatives	Disk batteries
Lidocaine (lignocaine) gel	Essential oils (e.g. real turpentine, pine oil, citronella and eucalyptus)
Paracetamol elixir	Methylene chloride (paint stripper)
Salbutamol	Organochloride insecticides
<i>Household products</i>	Organophosphorus insecticides
Alcohol-containing colognes, aftershaves and perfumes	Paradichlorobenzene mothballs
Bleach	Paraquat
Detergents	Petroleum distillates (white spirit, paraffin, turpentine substitute)
Disinfectants (most)	Phenolic compounds
Nail varnish remover	Slug pellets (metaldehyde)
Paints (oil based)	<i>Plants</i>
Pyrethrins	Arum lily
Rat or mouse poison	Deadly nightshade
Talc	Laburnum
Window cleaners	Philodendron
	Yew

can be regarded as having intermediate toxicity when taken accidentally should be regarded as potentially toxic when taken deliberately.

Poisoning in older children should be recognized as a serious symptom and an indication of child and family disturbance. Children who deliberately take poisons show more disturbed family relationships than children referred for psychiatric help for other reasons. They have a high level of psychiatric symptoms, especially depression. All children who take poisons deliberately should be admitted to hospital and should be assessed by a child and adolescent psychiatrist. Many will need educational, psychological and social work help as well as psychiatric assessment.

## CHRONIC POISONING

### Lead poisoning

Lead is a serious poison for children. Its toxic effects are due to its combination with sulfhydryl groups of essential enzymes resulting in disturbances in carbohydrate metabolism, cell membrane transport,

renal tubular absorption and other body processes. The blood level at which toxic effects become evident varies from child to child but in general major symptoms are unlikely if the whole blood lead level is less than 2.5  $\mu\text{mol/L}$  (52 mcg/100 ml). It is probable that behavioral and learning difficulties may result from exposure to only moderately elevated lead levels between 1.4 and 2.9  $\mu\text{mol/L}$ . Low-level fetal lead exposure at less than 1.4  $\mu\text{mol/L}$  may also affect mental development. Children in the UK may be poisoned by sucking or chewing lead paint. Lead from burning batteries, lead shot for fishing and lead from old water pipes are other potential sources. Children from the Indian subcontinent may be poisoned by *surma*, the lead-containing eye make-up used even in young babies.

### Clinical features

Children who are poisoned by lead are likely to present with pica (compulsive eating of substances other than food), anorexia, abdominal pain, irritability and failure to thrive. Severe lead poisoning may present

with neurological symptoms including drowsiness, convulsions and coma from lead encephalopathy. Lead poisoning may also present as progressive intellectual deterioration.

The diagnosis is made by elevated blood lead levels and anemia with hypochromia and basophilic stippling. There may also be increased bone density with transverse bands at the ends of the long bones on radiological examination.

### Treatment

The source of lead should be identified and removed. Chelating agents should be used to form nontoxic lead compounds. In mild cases D-penicillamine should be used orally in two daily doses of 10 mg/kg. In severe cases sodium calcium edetate (EDTA) should be used, 40 mg/kg by i.v. infusion over 1 h twice daily for up to 5 d. Each gram of EDTA should be diluted in 100 ml normal saline. The effectiveness of EDTA can be enhanced by the deep i.m. injection of dimercaprol 2.5 mg/kg 4-hourly for 2 d, 2–4 times on the third day, then 1–2 times daily until recovery.

### Mercury poisoning

This once common disorder was called 'pink disease' because of the color of the extremities or 'acrodynia' because of the accompanying pain. It was largely due to the use of mercury-containing teething powders which have now been withdrawn. There was anorexia, loss of weight and hypotonia as well as the characteristic painful red or pink extremities. A differential diagnosis of this condition is the red extremities of neglected children. Treatment of mercury poisoning is by the deep i.m. injection of dimercaprol 5 mg/kg 4-hourly for 2 d, 2.5 mg/kg twice daily for the third day and once daily for the next 10 d.

### Chronic boric acid poisoning

Chronic boric acid poisoning was a major problem in the 1940s and 1950s. It was caused by ingestion of boric acid used either as a treatment for nappy rash or as a pacifier. It presented with convulsions, vomiting and diarrhea.

## NOTES ON POISONING WITH INDIVIDUAL SUBSTANCES

### Intermediate toxicity

#### Medicines

Cough medicines. Most cough medicines do not cause serious symptoms in the doses available to children. Medicines based on antihistamines may cause drowsiness and anticholinergic effects. Drowsiness will usually not need treatment but if coma occurs resuscitative measures should be used. Medicines based on codeine should be regarded as potentially toxic.

**Fluoride.** Fluoride has a rapid action but is seldom toxic in the quantities taken by children. Symptoms include vomiting, nausea and abdominal pain.

**Ibuprofen.** Ibuprofen and other nonsteroidal anti-inflammatory agents only seldom cause symptoms in children. Symptoms may include gastrointestinal irritation, kidney and liver damage. Oral fluids should be encouraged.

**Laxatives.** Serious symptoms after laxative ingestion are rare. If diarrhea occurs it occurs quickly. Occasionally patients may need i.v. fluids. The child should be observed for serious symptoms for a short time.

**Lidocaine (lignocaine) gel.** Local anesthetics such as lidocaine are toxic in overdose, causing convulsions and circulatory collapse. Significant amounts of lidocaine gel are seldom ingested accidentally by children.

**Paracetamol elixir.** Paracetamol elixirs such as Calpol are sweet and sickly in large doses and serious accidental poisoning is very rare. There is insufficient paracetamol in most small bottles of elixir to cause problems. Blood levels should be checked 4 h after the ingestion if more than 150 mg/kg has been taken. Treatment (see potential toxicity section later) is only needed if the serum paracetamol level is above 200 mg/L at 4 h (or in rare delayed cases in children above 50 mg/L at 12 h). In most cases children can be discharged after a period of observation.

**Salbutamol.** There may be peripheral vasodilatation, muscle tremors and agitation. Serious symptoms are rare although severe hypokalemia and arrhythmias have been seen.

### Household products

**Alcohol-containing perfumes, cologne and aftershave.** Symptomatic cases are rare. Asymptomatic children can be allowed home after a short period of observation to make certain they do not become drowsy.

**Bleach.** Ingestion of household bleach causes fewer problems than would be expected.<sup>7</sup> Ipecac or lavage should not be used. Milk or antacids can be given orally. Local lesions in the mouth can be treated symptomatically and in the few cases where significant esophageal involvement is possible, endoscopy can be undertaken.

**Detergents (anionic).** Dishwashing liquid and shampoo are only toxic in large doses. Vomiting occurs in large doses. A period of observation may be needed.

**Disinfectants.** Serious cases are unusual.

**Nail varnish remover (acetone).** Observation for a period should be all that is needed but nausea and vomiting may occur, going on to coma if large amounts are taken.

**Paints (oil based).** Unless the paint has lead in it, the only problems that occur are caused by the petroleum distillate base. The stomach should not be emptied. In practice children do not seem to take significant amounts.

**Pyrethrins.** These insecticides are not usually a hazard if ingested or inhaled accidentally. The child should be observed for a short period.

**Rat or mouse poison.** The common ingredients of rat or mouse poison (warfarin or dichlorolose) are usually nontoxic in the doses taken by children. The exact type of poison should be identified using the poisons center and in most cases the child can be sent home after a short period of observation.

If large amounts of warfarin are ingested vitamin K can be used but this is not needed in most cases.

**Talc.** Talc is only toxic if inhaled. It may cause retching and choking due to pulmonary edema. Cases of ingestion only need a short period of observation to make certain inhalation did not occur.

**Window cleaner.** Most are nontoxic unless aspirated. The cleaner should be identified using the poisons center. In most cases the child can be sent home after a short period of observation.

#### Plants

**Berberis.** Very occasionally causes confusion, epistaxis or vomiting. The child should be observed for a short period.

**Fuchsia.** Unlikely to cause problems although potentially toxic. Observe for a short period.

**Holly.** Unlikely to cause problems although potentially toxic due to ilicin and theobromine.

**Pyracantha.** This causes nausea and vomiting but is unlikely to cause problems. The child should be observed for a short period.

### Potential toxicity

#### Medicines

**Barbiturates.** May cause coma and hypotension. Cases are becoming less common, as they are less frequently prescribed. Activated charcoal can be used.

**Benzodiazepines** – tranquilizers and hypnotics such as diazepam (Valium) and nitrazepam (Mogadon). These can cause drowsiness and coma, but problems are unusual in accidental ingestion. In very young children respiratory depression may need treatment with artificial ventilation.

**Carbamazepine.** This drug has some anticholinergic activity. Paradoxically convulsions and violent reactions may occur as well as cardiac problems such as heart block. Activated charcoal is useful to adsorb carbamazepine.

**Codeine-containing cough medicines.** If significant amounts are taken there can be respiratory depression, for which the antagonist naloxone can be used (10 mcg/kg i.v.)

**Clonidine.** Clonidine can cause bradycardia, hypotension, coma and gastrointestinal upset. The use of atropine and dopamine infusion for the hypotension is controversial and supportive treatment (including assisted ventilation) may be adequate for even the most severe cases.<sup>8</sup>

**Digoxin.** Digoxin can be a serious poison in children, with only a few tablets being fatal. Activated charcoal is useful. These children should be monitored very closely, probably in an intensive care unit, with careful ECG monitoring. Beta-blockers such as propranolol should be used in severe cases, with atropine if there is heart block. The serum potassium should not be allowed to go too low or too high. Digoxin-specific antibody fragments are now available for the reversal of life-threatening overdosage (Digibind, Wellcome).

**Diphenoxylate (the active constituent in Lomotil, the antidiarrheal agent).** This compound has an opiate-like action, which causes prolonged respiratory depression. Treatment is with the opiate antagonist naloxone (10 mcg/kg as i.v. bolus). There may be a transient improvement followed by relapse and cases should be observed for at least 36 h and repeated doses of naloxone given as necessary.

**Hyoscine.** Hyoscine may cause dilated pupils, dry mouth, tachycardia and delirium due to anticholinergic effects. Observation will be all that is needed with most patients.

**Iron.** Iron is a potentially very serious poison, initially causing vomiting and hematemesis, but going on to acute gastric ulceration and shock. Later convulsions and cardiac arrhythmias may occur. Iron tablets may be detected by X-ray of the abdomen. Further treatment should be aimed at preventing additional absorption of the iron, by the use of the chelating agent desferrioxamine methylate, instilled into the stomach (5–10 g in 50–100 ml of liquid). Desferrioxamine should also be used parenterally (15 mg/kg/h to a maximum of 80 mg/kg) in all cases where a potentially toxic amount of iron may have been taken. The severity of a poisoning episode can be judged by the serum iron level. Levels above 16.1 mmol/L at 4 h indicate significant poisoning.

**Mefenamic acid (Ponstan).** This drug rarely causes problems in young children. Activated charcoal is effective. Convulsions can be treated with diazepam.

**Metoclopramide (Maxolon).** In overdose this drug causes extrapyramidal signs, drowsiness and vomiting. If extrapyramidal signs develop antiparkinsonian drugs such as procyclidine can be used.

**Mianserin (Bolidon).** Mianserin has milder anticholinergic effects than the tricyclic antidepressants. Serious problems are uncommon. Drowsiness is the most common symptom.

**Paracetamol (acetaminophen).** Serious accidental ingestion of paracetamol is rare in children because the tablets are bitter and difficult to swallow and the elixir is too sweet to take in toxic quantities. Serious paracetamol poisoning may cause hepatocellular necrosis. Patients at risk of liver damage can be identified by measurement of blood levels 4 h after the ingestion. Treatment is needed if the serum paracetamol level is above 1.32 mmol/L (200 mg/L) at 4 h (or in rare delayed cases in children, 0.33 mmol/L at 12 h). Treatment is with oral methionine (at a dose of 1 g 4-hourly) for four doses. N-acetylcysteine intravenously is an alternative particularly in children who are vomiting or who present after 12–24 h when methionine is ineffective.

**Phenytoin.** Phenytoin ingestion may cause ataxia and nystagmus. Activated charcoal can be used.

**Quinine.** Quinine is a significant poison in children and has caused several deaths. It is used for night cramps. Quinidine and chloroquine are also toxic. Activated charcoal can be used.

**Salicylates.** Severe poisoning is now rare as aspirin preparations are no longer used for children because of the dangers of Reye's syndrome. Hyperventilation is an early sign of significant salicylate poisoning due to stimulation of the respiratory center with resultant respiratory alkalosis. There may also be a metabolic acidosis. In severe cases there is disorientation and coma.

The severity of a poisoning episode can be judged by salicylate levels. Toxicity can occur at levels above 2.2 mmol/L (300 mg/L) in children. In asymptomatic and mild cases nothing more needs to be done apart from encouraging fluid and electrolyte replacement and giving

vitamin K. Activated charcoal is useful. Forced alkaline diuresis can be used in moderate to severe cases but its use is controversial and alkalization of the urine is the important thing rather than the induction of excessive urine flow. Peritoneal dialysis can also be effective.

**Theophylline.** Theophylline can cause restlessness, agitation, vomiting, convulsions, coma, hypotension, hypokalemia and ventricular tachycardia. Activated charcoal can be used. Convulsions can be treated with diazepam.

**Tricyclic antidepressants.** Tricyclic antidepressants such as amitriptyline are serious poisons for young children. They may cause cardiac effects such as sinus tachycardia, hypotension and conduction disorders and death by their direct effect on the myocardium. There may be blurred vision and dry mouth from the anticholinergic effects. There may also be central effects of agitation, confusion, convulsions, drowsiness, coma and respiratory depression. Activated charcoal should also be used.

There is no specific antidote for tricyclic ingestion. The ECG should be monitored for cardiac arrhythmias. No treatment is indicated if there is adequate tissue perfusion and blood pressure. Metabolic acidosis should be corrected. Convulsions should be treated with diazepam. Life-threatening arrhythmias should be treated with propranolol. As tricyclics are protein bound active methods of elimination such as hemodialysis do not remove significant amounts of the drug.

### Household products

**Acids.** Acids tend to cause inflammation and ulceration at the pylorus rather than the esophagus. This may lead to stenosis. Emesis or lavage should not be undertaken and chemical antidotes should not be given as the heat of the chemical reaction may increase injury. The extent of the injury should be assessed by endoscopy at an early stage. Steroids should be used to suppress the inflammation (prednisolone 2 mg/kg/d).

**Alcoholic beverages.** These may cause severe hypoglycemia. Blood alcohol levels are useful in management. Hypoglycemia should be detected by frequent blood glucose measurements, and prevented and treated by i.v. glucose infusions.

**Alkalis.** Alkalis such as caustic soda and dishwasher powder can cause burns to the mouth and esophageal ulceration, leading to stricture: review by esophagoscopy and treatment with steroids have improved the outlook for this condition. Emesis or lavage should not be undertaken, nor any chemical antidotes as the heat of the reaction may increase injury. The extent of the injury should be assessed by endoscopy at an early stage. Steroids should be used to suppress the inflammation (prednisolone 2 mg/kg/d).

**Bottle-sterilizing tablets.** Bottle-sterilizing tablets contain a bleach-like substance (sodium dichloroisocyanurate). They effervesce with water to make a sterilizing solution. If this reaction takes place in the mouth considerable damage can take place with edema and ulceration. Cases need to be monitored for their airway patency and i.v. fluids may be needed. Monitoring for esophageal involvement by endoscopy may be needed in some cases. The use of steroids is logical in severe cases.

**Camphor and camphorated oil.** These are dangerous poisons for children. They are absorbed quickly and because they are lipid soluble, enter the brain causing delirium, rigidity, coma and convulsions. Convulsions should be treated with diazepam.

**Carbon monoxide.** Hemoglobin has an affinity for carbon monoxide over 200 times greater than for oxygen. Carboxyhemoglobin will reduce the amount of hemoglobin available to carry oxygen and also hinders oxygen release. The incidence of carbon monoxide poisoning has fallen since house gas no longer contains this substance. Carbon monoxide poisoning should be treated with 100% oxygen over a period of several hours. Hyperbaric oxygen should be considered in severe cases if it is available.

**Cetrimide.** Cetrimide is a cationic detergent and can be caustic when concentrated. The stomach should not be emptied. If problems with ulceration occur steroids should be used. Cetrimide may also have depolarizing muscle-relaxing effects leading to breathlessness.

**Disk or button batteries.** Mercury cell, alkaline manganese and silver cell batteries contain a strong alkali (usually potassium hydroxide) as a main ingredient. Mercury cell batteries contain toxic amounts of mercury. Silver cell batteries generally contain less toxic ingredients than the other types. Worn batteries are less toxic than new ones.

Disk batteries can cause problems if they lodge in the gut and become corroded and release their contents. They may cause ulceration or perforation from caustic injury if lodged in the esophagus or stomach and should be removed endoscopically if they lodge there. If they go beyond the stomach they are usually passed without problem. Their progress should be monitored by abdominal X-ray. Mercury levels should be measured when appropriate. If the battery shows signs of leaking or breaking it should be removed surgically.

**Essential oils.** Essential or volatile oils contain mixtures of cyclic hydrocarbons, ethers, alcohols and ketones. They include turpentine, pine oil, citronella and eucalyptus as well as such things as Karvol capsules. Their toxicity varies, with real turpentine (not to be confused with turpentine substitute) being very toxic. Symptoms of essential oils include vomiting, drowsiness and convulsions. Ipecac should not be used.

**Methylene chloride (paint stripper).** This is a very serious poison for children. It is caustic and may cause damage to the skin, stomach, mucous membranes and pharynx. Vomiting, dizziness, confusion, toxic myocarditis and hemoglobinuria may occur. Methylene chloride is metabolized to carbon monoxide and carboxymethemoglobin concentrations may be elevated for several days. The stomach should not be emptied. Fluids should be given to dilute the methylene chloride. High-flow oxygen should be given if carboxyhemoglobin is present.

**Organochloride insecticides.** These include DDT, dieldrin and lindane. Symptoms include excitability, muscle twitching and convulsions. Activated charcoal is valuable.

**Organophosphorus insecticides.** A wide range of compounds which include malathion. They act by inhibiting cholinesterase in the blood. Symptoms include confusion, nausea, vomiting, wheezing and convulsions. If symptoms appear atropine (i.v.) 0.05 mg/kg and pralidoxime 20–60 mg/kg as required, depending on the severity of the poisoning, should be given by slow i.v. injection and repeated if needed.

**Paradichlorobenzene mothballs.** Most cases of accidental ingestion do not have serious symptoms. Ingestion may cause nausea and vomiting and cyanosis may develop due to methemoglobinemia. This should be treated with methylene blue.

**Paraquat.** Paraquat weedkiller is available in two forms: a concentrated form (Gramoxone) available only to farmers and horticulturists and a granular form (Weedol) which contains only 2.5% paraquat. Accidental ingestion of the concentrated form is rare and ingestion of the granular form rarely causes serious problems. Paraquat causes local ulceration and in severe cases a proliferative alveolitis. Treatment should be to prevent absorption by Fuller's earth or bentonite.

**Petroleum distillates, e.g. kerosene, turpentine, white spirit and turpentine substitute.** These substances may cause a pneumonitis from lung aspiration. Ipecac or lavage should not be used. Kerosene poisoning is a particular problem in the Third World. Rhonchi are the most common physical sign and X-ray changes are common. Treatment in mild cases is symptomatic, together with the use of prophylactic antibiotics. Corticosteroids are often used, but clear evidence of their effectiveness is lacking. Severe cases may need oxygen and intensive respiratory care.

**Phenolic compounds.** These include cresols, menthols, phenols and hexachlorophene. Coal tar vaporizing solution contains cresol. They may cause local corrosive damage and there may be cerebral symptoms. Activated charcoal can be used.

**Slug pellets (metaldehyde).** Slug pellets contain about 3% metaldehyde which is toxic in children and 4 g is said to be fatal for a child. Experience suggests that problems do not arise after accidental ingestion. The child should be observed for 4–6 h to check for serious symptoms such as flushing, salivation and convulsions. Convulsions should be treated with diazepam.

## Plants

**Arum lily.** Causes gastrointestinal side-effects and later CNS manifestations.

**Deadly nightshade (atropa).** This plant has an atropine effect causing photophobia, visual disturbance, dryness of mouth, flushed skin, etc. If there are symptoms a slow i.v. injection of physostigmine can be used.

**Laburnum.** Causes vomiting, diarrhea and nausea. Although quite commonly taken, serious problems are very rare.<sup>9</sup>

**Philodendron (Swiss cheese plant) and Dieffenbachier.** This plant has a local caustic action due to oxalic acid and may cause a sore mouth and laryngeal edema. Steroids may be useful in severe cases.

**Yew.** Causes gastrointestinal side-effects and later CNS manifestations. There may be severe hypotension.

## UNINTENTIONAL INJURY

This section deals with the nature of injury, sources of data, the magnitude of the problem, and the etiology and prevention of injuries. In many cases websites are listed where up-to-date information and evidence-based material can be found. As scientific publications often refer to data 2–3 years previously, information in the print media is always somewhat dated. Many, but not all, websites are constantly updated, and where these are available they have been included as preferential references.

### DEFINING INJURIES

The first issue to determine is: what is an injury? Injury can be divided into physical injuries and psychological injuries. Physical injuries are due to tissue damage caused by excess energy transfer. When physical, radiation, or thermal energy absorbed by the body exceeds the innate capacity to deal with such forces, tissue damage results. Whether such injuries are recognized will depend on the extent of the damage and whether this causes sufficient pain or loss of function to come to the notice of the injured person. Many toddlers have bruise marks on their shins from bumping into objects but these are generally not considered to be 'injuries'. Generally, an 'injury' must reach a certain severity threshold before it is considered as such. This threshold varies between groups and cultures and depends to a considerable extent on the availability and ease of access to healthcare. The severity threshold for injury is often defined as one which leads to restricted activity for a given period (1 or 3 d are commonly used) or which leads to the injured person seeking medical attention. This leads to different methods of counting injuries, which to a large extent depend on available data sources. There are two main options: surveys and information abstracted from administrative registers, which are discussed later.

### SOURCES OF DATA ON INJURY

There are a considerable number of these, including data on mortality, morbidity, and disability.

### MORTALITY DATA

Mortality data are the most widely available with most countries collecting and reporting on the causes of death to their citizens. Publications on the causes of death are generally made available by national governments and some of these are summarized by bodies such as the World Health Organization (WHO). The WHO has an excellent site where it is possible to obtain a large amount of information on the scale of the burden of injuries.<sup>10</sup>

On this site it is possible to download major reports, such as the 2002 World Report on Violence and Health, and the 2004 World Report on Road Traffic Injury Prevention, and to access links to many useful sites and initiatives. Clicking on the research tools button brings one to a series of useful links, including the WHO mortality database.<sup>11</sup> Entering

this site allows the downloading of data from countries and also understanding of the completeness and coverage of mortality statistics around the world. Data are missing or incomplete from many middle and low income countries, making it impossible to accurately count the global total number of deaths or the exact distribution of causes of death. The WHO site has recently been amended to include a specific area for children.<sup>12</sup> This area includes the WHO–UNICEF document *A Global Call to Action: child and adolescent injury prevention*, published in 2006.<sup>13</sup>

This report estimates that a minimum of 875 000 children under 18 years of age die from injuries each year and that 95% of these occur in low- and middle-income countries. In children aged between 1 and 15 years four mechanisms of injuries appeared in the top 15 causes of death: road traffic injuries (6th), drowning (7th), fire-related burns (11th), and poisonings (15th). The WHO has followed up this report with an action plan to reduce this enormous burden on children's health with six areas identified for improvement: data and measurement, research, prevention, treatment services, capacity development and advocacy.<sup>14</sup>

The WHO will publish a World report on Child and Adolescent Injury Prevention in 2008.

In the UK mortality statistics are collated by the General Register Office for England and Wales,<sup>15</sup> with separate offices and statistics for Scotland<sup>16</sup> and Northern Ireland.<sup>17</sup>

Table 6.2 has been compiled by abstracting data from a publication by the Office for National Statistics<sup>18</sup> showing the distribution of injury-related deaths in children and young adults in England and Wales in 2003.

Table 6.2 shows several interesting patterns. The absolute numbers of deaths increases across the age groups but it should be remembered that the denominators are different. Rates are required for comparisons of groups or areas but absolute numbers can also provide easily interpretable information.

From the table it can be seen that transport accidents are a major cause of injury-related deaths at all ages. Pedestrian fatalities are a problem for all age groups but become hugely outnumbered in older age groups by occupant fatalities when this becomes the dominant mode of transport. Falls account for few deaths in any of the three age groups and are substantially outnumbered by deaths due to drowning or as a result of exposure to smoke, fire and flames. Accidental poisoning fatalities are exceptionally rare in the younger age groups but would be expected to be much more frequent than in those in older age groups. It is difficult to conceive of situations in which adults mistakenly ingest a toxic substance. The low rate in the young age group is undoubtedly due to the effectiveness of child-resistant containers introduced some decades ago, one of the most effective of all injury prevention initiatives.

The much higher number of accidental poisoning deaths in the 15–24-year-old age group does not represent accidental ingestion of substances but ingestion of greater than planned amounts of recreational drugs and which result in 'accidental' deaths. The lack of quality

control in the production of illegal recreational drugs produces variations in the strength and content of products. Whilst the risk is probably very low for each ingestion, the frequency of ingestion by large numbers of young people mean that even rare failures in quality control will result in frequent tragedies, both amongst new and habitual users.

Whilst the focus of this chapter is on unintentional or accidental injuries it should be noted that intentional self-harm is one of the commonest causes of death in those aged 15–24 and also that quite a few children and young adults are killed during acts of violence.

There are a limited number of studies providing international comparative data. One such study<sup>19</sup> compared death rates across European Union countries in the 1–4, 5–9 and 10–14 age groups. For both sexes injury deaths exceeded those due to infection of cancer at all age groups. Injury-related deaths accounted for a low of 27% of all deaths in girls aged 1–4 and a high of 51% of all deaths in boys aged 10–15. There was considerable variation between countries. The countries with the lowest injury-related death rates were Sweden and The Netherlands and the highest death rates occurred in eastern Europe.

Interpreting the meaning of variations in injury mortality across countries is not straightforward. Variations in death rates can be due to variations in exposure to certain factors or to the effectiveness of countermeasures. For example, warm countries with a lot of childhood exposure to open water, will inevitably have higher drowning rates than those which have much less open water or where the temperature is so cold that swimming is avoided. The excess deaths in the warm countries with a lot of open water will be due to a mixture of inadvertent exposure (falling in) and to difficulties encountered during planned exposure (swimming). The degree to which children are taught to swim and to which physical barriers and observation (lifeguards) protect children will also impact on the mortality rates. Generally speaking, mortality statistics are based on the place of usual residence and can mask holiday-related hazards. An analysis of childhood drowning deaths in the UK<sup>20</sup> demonstrated the much higher risk to UK children from unsupervised swimming pools whilst on foreign holidays than from pools in the UK. Similarly, mortality league tables for road traffic related injuries will be influenced by the degree of motorization within countries, as well as behavioral traits and investment in safety measures. Road traffic increases rapidly with industrialization and economic development and there is generally a marked rise in road traffic related deaths, which then plateau and decrease somewhat as safety measures and legislation are introduced and enforced.

## MORBIDITY DATA

There are several sources of information on nonfatal injuries, although these vary across and within countries. Sources include hospital discharge or separation data, A & E department attendance data, trauma registers, survey data and data systems operated by nonhealth bodies with a focus on high-risk events such as road traffic collisions and house fires. Unlike mortality data, information from these sources is rarely reported using methods which allow direct comparison. Guidance on methodological issues in comparing injury incidence data across countries has been produced.<sup>21</sup> Some of the apparent differences in morbidity rates between countries are due to differences in the supply and scope of different aspects of the health service, as described in the sections dealing with hospital admission and Emergency department data. Greater or lesser proportions of trauma care are provided as inpatient, outpatient or specialized clinics in different countries and settings.

Much of the data on hospital admissions and A & E departments in this section has been derived from the Collaboration for Accident Prevention and Injury Control (CAPIC) website.<sup>22</sup> CAPIC is a multidisciplinary, multi-agency voluntary body which supports injury prevention initiatives in Wales.

## HOSPITAL ADMISSION DATA

Table 6.3 shows hospital admission rates for all types of injury, by 5-year age groups in Wales in 2003. It can be seen that admission rates

Table 6.2 Numbers of deaths due to injury and poisoning by cause and age band to children and young adults in England and Wales in 2003 (Office for National Statistics, 2004)

Category	Age group		
	1–4	5–14	15–24
All injury and poisoning	100	172	1573
Transport accidents	18	23	221
Pedestrian	8	11	29
Motorcyclist	0	1	43
Falls	3	2	7
Drowning	11	2	6
Smoke, fire and flames	15	2	3
Poisoning (accidental)	1	0	29
Intentional self-harm	0	3	301
Assault	6	12	75

**Table 6.3** Hospital admission rates for all types of injury by 5-year age groups in Wales – 2003

Age group	Number of events	Rate/1000 population
0–4	2187	13.7
5–9	1779	9.8
10–14	2574	13.1
15–19	3249	16.6
20–24	2955	16.3
25–29	2233	14.4
30–34	2454	12.8
35–39	2436	11.5
40–44	2143	10.4
45–49	1617	8.6
50–54	1487	7.7
55–59	1571	7.8
60–64	1288	8.0
65–69	1367	9.6
70–74	1735	13.8
75–79	2401	22.6
80–84	3249	40.1
85+	4915	84.1
All ages	41640	14.2

for children and young adults are higher than in middle age but not as high as in older persons, when falls and osteoporotic fractures lead to many admissions.

The data in this section reflect age-specific hospital admission rates for Welsh residents in 2003 derived from the CAPIC data. Around 1.3% of all children and young people (0–19 years) are admitted to hospital with an injury each year. Major causes of hospital admission with an injury in this age group are falls ( $n = 3493$ ), accidental poisonings ( $n = 783$ ), being struck by or against objects ( $n = 659$ ), involvement in motor vehicle transport accidents ( $n = 541$ ), and from noncollision pedal cycle injuries ( $n = 440$ ). Injuries caused by glass ( $n = 242$ ), knives and tools ( $n = 80$ ), scalds ( $n = 276$ ) and unintentional fires ( $n = 35$ ) are less common but are often associated with substantial morbidity.

There are many factors which influence the probability that a person with an injury of moderate severity will be admitted to hospital. These include issues such as bed availability, variation in clinicians' propensity to treat fractures conservatively or with surgery, co-morbid conditions, uncertainty about intentionality, and social factors. These factors generally mean that it is difficult to use hospital admissions as a valid measure of the incidence of injuries of a given nature. Cryer and Langley<sup>23</sup> developed the most valid injury indicators to date for hospital admissions, based on a group of conditions with a probability of inpatient death of greater than 5.9%. This approach is useful for understanding national trends but the downside is that it includes a very small proportion of all injury-related hospitalizations. Generally speaking, there are insufficient numbers of these high-risk injuries to be able to use this technique for regional or local data and consequently it is not suitable for the targeting or monitoring of local preventative interventions. Guides to the evaluation of injury prevention initiatives can be found on the CAPIC website.<sup>22</sup>

## EMERGENCY DEPARTMENT DATA

Emergency department data are increasingly being made available as electronic collection of health information grows. In many cases the information collected merely involves the administrative and diagnostic details needed to treat individuals whereas in other cases the information systems used also collect data on the location, antecedent factors and activities resulting in the injury occurrence. Both types of data collection are useful for those interested in prevention but clearly the latter are much more useful. An excellent example of the latter is the Victoria Emergency (Department) Minimum Dataset (VEMD) in use in Victoria,

Australia and exported to many parts of the world.<sup>24</sup> Systems such as this have provided the basis of injury surveillance which stimulated preventative interventions and the basis of much of our knowledge on the effectiveness of interventions.

Many more children are seen and treated at Emergency departments than are admitted as inpatients. Generally speaking there are 10–20 injuries treated and discharged in Emergency departments for every admission.

In the US the on-line National Electronic Injury Surveillance System (NEISS<sup>25</sup>) allows queries to be run on the database. In 2004 there were an estimated 13 096 983 Emergency department attendances with an injury in the US. In Europe, EuroSafe, the European Association for Injury prevention and Safety Promotion, manage the European Commission's Injury Database and collate data from Emergency departments in participating countries.<sup>26</sup>

Table 6.4 shows age-specific injury attendance rates in Wales in 2004. Rates in females are about one quarter or one third lower than in males at all ages. Overall, around one in four or five children and young people attend an Emergency department with an injury each year. The importance of home safety initiatives for young children is shown by the fact that 69% of all injuries to children aged 0–4 took place in the home.

Emergency department attendances are influenced by many factors other than the presence of an injury. Many less serious injuries are self-treated or treated in primary care. Distance and access can have profound effects, with one study showing a 50% reduction in injury attendance rate over a distance of 10 miles.<sup>27</sup> This distance decay effect was present for all injuries with the exception of fractures. Consequently fractures are frequently used as an indicator variable. The fracture rates per 1000 populations in Wales in 2004 were 16 for the 0–4 age group, and 33, 55 and 39 in the next three 5-year age groups. These are higher than any age group other than those aged 85 and over (62/1000). A further revision of the fracture indicator has been proposed, selected radiologically verifiable fractures (SRVFs), due to changes in the clinical management of different injuries. This takes into account changes in practise relating to avoiding X-ray exposure for many head and facial injuries and the likelihood that many distal radial greenstick or buckle fractures in young children do not present to Emergency departments.

**Table 6.4** Estimated numbers and rates of injury for Wales, by age band, 2004

Age	Estimated numbers of injuries	Estimated rate (per 1000 population)
0–4	24560	182
5–9	27197	156
10–14	47338	241
15–19	46395	229
20–24	39104	187
25–29	29002	157
30–34	28878	141

85+	12493	184
Unknown	88	
Total	410704	133

## SURVEY DATA

Admission and Emergency department data are often not available and even where they are, details of how and where the injury happened may not be collected. These factors are crucial to understanding the etiology and in developing preventive strategies and interventions. In such circumstances survey data can be very helpful. The World Health Organization (WHO) has developed guidelines for those carrying out community surveys on injuries and violence.<sup>28</sup>

Community-based surveys are particularly useful in poorer countries where access to high-quality care is often scanty and most injuries are self-treated or attended to by traditional healers. The rationale for such surveys is to implement preventive measures as outlined in the four-stage public health approach (Fig. 6.1) recommended by the WHO.

Even in wealthy countries survey data can be useful for obtaining additional information on location of injury and antecedent factors not collected at Emergency departments and also for obtaining exposure metrics.

## DISABILITY DATA

There is a lack of data on the medium and long-term consequences of injuries. The Global Burden of Disease and Injuries project<sup>29</sup> has produced initial estimates but these are based on quite sparse data and in many cases there were no data for specific types of injury. The likely distribution of outcomes for each injury was obtained by asking the opinion of medical experts based in hospitals. This is problematic as most hospital clinicians see and treat acutely injured patients and do not have a systematic process of measuring outcomes, particularly measures of function and disability. Prospective studies and empirical data on outcomes at fixed points in time are required to answer these questions. Another issue with many of the existing studies is that the injuries included in the study were often selected using a severity measure, such as the Abbreviated Injury Scale (AIS).<sup>30</sup> The AIS is designed to measure the threat to life from injuries in order to improve the evaluation of counter measures. However, it is not clear how closely threat to life and threat to disability are related. A stab wound to the heart has a high threat to life but if the patient survives the probability of any physical disability is slight. Amputation of a thumb carries a very low threat to life but a very high threat to disability. One of the best studies of post injury disability in young adults was that carried out on the 1958 British National Child Development Study cohort in 1981.<sup>31</sup> In that study 12 537 participants were asked about unintentional injuries and disability since age 16. Two thirds of men and one third of women reported at least one injury requiring hospital treatment. Injuries requiring hospital admission carried the highest risk of disability (9.7%) but 54% of permanent disabilities reported by men and 74% reported by women resulted from injuries

treated as outpatients. Fractures accounted for one third of disabilities. Among injuries resulting in permanent disability hand injuries featured prominently (82% of disabling work injuries and 32% of disabling home injuries). The greatest gap in estimating the true burden on injuries is the lack of information on the medium- and long-term consequences of injury.

## INEQUALITIES IN INJURY

Social inequalities in health were 'discovered' in the nineteenth century by seminal public health figures, such as Virchow in Germany, Villermé in France, and Chadwick in England. However, interest in social inequalities in health faded in the twentieth century until the publication of the Black Report in the UK in 1980.<sup>32</sup> This study compared death rates between the social classes. The largest of all the differences in death rates occurred in childhood injury deaths where the children from parents of social class 5 (unskilled workers) were several times more likely to die than those whose parents were from social class 1 (professionals). The ratio varied by a factor of 4 for all injury deaths to 7 for pedestrian deaths and 15 for deaths due to household fires.

Studies using individual level measures of socioeconomic position, such as social class, income or parental educational level show the greatest difference between the extremes. Social class scales tend to differ across countries and are not universally available. Usually several questions have to be answered to apply the scales, which prohibits their widespread use. In some countries, such as the US, concepts such as occupational social class are not commonly used and metrics such as family or individual income or educational level are preferred. Many studies use ecological or area-based measures to categorize groups by socioeconomic standing. These measures are usually obtained from official statistics taken during population censuses or the distribution of state-funded benefits. Area-based measures are attractive as they are easily applied once an address, postcode or zipcode are known. In many cases they are more suitable than individual level measures as many injury-prevention initiatives are implemented on an area or group basis. The strength of the relationship between injury deaths and ecological measures of socioeconomic position is attenuated due to the application of average measures to everybody within a community and the inevitable misclassification which results from applying an average score to a heterogeneous population.

The situation is not as simple when nonfatal injuries are considered. Some injuries show a marked socioeconomic gradient with higher rates in the less affluent groups or areas but the reverse occurring for other injuries. A population-based study of childhood fractures in Wales<sup>33</sup> demonstrated little overall variation in fracture rates between the most and least affluent groups. However, the most affluent group reported higher rates from sports participation, particularly notable for fractures related to horse riding and in-line skating, sports which require financial support. In contrast, assault-related fractures were substantially more common in the most deprived group. Clearly, some of the variations between socioeconomic groups related to differences in the presence and degree of exposure to hazardous behaviors, activities and environments. Childhood pedestrian injuries demonstrate substantial inequalities between affluent and deprived areas<sup>34</sup> as do childhood poisonings resulting in hospital admission<sup>35</sup> and burns.<sup>36</sup> These particular injuries show such a steep inequality gradient that they should be a main focus of effort to reduce inequalities in child health.

## INJURY PREVENTION

Given the scale of the impact of injuries on children's lives, preventing injuries should be a major goal of society. Injuries are caused by interactions between individuals and their environments and the prevention of injuries requires an understanding of these issues. Few pediatricians or child health practitioners are taught the principles of injury prevention and how these can be applied to their everyday work environment. The World Health Organization has responded to this deficiency by

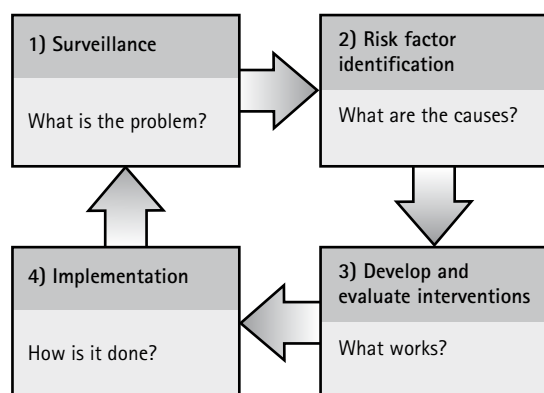

Fig. 6.1 A Public Health Perspective on injuries. (World Health Organization, p. 5 <http://whqlibdoc.who.int/publications/2004/9241546484.pdf>).

producing free teaching materials suitable for different circumstances. The teaching materials are suitable for three different levels of involvement: an intensive 2-day course; a 1-week short training course; and a 6-month training session. The materials are available from the WHO website.<sup>37</sup>

The learning objectives of the courses include:

1. to identify the basic principles of injury prevention, control and safety promotion;
2. to diagnose problems from a multidisciplinary perspective;
3. to design, implement and evaluate injury prevention and control interventions;
4. to advocate for injury prevention in communities;
5. to practice injury prevention control and safety promotion based on universally accepted ethical principles.

One important model to understand the causal chain of events involved in injuries is that proposed by William Haddon, commonly known as the Haddon Matrix (Table 6.5).

It is obvious from the matrix that injury prevention is a multidisciplinary and multi-agency task. There is scope for many different groups to become involved, either separately or in collaboration and there are many points at which preventive initiatives can be implemented. Initiatives can broadly be aimed at changing the environment, improving enforcement of safety legislation or at changing behavior through education. These are referred to as the three 'Es' of injury prevention. Clearly, each type of injury will require a tailored approach. Preventing injuries to the under fives at home will involve different groups and approaches to preventing childhood pedestrian injuries, for example. However, for almost every issue child health practitioners can play a substantial advocacy role. This is particularly the case where childhood injuries are very common or where there is social disadvantage and large inequalities in injury incidence. Advocating for those who are not in a position to protect themselves (children) and whose parents and guardians may lack the necessary information and influence to carry out this task should be a core function of child health practitioners. There are many groups which can provide assistance, including charities such as the Child Accident Prevention Trust (CAPT<sup>38</sup>), Royal Society for the Prevention of Accidents (RoSPA)<sup>39</sup> or the European Child Safety Alliance.<sup>40</sup>

Among the useful products produced by the European Child Safety Alliance is an 18-country Child Safety Action Plan. This action plan should help bolster support for injury prevention within participant countries and reduce the burden of injuries. Clearly, there is scope to copy this or similar initiatives in non-participant countries or with in regions and districts within countries. Child health practitioners are well placed to lead such activities but perhaps require additional training in advocacy and public health skills.

## THE EVIDENCE BASE

Knowing what to implement and how to get evidence into practice are important components of the knowledge and skills framework for injury

prevention practitioners. Like all aspects of health, publications relevant to injury prevention are increasing year on year and it is impossible for any practitioner or specialist to read all the published material. Several initiatives have made life easier.

For those with a need to know about latest developments SafetyLit<sup>41</sup> provides a weekly electronic current awareness service. This includes titles and abstracts sorted into categories from publications in over 2600 journals. For the more generalist approach to injury prevention the first source of information on effective interventions should be through systematic reviews. There are several sources of systematic reviews pertinent to injury prevention. The greatest supply of high-quality systematic reviews is produced by the Cochrane Injuries Group<sup>42</sup> based at the London School of Hygiene and Tropical Medicine. Their reviews are published by the Cochrane Library. Although the highest quality reviews are published by the Cochrane Group there are many others producing systematic reviews pertinent to injury prevention. Sometimes the conclusions of different groups looking at the same topics differ. This usually occurs due to differences in the thresholds set for study inclusion. The Collaboration for Accident Prevention and Injury Control (CAPIC<sup>22</sup>) provides a searchable database of all systematic reviews to allow the reader to identify all the relevant reviews and decide whether to focus on the most up-to-date review or read all the reviews. Some reviews focus on specific topics, such as the effectiveness of traffic calming or smoke alarms whilst others are broader ranging and cover many topics. One of the most broadly based reviews was that carried out by Elizabeth Towner and colleagues and published in two volumes,<sup>43</sup> in the journal *Injury Prevention*. These reviews cover a very wide range of topics from traffic calming to bicycle helmets to smoke alarms and educational interventions.

It is important to realize that systematic reviews only cover part of the evidence base. They are suitable for summarizing interventions which are amenable to evaluation by experimental design over a relatively short period. However, not all interventions can be evaluated using these methods. If observational studies demonstrate an intervention to be very effective then the ethical position of equipoise is lost and RCT cannot be instituted. If one considers trauma treatment as an analogy there is no trial evidence backing the use of plaster of Paris for immobilization of fractures. The evidence is based upon the principles of anatomy, physics and common sense. Nobody would ever suggest conducting a trial of immobilization versus watchful waiting to demonstrate the effectiveness of plaster of Paris although they might run trials to demonstrate the relative effectiveness of different methods of immobilization. At the other end of the spectrum it is very difficult to evaluate the effectiveness of long-term advocacy in changing cultural views in relation to the acceptability of implementing some injury prevention measures. No single mass media campaign has demonstrated effectiveness in reducing the incidence of driving whilst under the influence of alcohol. Yet, cultural attitudes to drink driving have changed over the past 30 or so years with a substantial reduction in prevalence and associated numbers of deaths.

**Table 6.5** The Haddon matrix (This model is reproduced from the WHO Teach Violence and Injury Prevention course materials with permission) ([http://www.who.int/violence\\_injury\\_prevention/capacitybuilding/teach\\_vip/en/index.html](http://www.who.int/violence_injury_prevention/capacitybuilding/teach_vip/en/index.html))

	Host (person)	Agent (vehicle or product)	Physical environment	Socio-economic environment
Pre-event	Is the person pre-disposed or overexposed to risk?	Is the agent hazardous?	Is the environment hazardous? Possibility to reduce hazards?	Does the environment encourage or discourage risk-taking and hazard?
Event	Is the person able to tolerate force or energy transfer?	Does the agent provide protection?	Does the environment contribute to injury during event?	Does the environment contribute to injury during event?
Post-event	How severe is the trauma or harm?	Does the agent contribute to the trauma?	Does the environment add to the trauma after the event?	Does the environment contribute to recovery?

How much of this change would have happened without mass media campaigns?

One area of evidence which is often derided is cross-national ecological comparisons. However, much can be learned from comparing practices and programs in different settings and cultures and trying to find out why some interventions seem to work in some settings and not others. One of the most useful reports on pedestrian safety in recent years is *Children's Traffic Safety: International Lessons for the UK* produced by Nicola Christie and colleagues for the UK Department for Transport.<sup>44</sup>

There were five things which distinguished the best countries, in terms of lower death rates, from the rest:

1. they had invested very widely in speed reduction measures, including environmental modification and low speed limits;
2. such measures were widely implemented outside schools;
3. there were outside play areas, such as parks and playgrounds, in most residential areas;
4. there were national publicity campaigns aimed at child pedestrian safety conducted at least once a year; and
5. they had legislation that assumes driver responsibility for accidents involving child pedestrians in residential areas.

Thus, the evidence base for injury prevention is very broad and includes systematic reviews, randomized trials, and observational, ecological and qualitative studies. Different study designs are appropriate for different questions. A comprehensive approach is usually needed to reach the correct conclusions. Providing and maintaining a broad evidence base is essential for advocacy, implementing proven strategies and developing new interventions to reduce the burden of childhood injury. The ultimate and only important aim is to have fewer dead, injured and disabled children.

## POISONOUS ANIMAL BITES AND STINGS

An overview of poisonous animal bites and stings published by the World Health Organization, stated that in excess of 100 000 deaths result worldwide each year from snakes bites, scorpion stings, spider bites, marine envenomations and anaphylactic reactions to stings.<sup>45</sup>

### SNAKE BITES

Snakes are the most widely distributed of the reptiles, and different species, often with highly individual features, predominate in different countries. Overall, there are 2.5 million snake bites each year, with a fatality rate of between 1.5 and 3%.<sup>45,46</sup> Tragically, in children, the mortality from snakebite is higher<sup>47</sup> and may reach in excess of 10% in some areas of Papua New Guinea.<sup>48</sup> Environmental change in some parts of the world has resulted in changes in the pattern of snakebite – as for example in parts of Africa, where prolonged drought has reduced vegetation cover, favoring the spread of *Echis ocellatus*, which has resulted in more bites.<sup>45</sup> Of the nearly 3000 known varieties of snake, only a minority are of medical significance and clinicians should concern themselves primarily with the characteristics and venomous effects of the poisonous snakes in their own area and importantly, have to hand details of their local supplier of antivenom.

### Adder bites (Europe)

The common viper or adder (*Vipera berus*) is found throughout Europe, with the notable exception of Ireland, and its bite seldom causes death in adults, although there are reports of deaths in young children.<sup>49</sup> The fully grown adder may be 50–60 cm in length and is recognized by the dark zigzag band which runs along the center of the back, although rarely the snake may appear uniformly black. It is a shy creature, normally disappearing quickly on the approach of people and is only likely to bite if disturbed unexpectedly.

### Clinical features

When the amount of venom injected is small, as is usual in a defensive bite, there may be few signs or symptoms, but fear often causes transient

pallor, sweating or vomiting. With moderate poisoning there may be local swelling and tender enlargement of the regional lymph nodes. This swelling may increase over 1 or 2 d to involve the whole limb but usually resolves within a few weeks. A burning pain is experienced at the place bitten. Vomiting may begin within a few minutes of the bite (often followed by diarrhoea) and may continue for up to 48 h. Shock is likely with weakness, sweating, thirst, coldness, absent pulse, hypotension, drowsiness and occasionally loss of consciousness. Swelling of the face, lips and tongue may occur, ecchymoses and swelling appear and may gradually extend up the limb. Bleeding may occur from gums, wound and infection sites. Other indications of envenomation include ECG abnormalities, peripheral neutrophil leukocytosis, elevated serum creatine kinase or metabolic acidosis.<sup>49</sup> With recovery, discoloration slowly changes from blue to green and finally to yellow before disappearing. The child generally recovers quickly from the initial collapse but in severe poisoning there may be persistent or recurrent hypotension, acute renal failure, and pulmonary or cerebral edema.<sup>49</sup> Full recovery may take 1–6 weeks.

### Treatment

A child who is bitten by a snake should be taken to hospital as quickly as possible and, *if it can be done without causing delay and without risk of further bites*, the reptile should be killed for identification. The bite should not be incised and the patient should be kept quiet and the limb maintained at rest by splinting, helping to retard absorption of venom. Tourniquets and compression should not be used. Both the child and parents should be reassured about the expected outcome. On admission to hospital paracetamol may be given for the pain and chlorpromazine, if required, for vomiting. In hospital, blood pressure should be monitored hourly, and bleeding time should be recorded; the white cell count (raised), serum creatine phosphokinase (may be raised), serum bicarbonate (may be low) and ECG should be determined twice daily. Tetanus toxoid should be administered if there is no record of tetanus immunization within the previous 5 years, but tetanus antitoxin is not required routinely. Broad-spectrum antibiotics are required if evidence of bacterial infection develops. Antivenom (two ampoules) should be given if there is evidence of systemic poisoning, especially hypotension, bleeding or ECG changes. It should be given diluted with isotonic saline, by slow i.v. injection or infusion over a period of 30–60 min. Adrenaline (epinephrine) and i.v. antihistamine and hydrocortisone should be ready in case of anaphylaxis.<sup>49</sup> If the patient does not show any clinical improvement, the treatment may be repeated.<sup>49</sup> If there is a delay in obtaining antivenom or if a history of allergy contraindicates its use, blood transfusion or i.v. fluids may help to combat collapse.

### Tropical and subtropical snakes

Morbidity and mortality from snake bites are highest in those areas where snakes have adapted to farm, plantation and village life and live in close proximity to large human populations. Examples are the Indian cobra, krait and Russell's viper in South-East Asia, some pit vipers in Latin America, the Taipan in Papua New Guinea and *Echis* species in Africa.

Land snakes may be roughly classified according to the presence or absence of poison injecting fangs, and their position when present in the snake's mouth (Table 6.6). Sea snakes, of which there are some 50 species, have characteristic flattened tails and short front fangs.

Although the Elapidae include many highly venomous varieties, these usually retreat when approached by humans and are generally non-aggressive unless cornered or molested. The large family of Colubridae contains only a few snakes of medical significance and these are rarely the cause of bites in humans. The Viperidae, on the other hand, are broad, sluggish snakes which hold their ground and may easily be trodden on (puff adder) or touched, on or in the ground or among rocks (rattlesnake, burrowing adder, berg adder). These snakes, despite their sluggishness, strike with great rapidity and power, virtually stabbing their victim with frontally situated large fangs which are swung forward during the strike.

Table 6.6 Classification of snakes

Group of snake	Features of groups	Common examples and habitat	Principal action of venom
Viperidae	Mobile front fangs	Viperinae Puff adder, widespread in Africa Gaboon viper, central and southern Africa Berg adder, southern Africa Night adder, southern Africa Rhinoceros viper, Tropical Africa Russell's viper, Asia and Indonesia Saw-scaled viper, India, Iraq, North Africa European viper (adder), Europe, Asia, Japan Crotalinae (pit vipers) Cottonmouth moccasin south-eastern United States Copperhead, N. America Fer-de-lance, Latin America; W. Indies Bushmaster, Central and South America Jaracara, South America Rattlesnakes, Mexico, southern and western United States	Cytotoxic (tropical rattlesnakes and berg adder are mainly neurotoxic)
Elapidae	Fixed front fangs	Cobras, widespread in Africa and Asia Mambas, east, central and southern Africa	Neurotoxic (king cobra also has cytotoxic effect)
Colubridae	Back fangs	Rinkhals, southern Africa Indian krait, India, Burma, Malaya, Indonesia Tiger snake, Brown snake, Australia Taipan; Death adder, Australia and New Guinea Coral snakes, southern United States; C. America Boomslang, widespread in Africa	Hematoxic
Hydrophidae (Now included in Elapidae)	Short fixed front fangs	Various species of sea snake. Mainly in the Pacific but a few species in the Indian Ocean	Neurotoxic; myotoxic
Nonvenomous	Fangless	House snake Grass snake Boas, pythons. Widespread in tropics.	Nil

Many nonvenomous snakes are capable of inflicting bites which are liable to become infected, sometimes with exotic bacteria, such as *Arizona* species.

Snake venoms broadly correspond with the families shown in the table. They are, however, complex mixtures of toxins and enzymes and effects depend upon which of these predominate. Viper (and spitting cobra) venoms are mainly cytotoxic but bleeding diatheses are common. Elapid venoms produce neurotoxic and cytotoxic effects, as do varieties of tropical rattlesnake (Crotalinae), but again microangiopathic and intravascular hemolysis may be a feature of the bites of some species. Overall, snake venoms are complex with varying mixtures of neurotoxins, myotoxins, procoagulants, anticoagulants and nephrotoxins.<sup>46,47,49,50</sup> The venoms may therefore also cause hemolysis, hemorrhage and coagulation disturbances.

Colubrid (e.g. boomslang) venoms are hematoxic and anticoagulant, while hydrophiid (sea snake) venoms are mainly myotoxic. Nephrotoxic properties have also been demonstrated in puff adder, sea snake and rattlesnake venoms.

Children are particularly at risk in areas where snakes are common because of their love of outdoor pursuits, together with their curiosity and carelessness. However, it is important to realize that all bites from snakes are not caused by venomous species. In the case of bites from nonvenomous snakes, two distinct puncture marks are not seen and the bites are irregular and lacerated to a greater or lesser degree, with little local swelling or pain. Even bites by venomous species do not always cause clinically significant envenomation as the bite may be deflected by clothing or the venom stores of the snake depleted. When envenomation has occurred, symptoms tend to be more severe in children because of their smaller size relative to the volume of injected venom.

Despite popular belief, while sudden collapse and death may occur (e.g. Australian brown snake, death adder), signs of systemic

envenomation in even the most poisonous snake bites seldom occur before 30 min. The earliest features are often those due to fright – shock, pallor, sweating, vomiting, weak pulse and faintness. Severe pain and swelling at the site of the bite, with rapidly spreading edema, are the first signs in most viper and spitting cobra bites. Later large bullae may form around the bite and painful lymphadenopathy may develop. Sometimes there is extensive bruising in superficial and deeper tissues. Within 5 or 6 h the whole limb may be tensely swollen. There is thus a profound local cytotoxic effect and subsequent systemic disturbance is largely due to this tissue damage rather than to circulating venom. Necrosis of superficial or deep tissues may be seen. Disseminated intravascular coagulation with resultant hemolytic anemia, hemorrhagic manifestations and hemoglobinuric nephrosis, can complicate the bite.

In heavy envenomation, especially by puff adders and Gaboon vipers, bloody saliva may be expectorated, and sudden death may follow due to circulatory collapse. Notable exceptions in this family of snakes are the hemorrhagic reactions seen in bites from saw-scaled and Russell's vipers and the neurotoxic effects occurring in tropical rattlesnake and berg adder bites.

Elapid bites generally cause much less local reaction, but have profound systemic effects which are predominantly neurotoxic. Spitting cobras are however a different entity – the bites may cause significant local tissue necrosis<sup>51</sup> and in a review of bites from the Australian copperhead, one third showed significant local effects.<sup>52</sup> The first symptoms of neurotoxic snake bite are usually ptosis, rapidly followed by strabismus, slurred speech and dysphagia, with drooling saliva. There is confusion and hypersensitivity to tactile stimuli. If untreated, the victim may be completely paralyzed within minutes and respiratory paralysis may result in death within 15 h. In survivors there are no neurological sequelae. In the case of mamba bites, the first systemic symptoms are combined with a sensation of tightness and pain across the chest.

Violent abdominal pain sometimes occurs after krait and coral snake bites. Local blistering may be seen after envenomation by some cobras and a burning sensation at the site is often described. Local pain after snake bites is, however, extremely variable. Hematuria and hemoglobinuria may occur as may hemorrhage or menorrhagia.

Some elapids, such as the spitting cobra and the rinkhals of southern Africa are able to eject venom with considerable force and accuracy at the victim's head. Should this enter the eyes, a severe keratoconjunctivitis can result, which may lead to blindness if not adequately irrigated and treated.

The family Colubridae covers many snakes, including the Montpellier snakes, the red-necked keelbacks, the yamakagashis, the herald snake and the vine snake<sup>49</sup> but the boomslang is the only venomous snake in this large family which is a significant hazard to humans. Fortunately bites from this species are rare, usually occurring in those handling or working with snakes. There is little or no local reaction apart from mild burning pain but severe headache about 1 h after the bite is a regular and unexplained phenomenon. Colubrid venoms contain mainly fibrinolysins and hemorrhagins, which result in severe, systemic defibrination and generalized hemorrhage, widespread cutaneous bruising especially at sites of trauma, and free bleeding from fang punctures. There may be massive intestinal, urinary tract or intracranial hemorrhage leading to death. As mentioned earlier, the venom of certain vipers and also some elapids (such as the Papuan black snake) produces similar hemorrhagic effects.

Sea snakes do not attack in water if unmolested. Most bites result from handling the snake when caught in fishing nets. The bite shows no local reaction and minimal pain<sup>53</sup> and in most sea snake bites no envenomation occurs.<sup>54</sup> Initial symptoms, due to a myotoxin, are seen after a latent period of 30–120 min. There is muscular pain, stiffness and trismus followed by ptosis and progressive weakness which may threaten respiratory function. Rhabdomyolysis, myoglobinuria, renal tubular necrosis and acute renal failure may ensue.

Hadley et al,<sup>55</sup> in southern Africa, found thromboelastography to be a good predictor of severity in snake bite in children. They felt that, although it did not supersede clinical observation in the management of snake bite in children, it did allow stratification into high- and low-risk categories.

### Treatment

The administration of antivenom, generally intravenously, is an effective treatment for a case of envenomation by a poisonous snake, but for many snake species, no antivenom may be available. The use of antivenom, especially polyvalent antivenom, carries a substantial risk of anaphylaxis and serum sickness because of its foreign protein content, but there is no doubt that the benefits of antivenom treatment far outweigh the risks.<sup>45,51</sup> Its administration in every case of snake bite is, however, dangerous, wasteful and unnecessary. As not all snake bites are due to poisonous snakes, it is obviously of paramount importance, as an initial step, to identify the snake accurately, or at least to decide clinically into which group it falls. Much can be deduced from the color and shape of the snake, manner and circumstances of striking, the situation of the bite and presence or absence of fang marks. For instance, the puff adder, responsible for 95% of poisonous snake bites in Africa, is encountered on paths or in grassy terrain, and almost always strikes at the feet or ankles. On the other hand, cobras often attack when they are surprised near out-buildings or chicken runs. They rear up prior to striking and bites are frequently inflicted above the knees or even on the trunk or upper limbs.

As many victims of snake bite are not within easy access of clinic or hospital, it is most important to lay down firm and easily understood guidelines which can be applied by a layman on the spot:

1. *Symptoms* developing within the first half hour of a bite are almost always due to fear and its effects – and not to envenomation. The patient should be calmed and reassured, and encouraged to lie down quietly so as not to disseminate the poison by restless body movements. The affected limb should be kept horizontal at this stage and gently splinted to avoid movement. A mild analgesic (paracetamol) should be given.
2. *Bites* from nonvenomous snakes should be thoroughly cleansed with a dilute antiseptic solution, any loose teeth removed, and a light dressing applied. Tetanus toxoid should be administered within 24 h to all cases of snake bite if there is no documented evidence that the child has received anti-tetanus immunization within the past 5 years, and broad-spectrum antibiotics should be given at the first indication of possible infection.
3. *Signs* of significant envenomation generally develop from half to 2 h after the bite. It is imperative to get the patient to a hospital, or a trained person to the patient, as soon as possible. Signs may be local in the case of viper bites, with swelling and pain, or systemic in the case of bites from snakes with neurotoxic and hematoxic venom, with varying manifestations including vomiting, abdominal pain and neurotoxic symptoms, as noted earlier.<sup>51</sup> They call for urgent administration of antivenom given intravenously. If this is not possible, the antivenom should be administered intramuscularly (see later). Sprivulis and Jelinek<sup>51</sup> advise that multiple doses of antivenom may be required. Premedication with parenteral antihistamine and low-dose subcutaneous adrenaline (epinephrine) (0.003–0.007 mg/kg) prior to administration of antivenom is advisable in sensitive individuals to prevent anaphylaxis. Sprivulis and Jelinek<sup>51</sup> recommend that a short course of oral steroids may reduce the incidence of serum sickness, particularly in children and in patients receiving polyvalent or multiple doses of monovalent antivenom.
4. *Tourniquets*: In many countries the use of tourniquets is generally discouraged and under no circumstances should any form of bandaging be applied in the case of bites by snakes with cytotoxic venom as the local effects and subsequent complications are aggravated by compression and such procedures waste transport time. However, where highly venomous snakes with pronounced systemic effects are incriminated (e.g. neurotoxic cobras, mambas, crotalids and sea snakes), and especially if there are already signs of systemic toxicity, it is recommended that a pressure bandage be applied to the affected limb to prevent further absorption. Australian experience with elapid bites has much to recommend it – replacing the previously recommended tourniquet for the 'pressure-immobilization method.' Thus it has been found that for this group of snakes, rather than using a tourniquet, venom movement, which occurs largely via the lymphatics, can be effectively delayed for long periods by the application of a firm crepe bandage to the length of the bitten limb combined with immobilization by a splint. The bandage is firmly applied to the bitten area and then continued to the distal end of the limb and then wound tightly back to the groin or armpit.<sup>50</sup> It is worth noting here that this 'pressure-immobilization' method may be used for all elapid snake bites and some other types of bites or stings such as those from bees, wasps, or ants in sensitive subjects, funnel-web spider bites and bites of the blue-ringed octopus and the cone shell.<sup>51,56,57,58</sup> It can also be used for sea snake bites.<sup>53</sup> However, exceptions when the method should *not* be applied include ant, bee and wasp stings in normal, nonsensitive subjects, red-back spider bites and jellyfish stings<sup>56</sup> and, as stated earlier, after viper or spitting cobra bites. Where pressure immobilization is impractical (e.g. a bite on the body), then infiltration around the bite site with diluted adrenaline (epinephrine) is suggested by Sprivulis and Jelinek.<sup>51</sup>
5. *Suction*: suction apparatus is available in many commercial snake bite kits but is probably of doubtful value. Suction by mouth entails a definite risk of absorption of venom through the oral or intestinal mucous membranes. In general, suction is not recommended for snake bite.<sup>45</sup>
6. *Incision*: Incisions over fang marks as a first aid measure is not recommended.
7. *Other local measures*, such as freezing, injection of antivenom, EDTA or other agents into the bite and application of permanganate crystals to incised wounds, have no place in the management of snake bites, and can only serve to aggravate tissue damage.

## Antivenom

Some 30 centers in different countries manufacture antivenom appropriate to local snake species. Polyvalent antisera generally cover most bites encountered, but in the case of certain snakes (e.g. boomslang) monospecific antisera are required. Antivenom is preferably given intravenously. In the past it has sometimes been suggested that a small intradermal test dose of antivenom be given. However, prevailing opinion is that, to quote Eddelston et al:<sup>59</sup> 'There is no point giving a test dose of antivenom as it poorly predicts the individuals who will have an anaphylactoid response.' Adrenaline (epinephrine) should always be at hand to combat possible anaphylaxis. However, adrenaline may induce serious cardiovascular effects, especially in adults. It is advisable to give a corticosteroid, such as hydrocortisone, prior to antivenom as this tends to modify serum reactions as well as having anti-inflammatory and antihypotensive effects. Corticosteroids will not, however, prevent anaphylaxis. In a recent Cochrane Review<sup>60</sup> based upon one trial, the authors concluded that 'routine prophylactic adrenaline for polyvalent antivenom known to have high adverse event rates seems sensible' but they believed that 'antihistamine appears to be of no obvious benefit in preventing acute reactions from antivenoms.'

Once a decision to administer antivenom has been reached, it must be given in adequate dosage.<sup>61</sup> Pearn<sup>62</sup> has commented that as many as 10–12 ampoules may be required to neutralize the pro-coagulant components of bites by the Australian Brown Snake. It must be emphasized that the dosage of antivenom for children is the same as that for adults.<sup>45</sup> Antivenom is best given in an i.v. drip, diluted in two to four times its volume of normal saline over a period of half an hour. A recommended initial i.v. dose is 50 ml of the polyvalent antivenom and the volume of diluent can be adjusted. This should be repeated every 4 h if clinical response is not satisfactory and if necessary up to 200 ml should be given within the first 24 h. The doses of the different antivenoms differ quite substantially. When large doses are used, steroids should be continued to modify possible serum sickness reactions. Anaphylactoid reactions generally respond quickly to prompt adrenaline (epinephrine) injection. If a doctor is not available, the usual dose of antivenom that can be tolerated intramuscularly is about 20 ml.

In the case of ophthalmia due to a spitting cobra, the affected eye should be well washed with water or other bland fluid. Instillation of dilute antivenom is not recommended (G. Muller, personal communication).

ELISA kits (CSL Diagnostics, Australia), suitable for field use, are available in some countries such as Australia for venom detection and species identification in snake bite washings, blood or urine.<sup>51,61</sup> Thus in Australia, it is recommended that snake bite wounds are *not* washed as part of initial first aid technique.<sup>51</sup>

## Further supportive care

Unless it has been shown with the passage of some hours that the bite is trivial all cases of poisonous snake bite require admission to hospital.

If severe bulbar or respiratory paralysis has developed, airway suction, oxygen and assisted respiration are indicated.

Management of acute renal failure should be anticipated by adequate i.v. replacement, careful monitoring of input and output, urinalysis and measurement of plasma urea and electrolytes and tests for myoglobinuria (including rhabdomyolysis).

Hemorrhagic manifestations require careful appraisal with a coagulation profile as hemorrhagins (Russell's viper), fibrin degradation products (boomslang) or intravascular clotting (puff adder) can be responsible. Antivenom administration is the only treatment modality which is effective. Other supportive measures include: i.v. vitamin K, blood transfusion, fresh plasma or fibrinogen, low molecular weight dextran, or alpha-aminocaproic acid may be required according to circumstances. The use of heparin is not recommended.<sup>49</sup>

In the event of severe local swelling, the limb should be kept slightly elevated on a pillow. Bullae should not be burst as this increases the likelihood of infection. Skin or fascial release to ease jeopardized circulation, debridement of necrotic tissue, and subsequent grafting or amputation are not uncommonly required, especially in untreated puff adder bites.

The prime cause of death from snake bites is delay in getting the patient to a medical facility. Sutherland<sup>63</sup> in Australia and Gold et al<sup>47</sup> in the USA have emphasized that snake bite deaths are more common in children and the elderly and result from:

1. victims not being observed for an adequate period – suspected snake bite victims should be observed for at least 12–24 h after the bite;
2. antivenom being withheld despite clear indication of systemic envenomation;
3. giving the wrong antivenom – often more than once;
4. giving too little of the correct antivenom or not giving more antivenom if signs and symptoms reoccur.

Pearn<sup>62</sup> has pointed out that a chronic elapid envenomation syndrome may develop in patients who have not been given antivenom for whatever reason, after a snake bite. This may involve both local and systemic effects including lassitude, weakness, loss of appetite and nausea.

## Prevention

To develop a snake bite prevention strategy for a particular locality, health care workers need to understand the epidemiology of snake bites for their particular area along the lines discussed for Papua New Guinea by Williams and Winkel.<sup>48</sup> However, general guidelines include:

1. Establish where your closest medical facility and local poisons information center are and have their telephone numbers readily at hand.
2. Treat all snakes with respect.
3. Endeavor to know the snakes in your area.
4. Watch out in summer months, particularly after first rains. Be careful when walking at night; use a torch.
5. Wear boots and leggings or at least shoes and socks when walking in the bush (80% of human snake bites are on the legs and 55% on the ankle and foot).
6. Avoid thickly bushed country, long grass, etc.
7. Do not panic and run away when confronted by a snake; movement will attract attention whereas the snake is likely to move off if you keep still.
8. Keep an appropriate anti-snake bite kit with you.

It has also been found important in Australia to emphasize the need to believe a child who claims to have been bitten by a snake.<sup>64</sup>

Detailed coverage of dealing with snake bites can be found in Brent et al<sup>65</sup> and the publications of Warrell.<sup>49,66,67</sup>

## INSECTS, SPIDERS, TICKS, BEETLES, SCORPIONS, CENTIPEDES AND CATERPILLARS

### Hymenoptera stings

All stinging insects, such as bees, wasps, hornets and ants, are included in the order Hymenoptera. Bee venom contains many toxic fractions, the most important being mellitin, which alters capillary permeability, causes local pain, hemolyzes red cells, and lowers blood pressure. The venom also contains antigenic components which are capable of invoking an allergic hypersensitivity response in a significant proportion of the population if subjected to a subsequent challenge. Cross-antigenicity may occur between wasp and bee stings and even on occasions, the rare stings by bumblebees.

In Australia, bee stings and bee sting allergy continue to be a major cause of venom-related mortality<sup>68</sup> and serious clinical problems are becoming more common owing to severe allergy to jumper ant (*Myrmecia pilosula*)<sup>69</sup> and bull ant (*Myrmecia pyriformis*) bites and stings.

The management of insect stings has been well reviewed by Reisman.<sup>70</sup> In general terms, uncomplicated stings require no treatment, apart from mild analgesics. Bee sting barbs should be carefully removed with a flat blade, taking care not to express further venom, which will happen if the sting is grasped with forceps. It has been claimed that meat tenderizer, available in most homes, applied in a dilute solution (a quarter teaspoon mixed with 1 teaspoon of water), rubbed into the sting denatures the protein and relieves all pain within seconds. In sensitive individuals, however, even a single sting may result in acute anaphylactic shock with urticaria, hypotension, tachycardia and sweating, glottic

edema, or bronchospasm. Prompt treatment is vital. Adrenaline (epinephrine) is indicated. In the case of laryngeal edema, hydrocortisone should be injected intravenously. Tracheostomy may be life saving in the event of severe edema of the glottis.

Skin tests to detect hypersensitivity to Hymenoptera stings are unreliable. However, children who are known to react in a hypersensitive manner should undergo desensitization with a carefully planned immunization schedule, using venom immunotherapy (VIT) – a point reiterated in a recent analysis of bee sting mortality in Australia.<sup>68</sup> Hymenoptera antigen immunotherapy may become more reliable with the development and use of pure venom immunization and phospholipase A, when and if it becomes available. However, children appear to exhibit considerably less frequent severe side-effects to stings than adults, which has led Valentine et al<sup>71</sup> to believe that immunotherapy is unnecessary for most children allergic to insect stings.

Multiple bee stings may induce a life-threatening toxic syndrome due to the cumulative effect of the toxins (short chain peptides, vasoactive amines and antigens). Bee venoms also possess hemolytic properties and multiple stings, usually in excess of 100, may result in significant hemolysis with acute anemia and subsequent renal failure, rhabdomyolysis and hepatic, respiratory and cardiac dysfunction. Cases of massive bee stings should be admitted to hospital and carefully observed for early signs of these complications, where prompt treatment can be instituted and renal failure minimized by ensuring a high urine output. Biphasic renal failure has been known to occur with early renal failure due to hemolysis and a second episode of azotemia about 10 d later, corresponding with a depressed serum complement C3 level and nephritic changes on renal biopsy – a phenomenon probably representing a serum sickness reaction caused by a large volume of foreign protein.

Studies in Australia have shown that 'Stingose' (an aqueous solution of 20% aluminum sulfate and 1.1% surfactant) is an effective, wide-acting first aid treatment to counteract the venoms of insects, marine invertebrates and plants when applied topically soon after the bite or sting.

The application of ice packs to insect stings (and platypus stings in Australia) will help to relieve local pain.<sup>72</sup>

## Spider bites

Only a small fraction of the several hundred genera of spiders contain poisonous species and Alexander<sup>73</sup> has discussed these in detail. Although spiders belonging to the genera *Latrodectus* and *Loxosceles* can be dangerous to humans, most spider bites cause only minor clinical effects.<sup>74</sup> The topic is well covered in Brent et al.<sup>65</sup>

### *Latrodectism*

*Latrodectus mactans* (the black widow spider of the USA), *L. indistinctus* (the button spider of South Africa), and *L. geometricus* (the brown widow spider – a cosmopolitan species) are the commonest species of the genus being widely distributed throughout the warmer areas of the world. In Australia, *L. hasseltii* (red-back spider) and in New Zealand, *L. katipo* (katipo spider) are found.<sup>58,73</sup>

Of the various species and subspecies of the genus *Latrodectus*, only the females are hazardous to humans. They have black or dark velvety globular bodies about 15 mm in length with orange–red markings often in the shape of an hourglass on the ventral surface of the abdomen. While they can be found under garden rocks, they tend to spin their webs in dark places, such as buildings (and especially outbuildings), garage doors, garden furniture and post boxes. Another favorite place is under lavatory seats – hence the number of bites which occur on the buttocks or genitalia. *Latrodectus* venoms (alpha-latrotoxin) possess neurotoxic properties, causing the release of peripheral neurotransmitters. Following a bite from *Latrodectus*, there is a very variable local reaction. Signs of systemic envenomation occur between 20 and 200 min later. There is often a regional lymphadenopathy within 30 min of the bite, followed by severe muscular pains involving the limbs and trunk with tightness around the chest and abdominal rigidity which may mimic an acute abdomen. Hyperreflexia is often present. Death is rare, even in untreated cases, but when it occurs, is usually due to respiratory

failure. Pressure immobilization should *not* be used as the venom is slow acting and pressure will tend to increase the pain. A cold compress can reduce pain at the site of the bite. Treatment is aimed at relieving muscular spasm. It is worth noting, however, that only about 25% of people bitten progress to systemic envenomation, depending on the species of *Latrodectus* involved.<sup>58</sup> Calcium gluconate 10% (5–10 ml by slow i.v. injection) is effective in temporarily depressing the excited neuromuscular junctions. However, specific *Latrodectus* antivenom is the only treatment modality which will relieve pain and is available in most endemic areas.<sup>61</sup> The antivenom should be given intravenously (5 ml) and if necessary repeated. If the victim shows only a mild local reaction to the bite and no systemic effects are detectable after 24 h then antivenom should not be given.<sup>63</sup> The possibility of adverse serum reactions although uncommon should be borne in mind and adrenaline (epinephrine) and corticosteroids should always be at hand.

The effects of untreated Redback spider bites can persist for weeks to months – a picture similar to that seen in chronic fatigue syndrome.<sup>70</sup>

### *Loxoscelism*

The genus *Loxosceles* (the violin spiders) includes many long-legged spiders occurring throughout Latin America as well as in focal areas elsewhere. The venom is cytotoxic and a bite is accompanied by severe local pain and bullous skin lesions, rapidly followed by marked edema, which may progress to necrosis. It may also induce systemic effects including hemolysis, coagulopathy and sepsis. Treatment is aimed at controlling the local reaction. Parenteral antihistamines have been shown to decrease both the pain and the swelling.

### *Funnel web and related mouse spiders*

In Australia, the Sydney funnel web spider (*Atrax robustus*), and various species of the genus *Hadronyche* are the cause of serious spider bites each year. These are large aggressive spiders which rear up before attacking when disturbed and in this group of spiders, it is the male which is the more dangerous. They have a complex venom (robustoxin, an excitatory neurotoxin) and with multiple bites being the rule, considerable pain and panic ensue. In cases where systemic envenomation develops, it may occur within about 10 min of the bite, with dry mouth, circumoral paresthesia, salivation, nausea and vomiting. Muscular fasciculation is regarded by Raven and Churchill<sup>75</sup> as the unique characteristic of funnel web bites. Pulmonary edema and loss of consciousness may occur, and death can result from cardiac arrest.

In management of bites from this spider, atropine and diazepam are said to help.<sup>73</sup> Encouraging results have been obtained in the development of a funnel web spider venom antagonist.

It is claimed that the bite of several species of spider, such as the white-tailed spider *Lampona cylindrata* in Australia can cause chronic nonhealing skin ulcers,<sup>58,76</sup> but definitive evidence is lacking.<sup>74</sup> This condition is sometimes termed 'necrotic arachnidism' or 'necrotic araneism' although Warrell<sup>74</sup> is not happy with this terminology and feels it is misleading. Other spiders in Australia which are sometimes claimed to be dangerous, are the wolf spider (*Lycosa* spp.) and the mouse spider (*Missulena occatoria*).<sup>58</sup>

### Tick bites: tick paralysis

Ticks are the vectors of a number of human diseases in both tropical and temperate regions. These include the tick bite fevers, certain arbovirus diseases and Lyme disease due to *Borrelia burgdorferi*.<sup>77</sup> However, as well as this role in the transmission of infectious diseases, dealt with elsewhere, tick bites may cause itching, irritation, can become secondarily infected and in some species, may cause paralysis.

Engorging ticks should be encouraged to detach themselves, by applying a lubricant such as liquid paraffin, before gently extracting them. They should never be hastily pulled off, as the tick's mouthparts may be retained in the skin. This may subsequently give rise to a granuloma composed of a dense dermal granulomatous reaction associated with overlying pseudoepitheliomatous hyperplasia, which on occasions may be so marked in biopsy material that it can lead the unwary pathologist to

an erroneous diagnosis of squamous carcinoma. On other occasions, the bite may lead to ulceration which is slow to heal. It remains covered by a necrotic, black eschar which takes many days to separate or the lesion may persist for months as a granuloma under the skin.<sup>62</sup>

Although rare, deaths from anaphylaxis following a tick bite are recorded.<sup>62</sup>

Certain ticks of the genera *Ixodes*, *Dermacentor*, *Haemaphysalis*, *Rhipicephalus* and *Hyalomma* produce a neurotoxin in their saliva which may cause 'tick paralysis'. The condition is commoner in children than in adults and particularly tends to afflict girls, probably because their longer hair hides the tick engorging on the scalp or neck, often with little or no local discomfort. A period of irritability starts 5–7 d after the tick has started feeding. This is followed by ascending symmetrical flaccid paralysis. Initially there is difficulty in walking and standing.<sup>73</sup> Within a day or two, paralysis spreads up from the legs to involve the trunk, arms and neck. Bulbar involvement causes dysphagia, slurring of speech and may result in death from respiratory failure. A local paralysis of the face, for example, may result when the tick is attached to the eardrum. Sensory changes are minimal although there may be paresthesia in the paralyzed limbs. The cerebrospinal fluid remains normal. Mortality may be significant, although death is uncommon if the engorging tick is removed.<sup>73</sup> Tick paralysis should be considered in the differential diagnosis of Guillain-Barré syndrome and it can mimic poliomyelitis.<sup>73</sup> Rapid and complete recovery usually attends the removal of the offending tick, although sometimes neuroparalysis may become transiently worse after removal of the tick. In Australia a canine tick antivenom is available<sup>61</sup> and has been used in children with promising results.

## Beetles

Two large families of beetles, found in many parts of the world, produce urticating toxins. These are the Staphylinidae (rove beetles) and the Meloidae (blister beetles).

In Africa, and parts of Asia, America and Europe, rove beetle dermatitis due to the genus *Paederus* poses a difficult problem. When the beetles are brushed off the skin, or crushed, an irritant toxic principle, paderin, is released. This may cause blistering 1–2 d later. The blisters vesiculate in 2–8 d and have a tendency to spread as a result of the release of fluid. Thereafter, the lesions flatten and dry out with subsequent peeling. On occasions the blistering is accompanied by systemic symptoms such as headache, fever, myalgia and arthralgia. A severe conjunctivitis, commonly known as 'Nairobi eye' results if paderin comes into contact with the eyes.

Several genera of Meloidae, including *Lytta vesicatoris*, the 'Spanish fly', produce a vesicant, cantharidin, which is falsely credited with aphrodisiac properties, but which is toxic if ingested or absorbed through the skin.

In the treatment of dermatitis due to rove or blister beetles topical application of compresses, such as magnesium sulfate is beneficial, and eye lesions should be bathed with isotonic saline.<sup>73</sup> Additionally the skin should be thoroughly washed with soap and water as should all contaminated clothing.

The condition termed 'Christmas eye' in Australia is as yet of undetermined origin. It may prove to be due to an orthopteran of some type, but a blister beetle seems more likely.

## Scorpion stings

Scorpions have a single caudally placed sting with which they can inject venom. Some varieties, such as the genera *Parabuthus* (Southern Africa), *Androctonus* (North Africa; Turkey), *Centruroides* (Arizona; Texas) are dangerous especially to young children. Scorpion venoms are neurotoxins and their overall effect is hyperactivity of peripheral nerves, both somatic and autonomic. Alexander<sup>73</sup> notes that scorpion stings are more serious in children than in adults and that most deaths occur in children.

Serious stings are characterized by severe burning pain and local swelling at the site of the sting, hyperesthesia and myalgia in the affected limb, quickly followed by generalized weakness, muscle spasm, excessive salivation and rhinorrhoea, excitement, coma, convulsions (especially in

small children) and respiratory failure – often fatal.<sup>73</sup> Pancreatitis is a reported complication in severe cases of scorpionism. Less venomous varieties or stings in older subjects may result in only local pain and swelling, sometimes with lymphangitis.

## Treatment

In many countries, it has been noted that scorpion stings in children can have a high mortality rate unless adequate symptomatic and specific therapy are given – especially respiratory support. Prompt application of a crepe bandage will slow the spread of venom but there may be problems in applying this to children because of the pain. Ice packs applied to the sting site are seldom effective and the most effective method of pain relief is infiltration of the sting area with local anesthetic (Muller, personal communication). Scorpion antivenom is available and this, together with respiratory support, can be life saving in cases of severe envenomation; 10 ml should be given intravenously, as soon as possible, keeping adrenaline (epinephrine) and corticosteroids on hand in case of anaphylaxis. When antivenom is not available, general supportive treatment is needed and subcutaneous atropine and i.v. calcium gluconate have been reported to be effective. *The need for assisted respiration must be anticipated.* In milder stings injection of a local anesthetic into the site is often the only treatment needed. The topic is covered by Brent et al.<sup>65</sup>

## Centipedes

Centipedes are segmented arthropods with one pair of legs per segment. The first pair of legs are modified to form toxognaths with strong claws on which open the ducts from the venom glands. Bites from centipedes can cause considerable pain and swelling, and sometimes local ulceration and spreading lymphangitis result.

## Caterpillars (Lepidopterism/erucism)

Lepidopterism refers to a disease caused by contact with adult or larval butterflies and moths, while erucism is an illness caused by the larval and pupal stages of these insects.<sup>78</sup> The fine, spiny, venom-containing hairs of some species of caterpillar induce a very painful urticarial or vesicular dermatitis. This may be acquired by actual contact with the larva or from hairs blown in the wind. Where caterpillars are very prolific, severe symptoms may occasionally be induced in children, with extensive rashes, fever, vomiting and even paralysis. Hairs are best removed by applying adhesive tape to the site. Immersion in a very hot bath is soothing, and analgesics may be required. There is little evidence for the development of an allergic response from repeated exposure. Severe clinical effects including mild to severe shock and coma can follow contact with the stinging hairs from caterpillars of the genus *Megalopyge* in the southern USA and parts of Latin America.<sup>73</sup>

Calamine lotion applied to caterpillar hair stings helps alleviate the pain and removal of stinging hairs with sellotape stripping is suggested as a first aid measure.<sup>73</sup>

## STINGS FROM VENOMOUS MARINE ANIMALS

Stings from venomous marine animals can be a major health problem in many parts of the world, including Australia, Papua New Guinea, South-East Asia, Asia and the Far East, the Mediterranean, North and Latin America, the Caribbean and even Russia.<sup>79</sup> As might be expected, the problem is greatest in tropical waters and its magnitude can be gauged by figures from Australia where, over the summer months of 1990–1991, more than 18 000 people were treated for marine stings<sup>80</sup> while in the USA, in Chesapeake Bay alone, about 500 000 jellyfish envenomations occur each year.<sup>81</sup>

Although mostly seasonal, the problem of marine stings in the waters of northern Australia is so significant that it often precludes swimming during the summer months, except in areas protected by special nets – termed 'stinger enclosures'.

Overall, the most common cause of jellyfish stings are coelenterates of the genus *Physalia*, the common blue bottle or Portuguese

man-of-war. Stings from these animals occur in the water or on the beach and, especially with the short-tentacled species, can be painful for up to an hour or so, but are not usually life threatening.<sup>72</sup> Stings from the multiple-tentacled species, however, can be severe and rare fatalities are on record.<sup>72,80</sup>

The so-called 'nematocyst dermatitis' from the blue bottle jellyfish is often exacerbated by the tentacles sticking to the skin, with subsequent discharge of the nematocysts causing ongoing pain and discomfort.

Treatment of blue bottle stings consists of covering the affected area with a plastic bag containing ice to alleviate the pain.<sup>72</sup> The use of heat to reduce blue bottle sting pain is more controversial, needing further research but is not really practical in the first aid situation.<sup>82</sup>

By contrast, stings due to the seawasp or box jellyfish (*Chironex* spp.) are excruciatingly painful and are associated with a significant mortality. Thus stings by this species in northern Australia have resulted in over 300 cases between 1984 and 1994, with in excess of 80 deaths being recorded from these stings in the twentieth century in Australia – often only minutes after the sting has occurred in the water.<sup>76,83</sup>

The bodies of people stung by this jellyfish are often covered with long red wheals which, if the victim survives, can result in permanent scarring.<sup>72</sup> Reactions to the sting may, however, in some cases, be delayed for some time.<sup>80</sup> The toxin of this species has three modes of action – it damages the skin, attacks the red blood cells and, most importantly, can affect the heart and respiration.<sup>76,83</sup>

The treatment for *Chironex* stings is the immediate application of vinegar by pouring it liberally over the affected area to prevent further nematocyst discharge. Irrigation with fresh water is contraindicated as it will cause further nematocyst discharge. In severe cases, CPR can be life saving<sup>83</sup> and the use of a specific *Chironex fleckeri* antivenom produced by the Commonwealth Serum Laboratories in Melbourne, Australia is beneficial<sup>53,61</sup> but may need to be given within minutes and possibly at high doses to be effective.<sup>82</sup> The recommended dosage should not be reduced for children.<sup>80</sup> Fenner<sup>82</sup> has suggested that the use of antivenom with magnesium might be worth considering if the antivenom alone fails.

It is worth reiterating that vinegar is essential to inhibit the discharge of further nematocysts of *Chironex* but will not reduce pain and, paradoxically, may initially increase pain. Compression-immobilization bandaging, once thought to be helpful,<sup>53,84</sup> is now not recommended.<sup>82</sup>

In Australia, a third type of jellyfish sting is the so-called 'Irukandji sting syndrome' caused by a minute carybdeid jellyfish (*Carukia barnesi*) and a number of other species;<sup>82</sup> this sting can result in severe joint, low back, and trunk pains; muscle cramps; anxiety; headache; shivering; sweating; hypotension and cardiac involvement.<sup>53,76,82,83,85</sup> Stings usually occur in the water in the afternoon and the jellyfish, being so small, is often not seen.

In Irukandji syndrome, initial treatment with vinegar should be used to prevent further envenomation and this should be followed by treatment for the pain using ice packs.<sup>82</sup> The use of 20 mg i.v. furosemide (frusemide) proved beneficial in one case.<sup>80</sup> Immediate transfer to hospital for intensive care treatment is advisable. The use of sublingual nitrate sprays, topical analgesia (topical Fentanyl) and i.v. magnesium sulphate are all discussed by Fenner.<sup>82</sup>

Other jellyfish known to cause stinging of humans include the large carybdeids ('firejellies') in Tomoya or Morbakka stings; the 'hairjelly' or 'sea blubber', *Cyanea*, and *Pelagia noctiluca*, the 'mauve blubber'.<sup>72,83</sup>

There are, of course, a large number of other potentially dangerous marine animals, including stingrays, the blue ringed octopus, sea urchins, starfish, stonefish and lion fish amongst others.<sup>79</sup> The management of such a diverse range of envenomations is obviously beyond the scope of this chapter, but the topic has been well reviewed by Williamson et al.,<sup>79</sup> Fenner,<sup>82</sup> Pearn,<sup>83</sup> Auerbach<sup>86</sup> and is covered in detail in Brent et al.<sup>65</sup>

## ACKNOWLEDGEMENTS

We would like to thank Dr Gerhardus Muller for his comments, criticisms and his many constructive suggestions.

## SUDDEN INFANT DEATH SYNDROME

Sudden unexpected infant deaths have been recognized since antiquity, but it was not until post-neonatal mortality rates substantially fell in the Western world during the early part of the twentieth century that greater attention was paid to the phenomenon of unexpected and unexplained deaths in apparently healthy infants.

Sudden infant death syndrome (SIDS) was proposed in 1969 as a descriptive term for those infant deaths that were unexpected and remained unexplained after thorough investigation. In 1994 a more precise definition of sudden infant death syndrome was proposed.<sup>87</sup>

*The sudden death of an infant, which is unexplained after review of the clinical history, examination of the circumstances of death, and postmortem examination*

In 1892 Templeman,<sup>88</sup> and in 1904 Willcox<sup>89</sup> noted the excess of unexpected infant deaths in the poorest families, and agreed that the majority of such deaths were due to accidental overlaying whilst bed-sharing, recommending that parents be encouraged to use cribs for their babies to sleep in. One hundred years later the American Academy of Pediatrics made a similar recommendation, though the evidence for this has been the subject of wide debate.<sup>90–92</sup>

## EPIDEMIOLOGY OF UNEXPECTED DEATHS

### Diagnosis of SIDS and subsequent decline in the SIDS rate

The diagnosis of SIDS is unique in that it is not a cause of death but rather a diagnosis of exclusion, arrived at only after thorough investigation. Only when recognized causes of infant death have been excluded can the death be labeled SIDS and there are valid concerns that such labeling could attribute too much homogeneity to what might be disparate causes of death.<sup>93,94</sup>

From the 1950s to the late 1980s the number of unexpected and unexplained deaths in the UK was probably between 1400 and 2000 per year, giving a rate of around 2/1000 live births.<sup>95</sup> In the late 1980s epidemiological evidence from several different countries<sup>96–101</sup> suggested that SIDS could be related to infants sleeping in the prone position. In 1991 the 'Back to Sleep' campaign was initiated in the UK to encourage parents to avoid placing their infants on their front and the SIDS rate fell from a peak of 2.3 deaths/1000 live births in 1988 to 0.7 per 1000 live births in 1994 (Fig. 6.2). Similar dramatic reductions have since been observed in many other countries following such an intervention campaign. The possibility that other modifiable risk factors might be amenable to further interventions in this mysterious group of conditions has led to multiple epidemiological studies of the residual deaths. Further identification of other unsafe infant care practices, particularly within the sleep environment have led to additional amendments and revision of the initial campaign message and probably helped to reduce the rate further over the last 10 years to 0.4 per 1000 live births. This equates to the prevention of over 10 000 infant deaths in England and Wales since the campaign was first launched, and more than 100 000 worldwide.

The fall in numbers of deaths has been accompanied by several major changes in the epidemiologic characteristics of SIDS,<sup>102</sup> most notably an increased proportion of the deaths occurring in deprived families and whilst bed-sharing. Some pathologists are reluctant to use the label 'SIDS', preferring to use the term 'unascertained', when parents have consumed alcohol or illegal drugs or the circumstances of death raise the unproven possibility of overlaying.<sup>103</sup> Such practices emphasize the importance of a detailed multiprofessional review in establishing the final allocated 'cause' of unexpected infant deaths (see later).

### Epidemiologic features of SIDS

Prior to the 'Back to Sleep' campaign in 1991, many epidemiologic characteristics of SIDS had been described. Unexpected, unexplained deaths of infants occurred in all cultures but the incidence varied widely. There were relatively fewer SIDS deaths in several Asian cultures but more deaths amongst certain indigenous populations such as Maoris, Australian Aborigines and Native Americans. The incidence in the UK

Fig. 6.2 SIDS rate in England and Wales 1985–2005 (Office for National Statistics and the Foundation for the Study of Infant Deaths).

was lower than in the white populations of New Zealand and Australia but higher than in the Nordic countries. The majority of deaths occurred within the first 6 months of life, with a peak around the third and fourth month. Many of the deaths occurred during the night-time sleep periods, and although some studies noted an excess of deaths at weekends this has not been consistent.<sup>104–108</sup> More deaths occurred in males and in winter months. SIDS occurred in all social strata but was more common in the socioeconomically deprived groups, particularly if parents smoked. Many of the SIDS infants had lower birth weight, shorter gestation and more perinatal problems. There was a strong correlation with young maternal age and higher parity and the risk increased with multiple births, single motherhood or a poor obstetric history.

Many of the risk factors associated with SIDS are also closely associated with other infant deaths; only the characteristic age distribution and high prevalence of tobacco exposure distinguished SIDS infants from infants who died suddenly and unexpectedly from identifiable causes.<sup>109</sup> Deaths from congenital malformations decrease steadily from early age whilst deaths from respiratory or infectious diseases remain relatively constant over the first year of life.<sup>110</sup> Overall, infant mortality rates are highest in the first month after birth, when infants are at their most vulnerable.<sup>111,112</sup> However few SIDS deaths occur in the first month, with a peak occurring at 3–4 months and a steady decline thereafter. Whilst smoking is most prevalent amongst mothers in the more disadvantaged socioeconomic groups, the incidence of smoking is higher amongst the mothers of SIDS infants than matched controls in all social groupings.<sup>108,113</sup>

It is perhaps in the infant sleeping environment that the epidemiological study of SIDS has had the most success. Prone sleeping was actively encouraged in some Western countries in the 1960s and 1970s<sup>114</sup> to improve infant posture and skeletal growth,<sup>115</sup> prevent flattening of the skull<sup>116,117</sup> and avoid the perceived risk of aspiration in the supine position.<sup>118</sup> This was also a time when neonatal intensive care units were expanding and apparent benefits of using the prone position were found amongst pre-term infants including less apnea, better gastric emptying, better oxygenation, and more effective ribcage and abdominal coupling with decreased work of breathing.<sup>119–122</sup> What was best in the early neonatal period for the relatively small number of pre-term infants however was not necessarily beneficial for the rest of the infant population or beyond the immediate neonatal period. Historical references to infant sleeping position in art and early medical texts suggest that very few if any infants were placed prone to sleep before the twentieth century.<sup>123</sup>

In the 1980s a number of population-based studies identified the prone sleeping position and heavy wrapping and/or warm environments as major risk factors associated with SIDS.<sup>101,124–126</sup> Gilbert found that the combination of viral infection and heavy wrapping was associated with a high relative risk<sup>124</sup> whilst in a study from Tasmania Ponsonby<sup>125</sup> found the risk from prone position was potentiated by overnight heating, swaddling, recent infection and mattress type. Williams confirmed these findings in a study from New Zealand and found a small additive effect if the mother smoked.<sup>127</sup>

### ‘BACK TO SLEEP’ CAMPAIGNS

Although positioning and wrapping were not sufficient to fully explain the death they could be linked to some causal chain of events and intervention campaigns to advise parents against these practices were instigated in many countries from 1990 onwards. In all countries in which risk reduction campaigns were conducted, a fall in infant prone sleeping was followed by a fall in SIDS rate. Also publicized in some campaigns was the potential risk of heavy wrapping. Studies of control infants in Avon before and after the ‘Back to Sleep’ campaign<sup>124,128</sup> showed that the thermal resistance (tog value) of bedding and clothing with which normal infants were usually covered fell by almost half after the ‘back to Sleep’ campaign, and the winter peaks of SIDS deaths have almost disappeared in the UK.

### EPIDEMIOLOGIC CHARACTERISTICS SINCE THE FALL IN NUMBERS OF SIDS

#### Distal factors

A longitudinal study conducted in Avon from 1984 to 2003<sup>102</sup> showed that amongst SIDS families the proportion from the most disadvantaged socioeconomic groups rose from 47% to 75%. This change in the socioeconomic distribution of SIDS families was accompanied by an increased proportion of single mothers, younger mothers, mothers who smoke and lower birth weight infants. The prevalence of maternal smoking during pregnancy amongst SIDS mothers (80–90%) was twice the level expected amongst control mothers with similarly deprived socioeconomic backgrounds,<sup>113</sup> lending support to the hypothesis that infant exposure to tobacco smoke is some part of a causal mechanism. There is a clear increase in risk of SIDS with increasing levels of exposure to tobacco smoke, both in utero and after birth<sup>129–131</sup> and a recent review by Mitchell and Milerad suggests this risk has grown despite advice against smoking in almost all risk reduction campaigns.<sup>132</sup> In recent studies over one third of SIDS victims were preterm, compared to a UK population prevalence of 5% for preterm delivery. For such infants the effects of other risk factors in combination with the increased risk from prematurity leads to very high risk (e.g. for preterm or low birthweight infants put down on the side: OR = 9.13 [95% CI 4.93–16.90], and for those put down prone: OR = 62.8 [95% CI 12.06–327]).<sup>133</sup>

The previously recognized increase in risk of SIDS with increasing birth order may be changing. The longitudinal study from Avon suggests that SIDS is now most common amongst first-born infants.<sup>102</sup> Several studies have now shown no evidence that immunization is associated with an increased risk of SIDS, and some evidence that the risk may be reduced.<sup>134</sup>

#### Proximal factors

New evidence on risks within the infant sleeping environment has changed some of the advice now given to parents.

### **Risk of positioning infants on the side to sleep**

Before the 'Back to Sleep' campaign few studies had looked at the use of the side sleeping position and the findings were inconclusive;<sup>126,135-137</sup> the side position with the lower arm extended to avoid infants rolling on their front was suggested as a safe alternative to supine sleeping. More recent studies<sup>128,138-142</sup> show the side sleeping position carries a significant risk, partly because the position is unstable, and some infants who roll from side to prone have difficulty extricating themselves from this position. Certain infants with abnormalities of the upper airway (e.g. Pierre Robin syndrome) may experience airway obstruction if placed supine, and some may benefit from side or occasionally prone positioning for sleep, but many can be safely placed supine. Whilst gastroesophageal reflux is slightly reduced in the prone position compared to supine, the increased risk of SIDS means that this position should not be used to treat reflux unless this is causing severe symptoms (e.g. growth failure or recurrent aspiration) that have not responded to alternative treatments. Apart from these uncommon conditions, in most countries the only recommended sleeping position for infants is supine. In some countries use of the side position may have increased despite knowledge of its potential risks,<sup>143,144</sup> many parents and health care professionals citing either outdated SIDS guidelines or fear of aspiration, cyanosis or apnea when the infant is placed supine.<sup>145-148</sup> These concerns are not supported by findings from either pathology or epidemiology. A review of 196 infant deaths in South Australia found evidence of aspiration of gastric contents into the airways and alveoli of three infants, all of whom were found face down in the prone position.<sup>149</sup> Similar findings linking aspiration with the prone rather than the supine position have been found in the UK,<sup>150</sup> whilst a large cohort study of over 8000 surviving UK infants showed no association between the prevalence of vomiting and infant sleeping position.<sup>151</sup> A recent study from New Zealand<sup>152</sup> has linked the increase in sleeping supine with nonsynostotic plagiocephaly, recommending that parents should vary the infant head position when putting them down to sleep and to give their infants 5 min of supervised 'tummy time' each day. This may also help reduce the risk of 'unaccustomed prone' position, when infants roll into or fall asleep in this position for the first time. In studies in Australia, the US and the UK, supine sleeping was not linked to apnea or cyanosis and no demonstrable increase in symptoms or illness amongst supine sleeping infants was found.<sup>151,153,154</sup>

Studies in the UK<sup>155</sup> and in Canada<sup>156</sup> have shown minor differences in gross motor skills in early infancy with infants who usually sleep supine, showing slightly slower developmental progress than those who sleep prone. In the UK study these differences had disappeared by age 18 months, but in the smaller Canadian study the differences, though small were still present at 15 months.

Both the minor developmental disadvantages and the risk of positional plagiocephaly from supine sleep position can be largely prevented by the use of periods of 'tummy time' – placing infants prone for regular periods when awake and supervised.<sup>157</sup>

### **Risk of soft sleeping surfaces**

Soft surfaces for infant sleep have been associated with an increased risk of SIDS<sup>108,158,159</sup> and there is some evidence that this risk is even higher in combination with established risk factors such as the prone sleeping position<sup>160,161</sup> and heavy wrapping or warm environment.<sup>162</sup> Pillows, cushions and bean bags have been used not just as a sleep surface but also as a prop to maintain the body position of a sleeping infant or provide easier access to bottle feeding. This practice presents the additional risk, even to supine sleeping infants, of such objects potentially covering the external airways.<sup>163</sup> This includes the adult size V-shaped pillows used to facilitate breastfeeding.<sup>164</sup> The current advice is to sleep infants on a firm mattress and away from soft objects.

### **Risk of bedding covering the infant**

It is not uncommon for SIDS infants to be discovered dead with bedclothes covering the head and face, indeed 'accidental mechanical suffocation'

was, prior to the introduction of the term 'sudden infant death syndrome', a term commonly used to describe these deaths, despite a lack of any evidence of suffocation or asphyxia.<sup>165-169</sup> Uncontrolled observations from early studies<sup>170-173</sup> that around one fifth of SIDS infants were found with bedding covering the face or head were attributed to the agonal struggle just prior to death. Subsequent findings of reduced arousability during the sleep of SIDS infants,<sup>174</sup> observations of undisturbed bedding<sup>175</sup> and lack of such a struggle during recordings of several SIDS infants who died whilst on a monitor<sup>176</sup> do not support the idea that head covering is just a consequence of the terminal event. Whilst postmortem examination cannot distinguish between the possible mechanisms of airway obstruction, re-breathing or thermal stress, over 20% of SIDS victims are found with bedding over the head,<sup>102,140,142,161,170,177-180</sup> ten times more than the incidence amongst live age-matched controls and highly significant even after adjusting for other risk factors. Studies have linked head covering to loose bedding, infant movement down under the covers and the use of duvets or quilts.<sup>102,108,181-183</sup> In 1997 a 'Feet to Foot' campaign, was launched in England and Wales by the Foundation for the Study of Infant Death to encourage parents to tuck the bedding in firmly, avoid using duvets or pillows and place the feet of the infant at the foot of the cot. This approach was subsequently endorsed by the American Academy of Pediatrics.<sup>90,184</sup>

### **Risk associated with unobserved sleep**

Despite a complete absence of supporting evidence, many childcare 'experts' in the 1950s to 1990s recommended that infants should sleep in a room separately from parents.<sup>185,186</sup> Throughout history most human infants slept in a consistently rich sensory environment with close and continual contact between mothers and babies and the solitary sleep experience of Western societies was a recent development.<sup>187</sup> Reports from New Zealand and the UK showed that the risk of SIDS was lower if infants shared a bedroom with parents,<sup>188-190</sup> and further analysis of the UK data suggests that parental supervision for day-time sleeps is equally important.<sup>191</sup> Parental presence during infant sleep does not guarantee the infant would be constantly observed, nor, indeed that parental intervention would prevent death from occurring. However having the sleeping infant nearby during the day may alert parents to circumstances such as young infants rolling from the side to the prone position or bedclothes covering the infant head or face.

### **Risk associated with bed-sharing**

Unexpected infant deaths can occur in any sleep environment. Recent case-control studies show that up to half of the deaths occur whilst infants share a sleep surface ('co-sleep') with an adult,<sup>142,161,192,193</sup> a marked rise from studies in the 1980s. This proportional rise in co-sleeping SIDS deaths has led some authorities, including the American Academy of Pediatrics<sup>90</sup> to recommend against bed-sharing.

Longitudinal data from Avon over the last 20 years shows that although the *proportion* of bed-sharing deaths rose from an average of 16% of all SIDS deaths prior to the 'Back to Sleep' campaign to 34% after the campaign, the *number* of bed-sharing SIDS deaths fell (by 50%), but this is less marked than the 80% fall in deaths occurring in the cot.<sup>102</sup> More worrying is the rise in both prevalence and number of SIDS infants found after sleeping with a parent on a sofa, which carries a markedly increased risk.<sup>128,142,190</sup> At least some of these deaths occurred when mothers inadvertently fell asleep whilst feeding on a sofa during the night.

Bed-sharing is perceived to be and is treated as a risk factor in the field of SIDS epidemiology and when considered in this rudimentary way there is ample evidence to advise against such a practice. On closer inspection however there are several things to be considered. Adjusting for potential confounders specifically associated with the adult co-sleeping environment such as recent alcohol consumption, sleep deprivation, overcrowded conditions and adult-sized duvets renders bed-sharing nonsignificant as a risk factor suggesting it is not bed-sharing itself but the particular circumstances in which bed-sharing occurs that puts an infant at risk.<sup>190</sup> An intriguing aspect of this debate is that in certain Asian cultures where particular forms of mother-infant co-sleeping (sleeping on futons) is common such as Japan<sup>194</sup> and Hong Kong<sup>195</sup> the cot death

rates are very low; corresponding to findings in the Bangladeshi<sup>196</sup> and other Asian<sup>197</sup> communities in the UK and the Pacific Island communities in New Zealand.<sup>198</sup> Another aspect is that of generalization: the majority of bed-sharing SIDS mothers smoke whilst the majority of bed-sharing mothers in the population do not. The magnitude of any increase in risk for nonsmoking breast-feeding mothers who are bed-sharing on a firm flat surface, and who have not taken alcohol or other drugs, is unclear, but certainly small.<sup>142,190,199–201</sup> There is also the wider debate beyond the field of SIDS in terms of the potential advantages associated with bed-sharing. Before the last century and in most nonWesternized cultures today the normative practice is for the mother to share a sleep surface with the infant.<sup>202</sup> Postulated, but largely unproven potential physiological benefits of close contact between infants and care-givers include improved cardiorespiratory stability and oxygenation, fewer crying episodes, better thermo-regulation, an increased prevalence and duration of breast-feeding, and enhanced milk production.<sup>203,204</sup>

It is becoming clear from recent studies that bed-sharing both for infants and mothers results in complex interactions which are completely different to isolated sleeping and which need to be understood in detail before applying simplistic labels such as 'safe' or 'unsafe'.<sup>205–207</sup> The unusual level of criticism and hostility generated by the recent Policy Statement by the American Academy of Pediatrics against bed-sharing<sup>90–92</sup> is a testament to the current polarized debate. Current advice in the UK does not advise against bed-sharing but describes particular circumstances when bed-sharing should be avoided. Co-sleeping with an infant on a sofa should always be avoided.

### *Apparent protective effect of infant pacifier use*

The current debate on bed-sharing holds many parallels with the debate on dummy use (pacifiers). Several studies have examined the prevalence of infant dummy use and shown a reduced risk for SIDS.<sup>142,161,193,208–213</sup> Actively encouraging dummy use, like the advice on bed-sharing, has been met with criticism mainly concerning the potential adverse effects on breast-feeding. The evidence of a significant association is not in dispute but whether this association is causal in itself is still being debated.<sup>91,214,215</sup> The mechanism by which a pacifier might reduce the risk of SIDS, or by its absence increase the risk, is unknown, but several mechanisms have been postulated. These include avoidance of the prone sleeping position, protection of the oropharyngeal airway, reduction of gastroesophageal reflux through non-nutrient sucking<sup>209</sup> or lowering the arousal threshold.<sup>216–218</sup> These mechanisms however assume the presence of a pacifier in the infant's mouth but the evidence suggests pacifiers generally fall out within 30 minutes of the infant falling asleep<sup>219</sup> whilst many of the night-time deaths are thought to occur much later during the sleep.<sup>191</sup> Alternatively dummy use may be a marker for some protective factor that has eluded measurement. The physiology not only of infant dummy use, but also non-use amongst routine users and infant thumb sucking, which leads to identical physiological effects but is inhibited by pacifier use<sup>220</sup> deserves further investigation.

Before recommending the use of pacifiers the potential disadvantages must be considered. There appears to be a clear relationship between frequent or continuous pacifier use and a reduction in breastfeeding,<sup>221–224</sup> and a significantly higher risk of otitis media and oral yeast infection.<sup>225–228</sup> Other potential disadvantages include accidents (airway obstruction<sup>229</sup>), strangulation by cords tied to the dummy,<sup>230</sup> eye injuries<sup>231</sup> and dental malocclusion.<sup>232</sup> The current advice in the UK is no longer to discourage the use of dummies but falls short of recommending them as a preventive measure against SIDS.

## INFANT PHYSIOLOGY AND PATHOPHYSIOLOGY OF UNEXPECTED DEATH

Whilst the final sequence of events leading to death is not known for the great majority of unexpected infant deaths, and there is no reason to presume that there is a single mechanism involved, a number of studies have been published of unexpected infant deaths that have occurred whilst the infant was undergoing physiological recordings.<sup>176,233</sup> These

recordings have shown a range of physiological events leading up to the final collapse and death, but in some infants there was an initial period in which there was normal respiratory activity but a relative tachycardia. In several infants the final event was one of profound bradycardia, with respiratory activity continuing until a late stage. In many of these recordings, despite the carers having been alerted to the bradycardia by audible alarms, and having attempted resuscitation, this was not successful. This sequence of events is more suggestive of a cardiovascular rather than a respiratory event as the primary trigger for the final collapse. One possible physiological explanation for such a pattern might be a catastrophic fall in blood pressure as a consequence of sudden peripheral vasodilatation, e.g. in response to toxins or as a consequence of heat stress.<sup>234</sup>

Several population-based case-control studies have shown that infants who died unexpectedly were more heavily wrapped and more likely to be sleeping in warm rooms than age and community-matched controls.<sup>108,101,201</sup> The increased risk of SIDS from heavy wrapping was greatest for the older infants (more than 3 months of age), and was especially high for those infants with evidence of an acute viral upper respiratory tract infection.<sup>124</sup> In a study of the metabolic response to acute viral upper respiratory tract infection, younger infants (less than 3 months of age) commonly showed a fall in metabolic rate with infection, whilst those over 3 months usually showed an increase, commonly accompanied by fever.<sup>235</sup> The metabolic rate of infants during sleep rises over the first few months after birth, such that by 3 months of age healthy infants excrete up to 50% more heat per unit surface area than in the first week after birth.<sup>236,237</sup> Thus infants over 3 months of age might be more at risk from heavy wrapping that compromised their ability to lose heat, particularly at the time of an acute minor viral infection.

In a population-based observational study of infant thermal care at home most mothers accurately achieved conditions of predicted thermal neutrality for their infants, but younger mothers, those who smoked, and those who did not breast-feed were more likely to wrap their infants more heavily.<sup>238</sup> In a prospective longitudinal laboratory study of mothers and infants sharing a room or sharing a bed for overnight sleep, despite a much warmer microenvironment, infants thermoregulated more effectively, with a slightly greater diurnal fall in rectal temperature when bed-sharing with their mother than when sleeping in a cot adjacent to the mother's bed<sup>207</sup>.

The development of the diurnal fall in core temperature occurs at ages between approximately 3 and 4 months, occurring earlier in girls and breastfed infants than in boys or bottle fed infants.<sup>239</sup>

Blackwell and Morris have each shown the potential importance of toxigenic Staphylococci as contributory agents to circulatory collapse and sudden death in infancy.<sup>240,241</sup> Toxin production by such Staphylococci increases with increasing environmental temperature and is minimal below 37 °C.<sup>240</sup> SIDS victims have increased nasopharyngeal colonization with staphylococci compared to healthy age and community-matched controls.<sup>234</sup> In the prone position, or with head covering (particularly in the presence of potential re-breathing), nasopharyngeal temperature is likely to rise above the normal value of 32 °C, with resultant increase in toxin production by any toxigenic staphylococci present on the mucosal surface.<sup>242</sup> Transmucosal absorption of toxin might thus lead to circulatory collapse and death without the need for invasive infection to occur.

Elevated levels of interleukin 6 (IL-6) in the cerebrospinal fluid of SIDS victims compared to age-matched controls dying of known causes raised the possibility of a vigorous pro-inflammatory response being part of the pathophysiology of SIDS.<sup>243</sup>

Drucker has recently shown that common polymorphisms, leading to high levels of pro-inflammatory cytokines (e.g. IL-6, VEGF) or low levels of anti-inflammatory cytokines (e.g. IL-10) are associated with increased risk for unexpected deaths in infants.<sup>242</sup> A high pro-inflammatory response to infection, with vigorous sympathetic activity including peripheral vasoconstriction and pyrexia might indirectly lead to further toxin production in the nasopharynx.

The relationship between the pro-inflammatory cytokine IL-1 $\beta$  and the risk of SIDS is complex, and Moscovis et al<sup>244</sup> have shown potentially important ethnic differences in the patterns of gene polymorphisms. In both Aboriginal Australian and Bangladeshi infants a particular polymorphism (TT) is found, which is uncommon in infants of European origin. This polymorphism is associated with a marked increase in IL-1 $\beta$  production, and increased pro-inflammatory responses on exposure to tobacco smoke. This may partially explain the major difference between Aboriginal Australian infants with high maternal smoking rates and high SIDS rate, and Bangladeshi infants, who are genetically similar with regard to IL-1 $\beta$ , but have very low rates of maternal smoking and very low SIDS rates.

The potential interaction between genetic and environmental factors is further exemplified by the anti-inflammatory cytokine IL-10, production of which is markedly decreased by exposure to tobacco smoke.<sup>244</sup>

Associations have also been described between the risk of SIDS and polymorphisms of genes involved in the development of the autonomic nervous system,<sup>245</sup> various cardiac channelopathies,<sup>246</sup> and the serotonergic system in the brainstem.<sup>247</sup> This latter group is of particular interest in the light of recent histological evidence of abnormalities of serotonergic neurons in the brainstem of SIDS victims.<sup>248</sup>

### ‘TRIPLE RISK’ HYPOTHESES AND PROSPECTS FOR PREVENTION OF SIDS

There is considerable evidence that SIDS represents a possible consequence of a wide range of genetic/developmental/environmental interactions.

The ‘triple risk’ hypothesis – which envisages SIDS occurring as a result of a final insult (one which is not usually fatal on its own) that affects a baby with an intrinsic vulnerability (arising from genetic or early developmental factors), at a potentially vulnerable stage of physiological development (e.g. immunological, respiratory, cardiovascular, thermal), has been proposed in various forms by a number of authors over the past 15 years.<sup>249</sup>

The recent developments in our knowledge of environmental, immunological, genetic and physiological factors in infants, and recognition of the changes in all these systems that occur during the first few months after birth as outlined earlier strongly support a ‘triple risk’ model of causation for most unexpected infant deaths, including some for which a partial or even a complete ‘explanation’ can be identified on thorough investigation.

This approach to understanding the pathophysiological processes that may contribute to unexpected infant deaths holds great promise for targeted interventions to further reduce the number of such deaths.

### INVESTIGATION AND CLASSIFICATION OF UNEXPECTED INFANT DEATHS

The process of investigation after any unexpected infant death should seek to collect as much information as possible about factors that may have contributed to the death, in order to help understand (and in future possibly prevent) such deaths. It is essential however that the investigation is conducted with both thoroughness and sensitivity, bearing in mind that whilst the great majority of such deaths are natural tragedies it is important to identify those instances in which neglect or abuse may have caused or contributed to the death.<sup>250,251</sup>

The precise nature of the investigation and composition of the investigating team will vary according to the requirements of the relevant state or national legislation. In England, regulations introduced under recent legislation have defined these requirements, which will be mandatory from 2008.<sup>252</sup> These regulations were based upon the conclusions of the Working Party chaired by Baroness Helena Kennedy, which involved wide consultation and contributions from pediatricians, pathologists, police, coroners, social services, Government, the Judiciary and representatives of parents’ organization.<sup>251</sup> An overview of the requirements of these regulations is given below as an example of the needs for thorough and integrated investigations.

### KENNEDY PROTOCOL FOR INVESTIGATION OF UNEXPECTED INFANT DEATHS<sup>250,251</sup>

The protocol involves emergency first responders, clinical staff, police, pathologists, coroners, social services and other agencies working together and sharing information to minimize duplication and maximize available information to help identify contributory or causal factors. The initial investigation must include a careful and detailed medical, social and environmental history, with a thorough review of the circumstances of death, including visiting and carefully examining the scene of death. This home visit with the parents or carers should ideally be conducted jointly by a pediatrician and a child protection police officer whose combined expertise in infant physiology and development and in forensic examination respectively maximize the potential to recognize both natural and unnatural contributory factors. The pathologist (who must have appropriate pediatric training) should conduct a thorough postmortem examination to an evidence-based protocol,<sup>108,251,253</sup> and should be provided with as full an account as possible of the history, clinical examination of the infant and scene examination before commencing the procedure. At all stages of the investigation all agencies must continue to share information and, except in those rare instances in which criminal prosecution might be compromised by so doing, the parents must be kept fully informed. Meeting the needs of parents for care and support must be central to the process. Finally, when all investigations are completed – usually 2–4 months after the death, a multi-agency case review meeting should be convened – usually in the primary care setting. The aim of this meeting is to ensure that all professionals share information; review, and if possible come to conclusions about the cause of or contributory factors to the death; agree who is to inform the parents of the results of the investigations (usually the pediatrician plus a member of the primary health care team); and produce a report for the coroner to inform and facilitate the Inquest.

Thus the ‘cause’ of death as finally certified through the coroners’ system reflects the full breadth of professional expertise in understanding both natural and possible unnatural contributory or causal factors.

The careful review of potentially contributory factors allows unexpected infant deaths to be separated into those for which no significant contributory factors were identified, those in which one or more factors were found that may have contributed to the death but do not in themselves give a complete explanation, and those for which a complete and sufficient explanation was found. Several classifications of unexpected infant deaths using such approaches have been published, and allow studies to distinguish varying degrees of contribution from environmental, infectious, physiological or genetically determined factors in different infants.<sup>250,254</sup> Table 6.7 shows the Avon Clinicopathological Classification, which is based upon this approach, and has been widely adopted in the UK.<sup>102,108,250,251</sup>

Most epidemiological background factors associated with unexpected but explained infant deaths (i.e. those deaths classified as III in Figure 6.3, e.g. previously unrecognized overwhelming infection) are very similar in character to those factors found amongst SIDS victims (i.e. those deaths classified as I to IIB in Figure 6.3).<sup>109</sup> Indeed there is some evidence that improved investigation has led to an increase in the proportion of deaths that are explained, in particular deaths due to metabolic disorders.<sup>102,108,250</sup> Thus it is important that similar investigation should be applied to all such deaths, and any studies of unexpected infant deaths should include all sudden unexpected deaths in infancy (SUDI), and not be restricted to those classified (either by arbitrary assignment at the beginning of the investigative process, or at the end of a full investigation) as SIDS.

Although there has been some reluctance by professionals to fully engage in such a process, on the grounds that it is demanding of both time and energy, and may not be sustainable, recent studies have shown that with minimal additional resources such an approach can be implemented and sustained over many years.<sup>102</sup> Certainly the savings – both financial and emotional – from avoidance of inappropriate criminal

Table 6.7 The Avon Clinicopathological Classification of Sudden Unexpected Infant Deaths<sup>164,165\*</sup>

Classification	0	I A	I B	II A	II B	III
Contributory or potentially 'causal' factors	Information not collected	Information collected but no factors identified	Factor present but not likely to have contributed to ill health or to death	Factor present, and may have contributed to ill health, or possibly to death	Factor present and certainly contributed to ill health, and probably contributed to the death	Factor present, and provides a complete and sufficient cause of death
History: (1)						
Death-scene examination (2)						
Pathology (3)						
Other (specify)						
Other evidence of neglect or abuse?						
Overall classification (4)						

The grid is completed at the multidisciplinary case discussion meeting (usually held 8–12 weeks after the death). An entry must be made on the line of each heading line, and a score (0–III) accorded to each line as agreed by all professionals present. The overall score is generally equal to the highest score within the grid. A score of III equates to a complete and sufficient cause of death. Scores of I–II B meet the definition of SIDS. 1, To include a detailed history of events leading up to the death, together with medical, social and family history, plus explicit review of any evidence suggesting past neglect or abuse of this child or other children in the family. 2, results of detailed review of the scene of death by the paediatrician and police child protection officer in the light of the history given by parents or carers. 3, pathological investigations to a standardized protocol, including gross pathology, histology, microbiology, toxicology, radiology, clinical chemistry, and any relevant metabolic investigations, including frozen section of liver stained for fat. 4, this will generally equal the highest individual classification listed above.

charges, together with the recognition of genuine child protection issues, whilst providing appropriate support and care to families – warrant the adoption of a robust and thorough but sensitive investigation after all unexpected infant deaths.

Bereaved parents and their organizations have spoken strongly in favor of such an approach, in which the needs of parents for help, support, information and explanations, whilst avoiding blame or unwarranted suspicion, are explicitly integrated into the practice of all professionals involved in the process.

## CURRENT RECOMMENDATIONS

The scientific rigor with which data is gathered is not easily applied to the dissemination of the results and formulating advice can be a

subjective exercise of weighing up the available evidence and constrained by attempts to simplify the message. The debate on the safety, advantages and disadvantages of infant care practices must be informed not just by epidemiological evidence from one narrow field but from many disciplines from different fields if it is to become more than the exchange of mere opinion. The advantages of getting the advice right are evident in the dramatic fall in SIDS deaths after advice against the prone sleeping position, but it should be remembered that adoption of the prone position was initially largely a consequence of medical advice.

## INTRODUCTION

Developmental pediatrics is concerned with the processes of children's learning and competent adaptation to the environment from birth to adulthood. There are three purposes:

1. to promote optimal physical and mental health and development for all children, applying principles of prevention of impairment, wherever possible, and to reduce, where possible, disability and maximize function (Table 7.1);
2. to ensure early diagnosis and effective treatment of impairments of body, mind and personality;
3. to discover the cause and means of preventing such impairments.

Increasingly pediatricians and other clinicians caring for children will find their time spent with chronic illness, chronic physical or mental disability, learning or behavioral problems. Acute illnesses are likely to be shorter, self-limiting or more rapidly responsive to treatment. This chapter looks at the process of development, how it can be observed and how abnormalities can be identified and interpreted. The context for observing a child's development is the family, school and community. Family, educational, social, cultural, spiritual, economic, environmental and political forces act favorably or unfavorably, but always significantly, on children's health and functioning.<sup>1</sup>

## THEORIES OF CHILD DEVELOPMENT

There is a particularly long developmental period in humans, which must be adaptive for social and cognitive competence. Childhood marks the change from the entirely dependent baby into the mature independent adult. During this period the child:

1. builds up a store of knowledge about the environment;
2. learns motor skills to survive;
3. learns a language with which to communicate and think;
4. develops a sense of self, self-regulation of emotions and behavior and the coping strategies for successful interpersonal relationships.

Philosophical views of child development (e.g. Rousseau) were replaced last century by the more empirical approach of direct observation of children's behavior and experimentation. Theories have included:

1. the 'maturational' view exemplified by Gesell (i.e. developmental progression depends upon neurological maturation);
2. 'behavioral' (i.e. changes in the environment are the most important influence in shaping the child);
3. 'psychoanalytic/psychosocial' theories of Freud and Erikson (unconscious motivations);
4. 'cognitive' theories developed by Piaget, which emphasize stages of development and the mental process of constructing knowledge from interaction with the environment that builds the next stage upon the previous one.

These theories continue to influence the ways in which we think about a child's development. Mental growth and development are dependent both on maturation of the nervous system and on experience. At 5 months the fetus has the full adult complement of 12 billion or more nerve cells. As the fetus and infant grow, the developing interconnections between these cells result in patterns of behavior that are generally similar, but the acquisition of knowledge and the refinement of skills depend on the child's opportunity to observe, copy and experiment. Neuronal maturation of the brain continues into postnatal life and myelination is completed in sensory and motor areas first and association areas last. Neural systems stabilize to optimal patterns of functioning via a process of reorganization and subtraction within neonatal architectural constraints and biases, which lead to recruitment of specific pathways. There is a capacity for plasticity, which becomes less flexible with age. At an anatomical level, the resultant brain-behavior relationships show domain specificity (e.g. specific areas devoted to language processing and learning).

There are many other theories which contribute to our understanding of child development.

1. Nativist or innate theories continue to be influential, for example in language learning<sup>2</sup> and motor development – theories of self-organization.<sup>3</sup>
2. 'Modern social learning constructivist' theories emphasize cognitive processes as mediators of environmental/behavioral influences.
3. Bronfenbrenner's 'ecological theories' emphasize the importance of the context in which children grow up, the goodness of fit and other features of the environment (i.e. the family situation, parents working, early child care and the wider cultural influences).

**Table 7.1** Definitions of impairment and disability. There are many definitions and the term is used differently in different legislation

#### The Children Act 1989

'A child in need' is unlikely to achieve or maintain or to have the opportunity of achieving or maintaining, a reasonable standard of health or development without the provision for the child of services by a local authority

The health or development of 'a child in need' is likely to be significantly impaired or further impaired, without the provision for the child of such services

A disabled child is 'a child in need'

#### The Disability Discrimination Act 1995

This Act defines a disabled person as someone who has: 'a physical or mental impairment which has a substantial and long term adverse effect on his/her ability to carry out normal day to day activities'

#### The World Health Organization International Classification (ICDH)

Impairment is 'a loss or abnormality of body structure or of a physiological or psychological function'

Disability is 'the functional effect of any impairment'

Handicap is 'the limitation or prevention of fulfilment in life normal for that individual because of impairment or disability'

#### The new ICDH-2

The concept of disability is replaced by the 'activity' of an individual and the extent of their functioning

The concept of handicap is replaced by measure of participation

4. Vygotsky emphasized the immediate context for social learning, described as the 'zone of proximal development', as that area where the child cannot manage a task independently but can do more with supportive assistance. This is particularly relevant to his views of the development of language and thinking where social meaning is conferred on language and actions by the social sharing of ideas with others.
5. More mechanistic learning models and 'connectionist' theories are based on information processing and the perception, conception, storage, manipulation, transformation and retrieval of information. They are also based on the limitations that these processes place on functioning through memory capacity and attentional skills such as selection, shifting, inhibition, multi- and crossmodal functions, speed of processing, the development of automaticity and metacognitive skills, such as knowing about things and making comparisons and judgments. These are universal learning mechanisms incorporating theories of efficiency such that the mental resource and effort that is devoted to interaction with the environment and problem solving for the individual is minimized while retaining flexibility and increasing hierarchy and coherence.
6. 'Dynamic systems' theory integrates elements from all of the above. Children actively construct their understanding of the world by interacting with it, thus developing schemes and strategies that can be applied to a wide variety of situations. Intelligence reflects the child's capacity to initiate and assimilate new experiences and to profit by past experience.

## FACTORS THAT AFFECT DEVELOPMENT

### NATURE VERSUS NURTURE

Although there is now little disagreement that there are both genetic and environmental contributions to development of intelligence and personality, the nature/nurture debate continues. The contribution of each is complex because both the individual and the environment are continuously changing over time and the interaction between them, which molds psychological growth, is fluid and dynamic.<sup>4</sup> The genetic

influences on a child's development extend to the environment through the parental phenotype.

### ENVIRONMENTAL RISK FACTORS

Environmental factors may act in two ways:

1. by altering the child's opportunity to learn by limiting or expanding his experience – psychosocial factors;
2. by affecting the perceptual or effector organs and brain biologically at any stage from prenatally onwards.

### PSYCHOSOCIAL FACTORS

In general, people rather than physical elements are the most important factors in the environment of the young child. Parents are responsible for giving the child the opportunities to enable learning, form relationships and develop social understanding. Crucially, if an infant does not develop a sense of trust in people and attachment from that first relationship with a parent then he/she is more likely to have lifelong difficulties with relationships. Various factors including material deprivation affect the parents' capacity to cope well with the task of child rearing and provision of an optimal learning environment. Resilience to life events is related to temperament as well as to family factors of warmth, cohesion and support and external support.

### Temperament

Temperament is a major influence on all aspects of adaptive development as well as social-emotional development, both through the effect on the child's adaptation to the environment and his/her personal regulation, but also through the effect on the caregivers/parents and broader social context. Temperament can be seen from the earliest weeks as a mix of activity, adaptability, attention and emotional responses. Continuities of temperament over time have been well documented. For example, high reactors as infants are more inhibited in new situations at age 4 years.<sup>5</sup>

Most individual children do not fall simply into one particular pattern of behavior but patterns described are:

1. the easy child;
2. the slow-to-warm up child;
3. the difficult child.

Current research emphasizes both 'emotionality' and 'self-regulation' as important. Differences within children may mean that some are more sensitive than others to maternal 'sensitivity', which is thought to be an important influence on attachment in infancy.

### Parenting style and parental mental illness

Depression in mothers in the postnatal period is associated with effects on children's social-emotional and cognitive development. Parental inconsistency in methods of behavioral control is linked to children's behavior problems. However, a diversity of methods of parental control of children's behavior is normal and a balance of approaches – e.g. praise and punishment – is important, providing a 'good enough' environment for most children. The emotional context is particularly important. Parental conflict can adversely affect children's performance. The social learning environment that promotes moral development is warm not punitive, emphasizes others' feelings and perspectives and models appropriate behavior. Children continue to practice skills if they are rewarded or the behavior is reinforced. A young baby hits an object during an involuntary action. If it makes a noise or looks attractive she is likely to try again and start the process of exploring the environment. If when babies wave their arms around and make a noise there is no feedback or response from their environment or they are shouted at, they are likely to stop exploring and keep quiet. It has been suggested that in this way severe deprivation in the first year of life can affect children's ability to learn for the rest of their lives. The more infants see and hear the more they want to see and hear later.

## Deprivation

Material deprivation can impair parents' capacity to give time and attention to their children and increase the risk of maternal depression. Children from deprived environments (especially where neglect is prominent) may show developmental delay, particularly of language.<sup>6,7</sup> Children best learn the meaning of words when the word and the object are closely and frequently associated. The child deprived of simple play with adults does not have the opportunity to hear language related to the immediate environment. He/she may be surrounded by more complex visual and auditory stimuli from television or older siblings, but may be unable to interpret and learn from these stimuli because of their complexity or because of interference from background noises.

Recent studies of children who have been adopted from Romanian orphanages attest to both the resilience and the vulnerability of developmental processes. When reassessed at the age of 4 years, those children adopted within the UK by the age of 6 months had shown cognitive catch up, despite having shown severe physical and developmental retardation. Those adopted after 6 months of age showed catch up, but not to the same extent.<sup>8,9</sup> Social, cognitive and interactive development are particularly at risk. Age of adoption was a greater predictor of outcome than nutritional state.

## BIOLOGICAL FACTORS

A child's development may be affected by abnormalities of brain function, of special senses or of effector organs such as the limbs and muscles, either as part of innate development or acquired through some damaging event.

### Brain damage or dysfunction

Brain damage or dysfunction may affect all areas of function or only specific areas. Diffuse insults may produce specific dysfunction because of the vulnerability of a particular area of the brain at the time of insult (e.g. periventricular leukomalacia and basal ganglia damage due to hypoxia at term). Influences may be prenatal, through genetics, or maternal disease or postnatal, such as illness, injury or deficiencies.

Deficiencies are rare in developed countries, but iron deficiency anemia has been reported to have effects on development, and a number of studies report that the type of milk given to premature newborns affects cognitive development.<sup>10</sup>

The effects of certain types of brain damage (e.g. cranial irradiation) may not be immediately apparent, but only materialize when new learning is attempted. Concepts of neural plasticity are invoked in the context of damage, although some areas of differentiated function appear to show less of this (e.g. the primary motor cortex) than others.

Effects of early brain injury are often attenuated relative to later injury, for example the effects of stroke on language development in children with dominant hemisphere, but unilateral, cerebral damage. In this situation language learning is relatively unimpaired if they are under 6 or 7 years of age. In many children who have so-called 'developmental disorders', for example dyslexia and language disorder, there is no evidence of brain damage, but newer imaging techniques may identify specific areas and/or processes of dysfunction, often in the context of a strong family history.<sup>11</sup>

### Chromosome abnormalities

Chromosome abnormalities (see Ch. 15) may affect general learning processes or have specific effects, and can result in the development of recognizable behavioral phenotypes, for example:

1. Prader-Willi: chromosome 15 deletion or uniparental disomy (early feeding difficulties and hypotonia, learning problems and later eating/hunger control disorder, see Ch. 16);
2. Smith-Magenis: chromosome 17 deletion (severe mental retardation with severe sleep disturbance, behavior problems of aggression and self-mutilation and the stereotyped behavior of upper body hugging).

## Single and multiple gene disorders

The most common single gene disorder causing learning disability is Fragile X. Many developmental disorders are increasingly being recognized as having substantial genetic predisposition, but are likely to be related to the combined effects of variations within multiple genes rather than single gene defects.

### Defects of special senses

Defects of special senses most commonly affect vision and hearing and can result in a severe restriction of the information a child receives, which is essential to normal development. When impairments are severe it is obvious that development will be affected. When impairments are less severe, or intermittent, as in the case of secretory otitis media, it is more difficult to assess the effect on development; however, where other impairments exist, the effect is likely to be cumulative.

### Defects of effector organs – structural and movement disorders

Disorders of movement may be due to abnormality of the brain (cerebral palsy), spinal cord (paraplegia), nerves (spinal muscular atrophy) or muscles (dystrophy). These disorders have a direct effect on movement and also limit the child's experience. The child who cannot move independently does not experience space and distance and cannot reach things to manipulate them. It is important for parents and therapists to recognize this and to provide the child with compensatory experience.

Those disorders where there is no central brain involvement are less complex from the learning point of view, but some disorders that predominantly affect muscles (e.g. muscular dystrophy) have a significant effect on learning through a direct brain effect.

Other structural problems, such as facial disorders and cleft palate, influence development through direct effects (e.g. speech articulation), indirect effects (e.g. conductive hearing loss) or associated learning problems (as in chromosome 22 abnormalities: the velocardiofacial syndrome).

### Sex and development

Although the mediation is unknown and texts of milestones of development do not necessarily differentiate, there are some differences between boys and girls in development. For example, in the MacArthur study of language acquisition boys were on average 1 month behind girls, but the difference accounted for less than 2% of the variation within and across ages.<sup>12</sup> Nearly all the developmental disorders are more common in boys than girls. One theory proposed by Geschwind and Galaburda<sup>13</sup> suggests that the influence of testosterone is to delay maturation of specific processes within the brain.

### Gestational age

Gestational age is a relevant consideration for children under 24 months of age. Convention suggests that full correction for gestation should be made up to this time, but clinically there should be caution and some would advocate using less than the whole correction from 12 months onwards, especially in cognitive skills.

### Compounding effects of impairments

Biological and social factors may interact. When there is a biological abnormality, psychosocial factors become even more important determinants of the child's future, but it is precisely in this situation that parental resources are stretched. The child with a disability may have particular characteristics that are likely to make it harder for the parents to react to her. For example, the child may not smile or may go rigid when picked up and thereby not elicit the normal parental response. This can result in a vicious cycle, with the child becoming more disabled than originally expected. The severely visually impaired child may withdraw into self-stimulation, the rarely handled child with cerebral palsy become more rigid. The child with a communication disorder such as autism may not respond as expected, so caregiver behavior changes.

The ability of parents to consciously modify their reaction and provide for the child's special needs depends on their internal and external resources.

## NORMAL DEVELOPMENT

A developmental framework is essential for understanding a child's functioning and behavior and should be conceived over a life course.<sup>14,15</sup> Traditionally development is described as steps or stages of ages and in various fields of behavior, for example prenatal, infancy (from birth to 24 months), childhood (2–5/6 years), in areas such as physical, motor, adaptive, cognitive and language, personal, social and emotional. This should not detract from the fact that a child's development at any specific age is an integrated whole and over time is a continuous process. The integration of all aspects of development through to adolescence is shown in Table 7.2.

Descriptions of development tend to focus on universals rather than individual differences. They also tend to focus on skills acquired rather than processes of learning. Age is an ambiguous variable and is often a proxy for other processes (e.g. brain maturation). Change and continuity both need to be emphasized for individuals. At a number of time points critical periods occur with consequent disturbances to development. For example the presence of a cataract in a child's eye that prevents visual information reaching the visual cortex may result in failure to develop vision unless the cataract is removed within the first weeks of life. Whether there are other critical periods for learning social or cognitive skills remains contentious.

The following section looks at the sequence and process of development in different areas.

## PHYSICAL GROWTH

Physical growth is discussed in Chapter 15. Hormones affect development and behavior but physical and mental growth may be dissociated.

## MOTOR SKILLS

Figure 7.1 gives a description of motor development at different ages.

The acquisition of motor skills depends on:

1. Postural control, itself depending on reflex adjustment of tone in a large number of muscles in response to visual and proprioceptive feedback, develops in a cephalocaudal direction starting with head control, then progressing with sitting, standing, walking and running.
2. The development of a body schema or image through interpretation of proprioceptive, vestibular, tactile and visual information.
3. The loss of primitive reflexes. (The fetus moves in utero and the newborn infant shows movements, some of which are reflexly determined. After birth reflex movements that initially may be useful have to disappear before purposeful controlled movements can develop. For example, the asymmetrical tonic neck reflex, most evident at 2–3 months, may contribute to the development of visually directed grasping but its persistence is abnormal, as in some children with cerebral palsy, and interferes with bimanual manipulative skills.) Primitive neonatal reflexic behavior declines as both gross and fine controlled movements increase.
4. An increasing ability to interpret the visual information in the environment in order to judge, for example, distance, depth, trajectory and weight correctly.
5. The development of movement patterns which are rapidly adjustable in response to environmental circumstances so that actions are smooth, refined and economical, and where movements are increasingly separable from each other (e.g. arm and hand reach without whole body movement – as happens in cerebral palsy).

The child cannot develop sophisticated movements without first achieving postural control. All forms of movement are sequential postural adjustments, so that without resting tone or balance movement is uncontrolled. The secondary protective reflexes of propping and saving, which develop from 20 weeks onwards, are developmental and can be absent or abnormal in motor disorders.<sup>16</sup> Mirror movements may be a feature of normal motor development.

Table 7.2 Integration of all aspects of development through to adolescence

	Ages (years)				
	0–1	1–2	3–5	6–12	12+
Stages	Infant	Toddler	Preschool	School	Adolescent
Motor	Sitting → Stand → Walk → Run Grasp → Finger/thumb grip → Handedness → Bimanual coordination for complex tasks				
Cognitive and play	Sensorimotor → Representational (defining by use) → Imaginative and pretence Manipulative → Matching → Categorization (conceptual) Object permanence → Concrete thinking (increasingly symbolic) → Abstract thinking Means-end → Increasing linking of events → Dual representation of ideas and theory of mind Observation → Imitation				
Communication	Joint action → Increasing sharing Joint attention (initiated and receptive) → Reciprocity and conversation				
Language	Recognizes familiar → Increasing understanding of → Increasing understanding of abstract setting/shows meaning of words outside concepts (e.g. time, distance, motions) understanding in familiar context				
Speech	Babble → Gesture → Point → Words → Sentences → Understands and uses range of facial communicative and emotional expressions				
Social/emotional	Egocentric → Increasing awareness of other needs Dependent caregiver attachment → Explores from secure base → Peer group play → Individual friends → Extended peer group Friendly to all → Stranger awareness Fed → Feeds self → Increasing independence dressing, feeding, continence				
Moral	Aware of action/reaction → Self/other action on others → Rules → Ideals				
Attention	Distractible/single channel → Own control				
Psychosexual	Gender identity → Gender-typed behavior → Single sex play → Sexual object choice				

Position	Newborn	4 weeks	6 weeks	8 weeks	12 weeks	16 weeks	20 weeks	24 weeks
Supine					Head midline, finger play 		Head lifted more 	Rolls from prone to supine. Head lifted spontaneously, legs lifted, foot play 
Pull to sit	No head control 	Almost complete head lag	Head lag not quite complete 		Good head control - only moderate head lag 		Head lifted in anticipation of being picked up 	Pull to sit - head lifted off couch when about to be pulled up - hands are held up to be lifted
Sitting	Curved back 	Held in sitting position may hold head up momentarily 		Head is held up but recurrently bobs forwards	Holds head steady and erect for several seconds, lumbar curve 	Held in sitting position - holds head well up constantly - looks actively around but head still wobbles if examiner causes sudden movement of trunk	Partial response to sideways tilt of trunk, righting but not propping with arm 	Sits in high chair for few moments (supported); sits propped forwards 
Prone	Legs tucked under 	Momentarily holds chin off couch	Lifts chin off couch. Legs extended 		Prone - lifts head and upper chest off couch - bearing weight on forearms  Good head control	Curvature of back - now only in lumbar region compared with rounded back of earlier weeks		Prone - weight borne on hands with extended arms - chest and upper part of abdomen being off the couch 
Ventral suspension in prone position with hand under abdomen			Momentary tensing of neck muscles should be noted	Ventral suspension holds head up so that its plane is in line with that of the body 				Partial forward parachute 
Standing	Automatic stepping 				Off feet 			Held in standing position - bears large fraction of weight Downward parachute response, feet meet ground plantigrade when baby held and rapidly lowered (not shufflers) 

Fig. 7.1 Summary of development of spontaneous movement and posture control.

(Continued)

Position	28 weeks	32 weeks	36 weeks	40 weeks	44 weeks	48 weeks	1 year	15 months	18 months
Supine	Supine - spontaneously lifts head off couch, rolls from supine to prone								
Sitting	Sits with hands forward for support	Sits for a few moments when unsupported. 90% at 8 months 	Sits steadily for 10 minutes, leans forward and recovers balance (cannot lean sideways)	Sits steadily without risk of falling over except for occasional accident  Pulls self to sitting position, goes forward from sitting to prone and from prone to sitting	Sitting - can lean over sideways	Sitting - can pivot, can turn round and pick up objects 			Seats itself in chair often by a process of climbing up, standing, turning round and sitting down
Prone	Prone - bears weight on one hand		Prone - in trying to crawl may progress backwards - may progress by rolling	Creeps pulling self forward with hands, abdomen on couch	Prone - crawls (abdomen off couch) 	Prone - walks on hands and feet like a bear - may shuffle on buttocks and hands 		Creeps upstairs	
Evoked responses	Puts arm out to save if tilted off balance - sideways prop 	Full propping response both sides  And tilt response 		Forward parachute response, forward descent to ground, arms and hands extended 	Oblique suspension. Baby held under pelvis sideways arm and leg extended 				

Fig. 7.1 Continued

## SENSORY AND PERCEPTUAL DEVELOPMENT

Specific domains process the perceptions of vision, hearing, smell and touch and their components (e.g. movement, form, color and dimension for vision). There are critical periods for visual information and speech sound processing. Information processing will include speed of processing, intermodal and crossmodal integration, such as the coordination of vision and hearing perception at 3 months. The meaning (conceptual understanding) of what is seen or heard probably builds on innate recognition patterns (e.g. of the face).

### Vision

At birth the newborn eyeball is short and the ciliary muscles immature. The focal length for clearest vision is thus near to the baby and helped by high contrast. Movement, form and color are all perceived early. The infant scans the edges of shapes first and then internal features, showing pattern preferences (e.g. faces rather than jumbled features). By 6–7 months the baby not only recognizes faces but discriminates between facial expressions (e.g. happy or fearful). Various ingenious experiments show that by 6–7 months depth perception is present as well as an

understanding that shapes stay the same whether you are close or far away (called size and shape constancy). The visual cortex appears to be highly specific and to show critical periods for its development.

### Sound perception

The ear is fully developed at birth and sound perception is possible in utero. Speech perception and recognition of voices of different speakers are present shortly after birth. The capacity for smell and touch as well as the other senses are similarly developed at birth and play an important part in the perceptual learning about the environment.

### Crossmodal perception

Crossmodal perception (i.e. the integration of information from different senses) is demonstrable within the first months and contributes to the conceptual development of the meaning of experiences stored in memory and the expectation of constancy of experience – shown experimentally as confusion. The 'meaning' that the child is able to attach to sensations and perceptions is the cognitive end point and this depends not only on the process of perception and conception, but also the social and cultural context, which attaches meaning as well.

Position	28 weeks	32 weeks	36 weeks	40 weeks	44 weeks	48 weeks	1 year	15 months	18 months
Standing	Standing position - can maintain extension of hips and knees for short period when supported. Bounces with pleasure having previously sagged at hips and knees	Readily bears whole weight on legs when supported	Stands holding on to furniture 	Pulls to standing position	When standing holds on - lifts and replaces one foot	Walks sideways holding on to furniture. Walks with two hands held	Walks with one hand held  May stand unsupported for a moment  Walking alone	Can get into standing position without support, walks without help with broad base - high stepping gait and steps of unequal length and direction. (The maturity of the gait must be noted from now onward.) The wide base decreases as balance improves and arms are released for carrying  Lower guard	Walks well with feet only slightly apart - pulls toys as he walks - climbs stairs holding rail or helping hands. Runs rather stiffly - seldom falls. Throws ball without falling  Squat and rise

Position	21 months	2 years	2.5 years	3 years	4 years	5 years	By 10 years
Walking skills	Walks backwards in imitation - picks up object from floor without falling, walks upstairs two feet per step	Goes upstairs alone, and down holding on, two feet per step	Jumps on both feet - walks on tiptoe when asked - kicks a large ball	Goes upstairs one foot per step - downstairs two feet per step  Jumps off bottom step - stands on one foot for a few seconds	Runs, avoiding objects easily  Goes up and downstairs one foot per step	Skips, hops, dances	Walks heel to toe backwards  Can do 'fog' tests - walk on outer borders of feet with arms loose at sides
Other skills				Rides tricycle, catches well-directed ball with arms outstretched		Throws and catches a ball well enough to join in group games, but catching with one hand is not reliable until 9-10 years	

Fig. 7.1 Continued

**Motor perception and manipulation skills**

Figure 7.2 shows normal manipulative, visual and hearing development.

Once a child achieves reliable postural control increasingly accurate manipulative skills can be developed – integration of visual input and motor output is essential for normal acquisition of these skills. Grasping is shown in Figure 7.3.<sup>17</sup> Voluntary, accurate release is as essential as grasping for later manipulative skills. Handedness (which hand is dominant) is clear in

many children by 24 months and is expected in the majority by 42 months. Delayed development of which hand is dominant is frequently associated with specific as well as general learning difficulties.

Manual competence can be assessed in component skills:

1. use of tools (e.g. putting a bead in a screw top jar, putting a pen together);
2. imitation of gestures (these can be miming, how to brush hair after being shown a hairbrush or a picture of one, or copying hand

Age	Manipulation	Vision	Hearing
4 weeks		Watches mother when she talks to him. Looks at a dangling toy in line of vision and follows briefly	Quiets to familiar voice
8 weeks	Hands more frequently open	Follows dangling toy from side to side past midline, eyes show fixation and convergence in focusing	
12 weeks	Watches movement of own hands, pulls at clothes, shows a desire to grasp objects and holds rattle briefly when placed in hands	Follows dangling toy from one side to the other through 180° and vertically	Turns to familiar sounds in supine
16 weeks	Hands come together, approaches objects with hands – often fails to reach. Plays for longer periods with object placed in hand	Recognizes objects, for example familiar toy	Turns head towards a sound
20 weeks	Two-handed scoop for object  Arm movements increasingly better controlled to reach directly for objects	Smiles at self in mirror	Recognizes individual voices, listens to conversation
24 weeks	Manipulation – reaches and grasps objects on table surface with raking palmar grasp. Puts hands up to hold bottle, drops one object if holding when another offered	Sees and recognizes at adult distance  Looks at falling objects	Turns to sounds when sitting if sounds on ear level  Distraction tests used to test functional hearing
36 weeks	Has learned to transfer objects from one hand to another and can hold an object in each hand. Uses index finger approach to touch objects, can pick up small object between finger and thumb. Enjoys releasing objects over the side of cot or chair	Sees crumbs on floor  Looks for fallen objects out of sight	Locates sounds made above and below ear level and at greater distance
1 year	Has mature prehension and can release object precisely. Can now hold two cubes in one hand, brings one cube in each hand together in the midline and imitates clicking and tries to build two cubes	Recognizes pictures of objects	Recognizes tunes and tries to join in  Locates sounds above ear level
15 months	Can take objects out of container and replace more precisely (e.g. pegmen in wooden boat)	100s and 1000s used for near vision	Distraction test to specific frequencies used
18–24 months	Refinement of release enables the child to build cubes to an increasing height and post objects accurately through holes. Increasing control of finger movements can be used by the child to manipulate tools (e.g. spoon, crayon) and pages of a book. Initially pencils are held with a fistful cylindrical palmar grip then a high shaft pronated grip		

Fig. 7.2 Development of manipulation, vision and hearing.

(Continued)

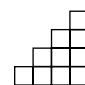

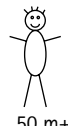

Age	Manipulation	Vision	Hearing
24–36 months	<p>Learns to use a more adult grip, turn single page carefully, stack eight bricks (90% by 30 m) and take off socks</p>  <p>33–36 m 80% at 39 m</p> <p>Copies  from model 36–39 m</p> <p>   Shapes inserted 24 m</p> <p>Insert puzzle-pieces recognized at 30 m and orientated 33 m</p> <p>Draws man </p>	<p>Tested with matching letters from 2+ years. Can use the Kay pictures from 24 months (naming pictures) but monocular testing difficult before 42 months</p> <p>Sonksen-Silver linear chart from 30 m</p>	<p>Hearing tested by pointing at toys/pictures from 24 months chosen for their range of component sounds (e.g. McCormick toys) and by conditioning to sounds from 30 months (to put an object in a box when a sound is heard). This leads on to pure tone audiometry; individual ears may be tested in some children at 3 years</p>
4 years	<p>Holds a pencil in the adult way, a dynamic tripod, is able to cut with scissors and thread beads</p> <p>Copies from model</p>  <p>39–42 m</p>  <p>48 m</p> <p> Man </p>	<p>Monocular testing possible in majority</p>	<p>Speech/word tests and pure tone audiometry in each ear</p>
5 years	<p>Shows great precision in hand movements and in the use of tools. Can cut a strip of paper neatly, and when building bricks holds the cubes with the ulnar fingers tucked in and hand diagonal to get a better view. Can feed tidily with a spoon and fork, dress and brush teeth. Refinement of finger movements can be demonstrated by increasing speed at inserting pegs in a board and threading beads</p> <p>Copies</p>  <p>60 m</p>  <p>66 m</p>  <p>50 m+</p>	<p>Screening recommended by orthoptists in school</p>	<p>Audiometric screening recommended in school</p>

Fig. 7.2 Continued

postures that are increasingly complex and may or may not be symbolic) – miming the use of a familiar object is a skill shown by 5 years; all others show a steady progression to the age of 12 years;<sup>18</sup>

3. learning a sequence of motor actions and writing/drawing. Perceiving shapes correctly and being able to reproduce them are essential for reading and writing. The ability to match shapes can be demonstrated by the use of form boards with different shapes (e.g. circles, squares and triangles), which have to be fitted into the appropriate space on the board. The ability to copy shapes is shown by asking the child to copy a three-brick bridge (3 years) and five-brick bridge (5 years). The ability to copy shapes with a pencil starts with a vertical line (second year) and a horizontal line and circle (third year). This progresses to letters and more complex shapes requiring juxtaposition of vertical, horizontal and oblique lines (Bender Gestalt test, see p.103).

Harris<sup>19</sup> devised a scoring system giving age norms for the ability to draw a man. Such ability is related to control of pencil movement, ability to reproduce shapes and concept of body image. By 3 years the child

has just learned to draw a circle and during the next year will add to this – vertical lines to represent legs, horizontal lines as arms and one or two features such as eyes and mouth (Fig. 7.4). It is not until 5 years that arms and legs are appropriately placed on a trunk (Fig. 7.5) At this age children can also draw a square and therefore a house with windows (some can do this at a younger age; Fig. 7.6).

## LANGUAGE, SPEECH AND COMMUNICATIVE DEVELOPMENT

An essential feature of human life is the use of a system of symbols for communication and thought. The attachment of names to objects and actions is an essential prerequisite not only for language but also for thinking. If we had no such system we would need to produce the object itself each time we wished to discuss it. It is conventional to consider 'speech' separately from 'language' and both as having 'receptive' and 'expressive', or 'input' and 'output' components. The component structures of language are:

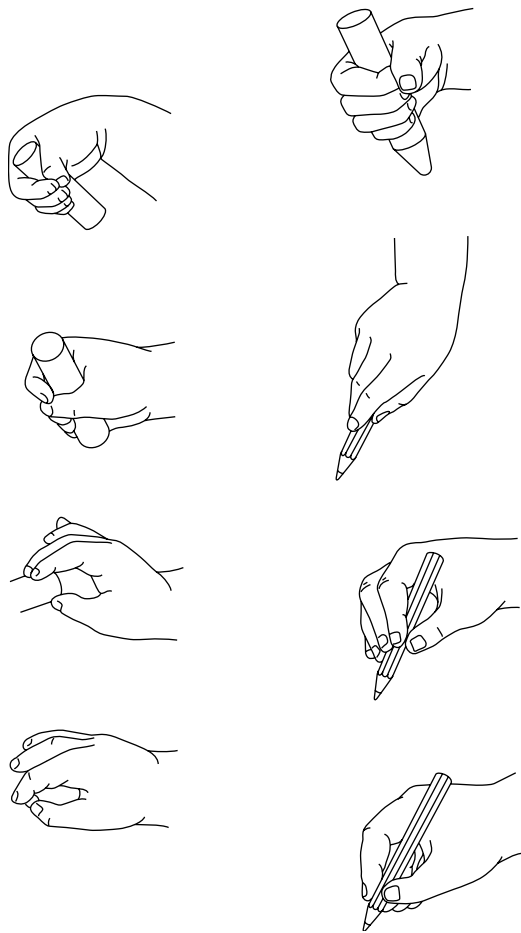

Fig. 7.3 Grasping. (Illustrations from The Erhardt Development Prehension Assessment, from Developmental Hand Dysfunction, 2nd edn. Copyright © 1994 by Rhoda P Erhardt. Published by Erhardt Developmental Products, Maplewood MN 55119, USA. Reprinted by permission.)

Fig. 7.4 By 3 years the child has learned to draw a circle and during the next year will add to this – vertical lines to represent legs, horizontal lines as arms and one or two features such as eyes and mouth.

Fig. 7.5 It is not until 5 years that arms and legs are appropriately placed on a trunk.

Fig. 7.6 At 5 years, children can draw a square and therefore a house with windows.

1. phonological (the perception and production of sounds to words and sentences);
2. semantics and syntax (words, their meaning, the small grammatical features – morphemes – and rules combining words in sentences);
3. pragmatics refers to the understanding and use of language in context.

### Overview of theories applied to speech, language and communicative development

Theories of language development range from the structural linguistic to the functional social and from language as a domain-specific skill to a continuity of general cognitive processes applied to linguistic symbols.

Chomsky<sup>2</sup> proposed that the brain must be pre-programmed to extract and master the specific grammatical structures of spoken language. He introduced the concept of the 'language acquisition device', suggesting the nativist view that language is a robust and pre-programmed biological

function, separate, to some extent, from other intellectual functions and dependent only to a limited extent on environmental input. Some children with specific language impairments have a particular problem with acquisition of grammatical morphemes, leading to the search for particular grammatical markers of language impairment.

The psycholinguistic approach uses a language processing model of language disorder to identify the specific problem in language processing and offer remediation.

'Connectionist theories' of computer-simulated parallel processing combine sensitivity to language input with dependence on a learning architecture in the brain. Models have been described for the learning of past tenses of verbs, vocabulary, concept words and syntax. Learning takes place as the system is presented with regular and then irregular verbs and is modulated by a number of weighted activations assessing the probability of any particular ending for any particular verb stem. General learning processes, such as imitation and context bound chunk learning, followed by increasing symbolic representational development and abstraction with creativity, are thought to be important in word, verb and syntactic development.

The degree to which language and thinking are separable has taxed theorists. Vygotsky<sup>20</sup> conceives of language as a speech processing/word formation system developing independently and, for technical perfection and intelligibility, dependent upon a domain-specific learning system. However, the meaning of the speech processed and used depends on the social context in which it is learned and this has its basis in the social cognitive ability of the child as well as the environment and responsiveness of the parent/caregiver. Thus language acquisition is inseparable from the development of social communication, both verbal and nonverbal, and the social relationship. The meaning of communication is learned in a social cultural context and requires broader social – cognitive skills to interpret the meaning of all the coordinated forms of communication, such as body posture, facial expression, eye gaze, tone of voice, speech and gestures, which are all smoothly combined in the adult – the pragmatics of language use.

The child is an active partner in language acquisition. Babies have an innate social interest in other humans, displaying an early ability to perceive aspects of the face and the meaning of facial expressions and posture, actions and sounds in varying combinations, and are therefore programmed to develop an interest in human communication. The baby responds to facial expression and tone of voice (6 months) long before she understands the meaning of words. The baby seeks the 'meaning' of social actions from a number of cues, especially emotions. Mothers reflect back certain things babies do and give them meaning. Physical actions are usually easy to interpret. The understanding that the focus of an adult's visual attention is likely to be what they are talking about is an important cognitive step. The child's understanding that objects have labels is helped by the spontaneous behavior of adults who when they see children looking at or pointing to an object will tend to name it (e.g. 'yes, that's the cat').

The child and parent develop 'joint' attention through shared actions.<sup>21</sup> The child learns to coordinate his attention and interest between an object and person, seen in gaze switching, facial expressions and vocalizing. The baby uses sounds in a reciprocal or turn-taking manner before they are intelligible as words. Early conversations have all the important elements of social discourse, initiating, responding and repair (i.e. making some effort if the exchange breaks down). Towards the end of the first year, the baby shows increasing awareness of self and others and becomes an intentional communicator, also showing anticipation of the parents' actions, intentions and feelings, and checking the parents' response to new situations by observing their facial expression ('social referencing').

The initiation of shared interest with an adult by the child is a good marker of normally developing social communication skills in a child of 12–18 months. Gaze switching and the frequency of this behavior in a play situation is easily observed. Communication accompanied by eye gaze has greater social meaning. The child learns to form predictions of complexes of behaviors. Early joint attention skills are deficient

in children with autism<sup>22</sup> and representational forms of communication may not be understood as having relevant meaning. In blind children, establishing meaning can be particularly difficult. For the deaf child in a speaking household this can also be a problem. For the learning disabled child (e.g. Down syndrome) it is a slow process needing more time for both assimilation and response.

## Vocalization and speech

The development of vocalization and speech depends upon an intact motor learning system as well as hearing speech, and evolves rapidly from a limited repertoire of sounds during the first few months. From about 6 months onwards, the sound patterns take on the qualities of adult speech. By the end of the first year, the sound patterns of the child's 'native' language are established and the ability to discriminate the sounds of other languages diminishes (e.g. 9 month olds prefer to listen to native words rather than non-native). They learn to reproduce pairs of syllables by integrating the sequences in which they are presented as well as the rhythm (at 6 months babies are sensitive to the rhythm, but not the sequences of syllables). Strings of babble become more connected, intonation takes on the pattern of adult speech and the child begins to imitate phrases and words. At this stage, the words and sentences may not be analyzed into their component parts. The child may copy a whole word or phrase by the rhythm it makes.

Children vary in their rote memory capacity for memorizing chunks of speech. Constant practice in making sounds reinforces motor patterns, which become increasingly automatic. The amount of babble is correlated with early vocabulary. Abnormal or infrequent speech sounds in the first year can be a marker of later speech and language problems or deafness.

At the early stages of communicative development some children may tend to use gestures without also using spoken words, while other children use both gestures and words. Bates et al<sup>23</sup> suggested that this reflects individual variation in communicative style or preference. The developmental sequelae of these different early communicative styles are not known. Fenson et al<sup>24</sup> suggested that symbolic and communicative gestures may act as a 'bridge'<sup>25</sup> from word comprehension to word production.

Pointing behavior is particularly important because it indicates a precise referent on the part of the child rather than undifferentiated need and is a precursor of symbolic development.

Two reasons for pointing behaviors can be observed.

1. Proto-imperative 'indicating' behaviors represent the child's demand for needs to be met. This may be done by pointing or vocalization. Such behaviors do not necessarily involve any shared interest or attention (or mental idea of other people).
2. By contrast, proto-declarative communicative behaviors are a preverbal effort to direct the adult's attention to an event or object. This purpose of pointing is to 'share' interest with another person. Proto-declarative behaviors correlate highly with the emergence of first words and predict in normal development the vocabulary at 20 months and the sentence length at 28 months.

During the first 10-word stage words may be largely imitative or bound to context, they may be formulaic and learned in association with a particular event and may be presymbolic. The words are not necessarily securely fixed in the mental representational linguistic system.

The first words that a child utters are very dependent upon shared referents with parents: for example in the Korean culture, verbs are commoner than nouns; the opposite is true in English speakers. Children vary in the predominant types of early vocabulary they use. Some use more context-bound phrases (names of people and objects) while others begin with more communicative social words (such as 'look' or 'here y'are', or words such as 'more' and 'gone'). Most children use both styles.

Language and thinking are intimately related as the child learns to map words onto existing thoughts or concepts and the learning of a word can stimulate new concepts. While acquiring early vocabulary the child's next cognitive stage is the move from the primary and simple

associative use of the sounds of language to a more symbolic, representational and decontextualized use. Overextensions are common at this stage (e.g. 'daddy' for all men).

Comprehension of language is in advance of expression in normal development. Nouns are the largest class of words in early vocabularies. When new words are used, a child tries to find a meaning for them. The development of grammar does not seem to depend on repeating adult structures; rather children seem to extract the rules of grammar and experiment for themselves, sometimes to comical effect – for example:

Lucy: Squeak, squeak – that's what mouses does.

Mother: That's what mice do.

Lucy: What do mices does?<sup>26</sup>

### Wide normal range

As with many skills of development there is a wide normal variation in the acquisition of speech and language (e.g. in the MacArthur scales<sup>23</sup>). At 16 months children in the top 10% produce 154 words, those in the lowest 10% produce none; 80% of children at 16 months understand between 78 and 303 words (–1.28 SD to +1.28 SD). Severe delays have predictive significance, but there is no best age for determining milder speech and language delays. A child who is delayed at 18 months will not necessarily be delayed at 3 years.

## SOCIAL LEARNING, SELF AND OTHERS, PLAY AND ADAPTIVE SKILLS

Social learning, self and others, play and adaptive skills include:

1. the child's social reactions to other persons and to peers through the development of attachments and social understanding;
2. development of self-awareness and self-regulation;
3. mastery of skills such as feeding, elimination and dressing.

The normal development of cognitive and adaptive skills, play, language comprehension and speech, communication and social interaction is outlined in [Table 7.3](#).

Social learning, becoming aware of self and others, and the development of other play and adaptive skills marks the change from a dim awareness of self and mother to an understanding of the complex rules of social behavior and interaction. Even neonates are socially competent, in that they are able to elicit the attention of their parents. It has been shown that mothers respond to their babies' behavior more often than the other way round. Thus features of an infant's temperament and her potential for social communicative drive and competence will be relevant to how the parent behaves. Studies of blind babies and their mothers show how easy it is for parents to miss cues for communication when they are not conventional. The non-initiating, nonresponding, autistic child soon trains a parent not to initiate interaction. The parent of the baby with Down syndrome needs to wait for the often rather slower initiating and responding behavior so that the rhythmic turn taking of communication is not lost.

Babies respond to the human face and to objects quite differently. In response to a face their eyes widen, posture is relaxed and by 6 weeks a smile arises. This simple milestone is a very reliable indicator of abnormality if delayed beyond 8 weeks. During the latter half of the first year babies lose their indiscriminate warm response to all people and begin to recognize familiar adults and to become wary of strangers. They develop a strong attachment to their caretakers and separation at this time and during the second year of life is particularly distressing to a child. Securely attached children who are confident of their mother's warm presence are able during the second year to begin to explore and to achieve mastery of feeding and elimination.

An important stage of social cognitive development is that of joint attention (described in the language section above) shown in the transition from dyadic to triadic attention (from focus on object or focus on person to focus on object then switching focus to person and back again to object). The latter involves the sharing of focus, which is the indication of interest by the child and recognition that there is mutuality of meaning with the parent and the sharing of an idea. Such behavior appears to

be the precursor of social understanding of others' feelings and perspectives, the knowing that other people have minds. Understanding other people's emotions is an important part of learning about them and sharing those feelings may lead to the development of empathy. Emotional 'knowing' and 'display' may not be the same as understanding the thinking of other minds (a connected but possibly separable skill).<sup>27</sup> Understanding and using the knowledge of how someone else might feel is also an important component of moral development.

In normal development, children initiate joint attention. They direct their parents to something they are interested in and respond to parental behavior that does the same, shown by gaze shifts to share looking at things and following index finger pointing. The social referencing behavior of children, in new situations, when they scan the faces of people, but especially parents, to give them cues about how they should then respond, is seen in the last trimester of the first year.

The child shows increasing independence from adults and awareness of self in relation to others during the second and third year, and this is observable both in play and language use.

During the nursery years (3–5 years) children's horizons widen as they are faced with a new social world of adults and other children. The child becomes less egocentric and learns how to play with other children, taking into account their wishes and needs, although the cognitive capacity to consider two perspectives simultaneously and reflect upon them in a judgmental way does not mature until nearer 8 or more years.

Behavior should get easier as reasoning becomes more possible and the child learns about 'deferment'. Instead of just reacting, children cognitively appraise and interpret events. The personal memories that form the basis of reflection are constructed from the experiences of the child woven into a mental schema or narrative of representations and feelings. Ideas of truth and moral rightness develop. For example, young school-age children (but not preschoolers) can accept an action by someone who is mistaken in their belief, but not where they are morally wrong. Thus it is alright to give more food to boys than girls if you believe they need more but not if it is done because it is OK to be nicer to boys!<sup>28</sup> Moral development, the rules and conventions of interpersonal behavior, require both the behavioral opportunities for learning (i.e. example, reinforcement, rules/punishment) and the cognitive skills to be able to take perspectives and self-reflect. The environment needs to be warm, not punitive, model what is appropriate and emphasize other people's feelings and perspectives.

The child obtains final mastery of dressing and toileting self-help skills, and by 5 years of age is ready for more formal education. The child is, however, still essentially home based in outlook and influences. During the primary school years, the rules of the group become increasingly important, so that by 10 years of age they are often quoted to parents in a rather rebellious way. At this age boys and girls tend to form separate groups or gangs and the peer group social perspective becomes more important. The teenager is able to think in the abstract, work out the principles behind actions and is therefore able to become more independent. Freeing from parental authority is associated with a desire for acceptance and popularity in the peer group. However, developing sexual maturity is associated with many other concerns, which are dealt with in the chapter on adolescence (see Ch. 35).

## COGNITIVE AND LEARNING DEVELOPMENT

Children learn about their world by listening, observing, copying and experimenting. The world of infants is very small and their repertoire of skills limited. They learn about their world through observation, by reaching and grasping objects and by copying sounds and actions. By contrast, toddlers are mobile and their worlds are large. Their motor skills are greater and they begin to attempt constructional tasks, thereby learning about aspects such as size, shape, the properties of objects and space.

The child is an active participant in the learning process. Progress depends upon not only the learning opportunities, but also the child's

**Table 7.3** Normal development of cognitive and adaptive skills, play and nonverbal skills, personal skills, communication and social interaction, language comprehension and speech

Age	Play and nonverbal skills	Personal skills	Communication/social interaction	Comprehension	Speech
6–8 weeks			Smiles responsively when mother talks to or smiles at. Opens and closes mouth imitatively		
3 months	Interested in everything seen/ increasing intention to touch objects		Vocal turntaking, gurgles/ coos with pleasure Generally social to friendly adult but knows caregiver	Regularly localizes speaker with eyes	Often vocalizes with two or more different open vowel sounds/up to two syllables
6 months	Reaches for and grasps toys, usually both hands – takes to mouth. Watches objects disappear – no sustained searching. Excited by familiar toy	Tries to hold cup/bottle, poor tipping	Shares interest by gaze and gesture in peek-a-boo game. Makes noise to get attention. Tries to imitate (e.g. tongue protrusion). Smiles at image of self in mirror	Situational understanding of familiar phrase and angry/friendly voices. Localizes and recognizes different speakers	Occasionally vocalizes with four or more different syllables at one time. Nonspecific indication of emotion/ need etc. but tries to attract attention vocally
9 months	Persistent in getting toys. Transfers toys hand-to-hand, bangs toys (7 m) Looks for objects that disappear. Stage of 'sensorimotor' play and early 'cause and effect'. Pulls string to get toy	Interested in mirror play. Aware of different types of clothing. Finger feeds and early chewing. Some anticipation of familiar events	Responds to parental 'indicating' gesture. Beginnings of imitation of gesture (e.g. waves bye-bye, claps hands 10 months) and shows joint attention – ability to switch gaze between object and person to share interest. Understands and takes part in lap games with anticipation, demanding of repeated 'games' (e.g. peek-a-boo). Now more wary of strangers	Regularly stops activity in response to 'no'. Responds to own name and names of familiar people (e.g. 'daddy'). Understands gestures (e.g. holds out toys or other objects to a parent on verbal request with gesture, e.g. hand out) but may not yet have skills of release	Intoned babble with sequences of sounds. Babble more complete with different vowels and consonants. Imitates sounds. Attracts attention to self frequently
Around 12 months	'Container' play putting objects in and out. Interested in picture book. Finds hidden objects. Shows recognition of familiar objects (e.g. brush, telephone, cup and spoon and car). Less mouthing, may 'cast' – throw objects on floor. Imitates actions with objects (e.g. clicks bricks, rings bell, tries to build bricks)	Cooperates with dressing by putting arms up. Drinks from beaker held by self	Points to indicate need. Separation anxiety on leaving parent common. Quite distractible and switches to new dominant stimulus easily. Repeats performance to be laughed at	Generally shows intense attention and response to speech over prolonged periods of time – understands people's names and familiar words (e.g. 'shoes'/responds to familiar requests)	'Talks' to toys and people throughout the day using long verbal patterns (jargon)– protowords, or words accompanying communicative gesture. Shakes head for 'no'
Around 15 months	Early definition by use of play on self (e.g. brushes hair or mother's hair). Builds two-cube tower Uses pencil to mark paper Plays to and fro game with ball or truck	Increasing awareness of self/others shown in shift of object play from self to doll, use of me/mine pronouns and awareness of aspects of self in mirror. Increasingly persistent in attaining goals. May indicate when wet	Frequent communication initiated by child accompanied by showing and bringing of toys and pointing for interest and need. Follows adult point at object	Understands simple requests in context. Recognizes and identifies many names of objects in familiar surroundings. Points to pictures in book	More frequent use of words with meaning, final or beginning consonant often missing. Asks for objects by vocalizing and pointing

(Continued)

**Table 7.3** Normal development of cognitive and adaptive skills, play and nonverbal skills, personal skills, communication and social interaction, language comprehension and speech—cont'd

Age	Play and nonverbal skills	Personal skills	Communication/social interaction	Comprehension	Speech
Around 18 months	Uses real and toy objects appropriately. Briefly imitates everyday domestic and personal activities. Shows preference in play. May use dolly/teddy to feed/put to bed. Builds a tower of three bricks. Can match circular shapes in insert puzzle	Feeds self with spoon without rotating it at mouth. Takes off hat/shoes. Alternates between clinging and resistance	Attends to own choice of activity, but attention can be caught by calling name and producing new toy. Verbally requests and comments. Watches others play and plays near them	Listens to adult and identifies two or more familiar objects on request from a group of four or more familiar objects. Generally understands more than 100 words in familiar setting	Begins repeating words overheard in conversation (mean 50–100) – uses minimum of 10–20 words spontaneously – range of vowels and m, p, b, t, d
Around 24 months	Play now more toy based linking actions (e.g. feed doll and then put to bed). Builds tower of six/seven bricks. Turns pages of book singly. Copies line with pencil. Able to play for more lengthy periods of time. Turns door knob and unscrews lids	Dry by day, pulls pants up and down. Helps with simple putting away when asked. Understands spills and tries to rectify. Behavior can be active and oppositional. Bowel control often attained	Mainly with adult still – watches other children. Simple chase games develop. Wants to please adult/shows off	Recognizes new words daily at an ever-increasing rate. Listens to conversations and responds. Carries out simple instructions. Understands objects by function (e.g. which one do we sit on). Points to several body parts	Speaks more and more new words each week, gesture used less often. Echoes some of the adult's speech. Puts words together in phrases 'me go'. Verbally very demanding
Around 36 months	Builds tower of eight cubes. Vivid make believe. Understands stories, can make plans. Beginning to draw recognizable man with head, eyes, legs. Copies circle and can do simple inset puzzle (orientate and insert all pieces) and match colors. Can unbutton buttons. Tries to cut with scissors. Able to show sustained concentration	Feeds with spoon and fork. Shows a sense of danger. Understands rules, right and wrong behavior related to self – more amenable. Can remove front opening garment and many other clothes. Attends to toilet needs without help	Can share, comfort others distressed. Plays with other children. Affectionate and confiding. Shows understanding that others can 'know' things. Shows sense of humour. Understands polite behavior	Understands on/in/under/big/little. Can give full name, age and sex. Beginning to count. Understands why, who, how many and questions such as 'what should you do when you're hungry?'	Uses sentences of three–four word phrases, personal pronouns, plurals and prepositions. Asks 'what', 'where' and beginning to ask 'why'? Relates own experiences. Able to have simple conversations. Immaturities of articulation common but mostly intelligible
Around 48 months	Able to show sustained concentration. More extended make-believe. Draws man with body. Copies cross and six brick steps	Aware of being in a group and expected behaviors		Understands concepts of number up to 3, colors, listens to a short story and can answer simple questions about it. Can listen to and answer two-part question and understand some words relating to feelings. Likes rhymes	Sentences of four–eight words, mostly grammatically correct. Counts to 10. Talks about experiences and can retell a simple story. Uses approximately 1500 words
Around 5–6 years	Copies square (5) and triangle (6) and ten-brick step from a model. Draws a man with head, body and features and a house with windows	Can care for most toilet needs independently. Can dress self except for shoe laces	Can have conversations, tell jokes and discuss emotions. Able to retell in a different way to assist others' understanding. Most children show 'first order theory of mind' (i.e. that someone else can 'know' something that is different and may be incorrect). Makes friends and has a preferred friend	Knows simple time concepts, can follow three commands together. Can define common objects in terms of use and answer 'what if' questions. Understands common opposite (e.g. hot/cold). Follows instructions given in a group. Can tell an unfamiliar story from pictures	Speech completely intelligible including consonant blends (e.g. Sh, th), rate, pitch and volume

learning strategies and processes. Information processing in infants is related to later cognitive abilities in memory and speed of processing, thus in visual recognition tasks, habituation, learning, object permanence and attention, including crossmodality.

In older children, the features of new problem solving that are linked to learning are variability, ability to shift focus, frequency of self-correction and diversity of strategies.

### Problems with the learning process

In some infants, perceptual processing that depends upon innate recognition may be damaged and perceptual attributes that lead to salience may not be perceived. Perception that depends upon temporal processing may be slowed and crossmodality may be impaired. Meaning may be more easily accessed visually (i.e. what is seen may make more sense than what is heard). Infants learn from the repeated familiar and respond to difference – a learning style used in the ‘habituation to repeat stimulus’ in developmental experiment.

Learning from the familiar needs repeated stimulus and is enhanced if as many features as possible are fixed and what is remembered depends upon the match between context and item. This is a stage of normal development referred to as ‘context bound’ learning, when children recognize their own cups or shoes, for example, but not ‘cupness’ or a sentence said by one person in one place but not another. Some children get stuck in this stage and require a sustained high degree of contextual or environmental sameness to show a skill. This is particularly shown in autism.<sup>29</sup>

Children learn from ‘contingency’ – the event that follows within 3–5 seconds of their action. This may be disrupted by a number of mechanisms, such as:

1. failure of the adult to make the response (depressed/mentally ill caregiver);
2. the child not giving a clear enough signal (as for those who are blind or who have cerebral palsy).

Aspects of maternal or caregiver behavior that promote learning need to be sensitively adjusted to developmental level. Thus at 2 years of age, language input needs to be explicitly directive and adult actions tied to the focus of child interests. By 3 years less parental direction is needed because the child has more language and is learning to manage her own goal-setting and problem-solving skills.

Play complexity is enhanced by caregiver behaviors that maintain a child’s focus of attention rather than redirect it. Children also learn more through the process of learning itself. For example, learning particular names of shapes accelerates shape learning generally, as though attention to the ‘shape concept’ allows noticing of ‘shapeness’. The child’s ability to inhibit and select responses and to try alternatives is crucial to all cognitive learning. This is seen in the progression from the ‘trial and error’ approach, where repeatedly forcing the square into the round hole is a less useful strategy than trying alternative placements with inset puzzles, which shows more flexibility of mental skills.

The progress from sensorimotor play, from mouthing to manipulation at 6–10 months, then to imitation and ‘definition by use’ play by 12 months is followed by increasing creativity in play. Make-believe play with dolls, in which the child is reconstructing events observed, is an important element of this period. It indicates early symbolic representation and concept formation. The child begins to use language to direct or describe the action of his play, and as command of language improves the need to act out the events decreases. Lack of ideas, failure of pretence and inability to play constructively are indications of a developmental problem.

The cognitive stage of mental symbolic development allows more complex thinking, including reflection and planning. Symbols (words) facilitate thinking about, and reference to, situations that are not in the ‘here and now’. Answering simple questions dealing with nonpresent situations presents difficulty before 3 years and even primary and junior school children still tend to be concrete in their way of thinking (i.e. real objects, here and now). Early in school life, judgments are made

intuitively on superficial appearances. With increasing experience and language at their disposal, children can imagine complex situations, think out the most appropriate solution and anticipate the outcome. This requires the ability to think abstractly and imaginatively. Thus, children develop logical thinking from assimilating experience into schemes or general laws that they can apply to a range of situations. The use of symbols also helps to inhibit prepotent responses of behaviors and allows increasing distancing from the ‘here and now’ (rather like the red card in football games). Children are developing skills of representation and object substitution in the second year, but the skill of mentally comparing reality with representation (dual reality) is not clearly seen in research studies until aged 3 years. For example, children shown where an object is hidden in a scale model of a room can find it in the real room at 3 years, but not at 30 months. At 3–6 years, children get increasingly skilled at knowing that others can hold particular views, even false views, and thus have what has been called a ‘theory of mind’. In the classic Wimmer and Perner task, roughly half the 4- to 5-year-old children could correctly show ‘knowing’, whereas over 90% of 6- to 9-year-old children were correct.<sup>30</sup> This understanding of children’s thinking is highly relevant when considering children’s perceptions of events and their reporting of them.

## DETECTING AND ASSESSING DEVELOPMENTAL PROBLEMS

Developmental impairments, learning and behavior problems are common. One of the aims of a child health service is to provide appropriate services for children with such problems, and their families.

An evidence based review of the UK Child Health Promotion Programme led to changes with increased emphasis on prevention at all levels, enhanced use of a parent – professional partnership model, and included active surveillance or formal screening only where there is appropriate evidence of effectiveness.

Changes to the elements of the program concerned with identification of developmental problems have not been introduced however without vigorous and continuing debate around the questions of which problems should be identified, how this should be achieved and whether early detection is beneficial.

## DEVELOPMENT: NORMAL OR ABNORMAL?

Very severe developmental problems are likely to come to the attention of appropriate services. However, early identification of less severe problems presents particular difficulties. Development is a continuous process, and the cut-off for definite abnormality is not always clear. Although a majority of children walk by the age of 18 months, those who do not will be a mixture of those with biologically based disease, general learning problems and normal variants.<sup>31</sup> Thus, failing to acquire a particular skill by the generally accepted ‘normal’ age does not definitely predict a disorder. (Equally, acquiring a skill by the ‘normal’ age does not predict that future progress with that developmental skill will remain within normal limits.)

Information about the predictive outcome of a particular delay at any moment in time is ideally required. Thorough knowledge both of normal developmental variation, and the natural history of recognized developmental disorders is thus required. Although it is conventional to describe ‘delays’ of development (meaning normal but slow patterns of skill acquisition) and ‘disorders’ (where the pattern is abnormal), the distinction is not always logical since slow skill acquisition can be a manifestation of cognitive impairment.

Caution should also be exercised in the use of the term ‘developmental delay’ to describe any individual child’s profile. While this may be a helpful term during initial evaluation and any investigation, its use long term can be misleading, implying, as it does to many parents, that ‘catch-up’ is expected at a later point. The best moment to characterize cognitive problems as ‘learning difficulties’ will vary according to individual and family need.

The wide variation in developmental norms means that it is unreasonable to expect that a single observation should lead to a definite conclusion. Therefore services will need to continue to include provision for observation while the child's skills unfold. For all children, there is increasing emphasis on advising and supporting parents in how to help promote developmental progress, whatever their level of developmental skill.

## IDENTIFYING DEVELOPMENTAL PROBLEMS: EARLY DETECTION AND SCREENING

Enthusiasm for early detection of impairments by professionals led to a program of universal developmental checks at visits to 'well baby' clinics at multiple time points in the preschool years in the UK, the so called Child Health Surveillance programme.<sup>32</sup> However, aside from formal attempts to identify problems with a known adverse developmental outcome, such a 'surveillance' program rested on assuming both that early detection was possible, and that it has specific advantages. Developmental checks were effectively being used as 'quasi' screening tests, despite the difficulties discussed above in establishing normal from abnormal. These difficulties are exemplified in a systematic review of screening for primary language delay<sup>33,34</sup>

Screening can be defined as the identification of a condition at an early or presymptomatic stage such that treatment offered will confer greater benefit. The criteria of Wilson and Jungner<sup>35</sup> and Cochrane and Holland<sup>36</sup> need to be applied to any condition and to any screening test (Table 7.4).

Any test has to be simple, quick, easy to interpret, acceptable to parents, accurate and repeatable. It should be:

1. Sensitive – that is it should have the ability to give a positive finding if the person has the impairment.
2. Specific – that is, it should have an ability to give a negative result in a person with no impairment.

Table 7.4 The criteria of Wilson & Jungner<sup>31</sup> and Cochrane & Holland<sup>32</sup>

1. The condition being sought for should be an important health problem for both the individual and the community
2. There should be an acceptable form of treatment for those with recognized disease or some other form of useful intervention should be available (e.g. genetic advice)
3. The natural history of the condition should be adequately understood
4. There should be a recognizable latent or early symptomatic stage
5. Equity of access across a geographical area must be ensured
6. There should be a suitable test for detecting the early or latent stage that is acceptable to the population. The distribution of test value should be known with an agreed cutoff, high sensitivity, specificity and high positive predictive value
7. There must be an agreed method of diagnosis in the screen positive and there must be systems in place for adequate diagnosis and counseling. It is important to note that there are dangers to overinclusiveness in the 'at risk' group. Research has shown that the worry of a false positive screen does not disappear easily
8. There should be an agreed policy on who should be treated
9. The treatment in the presymptomatic stage should be able to favorably influence the course and prognosis of the disease
10. It is important to ensure that all the above criteria for a screening program are met before primary care groups and districts embark upon it. Experience has shown that it is much more difficult to stop than to start a widespread program
11. The cost of case finding which should include the cost of diagnosis and treatment should be economically balanced in relation to the possible expenditure on medical care as a whole and the constant treatment of the patient does not present until the disease reaches the symptomatic stage
12. Case finding should be a continuing process

In considering sensitivity and specificity the prevalence of the disease is very important. The ideal is high sensitivity and high specificity, but in practice one is usually at the expense of the other. Further scrutiny of the established 'distraction hearing test' for hearing impairment showed that, although reliable in skilled hands, it did not show adequate sensitivity when applied across the population. Introduction of universal neonatal hearing screening is expected to overcome this problem as well as result in an earlier mean age of identification, which has proven benefits for parental adjustment and for language outcomes<sup>37</sup>.

As the previous system of developmental checks did not fulfill accepted screening criteria it is now generally believed that such a system is untenable. The reader is referred to 'Health for all Children'<sup>32</sup> and the American Academy of Pediatrics statement<sup>38</sup> for a fuller examination of this subject. In some areas there was considerable concern that time spent seeing families of normal children with no concerns diverted professional time away from families with greater needs. This has to be balanced against the findings that parents want to know about developmental problems early and that early intervention can be effective. For example, there is increasing evidence that appropriately targeted intervention improves outcomes in children with autistic spectrum disorders (reviewed by the National Research Council<sup>39</sup>), but a screening study of the general population showed at best moderate sensitivity.<sup>40,41</sup>

As research provides new information on effective interventions and appropriate screening tests, further adjustments to the program can be expected.

## IDENTIFYING DEVELOPMENTAL PROBLEMS: PARTNERSHIP WITH PARENTS

Regular 'surveillance' contacts also arguably marginalized the immensely important role that parents have in detecting developmental impairments. Most very severe impairments of motor, visual or general learning skills, not detected at birth, are detected by parents. Two thirds of children with cerebral palsy had this diagnosis confirmed by 24 months, in a recent population-based study, and 89 out of 145 were detected by the parent or other family member (Baird & Scrutton, unpublished data).

When a family feels concerned about a child's developmental progress, they require a prompt response including exploration of concerns, assessment and management, if indicated. Access to health service resources is an issue and many districts have had to develop imaginative schemes to ensure that particular ethnic groups, travelers and asylum populations receive both health and developmental care. There are particular challenges attached to 'looked after' children who may change geographical location frequently yet have complex problems.

### Using parental knowledge

Glascow<sup>42,43</sup> has developed and evaluated a model of seeking developmental concerns and evaluating the response required using a simple series of questions, which has the advantage of being able to be used at any age in the preschool years, the PEDS – Parents' Evaluation of Developmental Status (1997). She has found that parental concerns, carefully elicited, have a 75–80% sensitivity for childhood disability and 70–80% specificity for normal development. These questions are intended to be asked of parents.

1. Do you have any concerns about your child's learning, development or behavior?
2. Do you have any concerns about how your child talks and makes speech sounds?
3. Do you have any concerns about how your child understands what you say?
4. Do you have any concerns about how your child uses his or her hands or feet to do things?
5. Do you have any concerns about how your child uses his or her arms or legs?

6. Do you have any concerns about how your child behaves?
7. Do you have any concerns about how your child gets along with others?
8. Do you have any concerns about how your child is learning to do things for him- or herself?
9. Do you have any concerns about how your child is learning preschool or school skills?
10. Do you have any other concerns?

Glascow<sup>42</sup> has shown that parents who have no concerns (and where there is no literacy/language barrier) tend to have children without disabilities. Decisions about who to assess further can be based on the results of the PEDS. For example, a parent who has two or more significant concerns about the child should be referred for appropriate assessment without more screening. One significant concern should elicit a further screen in the appropriate skill and this improves specificity.

### Is parental identification sufficient?

Within the child health promotion program, regular points of contact between parent and professional are retained to allow provision of a number of health-related activities (accident prevention, nutritional advice and the immunization program<sup>32</sup>) including discussion of developmental progress. It has been argued that leaving the onus of initiation of concern entirely to parents would lead to inequity of health care, with the likelihood that those members of society most in need would find themselves least able to access care (the so-called 'inverse care' law). The job of the professional where parental concerns are not raised is to help parents see that there is a concern, to bring the parents to the point of seeking advice, and to provide assistance and a pathway to do so.

### PREVENTION OF DEVELOPMENTAL PROBLEMS

In the UK, the increasing emphasis on primary prevention is supported by the establishment of SureStart programs which aim to ameliorate the multiple disadvantages faced by children growing up in poverty. Evaluation will need to continue to ensure that local programs achieve the desired outcomes for those most in need.<sup>44,45</sup>

### PROBLEMS WITH DEVELOPMENT

#### For the infant and very young child

For the infant and very young child (i.e. under 18 months), most major defects will present neonatally, at the at-risk follow-up clinic or to the family. The presenting disorders include those of motor or general development, vision and hearing. They may be static or progressive and affect more than one area of development.

#### After 18 months of age

After 18 months of age, problems with speech and language, learning, motor competence and behavior problems typically present.

Estimates of prevalence of neurodevelopmental problems are shown in Table 7.5.<sup>43,46</sup>

#### Developmental assessment

Developmental assessment starts with 'information gathering' from all who know the child either informally or more formally using checklists. It then encompasses the 'interview' with parents/caregivers and the 'examination' of the child. The process results in a conclusion, if possible a diagnosis with an etiological explanation, but always a plan of action to meet needs.

Knowledge of the normal patterns of child development enables us to assess the developmental level of a particular child. A major change in the examination of young children with possible developmental problems is the number of norm-based psychometrically constructed tests with standard methods of administration available that examine or test behavior in a number of areas and provide a profile of development. Choice of formal or informal assessment depends on a number of factors.

**Table 7.5** Neurodevelopmental problems and estimates of their prevalence (in parentheses)<sup>43</sup>

<b>Learning impairments</b>
1. Severe learning disability (3.5/1000)
2. Moderate learning difficulties IQ 50–70 (1.8%)
3. Specific learning difficulty including dyslexia (underestimated at 2%)
4. Down syndrome (1/1000)
<b>Motor impairments</b>
1. Cerebral palsy (2.5/1000) – hemiplegia (30%); diplegia (20%); other types (50%)
2. Clumsy child syndrome – developmental coordination disorder (5%); deficits in attention, motor control and perception (1–3%) (overlaps with attention deficit disorder and with hyperactivity)
3. Neural tube defects (1/1000)
4. Hydrocephalus (0.1/1000)
<b>Neuromuscular disorders</b>
1. Duchenne muscular dystrophy (3/100 000)
2. Other neuromuscular disorders
<b>Other chronic neurological disorders</b>
1. Neurodegenerative disorders
2. Other chronic neurological disorders – survivors of brain infections, such as meningitis or encephalitis; damaged survivors of head injury; brain malformations
3. Epilepsy (0.8%) – usually associated with other disorders to require child development service
<b>Speech, language and communication disorders</b>
1. Severe speech language disorder (5/1000)
2. Autistic spectrum disorders (including Asperger syndrome) (116/10 000) <sup>33</sup>
<b>Visual impairment</b>
1. Partially sighted (0.4/1000)
2. Blind (0.3/1000)
<b>Hearing impairment</b>
Significant impairment (> 50 dB loss in better ear) (1.5/1000)
Many children have two or more coexisting disorders
<b>Associated problems</b>
1. Behavior (up to 30%)
2. Nutrition/gastroesophageal reflux/constipation
3. Recurrent respiratory infection
4. Orthopedic deformities
5. Other medical problems (e.g. asthma)
6. Social and family problems

Multidisciplinary professional assessment is the ideal, and the process should be sensitive to the family's awareness, concerns and cultural needs. The assessment process should be explained clearly in advance so that families are able to participate fully. Assessment timing and location should be according to family need rather than professional convenience.

All services should aim to:

1. enhance the parents' understanding of their child;
2. promote the relationship between parent and child;
3. support families as the most significant caregivers;
4. identify services to meet needs, provide practical help and emotional support;
5. use language that is understood by all;
6. evaluate barriers to service use by families.

#### The history

The general aspects of taking a history described in Chapter 8 apply to the child who presents with developmental problems. Here we comment on particular aspects of importance (Table 7.6).

Table 7.6 Topics for history taking

Growth and any medical problems
Feeding
Behavior
Vision
Hearing
Motor skills, including manipulation
Communication, speech and language
Play and interests
Social interaction and relationships
Self-help and personal skills
Drive and motivation for learning

Family history, social and family environment and the pre-, peri- and postnatal history, should all be covered, looking particularly for the risk factors as outlined below. More detailed questions follow, about the concerns in question, and other skill areas.

Certain risk factors increase the likelihood of a developmental impairment. Biological risks may be:

1. prenatal, e.g. use of drugs or alcohol, severe toxemia and viral infections, genetic disorders;
2. perinatal factors, such as prematurity, low birth weight, obstetric complications;
3. neonatal factors, such as neonatal encephalopathy, infections (e.g. sepsis or meningitis) and severe hyperbilirubinemia;
4. postnatal factors, such as injury or non-accidental injury, meningitis, encephalitis, exposure to toxins, severe continuous failure to thrive and severe epilepsy;
5. visual and hearing losses, and other specific learning difficulties.

Environmental risks, such as a parent with learning disabilities or significant mental health problems, history of abuse or neglect and concerns about parent/child interaction all increase the likelihood of a developmental impairment.

**Developmental history.** Although parental recall of milestones may not always be reliable, the most informative history can be obtained through the use of open-ended questions followed by requests for specific examples.

Parents are good at remembering whether or not they or other family members had concerns, and what those concerns were about. They are good at observing current behavior if the right questions are asked. Parents' interpretation of what their child does may be incorrect (e.g. he understands everything), but their observations are usually accurate (e.g. he will fetch his shoes only if they are visible). Parents find accurate estimates of comprehension difficult, as do professionals, unless a specific test is carried out.

Between 18 and 24 months is a particularly good time to note any delays of communication, for example not pointing or not using gaze to regulate communication. Between 24 and 30 months is a particularly good time to note delays in language development, because the child should move quickly from single words to putting words into simple sentences.

Some semi-structured interviews of history taking have been developed for certain situations, for example the Diagnostic Interview Schedule for Communication Disorder (DISCO 2000) developed for detailed history of both normal and abnormal patterns of development where a child might be suspected of having an autistic spectrum disorder, and the Autism Diagnostic Interview.<sup>47</sup> It is important to determine the rate of development of skills in order to establish whether the child has always had a problem or whether there is any possibility of regression (deterioration or loss of skills). If the latter is suspected then the exploration of etiology follows a different path from that of a static nonprogressive disorder. If there is a suggestion of regression, it is useful to inquire at what age the child was at her best and to jog memories with questions such as 'What sort of things was she doing on her last birthday that she cannot do now?'

Past history is directed at elucidating any cause for the problems, either real or wrongly attributed by the parents. Ruling out the latter (e.g. mother working or being depressed as a cause of autism) can reduce or remove parents' guilt and help them in accepting the child's difficulties.

It is particularly important that problems are not wrongly attributed (e.g. to obstetric intervention or pertussis immunization), such that a genetic problem is overlooked. Many obstetric interventions carried out to protect the infant (e.g. forceps delivery) only very rarely cause later problems. What is of greater importance is the underlying reason for intervention, e.g. fetal distress. However, fetal distress is not always the cause of brain damage identified later, since it may in itself be a manifestation of vulnerability resulting from damage caused antenatally.<sup>48</sup> The condition of the baby at birth, e.g. low Apgar score (< 5 at 5 and 10 min), poor feeding, fits, may also be relevant.

**General health.** The child's general health and any illnesses can also be relevant.

**Family history.** Family history is important and inquiries must be made about first and second degree relatives. Any diagnosis, even if apparently definite, must be pursued (e.g. a reported diagnosis of spina bifida in a male cousin turned out to be muscular dystrophy).

In boys with learning disability a history of affected males on the mother's side may highlight the possibility of fragile X syndrome. The parents may need to be examined (e.g. child with hypotonia whose mother has myotonic dystrophy).

**Social history.** Social history is important not only because of its role in etiology, but because social factors may affect the family's capacity to cope with a child with a disability.

### Examination: observations and interactive assessment

Gesell<sup>49</sup> stated that psychological/developmental examination should be regarded 'not as a series of achievement tests but as a means of eliciting significant behavior, which calls for diversified analysis rather than a meagre recording of success and failure'. The examiner needs to create a setting that will most easily show the spontaneous and elicited behaviors that need to be observed. Tables 7.7 and 7.8 and Figure 7.7 set the framework for observation.

The developmental examination should take place in a room with toys appropriate for the child and with one or both parents present. There should be a chair and table suitable for the child to sit at. A history is then taken, all the time observing the child's behavior and interaction with parents. This period of talking to the parents enables the child to get used to the environment and to see that the parents accept strange people. Toys and other play materials, appropriate for the age of the child, should be available (e.g. cause and effect toys, a bell, bricks, truck, doll or teddy, tea-set or other dolls' house toys for the 18 month old and for the older child, miniature toys for pretend play, crayons and pencil and paper and books with single pictures and stories). These are separate from those required for tests.

It is particularly valuable to allow time to observe how the child spontaneously makes use of toys or materials available, before moving onto adult-structured play and interaction. This is because, in certain developmental problems, children are able to function very well when a helpful adult interacts with them, as this creates structure which helps them to organize their responses. However, when left to his own devices the child may be less able to organize his environment and generate any ideas, manifesting in limited or repetitive play, or flitting attention for available activities. Such difficulties will not be apparent from the more structured assessment.

One of the cardinal rules of developmental assessment is not only to look at what the child does but also at 'how he does it'; thus all the time the quality of response is to be evaluated as well as the actual achievement. Following the history and informal observations, more structured and standardized tests for general and specific areas of

Table 7.7 Framework for making developmental observations – birth to 13 months

	Newborn	3 months	4 months	6 months	8 months	9 months	12 months	13 months
<b>POSTURE/GROSS MOTOR MOVEMENTS AND REFLEXES</b>								
Supine	Head to side	Head in midline Hands open Finger play		Lifts head spontaneously				
Pull to sit	No head control		Good head control	Lifts head in anticipation				
Sitting	Flopping forward	Head held up Back curved	Straight back	Sits with hands for support	Sits with no support			
Ventral suspension Prone		Good head control Shoulders up on forearms		Lifts chest off on hands	Forward parachute			
Supported standing				Weight bears Downward parachute		Stands holding on	Walks hands held	Walks alone (18 months age limit)
Primary reflexes	Strong stepping, grasp and Moro reflex	Asymmetrical tonic neck reflex present (2–3 months)	Most (e.g. Moro's) markedly lessen	No primary reflexes persist beyond 6 months				
<b>HAND FUNCTION/FINE MOTOR: Observe use of one or both hands, grasping and releasing spontaneously and on request</b>								
	Fisting persisting beyond 2 months is abnormal		Reaches with one hand- Brings toys to mouth Transfers from hand to hand	Index finger	Pincer grasp approach Releases brick in a container	Mature grasp	Can give a toy on request	
<b>VISUAL BEHAVIOR</b>								
Visual fixation and following	Looks towards bright light and by 4–6 weeks looks at mother's face	Follows face beyond midline	Follows objects through 180°	Fixes on smaller objects > 2.5 cm	Fixes on smaller objects > 1 cm	Fixes on 1-mm sweets		
<b>HEARING BEHAVIOR</b>								
Response to sound	Startle	Searches for sound		Turns head toward sound (at ear level – two stage for above and below)	Turns head to sound directly up and down (above and below ear level)		Turns to sound above head	
<b>LANGUAGE AND COMMUNICATION: Observe vocalization and gestures to attract other's attention, to indicate needs, in response to others' vocalization and to share emotions</b>								
		Cooing		Babbling	Responds to own name	Understands words in context	First word with meaning	
<b>PERSONAL–SOCIAL: Note awareness of parents/carers and strangers, initiation of interactions and response to others' approaches</b>								
	Smiles responsively 6 weeks		Stranger awareness		Waves bye-bye (copies)	Points to request and show		
<b>PLAY: Observe exploration and free play, use of real size and small toys on self and others and initiation and response to social games (e.g. peek-a-boo, pat-a-cake)</b>								
				Bangs and mouths	Looks for fallen toy, pulls string to get toy	Plays pat-a-cake, explores with finger		Uses cup/spoon/brush on self

**Table 7.8** Framework for making developmental observations – 15 months to 5 years

	15 months	18 months	2 years	2.5 years	3 years	3.5 years	4 years	5 years
<b>FINE-MOTOR/PERCEPTUAL COORDINATION: Note spontaneous effort, attention to directions, ability to copy from a model, response to help and praise, attention to task and quality of movements</b>								
Construction skills with 1-inch (2.5-cm) cubes	Tower of two cubes	Tower of three cubes	Tower of six cubes	Puts three cubes in a row for a train	Makes a train with a chimney (39 months)	Three-brick bridge from a model	Steps of six cubes from a model	Steps of 10 cubes from a model
Pencil grasp and drawing	Makes a mark on paper	Straight scribble	In prone at distal end Circular scribble	Middle of pencil Line in imitation	Mature grasp (tripod)	Copies: +	Copies square	Copies triangle
Shape sorting (visuospatial skills)		Simple shapes circles and squares	Circles, squares and triangles	Six-shape sorter	Good scanning of shape sorter before putting shape in and rotating shapes to align – little or no pushing of shapes			
<b>LANGUAGE, COMMUNICATION AND SOCIAL INTERACTION: Note speech quality, use of language: to express need, comment, describe, share interest and initiating and responding for conversation</b>								
Understanding	Simple requests in context: give me ...	Knows two to three body parts	Gives two or more objects on requests	Prepositions: in, on. Gives objects by function	Preposition under/size big/little	Size, color		
Communication and social interaction	Initiates communication, shows, points	Many spontaneous words, repeats words	Puts two words together in phrases		Sentences of three or more words, personal pronouns. Can give full name and gender. Asks what/where questions	Joined sentences, speech mainly clear		
<b>PLAY AND SOCIAL INTERACTION: Note initiating interactions and responding to parent/examiner/other children and use of eye contact and gestures</b>								
	Brushes own or mother's hair	Brushes doll's hair, may feed/put to bed doll/teddy	Plays with small toys, relates two toys. Watches other children	Develops sequence with small toys. Plays with other children. Can share. Offers comfort				

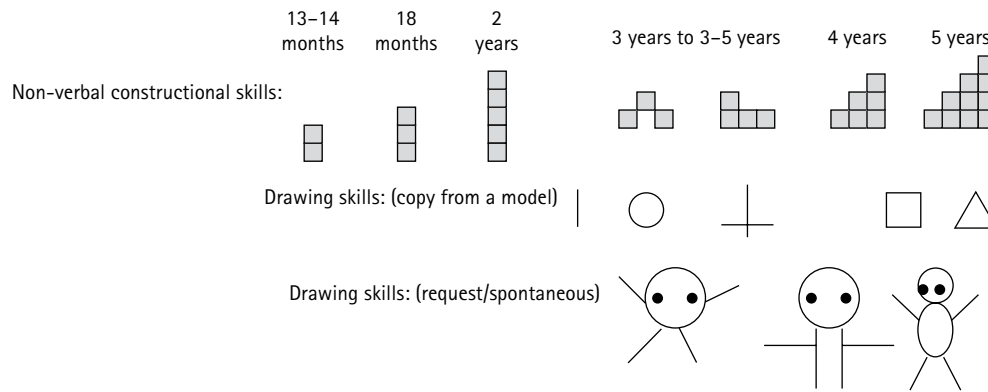

Fig. 7.7 Constructional and drawing skills.

development may be used (Table 7.9).<sup>19,50–52</sup> Some formal assessments deliberately include both structured and unstructured time, e.g. the play-based observation for possible autism, the Autism Diagnostic Observation Schedule.<sup>50</sup>

### Look for patterns of development suggestive of normal variation

Some developmental patterns cause delay in the acquisition of other milestones (e.g. shuffling is associated with late walking). The mean age of walking in children who ‘bottom shuffle’ is 16–17 months and the 90th centile is 23 months.<sup>53,54</sup>

### Look for patterns of development that suggest abnormal development

Besides looking for the acquisition of normal developmental skills, it is also important to look for skills that are present at an earlier stage which should have disappeared and are abnormal beyond a certain age. For example, mouthing is a normal pattern of investigation of the environment at 7–8 months, but after that hand and vision examination increasingly take the place of mouthing.

Persistent mouthing of objects beyond 18 months is indicative of a general learning problem. Persistent casting (throwing forwards or to the side) is a normal behavior at 12 months, but not at 24 months or beyond, and hand regard is a normal behavior at 3–4 months.

Some behaviors are abnormal at any age, for example the persistent visual inspection of objects out the corner of the eye seen in young children with autism. However, some of the excited arm/body actions seen persistently in older children with autism are also seen in normal development at the age of 6–9 months.

### Importance of skill delays

Delays in some areas of development are more important for long term learning than others, for example:

1. Developmental delay in motor skills only is of much less long term significance than persistent significant delays in language and cognitive skills. However, cognitive difficulties frequently accompany severe motor disorders, either due to co-morbidity or because severe motor impairment limits learning through exploration.
2. Self-help competence, for example toilet training, feeding and dressing, can also be dissociated from the level of general learning.
3. Some skills (e.g. symbolic play and language) reflect understanding of the environment and are therefore better indicators of intellectual ability.
4. Make allowance for prematurity under 12 months.

### Child's performance

The child may not perform at her best, and may need to be seen again, perhaps in a more familiar environment. Skills need to be developed in sharing uncertainty with parents and in negotiating a need for observa-

tions over time. It is always helpful to ask parents if the child's behaviors and responses seen are typical. Parents are more likely to accept an opinion if they think the child has behaved typically and it is based on two periods of observation.

### Motor skills, vision and hearing

Make sure that the motor, vision and hearing systems are functioning normally before making judgments about the rest of the child's development.

### Assessment of motor development

To assess motor development in the child under 2 years:

1. watch first;
2. then place in prone, supine, pull to sit, stand, ventral suspension and look for the secondary protective responses as illustrated (Fig. 7.8).<sup>55</sup> Assess tone, symmetry and spontaneous movements and then compare the motor development with other maturity milestones.

**Differential diagnosis of motor problems.** Problems with motor development are most likely to present concerns in the first 2 years of life, although ‘clumsiness’ is a common associated problem in many other developmental delays. Note, however, that early walking does not exclude other developmental problems.

The differential diagnosis of delay in motor milestones is:

1. a normal variant – e.g. shuffler, roller, asymmetrical head turner, toe walker – ask about family history; shuffling and other patterns may have a genetic predisposition;
2. global delay/general learning difficulties/mental retardation;
3. cerebral palsy/other neurological disorder;
4. early presentation of developmental coordination problems – hypotonia and delay;
5. connective tissue disorder.

Clues on examination are scissoring on downward parachute in diplegia (Fig. 7.9),<sup>55</sup> adopting a sitting posture on downward parachute, as in bottom shufflers (Fig. 7.10).

Definite persistent handedness at 6–9 months may indicate pathology. Headlag on ‘pull to sit’ after 8 months is abnormal.

Not walking by 18 months is delayed in a prone developing crawler.

An example of an evidenced-based approach to assessing motor delay is given in Case Study 1 on page 110.

Four common tests used to assess motor skills are reviewed in Wiart and Darrach.<sup>51</sup> As with all tests the emphasis is on knowing the tests and whether each test measures what it purports to measure and whether that is what is needed for that particular child.

### Oromotor skills

A significant impairment of central origin affecting motor development will affect oral skills, as demonstrated in delayed sucking (and with a severe cerebral palsy in abnormal swallowing and breathing). Less severe difficulties may not be so obvious until solids are introduced when textures, lumps, chewing and drooling problems may present.

Table 7.9 Psychometric tests in common use

Test	Age range tested	Training required to carry out test	Areas tested <sup>a</sup>
<b>Complete profile</b>			
Bayley scales of infant development	2 months to 3 years	Professionals including pediatricians	Mental, motor and behavior
Griffiths scales	0–8 years	Clinicians trained and certified in administration	Locomotor, personal social, hearing and speech, eye–hand coordination and performance
British Ability Scales (BAS 11)	2 years 6 months to 17 years 11 months	Psychologists	Verbal and nonverbal reasoning/attainments and diagnostic scales
Wechsler Preschool and Primary Scale of Intelligence (WPPSI-III)	2 years 6 months to 7 years 3 months	Psychologists	Four core subtests (2 years 6 months to 3 years 11 months) – 2 verbal, 2 performance Seven core subtests (4 years 0 months to 7 years 3 months) – 3 verbal, 3 performance, 1 processing speed VIQ, PIQ and IQ derived
Wechsler Intelligence Scales for Children WISC IV (WISC)	6–16 years	Psychologists	10 core subtests: 3 verbal comprehension, 3 perceptual reasoning, 2 working memory, 2 processing speed and 5 supplemental tests
Stanford–Binet intelligence scale, 4th edition	2 years to adult	Psychologist	5 subscales: verbal and nonverbal
Schedule of growing skills	0–5 years	Any professional	Profile of development in nine areas – based on Sheridan. Gives a general developmental overview
Miller assessment for preschoolers	2 years 9 months to 5 years 8 months	Any professional	Identifies developmental delays in sensorimotor and cognitive abilities in verbal and nonverbal areas
Kaufman assessment battery for children	2 years 5 months to 12 years 5 months	Psychologist	3 scales, sequential, simultaneous processing and attainments. Mental processing composite derived. There is an adolescent extension scale
Developmental neuropsychological assessment (NEPSY)	3–12 years	Psychologist	Attention/executive function; language; sensorimotor functions; visuospatial processing; memory and learning
<b>Language</b>			
Reynell DLS – Developmental Language Scale (RDLS111 (1997))	1–7 years	Speech therapists, psychologists, some teachers	Verbal comprehension and verbal expression
Test of Word Knowledge (TOWK)	5–17 years	Any professional, usually SLT	Detailed evaluation of semantic development and lexical knowledge; 7 subtests
Picture vocabulary test (Peabody or British)	2–8 years	Any professional	Tests single word vocabulary. The child selects picture most appropriate for the given word
Clinical Evaluation of Language Fundamentals, 4th edition (CELF)	5 years to 16 years 11 months	Any professional, usually speech therapist	Four core subtests provide a total language score, with additional composite scores in language structure, language content, language content and memory, working memory scores with supplementary subtests
Preschool CELF, 2nd edition	3–6 years	Any professional, usually SLT	Seven norm-referenced subtests in: sentence structure, word structure, expressive vocabulary, concepts and following directions, recalling sentences, basic concepts, word classes. With supplementary subtests and pre-literacy rating scale descriptive pragmatics profile
<b>Speech/articulation tests</b>			
Edinburgh Articulation Test (EAT)	3–8 years	Speech therapist	Picture naming task to assess English sound system
Renfrew Action Picture test (RAPT)	3–8 years	SLT	Picture description task designed to elicit specific information and grammar
Renfrew Bus Story	3–8 years	SLT	Story retelling task with pictures. Scored for information, grammar and sentence length
Preschool language scales	2 weeks to 6 years	Any professional usually SLT	A developmentally based assessment combining parental report and direct test – best for age 1–4 years
<b>Nonverbal intelligence tests – suitable for those with impaired hearing</b>			
Raven's Progressive Matrices and Vocabulary Scales	5 years to adult	Any professional	Assesses two complementary components of general intelligence: the ability to think clearly and make sense of complex data and the ability to store and reproduce information

Table 7.9—cont'd

Test	Age range tested	Training required to carry out test	Areas tested <sup>a</sup>
The Snijders–Oomen nonverbal intelligence test, revised	5 years 5 months to 17 years		Reasoning and spatial abilities subtests
Leiter International Performance Scale, revised	2 years to adult	Psychologist or appropriately trained professional	Visualization and reasoning battery, also attention and memory
<b>Visuomotor and motor tests</b>			
Goodenough–Harris drawing test (Harris <sup>19</sup> )	3–15 years	Any professional	The child is asked to draw a man and a score is derived from the content and converted to a mental age
Bender Gestalt test	4 years to adult	Test of perceptuomotor function	Nine designs for the child to copy
Movement Assessment Battery for Children <sup>47</sup>	4–12 years	Any professional usually physiotherapist or occupational therapist	Eight items divided into three subsections: manual dexterity, ball skills, and static and dynamic balance
Frostig – Developmental Test of Visual Perception (DTVP)	4–8 years		Five areas are tested: eye motor coordination, figure ground, constancy of shape, position in space and spatial relationships
Developmental test of visuomotor integration (Beery)	3–17 years		Developmental sequence of geometric forms to be copied with paper and pencil
Test of visual perceptual skills, 3rd edition (TVPS-3)	4–19 years	Occupational therapists, psychologists, education diagnosticians, developmental optometrists, learning specialists, and other assessment professionals	Perceptual skills: visual discrimination, visual memory, visual-spatial relationships, form constancy, visual sequential memory, visual figure-ground, visual closure
Motor-Free Visual Perception Test, 3rd edition (MVPT-3)	4 years to adult	Any professional	Visual perceptual ability without any motor involvement
Test of Visual-Reasoning and Processing Skills (TVRPS)	5–14 years	Any professional	Four subtests that measure visual-reasoning and processing abilities: visual picture completion, visual-spatial relationship, visual discrimination, part-whole relationships
Matrix Analogies Test – expanded form (MAT-EF)	5–17 years	Psychologists or appropriately trained professional	Four specific subtests: pattern completion, reasoning by analogy, serial reasoning, and spatial visualization
<b>Memory and attention tests</b>			
Children's memory scale	5–16 years	Psychologists	A variety of memory dimensions: attention and working memory, verbal and visual memory, short- and long-delay memory, recall and recognition, learning characteristics
Rivermead behavioral memory test	Childrens version: 5–10 years 11 months Adult version can be used 11–15 years	Psychologists	Assesses memory skills related to everyday situations both episodic and prospective
Test of everyday attention for children (TEA-Ch)	6–16 years	Psychologists	Comprises nine subtests: selectively attend; sustain their attention; divide their attention between two tasks; switch attention from one thing to another; withhold (inhibit) verbal and motor responses
<b>Play test</b>			
Symbolic play test of Lowe & Costello	1–3 years	Any professional	Four groups of toys presented without verbal instructions. Results in an age equivalent score
Autism Diagnostic Observation Scales ADOS (Lord et al) <sup>47</sup>			Social interaction, communication and imaginative play observed
<b>Tests for those with visual impairment</b>			
Reynell Zinkin scales	Birth to 5 years	Any professional	Five subscales: social adaptation, sensorimotor understanding, exploration of environment, response to sound and verbal comprehension, expressive language and a communication subscale for children with additional problems

(Continued)

Table 7.9 Psychometric tests in common use—cont'd

Test	Age range tested	Training required to carry out test	Areas tested <sup>a</sup>
<b>Behavior scales</b>			
Vineland adaptive behavior scales	0 to adult	Any professional	Survey or interview form: semistructured carer interview for assessment of communication, daily living skills, socialization and motor skills and a maladaptive section
Strengths and difficulties questionnaire (Goodman)			Teacher and parent version summarizes behavior problems in prosocial, hyperactivity, conduct, emotional and peer group areas
Other behavior schedules (see O'Brien et al <sup>52</sup> )			

<sup>a</sup> Most of these tests are available from NFER – Nelson, Danville House, Windsor 1DF, or Harcourt Assessment, Halley Court, Jordan Hill, Oxford, OX2 8EJ. SLT, speech and language therapist.

### Assessment of vision

Significant visual impairment has a potentially serious and complex impact on all areas of development, including cognition, language, social, gross and fine motor abilities. Early recognition and specialist rehabilitative support are essential. Techniques to improve vision in children with visual impairment have been shown to be successful in promoting visual development.<sup>56</sup> Improving vision to the level of object awareness from perception of light only in the first year of life can have a significant impact on developmental outcome.<sup>57</sup>

Assessment of vision in children should include history and examination. The history should cover:

1. any parental concern about the child's vision;
2. visual behavior relevant to the child's age (Fig. 7.2);
3. suspected squint.

Examination of the eyes includes assessment of:

1. any gross ocular pathology (including ophthalmoscopy);
2. the pupillary response to light;
3. eye movements (smooth pursuit and saccades);
4. squint – checking that the corneal reflection of a light is in the same position in the two eyes and by doing the cover test (in the cover test each eye is covered in turn while the child visually fixates on an object and a note is made of whether the uncovered eye moves to take up fixation).

Visual assessment includes:

1. measurement of visual acuity – ability to distinguish separation of two visual targets and therefore to distinguish detail;
2. detection vision – ability to recognize/detect individual targets;
3. electrophysiological measurement of retinal and visual pathway function.

Fig. 7.9 Downward parachute in (a) spastic cerebral palsy, (b) dystonic cerebral palsy. (After Milani-Comparetti & Gidoni 1967.<sup>56</sup>)

**1. Visual acuity.** The Snellen letter chart was the accepted standard for measurement of acuity until recent years. The acuity is expressed as the distance at which a particular letter size is seen by a person with normal vision. The result is given as a pseudofraction – on top the distance tested at (the standard distance being 6 m or 20 feet), and below the size of the letter seen, thus 6/6 is normal vision and 6/60 very poor vision.

The logMAR (log of the Minimal Angle of Resolution) is now the increasingly accepted standard. The smaller the letters on the chart, and the further away they are, the smaller will be the angle subtended to the eye by the letters and therefore the smaller the value of the logMAR score associated with it. The logMAR scale allows more effective and precise analysis of visual acuity scores because of the equal linear steps of the scale. The progression of letter height is that any line is 1.2589 times greater than the line below. This multiplier is the root of ten or 0.1 log unit. The results are expressed as a decimal, thus the line of letters equivalent to 6/6 is 0 and 6/60 is 1.0, and each letter recognized contributes to the acuity result, as a proportion of the number of letters on each line.

Letter charts with reduced type are used for near vision in both tests. Measurement of acuity by standard adult methods is reliably possible from the age of about 5–6 years.

In younger children tests need some adaptation to allow for several developmental issues, but this does not require compromise of the adult standard after 2.5–3 years.<sup>58</sup>

Although young children cannot name letters, by the age of 2.5–3 years over 85% of children are able to match letters and by 3 years most children can do so.<sup>59</sup> Difficulties with attention control arise at a test distance of 6 m and children also have difficulty understanding the task when several lines of letters are presented simultaneously. Visual acuity should be measured if possible in each eye separately; however, a significant proportion of children under 3.5 years of age are unable to accept occlusion of one eye (46% of 2.5–3 year olds and 73% of 3–4 year olds will accept occlusion).<sup>59</sup> In this age group it is therefore advisable to obtain a measure with both eyes open before attempting to cover one eye.

To address these issues Sonksen devised a test of visual acuity, the Sonksen logMAR test based on the adult logMAR standard recommended by Bailey and Lovie<sup>60</sup> with modifications to support the developmental issues without compromising the adult standard. The adaptations were those used for the Sonksen Silver Acuity System<sup>58</sup> based on the Snellen standard. The test includes a booklet with several cards, each with a single row of four letters of each size (using the six letters known to be least confusing for young children<sup>61</sup>) surrounded by a crowding bar, a key card for letter matching and a training booklet. Seating the child at a small table and using a test distance of 3 m also improves concentration and co-operation with the test. Using this test, an acuity measure for both eyes can be obtained in 80% of 2.5 to 3 year olds, in 94% of 3 to 3.5 year olds and in 99% of children after 3.5 years.<sup>62,63</sup> Other tests designed for younger children include the Cambridge crowding test and the Keeler logMAR test.

Sheridan<sup>61</sup> devised a test (STYCAR letter test) that involved the presentation of single letters of decreasing size at 3 m. This is still widely used for young children, but these tests have been shown to significantly overestimate acuity, especially in children with amblyopia, by as much as three lines and therefore linear acuity (as above) should be measured wherever possible.

The Crowded logMar Kay Picture Test<sup>64</sup> uses pictograms designed to be of equivalent proportions to Snellen letters and can provide an estimate of acuity in children from 19 months to 2–2.5 years, when children are unable to match letters or in the small proportion of children from 2.5 to 3.5 years who cannot complete a letter-based logMAR test. They do then require the vocabulary to name the pictures. This test is said to be accurate to within one line of logMAR acuity tested by standard methods.<sup>65</sup>

Visual acuity can be measured from 2 months using forced choice preferential looking tests such as the Teller, Keeler or Cardiff Acuity Cards.<sup>66</sup> In this test the infant is shown two targets on a card. One is uniformly gray and the other has either black and white stripes (Teller or Keeler) or a pictogram similar to the Kay pictures (Cardiff). The stripes or pictograms become sequentially narrower or smaller on each card according to a standard scale. An infant will automatically look toward the more interesting visual target until they reach the limit of their acuity.

Opticokinetic nystagmus may also be used in very young children to estimate acuity. It can be demonstrated using an opticokinetic drum with black and white stripes of varying diameter. Nystagmus will not be elicited at the limits of the child's acuity (i.e. the stripe width is too small for the child to discriminate).

Visual acuity gradually improves with age. This has been demonstrated using grating acuity in infancy, with the Sonksen – Silver Acuity System and the Sonksen logMAR test in children aged 2.5–8 years. A large population-based study demonstrated an increase in acuity with age that is steepest in the 30 months between 2 years 9 months and 5 years 3 months and continues up to age 8 years and beyond. At 2 years 9 months 50% of children achieve binocular acuities for linear displays of 0.200 (3/4.75), by 5 years 3 months this has risen to –0.075 (3/2.6) and by 7 years 9 months to –0.175 (3/2).<sup>63</sup>

**2. Detection vision.** In the infant, evaluation of vision should begin with observation of detection vision. Near detection will include observing the child fix and follow a silent object presented at about 30 cm from the face. In the first weeks of life the infant will be most likely to follow the examiner's face and may ignore other objects (Table 7.7). Infants show little interest in small objects on a table top until 9 months. By 9–12 months, near detection vision may be tested by observing visual fixation on one small sweet (a one hundred and thousand measuring – approx 1.2 mm), placed on a dark contrasting background. In children with normal vision, immediate and sharp fixation is expected. Children with significant visual impairment (equivalent of 6/60 or greater measured with Keeler cards) may show visual awareness of this small sweet, but they show slower fixation, inexact location and peering. Inability to locate this target therefore suggests a child has severe visual impairment and is likely to meet criteria for registration for Severe Sight Impairment (previously Blind registration).

Distance detection can be measured by establishing the size of the smallest object the child can see at a particular distance. Sheridan designed a test using ten white balls of standardized diameter, which are either rolled on a dark strip horizontal to the line of the infant's gaze at 3 m from the child, or mounted on sticks for presentation from behind a dark screen (STYCAR graded balls test). This test is most appropriate in children from the age of 9 months to around 15 months because it relies on a young child's attention being drawn to the major stimulus in the environment (as in the distraction hearing test); after this age it is less reliable. It is important to note that visualization of even the smallest ball does not denote perfect vision, and rolling the ball considerably enhances its visibility. These tests can be helpful in describing a functional vision in children with severe visual impairment and for some children with learning disabilities who are not able to do acuity tests.

**3. Electrophysiological Assessment.** Objective measurement of vision may also be obtained by measuring the electrical response to a given visual stimulus from the retina (the electroretinogram) and the visual cortex (the visual evoked potential). The response to a simple flash and to graded check patterns can be recorded.<sup>67</sup>

**Assessment of vision in the child with a visual impairment.** In the child with visual impairment, the largest sized letters may not be recognized at 3 m and so the distance of testing is reduced until the letters are identified. In children with the most severe visual impairment, measurement of acuity at a distance may be more difficult or impossible. A methodical approach to the observation of functional (near and distance detection) vision should therefore be made. Care needs to be taken in interpretation, because the detection of small objects at near distance may lead to an overestimation of vision (see above).

A description of the size of object, the visual complexity and the distance recognized, can be used to provide advice to parents and the professionals working with them about toys and educational material that will be appropriate for learning.

A useful visual scale for near detection vision in the most visually impaired has been developed by Sonksen (personal communication) using visual targets of standardized size, ranging from a light source in a darkened room, a large, light-reflecting dangling ball through to smaller nonlight-reflecting targets. The distance from the target and the child's

ability to fixate and/or follow can then be recorded. The Stycar fixed or rolling balls, everyday objects and pictures may be shown, initially at 3 m and then moving in methodically to 2, 1, 0.5 and less than 0.5 m. The distance at which the target is recognized is then recorded. The test material should only be presented once because a child may be able to make an intelligent guess when it is re-presented.

The ability to identify pictures both near and at a distance by a child with visual impairment will vary with the level of background contrast and the level of detail required for recognition within the picture. A child may recognize a clear picture of a dog on a white background, but fail to pick out the same picture on less well contrasted background or when part of a more complex picture. Advice to teachers about this is essential, because much educational material is presented in a visually complex way and at a distance. Sonksen and Macrae<sup>68</sup> devised a picture recognition test using a selection of Ladybird pictures graded according to visual complexity, which provides a helpful guide to advice.

Some more complex visual disorders are outlined below.

1. Sometimes there is a delay – so called delayed visual maturation – in which the visual behaviors outlined in Figure 7.2 are all slower, often by months. A proportion of such children are later found to have other developmental impairments, which become clearer with time.<sup>69</sup>
2. Some children, often with more profound neurological damage, have more permanent cerebral visual problems.<sup>70</sup> In these children vision may show apparent variability which reflects limitations of visual attention. Damage to specific areas of the complex visual pathways and visual areas in the brain may cause very specific defects (e.g. movements may be seen, but not the level of discriminating detail that allows recognition of objects or prosopagnosia – a difficulty of face recognition, which is usually, but not invariably, an acquired brain damage deficit).
3. Visuoperceptual skills, which are particularly at risk in premature babies under 32 weeks' gestation and affect pattern recognition and topographical skills which can be assessed with specific tests.
4. Eye movement disorders, such as ocular motor apraxia may present with signs of early visual impairment, but by deploying motor control skills, with maturity the visual acuity is shown to be unimpaired.

### Testing hearing

Persistent hearing loss can significantly impair speech and language development. Treatment is either by removal of the cause (in the case of middle ear effusion, or 'glue', causing conductive loss) or by aiding, either with conventional hearing aids or with a cochlear implant (in the case of sensorineural loss) and special teaching. Such interventions can change the outcome for young children and early detection is therefore a high child health priority, with 1–2 per 1000 children having sensorineural hearing loss. Even if no impairment is found on neonatal hearing screening a hearing loss may arise later due, for example, to secretory otitis media or late onset sensorineural loss.<sup>71</sup> Parental concerns should always be taken seriously and a hearing test should be arranged after any illness which has a high risk of hearing loss, e.g. meningitis, and should form part of the evaluation of speech delay. A history suggestive of 'risk' for hearing impairment (family history, ototoxic drugs, meningitis, NICU/SCBU experiences, structural palatal abnormality) should be elicited. Assessment of hearing in children with other developmental disorders needs particular attention as the effects of impairment on function tend to be cumulative.

Tests of hearing may be divided into objective and subjective – those reliant on child co-operation.

#### Objective tests

1. *Otoacoustic emissions.* This technique is applicable to the infant of any age, can be carried out in the neonatal period and has a sensitivity and specificity that makes it suitable for universal screening. However, it is only a screen of cochlear function and definitive threshold estimation requires brainstem evoked response testing.

2. *Brainstem evoked response audiometry [or auditory brainstem response (ABR) assessment]*. This technique requires a still or sleeping subject, and may therefore require sedation. The stimulus sound is delivered by headphones or insert earphones. The most common stimulus is a broad-band 'click' which facilitates neural synchronicity but contains most energy in the mid- to high-frequency range, limiting threshold estimation to these frequencies. In threshold ABR assessment, responses are recorded at different stimulus intensities, allowing threshold estimation. Diagnostic ABR involves the examination of the morphology and latencies of waves recorded at higher intensities, allowing assessment of the site of lesion in cases of known impairment.

**Subjective (behavioral) tests.** These depend on co-operation and developmental level. They are thus also a guide to the developmental level of function of the child (Fig. 7.2). The tests can be used at any age, depending on the functional level, i.e. a child or young person with learning difficulties may still be best tested using distraction or visual reinforcement audiometry techniques (perhaps with modifications) at any age. Care needs to be taken to distinguish between hearing acuity, auditory attention and speech processing and comprehension. For example, children with autism may hear normally or even show apparent hypersensitivity to specific sounds, but may not show any attention to adult speech. Children with disorders of attention may also be able to hear normally but not show sustained attention to listening tasks (or any other tasks). Children with speech delay may be slower processors of speech and language, present as poor listeners and later be shown to have poor auditory short term memories. Therefore, even when these children hear normally, they may show apparent impairment in subjective tests.

1. *Distraction test and visual reinforcement audiometry.* The ability to locate sounds at ear level is mature by 7–8 months and prior to otoacoustic emissions was used for universal screening. The technique requires a well and alert baby who is not in an overactive or distressed state, a quiet room, two people who are trained and skilled in the technique and an adult to hold the child who is instructed to remain neutral and nonresponsive. The adult in front (the distractor) gains and controls the child's attention with an interesting toy, which may be moved or presented in such a way to attract the child's attention, and then the interest is diminished either by stopping it moving, covering or removing it. Immediately on reducing interest in the distracting object, the other adult (or a mechanical device) introduces a sound stimulus. The test stimuli should be frequency specific at a measured sound level, and include voice (both low frequency and high, e.g. a sibilant 'ss'), a specially designed rattle (high frequency) and electronically generated 'warble' tones. The usual response is a full head turn to locate the stimuli. Minimal sound levels eliciting a reliable response can be measured using a sound level meter and the stimuli are designed to test the range of frequencies needed for speech development. The location ability on ear level at 6–7 months, above and below ear level at 8 months and above the head at 12 months are markers of perceptual/cognitive maturation. However, babies of 9 months and more may also learn to play games and check who is behind them! Other common invalidators of this test are visual cues (including shadows and/or reflections visible to the baby), auditory cues (e.g. creaking shoes, floors) and even olfactory cues.
2. For this, and other, reasons *visual reinforcement audiometry (VRA)* is an important technique. In VRA the child is generally seated, again on an adult's lap, between loudspeakers. Warble tone stimuli are presented, initially at suprathreshold level, and the child's attention drawn (by a tester seated in front of the child) to a visual reward (often a bright or animated toy hidden behind smoked glass) which is illuminated briefly. Once the child has associated the auditory stimulus with the reward the stimulus level is reduced and the reward delayed until the child has begun to search for it (a positive response). In this way assessment of threshold can be

performed for stimuli at different frequencies. The visual reward has been shown to elicit more responses than the social reward used in distraction testing, and the electronic stimuli used in VRA can be more accurately calibrated in terms of level and frequency. There are many reasons why these tests may not work well, but a failure to respond on the baby's part should be taken seriously as a developmental as well as a hearing concern.

3. *Behavioral tests:*
  - (a) *Speech discrimination tests.* The principle is choosing toys or pictures of objects that are paired and demand careful listening and hearing to discriminate, for example cup/duck, plate/plane. Children can start to co-operate with such speech tests from 24 months but this is dependent on development of understanding of language (noun labels) and the youngest children may not manage the full 14 toys of the McCormick test (a popular example) at that age. Speech tests in the form of word lists can be used for all ages. The child sits at the table with the examiner checking that all toys can be identified at normal speaking voice and then with the voice lowered and the mouth covered, the child is asked to show each in turn. For younger children the 'co-operative test' can be performed in which the child is asked to 'give' toys to 'mummy' (or 'daddy'), 'teddy' or 'dolly', allowing assessment of speech discrimination.
  - (b) *Conditioning/performance tests.* From 30 months and by 36 months children can carry out an action in response to a stimulus and have sufficient control to wait for the stimulus. The stimulus used is a machine emitting tones of a range of frequency and decibel level. The technique is a conditioning one. The child, sitting at the table, puts a brick in a box or a pegman in a boat every time the adult says 'go'. After managing this, the child listens for a tone and puts the brick in, or similar action. Once the child can do this action reliably, the child usually quickly learns to wear headphones and each ear can then be tested individually using pure tones (i.e. tones containing only one frequency), producing a pure tone audiogram – the gold standard hearing test. The ability to manage such tests can be a guide to developmental maturity.

**Testing children with developmental disorders.** The above tests can all be adapted for use with children with disabilities. Children with visual impairment will experience delay in sound localization and may therefore not respond by turning to sound in the distraction tests. Those with motor impairments may also have difficulty with location and/or hand actions. Objective tests are increasingly frequently employed to confirm normal hearing.

### **Problems with speech, language and communication**

**Speech and language delays.** Speech and language delays are among the commonest developmental problems in children, and parental concern should always be taken seriously. A problem with speech and language may be an indicator of a broader developmental problem and all children must have their hearing tested.

Co-morbidities are common and together with severity are important in prognosis.

In general, children have significant problems if they do not babble in the first year, have less than 10 words at 2 years and are not speaking in sentences by 3 years. Most children have adult syntax and grammar by 4 years and are intelligible to most people.<sup>72</sup> These milestone absolutes, however, ignore the qualitative impairments in the use of speech and language for social communication, which are such a key part of social skills.

A problem affecting speech or expressive language only is generally regarded as being less severe in terms of long term significance compared with comprehension problems. However, the view that expressive disorders all have normal receptive skills is less tenable, as increasing research has shown subtle problems not previously found on cruder tests. Many children have problems in all areas of speech, language and communication.

It is helpful to think of speech and language as a means for getting needs met, sharing interests and for mental representation for thinking abstractly – an inner language. Language and communication have forms and functions. The forms (i.e. speech, gestures, facial expressions), their maturity and complexity and how well they are coordinated together, need to be assessed as well as the functions of the forms – needs met, comments, requests, frequency (both initiation and response).

Getting needs met can be verbal through words/sounds, or the written symbol/word may substitute for spoken words, or nonverbal, e.g. through gesture and facial expression which are both social and symbolic. Other nonverbal methods can be nonsocial/nonsymbolic [where there is no representation of the object (or idea)]. These include not using another person at all but going to get something, either directly, or by pulling a chair over and climbing up, bringing an object (e.g. a bottle of juice because a drink is wanted), or taking the parent by the hand or pulling/pushing them towards the object.

Concerns about reciprocity in communication and its social and symbolic function are often not noted in young children, even when quite extreme under the age of 18 months, and especially in a first child. By this age, children should show not only an increasing understanding of phrases and interest in people talking to them, but a desire to share, show and take turns with pointing used both for needs and interests. Persistent failure to do this may indicate a social communicative problem. Indeed, a lack of gaze monitoring, in combination with a lack of pointing for interest and simple pretend play, by 18 months of age was highly predictive of autism in the CHAT screening study.<sup>41</sup> The same study showed that over 97% of 16 000 children were able to follow an adult pointing at a distant object, were using pointing themselves to get their needs met and show things, and 93% were said by their parents to show pretend play by 21 months of age.

Some children with speech and language delays will be slow in all aspects of these skills. Those with speech/articulation problems will have better comprehension and communication but poor unintelligible speech and may have oromotor delay or disorder.

A common clinical presentation is seen in young children with language learning disability in the transition from associatively learned words to symbolic language. Parents report that the child reaches the stage of imitating word forms, but then stops progressing and may indeed lose those first words. One explanation may be that these children have not truly mastered the connection between words spoken and representational meaning and have failed to progress to the higher levels of language learning. Another common experience is for parents to say that children produce words only in situations of extreme emotional provocation or only once and never again; the explanation is likely to be that the language is attached to very particular contexts. Rapid word learning, 'fast mapping', is a skill of normal language acquisition that is significantly poorer in language impairments. A prolonged period before the child moves from single words to sentences is also more common in delayed and disordered development.

Even experts can overestimate the child's comprehension of language. Where there are any concerns, specific tests should be carried out.

### **Behavior**

Food fads, sleep problems, night waking, problems of compliance and temper tantrums are part of normal development between 2 and 5 years of age, and show some continuity through those years. When the behaviors of normal development are functionally impairing for parent and child then they may or may not be called a disorder, but they certainly warrant assessment and intervention. Any developmental impairment puts a child at risk of psychiatric disorder, particularly severe learning and communication difficulties. Extremes of temperament also contribute to risk, as do family factors such as maternal mental ill health, family conflict, school-based difficulties and any other problem with parent – child interaction.

## **LEARNING IMPAIRMENTS**

The terminology of neurodevelopmental impairments leading to functional disability continues to be problematical and different in the USA, the UK and Europe. For example, learning disability is the preferred term in the UK for what would be referred to as mental retardation in the USA. This is defined as an impairment in intellectual learning and adaptive skills to a degree that significantly impairs normal function and on standardized tests falls outside two standard deviations below the mean. Although the implication is that all aspects of development will be affected, in practice this is variable and within mental and adaptive skills certain strengths and weaknesses are common. In severe to profound learning difficulties a child may show normal acquisition of motor milestones, but motor development is usually slower. This may be evident in delayed achievement of milestones, but with a normal pattern of motor development with or without hypotonia (floppiness). A distinction is usually made between:

1. general learning difficulties;
2. specific learning difficulties.

It is common, however, for these distinctions to be blurred and overlap in practice.

### **SPECIFIC NEURODEVELOPMENTAL IMPAIRMENTS**

The term 'specific' is used to mean that the skill in question is more delayed than would be expected from the overall level of cognitive ability. Although it is convenient to classify these as covering different functional domains, in practice overlaps of impairment are common.<sup>73,74</sup> This reflects the more common problem, seen in children, of integration of information processing in a developing brain, rather than the 'damage model' which comes from the study of adults, where brain behavior relationships may be much more specifically anatomically located. Both delay and disorder (differences in developmental pattern) occur in the problem area and often it is difficult to separate these elements. Specific neurodevelopmental impairments include:

1. specific developmental disorders of speech and language;
2. specific developmental disorders of acquired academic skills, for example reading, spelling and mathematics;
3. specific developmental disorders of motor function (developmental co-ordination disorder – clumsy child);
4. autistic spectrum disorders (also called the pervasive developmental disorders) – these disorders are usually classified in the international classification systems under the psychiatric disorders section, but can properly be considered as neurodevelopmental impairments;
5. specific impairments of memory (short or long term episodic or declarative) and learning;
6. specific developmental impairments of attention (usually with impulsivity and distractibility plus or minus hyperactivity and with failure of inhibition control as the likely underlying difficulty);
7. specific developmental impairment of executive function.

Developmental impairments of attention, with or without hyperactivity, are usually classified under the psychiatric disorders, but the range of functional impairments is due not only to a failure of inhibition. Often there are additional problems with other processes of executive function (i.e. the planning, organizing and carrying through of ideas and actions) and hence these disorders are included here as a neurodevelopmental impairment.

All neurodevelopmental impairments place the child at increased risk of additional developmental impairments and behavior problems, which may be of sufficient severity for a psychiatric disorder diagnosis. All these neurodevelopmental impairments have their origin in brain function, either at a neuroanatomical or neurochemical level, and can present as behavioral or emotional problems as well as deficits in input (perception) or output functions (e.g. in speaking or recording). They are probably underdiagnosed.

Combinations of developmental impairments that are particularly common are those of attention and motor perception with or without language and learning delay. These are referred to as Delayed Attention and Motor Perception (DAMP) by Scandinavian clinicians. The autistic spectrum disorders are frequently associated with language learning difficulties and problems with motor coordination. These neurodevelopmental impairments are all described in Chapter 22.

The developmental assessment of these varying problems requires analysis and description using appropriate tools for the child's age often by a multidisciplinary team.

## PHYSICAL EXAMINATION

A full examination should be carried out as described in Chapter 8. Some aspects are particularly important if the child has a developmental or neurological problem and these will be commented on. The physical examination is generally left to the end of an assessment as the child may become upset and this would interfere with the developmental examination.

### Motor examination

Motor examination is best carried out by observing the child's movement patterns and posture. This can be done during the developmental examination, when the child is walking, speaking and handling material (e.g. tendency to keep the forearm pronated and rather deliberate finger movements in mild spasticity). Indeed after observing the child, one should have a good idea of the nature and extent of any motor problem and examination of tone, reflexes and power is largely confirmatory.

### Compare both sides of the body

It is useful to compare the two sides of the body and to determine the child's hand preference. The motor skill, tone, reflexes or the size of the limbs may be significantly asymmetrical suggesting hemisphere dysfunction and therefore focal pathology (mild hemiparesis and visuospatial difficulties).

### Head circumference

Head circumference must always be measured and plotted on a centile chart and compared with the child's height and, if there is any discrepancy, with the parents' head circumference (as this is the most common reason for a large head).<sup>75</sup>

### Optic discs

Examination of the optic discs and fundi is difficult, but can be valuable in diagnosing particular disorders (septo-optic dysplasia) as well as raised intracranial pressure.

### Appearance

Dysmorphic features and congenital malformations must be looked for because they may suggest a particular syndrome or etiology (e.g. fetal alcohol syndrome).

### Skin

The skin should be carefully examined for pigmented and depigmented spots (e.g. looking for specific features of neurofibromatosis or tuberous sclerosis).

### Growth

Height, weight and growth rate should be determined as these may indicate a condition such as hypothyroidism.

### Mental state

The child's mental state should be observed, e.g. is the child hyperactive, impulsive? Does the child concentrate well? Is the child having absence or other seizures?

## Is there more than one problem?

Co-morbid neurodevelopmental conditions are common so it is important to remember that the child with one neurodevelopmental problem may have others.

## EVALUATION AND INTERPRETATION

The purpose of assessment to identify an impairment in development is to make a diagnosis and seek to intervene positively to improve outcome and function for the child and family. Evaluation and interpretation of the historical, observational and test data should lead to:

1. a profile of the child – both assets and difficulties (Table 7.10);
2. a management plan to be agreed with parents and to include ways of implementing it (Table 7.11);
3. appropriate onward referrals for intervention, specific therapy, genetic advice;
4. ensuring voluntary services and social services benefits are discussed and parents are supported to access these;
5. within the UK legal framework, if the child is likely to have special educational needs there is a duty to inform the education department, with parental permission, so that they can make their own assessment (Code of Practice Guidelines in the UK<sup>76</sup>);
6. family support through social services, including respite as needed;
7. written record of findings and discussion to be given to parents;
8. further appointment to discuss report and plan, identify a key worker if complex neurodevelopmental disorder, further information and counseling as needed and date for further appointment.

### Disclosure discussion

The sharing of information about possible impairment and disability (disclosure discussion) has been the subject of audit and research, which show how important this time is in its impact on the family both in the short and long term and how training can affect satisfaction.<sup>77</sup> A report by the NHS Executive Guide to Good Practice commented in 1996 that 'Despite publication of research and recommendations on good practice, this remains a subject of dissatisfaction to a significant number of families.'<sup>78</sup>

Important principles for disclosure are given in detail in a report by a voluntary organization SCOPE<sup>79</sup> and include the following key headings:

1. valuing the child;
2. respecting parents and families;
3. preparation; ensuring privacy, sufficient time;
4. who should be there; both parents;
5. tuning in to parents: effective communication;
6. next steps: practical help and information.

Table 7.10 Child profile

Diagnosis of the presenting condition
Any other specific neurodevelopmental impairments
Level of intellectual function
Medical condition, either associative or causative, to include a hypothesis about etiology that might need tests for confirmation or refuting
Associated psychosocial situations that may or may not be thought to be causative or contributory
Style of learning/motivation and needs

Table 7.11 Aims of appropriate onward referrals for intervention, specific therapy, genetic advice

Reinforcing acquired skills
Teach developmentally appropriate skills
Provide missed experience
Make use of other skills to overcome difficulties
Use learning style to promote learning

## INTERPRETATION OF ABNORMAL DEVELOPMENT USING AN EVIDENCE-BASED APPROACH AND DEVELOPMENTAL ASSESSMENT FINDINGS

### Case study 1: The child of 18 months who is not yet walking<sup>80</sup>

A boy is referred because of failure to walk independently at 18 months. Does this matter?

Not walking by 18 months places the child outside the 90th centile for British children. A literature search shows one relevant study of such children, an epidemiological survey,<sup>31</sup> and that less than 10% of such children had a neurological impairment, 11% had delays in other developmental areas. Bottom shuffling and a family history of late walking were common.<sup>34</sup> Although there is no clear evidence base to assess the yield of further physical examination or exclusion by family history of motor variants, there are two questions that are discriminatory:

1. Is the motor pattern deviant (e.g. toe walking or a pronated position of forearms suggesting spasticity) or does it look normal for a younger child? Observe the nature of the child's movement pattern and examine tone and reflexes, and look for any persistent primitive reflexes and fasciculation.
2. Is development in other areas normal or abnormal? At this age language and symbolic play should be assessed as well as adaptive competencies (e.g. building, simple shape sorting). If the child has a significant motor disorder affecting hand function the methods used to determine intellectual ability will need to be modified (e.g. eye pointing to named objects).

### *How likely is this to be a presentation of muscular dystrophy?*

The prevalence of muscular dystrophy in male births is 1 in 3802. Of children with muscular dystrophy 50% walk by 18 months of age (although later walking than the family pattern suggests is common). Muscular dystrophy is noted because the child's motor competence falls away from the normal trajectory, even though progress continues to be made for the first few years of life (e.g. running is invariably impaired or the child presents with more general delays such as speech). The risk of muscular dystrophy because of late walking is 1 in 228 for a boy not walking at 18 months. Further information from history and examination would be required to help with your decision making about the benefits and costs of further investigation [creatine phosphokinase (CPK) estimation].

### *Most likely etiology in a child with:*

1. A family history of bottom shuffling, no physical abnormality and no delay in other areas of development would suggest a familial pattern and reduce the likelihood of a pathological cause. Further investigation would have a low yield. You might consider review again until walking.
2. History suggesting global developmental delay and a maternal male cousin with learning disability. Likelihood of fragile X or muscular dystrophy would increase and suggest a higher yield from further investigation.
3. History of preterm delivery, 2 days' ventilation and no family history. Examination shows that the child tends to sit with a curved back and stands propped on toes with legs crossed. Tone and reflexes are increased in the lower limbs and the diagnosis is a spastic diplegia.

It is always extremely important to ascertain whether or not there is any question of regression because this would lead to another chain of inquiry and investigation.

### Case study 2: The child who is saying only a few single words by 30 months

At 30 months many children will be putting two or even three words together and most will have quite large vocabularies. The possible causes

of language delay are normal variation, specific language delay or disorder, general learning disability (mental retardation), deafness, autism, severe environmental deprivation.

A difficulty with speech (output unclear) may be due to specific motor disorders or other neurological disorders.

In order to discriminate between these it is necessary to determine the child's:

1. understanding of language;
2. ability in nonlanguage areas – drawing, brick building, shapes, symbolic play;
3. understanding and use of nonverbal communication and social interactive and sharing behavior (e.g. gesture, facial expression, response to and initiation of communication) – this can be observed in a play-based assessment and the peer social play assessed at nursery;
4. quality of speech – are the few words clear? – does the child speak jargon using normal speech sounds and intonation?;
5. pattern of speech development: is it following the normal lines or is it deviant in any way (e.g. use of the word rhinoceros before mum and dad)?

A persistent receptive language problem is of more global significance than an expressive problem only. From the Whitehurst and Fischel study<sup>81</sup> most 2-year-old children with 10 words only had caught up by 5 years of age. In another study, however, children with delays in speech and language at 4–5 years still showed impairments in language-based literacy skills in their teens<sup>82</sup> and children with severe receptive language disorder continue to show language and social impairments into adult life.<sup>83</sup> A family history of language delay might support a genetic predisposition, which is common in developmental language disorder.

Hearing should be checked in all children – even if it is not the main cause. A mild loss may be making a child with a potentially mild developmental language disorder worse.

### *Assessment of the language problem*

Developmental profile on the Griffiths test shows that this child's ability in nonlanguage areas is normal, so he does not have a global learning disability. His symbolic play is also normal. He is a social child who understands and uses pointing and some simple gestures. His social skills with peers, play and imaginative skills show that he is not therefore autistic. His understanding of language is a little delayed, but not as much as his expressive skills. The words he has are clear and he uses normal sounding jargon. There is nothing deviant about his language development; it is simply delayed. There is a history that his father had been slow to talk and later on had reading and spelling problems. The home environment is satisfactory. Hearing is tested and found to be normal.

This child therefore has a developmental language delay for which there is probably a genetic predisposition. As his language comprehension is reasonable and he is beginning to use words he is likely to make steady progress. It is possible he will also have reading and spelling problems at school. He should be reviewed by a speech and language therapist to make sure his progress is satisfactory, and to offer parents advice on how to encourage language development and anticipate any problems with phonological awareness predictive of reading delay.

## SERVICES FOR CHILDREN WITH NEURODEVELOPMENTAL DISABILITY

Children with neurodevelopmental disability require co-ordinated services between health, social services and education. Guidelines and government policy in the UK support the development of well-integrated and co-ordinated care for young children with disability. The document 'Together from the Start'<sup>84</sup> outlines guidance on the effective delivery of services to children with disabilities, from birth to their third birthday, and their families with the following key themes:

1. better initial assessment of need;
2. better co-ordination of multi-agency support;
3. better information and access for families;
4. improved professional knowledge and skill;
5. service review and development;
6. partnership across agencies and geographical boundaries.

This document was issued jointly by the UK Department for Education and Skills and Department of Health in May 2003.

Early Support (<http://www.earlysupport.org.uk/>) has become the central government mechanism to improve the quality, consistency and coordination of services for young disabled children and their families across England following the guidance of 'Together from the Start' and aims to facilitate better coordination of information and service delivery in response to the objectives set by the Government green paper 'Every Child Matters'.<sup>85</sup>

Health services for children with neurodevelopmental disability are often co-ordinated by child development centres or teams who provide specialist services for assessment and management of children with physical and learning disabilities, hearing, vision, speech and language and social communication problems. In the UK these services are provided on a district basis serving a population of about 250 000–300 000 people. Core members of a service for children with disability should include a pediatrician, speech therapist, physiotherapist, occupational therapist, psychologist, nurse/health visitor, teacher, social worker and administrator. The team will provide assessment, diagnosis and management of the child and team composition should be constituted according to the child and family needs. The service may be delivered in a child development centre, the child's home or in nurseries or schools.

Children with multiple disabilities, complex neurological problems or physical problems compounded by psychological and behavioral difficulties will require multidisciplinary and multi-agency assessment and management. Children with less complex or single neurodevelopmental disorders are more likely to require assessment and management by one or two disciplines.

Many services in the UK have been historically centered around the needs of children between 0 and 5 years of age.<sup>86</sup> However, continuity of care from preschool to school age is essential. There needs to be ongoing commitment for review and treatment of children with special educational needs in mainstream or special schools, including the provision of advice to the local education authority, contributing towards statements and reviews under the 1993 Education Act and Code of Practice (2001), together with responsibilities relating to social services under the Children Act.

Services that are family centered have been shown to promote the psychosocial well-being of children and their parents and in leading to increased satisfaction with services.<sup>87</sup> A standard measure of parents' perceptions of health care providers' behaviors (Measure of Processes of Care – MPOC) has been shown to be effective in evaluating the family centeredness of children's rehabilitation services.<sup>88</sup> The measure was developed with the participation of more than 1600 parents of children with chronic neurodevelopmental conditions throughout Ontario. It assesses five domains: enabling and partnership; providing general information; providing specific information about the child; coordinated and comprehensive care; and respectful and supportive care – domains that were most highly valued by parents.

Some essential principals of child disability services include.<sup>89</sup>

1. The need for co-ordinated multiagency services with local planning for provision between health, education and social services.
2. The need for comprehensive local knowledge and collaboration with primary care, education, social services, parent groups and voluntary groups in order to provide the best possible packages of care.
3. Provision of support, training and clear referral criteria and care pathways for primary health care (including general practitioners

and health visitors) who will be first line in the detection and ascertainment of children with disability.

4. Access to services via 'a single front door' – a single organizational and information base for all children with special needs.
5. Children with more complex disability should have a key worker to provide a single point of contact and co-ordination for the family's care package. Research has confirmed that key workers have a positive impact on many families' lives. The factors relating to better outcomes included the management of the service, definition and understanding of the key worker role, and provision of training and supervision for key workers. This research from the Social Policy Research Unit has resulted in a number of recommendations for the management of key worker services.<sup>90,91</sup>
6. Parent representative involvement in planning and organization of services.
7. The client group should include children and young people with developmental disability up to the age of 19 years.
8. Transitional care plans for transfer to adult services should be drawn up in collaboration between health, social services and education. In some areas this may require support for the development of appropriate adult services.
9. Established lines of communication and referral criteria to hospital pediatric services including systems for provision of information and combined protocols for management for ward staff on how to care for and communicate with the disabled child. The needs of adolescents and young adults for appropriate inpatient accommodation should be considered both for medical needs and acute mental health issues.
10. Easy access to more specialist regional and national services for childhood disability with clear care pathways and networks supporting local services which may include combined outreach clinics.
11. Child psychiatry support should be an integral part of the service
12. Other professionals and combined clinics provide important additional services and include: a pediatric ophthalmologist, orthoptist and peripatetic teacher for the visually impaired; audiology, hearing aid service, peripatetic teacher for the hearing impaired; dietitian; a clinic for severe neurological feeding impairment; specialist dentistry; orthopedic surgery, with access to gait analysis and to a spinal unit, good orthotic support; specialist radiology (X-ray, computed tomography, magnetic resonance imaging, videofluoroscopy); specialist neurophysiology (electroencephalography, auditory and visual evoked responses); podiatry; a clinic for neuropathic bladder.
13. Respite care is for families whose children have severe/complex disability.
14. Written information for the family is essential. Early Support provides standard materials for families including: a series of booklets giving information about particular conditions or disabilities and other useful sources of information and support – publications, organizations, helplines, support groups and websites; the 'Family file' – a family-held record and a Family Service Plan which encourages all agencies working with a family to discuss the support that is being provided and to agree priorities. Advice about benefits should be readily available.
15. Sensitivity to the particular needs of ethnic and cultural minorities.
16. Clear guidelines for the management of child protection issues.
17. Regular audit to ensure best practice. Some tools available include: the MPOC.<sup>88</sup>

Milner et al<sup>92</sup> and the Early Support Service audit tool (<http://www.earlysupport.org.uk/>) provide tools for auditing and evaluating services for children and families with special needs.

### INTRODUCTION

Despite the development of sophisticated laboratory and imaging techniques, the foundation of sound clinical practice continues to be history taking and clinical examination.<sup>1</sup> The aims of the consultation can be measured by the ability to establish the relevant facts of the history, elicit the findings from clinical examination, formulate a diagnosis or diagnoses and plan ongoing investigations and management. It is also impor-

tant to establish and maintain a partnership between the family and the medical profession, measured in trust, motivation and empowerment. Such a partnership is engendered by good communication, provision of information and credibility.

The pediatric history and examination also serve as a record of information for future health surveillance or clinical governance. It has an important role to promote health and prevent disease and to diagnose secondary illness (Table 8.1).

**Table 8.1** Purpose of the pediatric consultation

Diagnosis of primary disease
Establishment of an effective partnership with the family
Record of health and development
Diagnosis of secondary or concurrent illness
Information for health systems to use as audit
Health promotion and disease awareness

Of these functions, the opportunity for health promotion and disease prevention is most overlooked by health professionals. Guidance can be provided on a variety of health and lifestyle issues such as nutrition, dental health, drug abuse, injury prevention, exercise and contraceptive counselling. Educational fragments can be provided during the examination to help enable parents to recognize health and disease.

Pediatric history taking and examination is an art that requires thoughtfulness, patience, and versatility. Through practice it should become smooth and spontaneous. A skilled interviewer will pick up on subtleties and explore these clues. The pediatric history presents different challenges from the consultation in adults.

1. Childhood is characterized by considerable physical, cognitive and psychosocial growth and development.
2. The presentation of disease in children may differ; many symptoms and signs are nonspecific.
3. The history is usually taken from a third person.
4. Young children have limited verbal skills and comprehension.
5. Children are often uncooperative and unpredictable.

## AGE-APPROPRIATE CONSULTATION AND COMMUNICATION SKILLS

The specialty of pediatrics spans around 16 years and unless specializing as an adolescent pediatrician or neonatologist, a doctor must learn an array of interview and examination techniques to allow him versatility in his interaction with children. A child has autonomy and a separate identity from that of his parents and respect for this is fundamental to trust and communication even in the smallest child. A key right in the United Nations Convention on the Rights of the Child is a child's right to express views in all matters that affect them, and for due weight to be given to their views.<sup>2</sup> Health care professionals have an important role in sharing information with children and listening to their needs, empowering them to make confident decisions with their parents about treatment. Support of parents, who may express different needs and desires from those of their child, is also crucial in this process.

The age of the child will determine the nature and presentation of the condition, how the interview is conducted and the subsequent management of the condition. Remember that the younger the child the less specific the symptoms will be. The age of the child will also influence how he or she understands and responds to illness and its treatment. Provision of information should always be appropriate to the developmental age of the child. Children can be divided by age groups:

Neonates	First 28 days of life
Infants	First year
Preschool children	1–4 years
School children	5–16 years
Adolescents	13–16 years

Establishing rapport and gaining the parent's trust facilitates the relationship with the child. First impressions are important. Your attitude, demeanor and dress will influence the doctor–parent/patient relationship from the outset and it is important to be neat, clean and polite. On the other hand, take time to note the attitude, demeanor and dress of your patient. These nonverbal clues can be very valuable and often will add information to the history.

Ensure that the consultation will be quiet and private. This may be difficult in the hospital setting where medical students and nursing staff may be present. Consider the patient's dignity and privacy in all circum-

stances. Always introduce yourself and any other staff present. Ensure your hands and nails are clean and that you wash your hands before and after examining the child. Avoid having a desk between you and the family. Make eye contact and avoid scribbling in notes or typing on a keyboard while you or the parent is talking.

## TIPS FOR COMMUNICATING WITH CHILDREN

- Make the area safe and welcoming.
- Be friendly and smile.
- Be confident but gentle; warm hands and equipment help!
- Get down to their eye level and call them by their name.
- Distract, captivate and reward.
- Offer praise for cooperation.
- Talk about popular characters such as Thomas the Tank Engine, Postman Pat.
- Let them play with any equipment, if it is safe to do so.
- Mock examinations may allay fear, e.g. auscultating a teddy.
- Address questions to the child when appropriate and listen to all verbal offerings.
- Use language that they will understand.
- Older children appreciate being part of the discussion about what is wrong and how to make it better.
- Avoid the surprise factor – always explain what you are going to do in advance, but avoid *asking* young children to cooperate, they will often refuse! It may be better to tell them what is required of them.
- Have a small space or area with a chair and some toys or books.
- Be opportunistic, abandon structured examination techniques, and do what you can when you can.
- Leave unpleasant procedures to the end.
- Be sensitive to their modesty; let parents undress their child.

Infants and very young children will often be held on their parent's lap. No attempt should be made to remove them from that place of safety unless examination is required that necessitates it. In such a case the parent should place the child on the bed but remain beside them. Older pre-school children can be examined while at play with the parent nearby.

Children of an older age appreciate being asked about their health and concerns and they should be involved in any questioning, discussion of diagnosis, and plan of management. Some may be shy about answering questions but should be encouraged to take part in the process.

Adolescents may prefer to be interviewed without their parents and this should be respected. They should be aware that the content of the consultation will remain confidential. If information is required from their parent this should be made clear. Girls should be examined by a male doctor in the presence of their mother or a chaperone.

Remember that mothers are excellent observers of their own children and they will often surprise with their intuition. They will often have their own ideas as to what is the matter. Remember to get a mother to define the language she uses: 'constipation' to her may be passing a single hard stool, 'hyperactive' to one mother may be another's normal boisterous toddler.

## CULTURAL AND RELIGIOUS CONSIDERATIONS

The cultural aspects of history taking and examination are becoming increasingly important. Where previously families lived in large supportive communities, the family of modern society is a small unit of parents and their children, often with little input or contact from extended family. Furthermore, increasing rates of marital breakdown mean that many children are now brought up by a single parent or care is shared by parents who live apart. In the UK, one quarter of children are brought up in lone-parent households.<sup>3</sup> Many children live between two homes. Owing to changes in working patterns, children are more likely to attend child-care facilities than previously. Social isolation with little contact from neighbors or relatives is common. Social inequalities in health persist even in resource rich countries, where child poverty is not unusual.

Classical pediatric morbidities such as infectious diseases and infant mortality have given way to the modern morbidities of learning

disabilities, family dysfunction and emotional disorders. One in ten British children have a clinically diagnosed mental health disorder, including conduct, emotional and hyperkinetic disorders.<sup>4</sup> As many children respond to stress with a variety of somatic, psychological and behavioral strategies, today's pediatrician must have an appreciation of the interplay of family dynamics and social stresses on health.

The world has become smaller as travel and migration have increased. Children come from more diverse ethnic, religious and multi-cultural backgrounds than ever before and will present with unfamiliar medical and social problems as well as traditional conditions. To succeed in the role of pediatrician, an understanding of the complexities of such a culturally diverse society must be learned.

In the UK, around 8% of our society is from ethnic minorities, many having been born in this country. Visitors from the continent and immigrants from further afield are common and many will experience the new culture as unsympathetic and cold. Religious and cultural differences may influence the approach to illness and management. Expression of pain and grief vary considerably across cultures. Beliefs about death and what happens after death may be very different to one's own philosophy and this should be understood and accepted. Be sensitive of cultural differences to hand-shaking, hand gestures and eye contact. There may be very diverse approaches to infant feeding among different ethnic groups. Not only may racial differences influence a patient's approach to disease but race-specific diseases also need to be considered in the diagnosis (Table 8.2). Similarly there are ethnic variations in birthweight, growth and in neurodevelopment with black children frequently having more advanced motor skills than other racial groups. Screening and immunization requirements may also differ.

There may be considerable communication difficulties in the face of limited English.

Where a parent does not speak your language or is deaf or has communication difficulties, it is important to establish optimal communication. This may mean finding an interpreter, someone who can sign or a friend or relative who is used to communicating with this individual. In some cultures female emancipation lags behind that of Western society and a woman may commonly depend on her husband or male family member to translate for her. Remember that in order to protect her they may decide to hold back important details from her. Always document the name of the translator and their relationship to the parent.

The traditional doctor–patient relationship is now regarded as overly paternalistic and inhibiting. Most parents now want to take an active part in decisions about their child's health. Many will have researched what they believe is the problem before the consultation. The explosion of the World Wide Web has allowed people open access to a wide range of information. Media coverage of many health matters means that people are more knowledgeable about their health and their rights as a patient. Increasing numbers of parents seek alternative or complemen-

tary therapies for their child seeing such approaches as 'kinder', 'less toxic' and more holistic. It is acknowledged that few such parents will discuss with their doctor their use of such therapies.<sup>5</sup>

## CONFIDENTIALITY

Doctors have a duty of confidentiality to all patients including children. Health professionals must decide for themselves when they feel a child shows sufficient maturity to take responsibilities for decisions regarding themselves ('competency'). Details of the child's health can only be shared with individuals who are involved in that child's care. Disclosure to other individuals such as researchers, insurance companies and lawyers requires fully informed, written consent. It is only justified to disclose information without consent if it is thought a child may suffer through nondisclosure. In such cases the parent should be informed of the pending disclosure prior to this decision. The confidentiality of older 'competent' children, incurs the same respect. Adolescents often underutilize health care resources because of concern about confidentiality yet effective care at this age can help to preserve good health, development and future opportunities. Sensitive issues such as substance abuse and sexually transmitted diseases are more easily discussed with parents absent. It may be important to encourage the young person to involve their parents if it is in their best interests to do so. They must also be aware of circumstances that may require disclosure of confidential information, such as a life-threatening emergency. The General Medical Council has produced Standards of Practice on Patient Confidentiality, and the American Academy of Pediatrics has a policy statement on Confidentiality in Adolescent Health Care, both available on respective web sites ([www.gmc-uk.org](http://www.gmc-uk.org) and [www.aap.org](http://www.aap.org)).

## PRIVACY AND CHAPERONES

Consideration of privacy at all ages is important. Always explain to a child that you are going to look at them and touch them and ask permission from all but the smallest of children for examination. Many children find even a cursory examination scary, especially with the appearance of stethoscopes and other equipment and it is important to gain their trust during the interview.

If any part of the exam will be painful or uncomfortable, this should be explained beforehand. The doctor must be sensitive to the patient's feelings about examination of the genital, breast or anal area and remember that even young children may feel embarrassed about undressing in front of a stranger. It is seldom necessary to completely undress children older than 1 year. Selective undressing of the upper or lower half of the body as examination proceeds is a more sensitive approach. If the mother is not present it may be appropriate to ask for a chaperone to be present during the examination. A chaperone protects the interests of both the patient and the pediatrician but their presence may be awkward if the parent or patient has requested confidentiality.

## DOCUMENTATION

Documentation of the consultation, the diagnosis and plan of management make up a written record of the patient's medical condition to be shared by all who are responsible for the care of the patient. Notes therefore must be legible, accurate and clearly dated and signed. Under the Freedom of Information Act 2000,<sup>6</sup> parents are allowed free access to their child's notes and as such the record should be free of disparaging or judgmental remarks and hearsay. The legislation also gives parents the right to check for any errors in the record and insist that amendments be made if required. Similarly the notes are a legal record and may be used subsequently in a court of law. Avoid abbreviations unless they are in common usage and unambiguous. The extent of rashes, injuries and tenderness may be best documented in a diagram.

In the UK medical records belong to the NHS Department of Health and in children they are kept for a minimum of 25 years.

**Table 8.2** Diseases commoner to particular ethnic groups

Ethnic groups	Diseases
African	Sickle cell disease, glucose-6-phosphate dehydrogenase deficiency, tuberculosis, HIV
Amish	Ellis-van Creveld syndrome
Ashkenazi Jews	Gaucher disease, Tay-Sachs disease, breast and ovarian cancers, other autosomal recessive diseases
Asian Indians	Tuberculosis, autosomal recessive diseases
Chinese	Nasopharyngeal carcinoma, glucose-6-phosphate dehydrogenase deficiency
Hopi Indians	Oculocutaneous albinism
Mediterranean	Thalassemia, glucose-6-phosphate dehydrogenase deficiency
Yupik Eskimos	Congenital adrenal hyperplasia

Most patient records are shared by members of the multidisciplinary team, facilitating communication, avoiding duplication and encouraging a shared approach to patient care. Parent-held records are used in the UK until the age of 5 years, as a method of sharing communication between health professionals and parents. These also record developmental milestones and provide parents with substantial health advice.

Structured proformas for history taking and examination are used in some hospital settings where there is high patient volume and need for repeated screening procedures. Although these aids may facilitate rapid and thorough information gathering, there is a risk of careless ticking of boxes and under-documentation of free text that may compromise an objective and thoughtful approach to the history-taking.

## CLINICAL HISTORY

Before taking the history, the clinician should ensure that they read any appropriate referral letters and look through any available records. The history should be recorded clearly in the patient's notes with the date and time of consultation. The signature and printed name of the clinician should follow this record. Although history and examination are usually recorded freehand, many hospitals use proformas for admissions or clinic attendances to ensure optimal information is recorded. Recent introduction of computerized patient records have allowed more readable records and have many advantages such as easy retrieval of standardized information, but the process of entering information on a keyboard may interfere with the interview ambience. An open style of questioning invites the parent to talk whereas closed questions seek specific information that may add clarification to the history. As direct questioning allows the parent little scope for qualification, care must be taken that this type of questioning does not result in a biased response. A combination of both styles will be used during the history taking. Listen without interruption to the parents' concerns and encourage them to talk through looking interested and making encouraging comments. Direct your questioning to the child if he is old enough.

Throughout the clinical history, the examination is already taking place through careful observation of the child, his play and his interaction with family members. A quick evaluation of his level of wellness will determine the need for immediate resuscitation. Although most medical students learn to take a history and examination through a structured approach, this is not always possible or necessary in children, to whom a problem-based approach is more appropriate, focussing on the relevant aspects of the history (Table 8.3).

## PRESENTING COMPLAINT

Document the child's name, age, sex and date of birth.

Find out the reason for presentation, 'the problem'. The complaint will direct a line of questioning specific to that symptom, in order to

amplify and clarify the problem (Table 8.4). Ask the parents to describe the complaint, in their own words and at their own pace. Find out how long it has been present and how it started. Was there a precipitating factor? Does anything make it better? Does anything make it worse? What made them come to a doctor? What do they think the problem is? When a full picture of the presenting complaint has been obtained, the doctor will have a likely or differential diagnosis on which to direct the rest of the history taking and examination. A full systems review is not usually necessary and a selective approach may be more appropriate.

## PAST MEDICAL HISTORY

Obtain details of the child's birth and any antenatal or postnatal complications. Birthweight and gestation may be relevant. In children under the age of 2 who were born prematurely, chronological age in relation to gestation should be recorded.

Ask about general health and any chronic illnesses. Ask about any injuries or accidents. Find out whether there have been any previous presentations to the family doctor, any hospital admissions or attendance at specialist clinics. Ask about previous infectious diseases such as chicken pox, measles, pertussis or mumps and recent exposure to such diseases.

## FEEDING AND GROWTH

Find out what the child's general appetite is like and what kind of diet they have. Many parents who think their child has a balanced diet are unaware of what that means. In infants, ensure milk intake is adequate. In breast-fed infants, know the signs of a good milk supply and intake. In formula-fed infants, ensure parents know how to make up the feed correctly. Find out whether there are any difficulties with feeding such as choking or vomiting after a feed. Ask about bowel habit and in particular any change in bowel habit.

If there are concerns about a child's growth, ask to see any previous records the parents may have for comparison. Growth is detailed in Chapter 15.

## DEVELOPMENTAL HISTORY

Knowledge of the normal developmental milestones is important if a delay or arrest of development is suspected. Normal development is detailed in Chapter 7. Ask the age at which of the major milestones (smiling, sitting alone, walking, talking, toilet-training) were achieved. Remember however that recall may be poor and unreliable.<sup>7</sup> Previous examination notes or the child health surveillance record may be useful. All areas of development should be covered including gross and fine motor development, speech and language, cognitive development, hearing and vision. Ask whether there are any developmental concerns.

## SOCIAL, SCHOOL AND FAMILY HISTORY

The social history is a chronicle of human interactions and describes the relationship of the child with his family, environment and school. The child should not be seen in isolation from his or her family and extended social environment. Illness in the child can cause anxiety or depression, and may impact on family dynamics or ability to attend or function optimally at school. In children, worries about unfavorable home or school circumstances can translate into psychosomatic symptoms (Table 8.5). Importantly some problems present due to a change in the family's ability to cope: examples include mental health problems, physical illness or changes in social circumstances.

Take details about the other members of the family and the child's relationship to them. Find out if the parents are living together and if not, whether the patient has contact with the absent parent. Ask the occupation of the parents. Note the ages of parents and siblings and the presence of any current illness or inherited conditions. Construction of a family tree (a genogram) may be helpful and easily interpreted when a stan-

Table 8.3 Taking a pediatric history

Name, age, sex, date of birth
Presenting complaint: what symptoms, when and for how long, precipitating and relieving factors, treatment already given/advice already sought
Past medical history: perinatal (pregnancy, birth and neonatal problems), accidents, operations, surgery, hospital visits, infectious diseases and contacts
Feeding and growth: appetite, diet, growth
Developmental history: gross and fine motor, speech and language, cognitive, hearing, vision
Social, school and family: parents, carers, siblings, family history of disease, housing, school progress, friends, hobbies, sleeping pattern, foreign travel
Drug history: dosages, frequency, allergies
Immunizations
Summary: 'Is there anything else you would like to tell me?'

Table 8.4 Clinical history points and relevant amplification

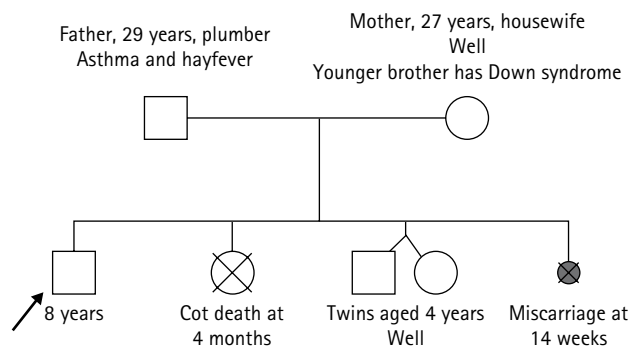

System	Symptom	Amplification
General	Pyrexia and night sweats	Duration, method of ascertaining temperature, rigors, sheet changing
	Weight loss	Amount, method of weighing, duration, other symptoms
	Rashes	Site, size, number of lesions, color, nature (petechiae, purpura, macules, papules, pustules, vesicles, bullae, ulcers), associated pain or pruritus
	Cyanosis	Peripheral or central, intermittent or persistent, association with environmental temperature
	Pain	Onset, nature, duration, severity, precipitating factors, relieving factors, associated symptoms, treatment sought
Respiratory	Discharge from nose, eyes or ears	Nature and duration
	Sore throat or earache	Localization, associated pyrexia or other respiratory symptoms
	Cough	Character, duration, exacerbating factors, sleep disturbance, association with pain, whoop, vomiting, other respiratory symptoms, nature of sputum
	Stridor	Associated color change or apnea
	Wheeze	Precipitating or exacerbating factors, diurnal variation, home peak flow testing
	Snoring	Change in cry or voice, mouth breathing
	Dyspnea	At rest or with exercise, intermittent or persistent, nocturnal or diurnal, association with cough, cyanosis or breath-holding
	Apnea	Duration, association with infection or airway obstruction
Cardiovascular	Breathlessness	At rest, or exertion or with feeding
	Tiredness and lethargy	Exercise tolerance, interest in play
	Slow feeding	Associated breathlessness
	Poor weight gain	Dietary intake
	Pallor or cyanosis	Intermittent or persistent, associated with crying or straining
Gastrointestinal	Appetite and feed tolerance need for special diet	Temporary or persistent impairment, food faddism, parental attitudes towards diet, vitamin or other supplementation
	Dysphagia	Often functional food refusal rather than organic, in organic dysphagia food is swallowed but soon regurgitated
	Thirst	Assess total daily intake of fluid and output of urine
	Vomiting	Amount, frequency, association with feeds, effortless or projectile, bilious or bloodstained, association with pain or impairment of consciousness
	Constipation	Consistency, frequency, pain on defecation
	Diarrhea	Nature of stool, consistency, frequency, presence of blood
	Abdominal pain	Site, nature, timing, duration, intermittent or constant, aggravation by breathing or movement, relationship of feeds, bowel movements or micturition, association with other gastrointestinal symptoms, sore throat, cough or purpura
	Jaundice	Onset, duration, nature of stool and urine, associated vomiting
Genitourinary	Incontinence or bed-wetting	Day or night, deterioration from before or regression in development, associated urinary symptoms, parental reaction, stress or bullying, treatment sought or tried
	Increased urinary frequency	Recent change in pattern, urine volume
	Dysuria	Pain, burning or cry related to micturition
	Change in odor or appearance of urine	Associated urinary symptoms, hematuria
Neurodevelopmental	Headaches	Site, manner of onset, severity, associated symptoms, aura
	Visual disturbances	Fixation and following, myopia or hypermetropia, color blindness, colliding with objects, associated symptoms
	Speech	Delay in onset or regression, nature, difficult comprehension or expression
	Hearing	Unresponsiveness or inattentiveness, functional or organic, family history
	Fits, faints, floppiness	Time, duration, frequency, tonic and clonic components, state of consciousness, known triggers, associated color change, oculogyrus, choking or incontinence, injury sustained
	Abnormalities in posture, gait or coordination	Deterioration from before or regression in development, falling and injury
	Involuntary movement	Nature, aggravating factors, injury suffered as a result
	Changes in mood, activity or behavior	Performance in normal play and household activities, interest in surroundings and excursions, tiring easily
	School performance	Normal or special school, extra support, bullying

**Table 8.5** Psychosomatic manifestations of stress

Somatic	Psychological
Headache	School refusal/truancy
Blurred or tunnel vision	Conduct disorders
Blackouts	Anorexia nervosa/bulimia
Tics	Sleep disorders, e.g. sleep-walking
Abdominal pain or infantile colic	Attention deficit/hyperactivity disorder
Nausea and vomiting	Anxiety and depression
Constipation	Self-harm
Enuresis/encopresis	Suicide/parasuicide
Poor appetite	
Weight loss	
Cough	
Eczema	
Other pain, e.g. back, neck, throat	

**Table 8.6** External factors that may impact on a child's health

Marital discord or breakdown
Parental illness or disability, including psychiatric illness
Bereavement stress
Parental absence
Unemployment
Poverty
Domestic violence
Physical, mental, emotional or sexual abuse
Parental substance abuse
Moving house
Immigration
New baby
Bullying
School stress: moving school, exams, learning difficulty

**Legend:**

- Squares indicate males and circles female
- The index case is marked with an arrow
- The birth order should be set out from left to right
- A crossed out symbol indicates a death
- Spouses are connected with lines, separations and divorces indicated by slash lines running through the lines
- Birth, marriage, divorce, or death dates may be indicated by the initial and date (e.g. b.89)

**Fig. 8.1** Example of a genogram.

standardized version is used (Fig. 8.1).<sup>8</sup> It may be relevant to find out whether the parents are consanguineous. Find out what impact the child's illness may have had on the family. Ask who looks after the child normally.

Check that the housing is adequate and whether there are any smokers and/or pets in the household.

Ask the name of the school and the class teacher. Ask whether the child is performing at his expected level and about school absences. It may be relevant to seek permission from the parents to obtain information from the class teacher about educational progress or behavioral difficulties.

Find out whether there have been any significant events in the child's life recently (Table 8.6). Ask about friends and whether the child attends any clubs or has any hobbies. Ascertain that the child gets adequate exercise through the week. Ask about sleep routine and behavior. A history of recent foreign travel may be relevant.

It may be appropriate in an adolescent patient to ask about lifestyle issues such as sexual history, smoking and use of recreational drugs. Remember that most will prefer that their parents are not present. Over 25% of adolescents will have had sexual intercourse before their 16th birthday. According to the 2000/2001 General Household Survey, 23% of British adolescents aged 11–15 admitted to having had an alcoholic drink in the previous week and such young people have doubled their average intake in the last decade.<sup>9</sup> As many as 15% of British children aged 11–15 years will have used illicit drugs in the last year and around 10% will smoke cigarettes regularly.<sup>10</sup>

**Table 8.7** Current immunization schedule for children living in the UK<sup>11</sup>

Age at immunization	Diseases protected against
2 months	Diphtheria, tetanus, pertussis, polio and <i>Haemophilus influenzae</i> type B Pneumococcus
3 months	Diphtheria, tetanus, pertussis, polio and <i>Haemophilus influenzae</i> type B Meningitis C
4 months	Diphtheria, tetanus, pertussis, polio and <i>Haemophilus influenzae</i> type B Meningitis C Pneumococcus
Around 12 months	<i>Haemophilus influenzae</i> type B and meningitis C
Around 13 months	Measles, mumps and rubella
3 years 4 months–5 years	Diphtheria, tetanus, pertussis, polio Measles, mumps and rubella
13–18 years	Diphtheria, tetanus and polio

**DRUG HISTORY**

Ask whether the child has been prescribed any medications or supplements and check that the child has been taking them as prescribed. Drug dosages and frequency of administration should be noted. Ascertain whether there have been any reactions to medications that may have caused a rash, diarrhea or anaphylaxis. Ask about nondrug allergies.

**IMMUNIZATIONS**

Know the current immunization schedule (Table 8.7)<sup>11</sup> and ascertain that the child is immunized fully to date. There may have been additional immunizations such as BCG or hepatitis B, particularly at birth.

**SUMMARY**

Before examining the child, summarize the information you have received from the parent to check it is correct and ask whether there are any other concerns.

**PHYSICAL EXAMINATION**

Examination begins at the moment the child and family enter the room. Careful observation often reveals more than hands-on examination, as localizing signs are often absent in children.

There is no single examination technique that is appropriate to all ages and situations. Doctors should develop their own style, inclusive of patience and empathy. It is usually not appropriate to examine each individual system in all children and the doctor should be guided by the clinical history and his initial observations. However for the purpose of this chapter, individual systems will be detailed. Tables 8.8 and 8.9 provide possible interpretations for some common physical signs. Landmarks for a child's chest are shown in Figure 8.2.

### GENERAL ASSESSMENT

- Inspect the child and observe whether the child is well or ill and whether he is in pain or comfortable.

- Observe behavior, demeanor and the interaction of the child with other family members. Is the child well cared for?
- Observe for signs of hydration and state of alertness.
- Look for signs that the child is well-nourished and appropriately grown for age.

### GROWTH

Growth parameters should be plotted on centile charts appropriate for the sex and age of the child. Use the most up-to-date charts available that will be most representative of the current population. In the UK, these are the UK90 growth charts, constructed from cross-sectional measurements of seven UK cohorts measured in 1990.<sup>12,13</sup> There are

Table 8.8 Common physical signs and their possible causes

System	Sign	Possible causes	
Skin	Albinism	Inherited, Chediak–Higashi syndrome	
	Alopecia	Stress, protein deficiency, iron or zinc deficiency, hypopituitarism, rapid weight loss, SLE, hypothyroidism, thyrotoxicosis, diabetes mellitus, renal failure, drugs	
	Bruising	Hemophilia, non-accidental injury, leukemia, ITP, liver failure, scurvy, Cushing syndrome, drugs	
	Butterfly rash	SLE, photodermatitis	
	Café-au-lait spots	Neurofibromatosis, tuberous sclerosis	
	Cyanosis	Congenital cyanotic heart disease, persistent pulmonary hypertension, cardiovascular collapse, respiratory failure	
	Depigmentation	Pityriasis versicolor or alba, vitiligo, postinflammatory, hypopituitarism, leprosy	
	Dermographism	Allergy or hypersensitivity	
	Herald patch	Pityriasis rosea, drugs	
	Hirsutism	Congenital adrenal hyperplasia, pituitary–gonadal tumors, hypothyroidism, steroid therapy, Albright syndrome, mucopolysaccharidoses	
	Lymphadenopathy	Infection, chronic inflammation, lymphoma, metastases	
	Petechiae/purpura	Meningococcal septicemia, ITP, vasculitis, leukemia, DIC, Henoch–Schönlein purpura, Waterhouse–Friderichsen syndrome, Cushing syndrome, congenital infection, neonatal alloimmune thrombocytopenia, hemorrhagic disease of the newborn, infective endocarditis, trauma, drugs	
	Scaly rash	Seborrheic dermatitis, pityriasis rosea, psoriasis	
	Spider nevi/telangiectasia	Liver cirrhosis, thyrotoxicosis, systemic sclerosis, hepatitis, ataxia telangiectasia	
	Striae	Cushing syndrome or disease	
	Subcutaneous nodules	Neurofibromatosis, tuberous sclerosis, rheumatic fever, sarcoid	
	Target lesions	Erythema multiforme, Stevens–Johnson syndrome	
	Tissue crepitations	Subcutaneous emphysema	
	Vesicles	Herpes zoster, herpes simplex, impetigo, contact dermatitis, pemphigus, pemphigoid, incontinentia pigmenti, epidermolysis bullosa, burns, drugs	
	White forelock	Waardenburg syndrome	
	Xanthoma	Hyperlipidemia, diabetes, cholestasis	
	Xeroderma	Ichthyosis, hypothyroidism, seborrheic dermatitis, eczema, psoriasis	
	Head	Microcephaly	Congenital infection, chromosomal abnormality, perinatal asphyxia
		Macrocephaly	Hydrocephalus, achondroplasia, gigantism, mucopolysaccharidoses, familial megalencephaly
		Acrocephaly	Apert and Crouzon syndromes
		Brachycephaly	Positional, Down syndrome
		Dolichocephaly	Ex-preterm infant
Plagiocephaly		Positional, coronal suture craniosynostosis	
Scaphocephaly		Sagittal suture craniosynostosis	
Prominent occiput		Edward syndrome, Beckwith–Wiedemann syndrome	
Frontal bossing		Rickets, chondrodysplasia, storage diseases	
Craniotabes		Rickets, prematurity	
Scalp defects		Patau syndrome	
Bulging fontanelle		Raised intracranial pressure, meningitis	
Sunken fontanelle		Dehydration	
Delayed fontanelle closure		Rickets, hypothyroidism, hydrocephalus, chondrodysplasias and chondrodysgeneses, other chromosomal abnormality	
Face and neck	Moon face	Cushing syndrome or disease, Prader–Willi syndrome	
	Triangular face	Russell–Silver syndrome, osteogenesis imperfecta, Turner syndrome	
	Coarse face	Hypothyroidism, mucopolysaccharidoses	
	Micrognathia	Familial, Pierre–Robin sequence, other chromosomal abnormalities	

(Continued)

Table 8.8 Common physical signs and their possible causes—cont'd

System	Sign	Possible causes
	Torticollis	Sternomastoid tumor, corpus striatum or labyrinthine disease, 11th cranial nerve palsy
	Neck webbing	Turner syndrome, Noonan syndrome
	Saddle nose	Down syndrome, chondrodysplasias, fetal teratogenicity
Eyes	Aniridia	Aniridia–Wilms tumor association
	Blue sclera	Osteogenesis imperfecta
	Buphthalmos	Congenital glaucoma
	Cataract	Congenital infection, Down syndrome, galactosemia, Alport syndrome, diabetes mellitus, malnutrition, trauma, ocular tumors, retrolental fibroplasia
	Chorioretinitis	Congenital cytomegalovirus infection
	Choroidal tubercles	Tuberous sclerosis
	Coloboma of eyelid	Treacher–Collins and Goldenhar syndromes
	Coloboma of iris	Idiopathic, CHARGE syndrome, Patau syndrome
	Corneal clouding	Hurler syndrome, other mucopolysaccharidoses
	Enophthalmos	Dehydration, malnutrition, Horner syndrome
	Exophthalmos	Thyrotoxicosis, cerebral, optic or orbital tumor, neurofibromatosis, malignant hypertension, Apert and Crouzon syndromes, Cushing disease
	Epicanthic folds	Down syndrome, other chromosomal abnormalities
	Hypertelorism	Various chromosomal abnormalities
	Hypotelorism	Holoprosencephaly syndrome, Patau syndrome
	Lens dislocation	Marfan syndrome, homocystinuria
	Lid retraction	Thyrotoxicosis
	Miosis	Bright light, convergence, narcotics, sympathetic nerve paralysis, Horner syndrome, drugs
	Mydriasis	Darkness, thyrotoxicosis, anxiety, iritis, inflammatory adhesions, coma, drugs
	Nystagmus	Normal in some infants and with watching moving object, labyrinthine and vestibular disease, brainstem lesions, central vision loss, septo-optic dysplasia, Friedreich's ataxia
	Optic atrophy	Glaucoma, retinal ischemia, optic neuritis, retinitis pigmentosa
	Papilledema	Raised intracranial pressure, optic neuritis, hypertension
	Periorbital edema	Nephrotic syndrome
	Ptosis	Bell's palsy, Horner syndrome, myasthenia gravis, 3rd cranial nerve palsy, congenital
	Raccoon sign	Basal skull fracture
	Retinal hemorrhages	Non-accidental injury, trauma, leukemia, hypertension, bacterial endocarditis, bleeding diathesis
	Retinal pigmentation	Congenital infection, mucopolysaccharidoses, Laurence–Moon–Biedl syndrome
	Strabismus	Intermittent normal in neonates, fixed due to birth trauma, raised intracranial pressure, 3rd, 4th or 6th cranial nerve palsy, severe miosis, chromosomal abnormality
	Sunsetting	Hydrocephalus
	Xanthelasma	Hyperlipidemia, cholestasis
Ears	Low-set ears	Branchial developmental abnormalities, various chromosomal abnormalities
	Malformed auricles	Various chromosomal abnormalities
	Deafness	Familial, congenital infection, postmeningitis, branchial developmental abnormalities, other metabolic and chromosomal abnormalities
	Pre-auricular tags or pits	Beckwith–Wiedemann syndrome, Treacher–Collins syndrome, may be associated with deafness
	Earlobe crease	Beckwith–Wiedemann syndrome
Mouth	Xerostomia	Anxiety, pyrexia, dehydration, diabetes mellitus and insipidus, cystic fibrosis, drugs
	Risus sardonicus	Tetanus
	Stomatitis	Iron deficiency, herpes simplex, Stevens–Johnson syndrome, Kawasaki disease
	Cleft lip/palate	Idiopathic, Pierre Robin syndrome, Patau syndrome, fetal teratogenicity
	Smooth philtrum	Fetal alcohol syndrome
	Blue gums	Lead poisoning
	Gum hypertrophy	Chronic phenytoin administration
	Glossoptosis	Down syndrome
	Macroglossia	Hypothyroidism, Beckwith–Wiedemann syndrome, mucopolysaccharidoses, other storage diseases
	Strawberry tongue	Scarlet fever, vitamin B deficiency
	White tongue	Milk, thrush, leukoplakia
	Anodontia/hypodontia	Osteochondrodysplasias, ectodermal dysplasia, Down syndrome
	Enamel hypoplasia	Tuberous sclerosis, Williams syndrome, Prader–Willi syndrome
Cardiovascular	Tachycardia	Exercise, pain, hypovolemia, infection, thyrotoxicosis, cardiac failure, anaphylaxis, pheochromocytoma, drugs
	Bradycardia	Hypothyroidism, heart block, raised intracranial pressure, hypothermia, cardiac failure, drugs
	Hypertension	Anxiety, renal disease, pheochromocytoma, aortic coarctation, raised intracranial pressure, Conn and Cushing syndromes, SLE, drugs
	Hypotension	Cardiac failure, hypovolemia, cardiogenic or septic shock, anaphylaxis, Addison's disease, electrolyte imbalance, hypothyroidism, drugs

(Continued)

Table 8.8 Common physical signs and their possible causes—cont'd

System	Sign	Possible causes
	Atrial fibrillation	Wolff–Parkinson–White syndrome, thyrotoxicosis, rheumatic valve disease, carditis
	Bounding pulse	Pyrexia, thyrotoxicosis, anemia, hypercarbia
	Collapsing pulse	Aortic regurgitation, PDA, VSD, heart block, thyrotoxicosis, hyperdynamic circulation
	Plateau pulse	Aortic stenosis, aortic coarctation
	Pulsus paradoxus	Severe asthma, pericardial effusion or tamponade, constrictive pericarditis
	Gallop rhythm	Left ventricular failure, cardiac dilatation, constrictive pericarditis
	Systolic murmur	Physiological, VSD, PDA, ASD, pulmonary stenosis, aortic coarctation, aortic stenosis, hyperdynamic circulation, mitral regurgitation, tricuspid regurgitation, cardiomyopathy
	Diastolic murmur	Venous hum, PDA, large VSD, mitral stenosis, aortic regurgitation, pulmonary regurgitation, tricuspid stenosis
	Thrill	Palpable murmur
	Pericardial rub	Pericarditis, rheumatic fever, pleurisy, pneumonia
	Bruits	Artery stenosis, arteriovenous malformation
	Thrust/heave	Apical – left ventricular hypertrophy, lower left sternal edge – right ventricular hypertrophy
Respiratory	Barrel chest	Emphysema, asthma
	Pectus carinatum	Asthma, rickets, chromosomal or metabolic abnormalities
	Pectus excavatum	Asthma, rickets, chromosomal or metabolic abnormalities
	Thoracic rosary	Rickets
	Barking cough	Croup
	Hemoptysis	Airway trauma, foreign body inhalation, infection, malignancy, arteriovenous malformation, bleeding diathesis
	Stridor	Croup, epiglottitis, laryngitis, laryngomalacia, infectious mononucleosis, diphtheria, subglottic hemangioma or cyst
	Wheeze	Asthma, bronchitis
	Bronchial breathing	Normal in young children, pneumonia
	Coarse crepitations	Bronchiolitis, bronchiectasis
	Fine crepitations	Pulmonary edema, atelectasis, pneumonia
	Pleural rub	Pleurisy, pneumonia, pulmonary thrombosis
	Hyperventilation	Anxiety, pain, pyrexia, metabolic acidosis, infection, hypoxia, drugs, Rett syndrome
	Hypoventilation	Raised intracranial pressure, drugs, lung disease
Gastrointestinal	Abdominal distension	Intestinal obstruction, ileus, peritonitis, ascites, masses, pregnancy, organomegaly
	Scaphoid abdomen	Congenital diaphragmatic hernia
	Abdominal mass	Organomegaly, tumor, fluid, hernia, cyst, abscess, pregnancy
	Hernias	Ex-preterm infant, hypothyroidism, Beckwith–Wiedemann syndrome, mucopolysaccharidoses
	Omphalocele	Idiopathic, Beckwith–Wiedemann syndrome, Patau syndrome, Edward syndrome
	Hepatomegaly	Congestive cardiac failure, any cause of infectious hepatitis, metabolic or liver storage disease, malignancy
	Splenomegaly	Infectious mononucleosis, infective endocarditis, portal hypertension, leukemia, lymphoma, hemolytic anemia, malaria
	Abdominal rigidity	Peritonitis
	Rebound tenderness	Peritonitis
	Visible peristalsis	Pyloric stenosis, acute intestinal obstruction
	Shifting dullness	Ascites
	Fluid thrill	Ascites
	Borborygmi	Intestinal obstruction, toxic enteritis
	Pale stool	Pancreatic insufficiency, bile duct obstruction
	Melena	Upper intestinal bleeding, iron therapy
	Green stool	Intestinal hurry, starvation
	Anal defects	VATER association, caudal regression sequence
Nervous	Hypertonia	Upper motor neurone lesions, extrapyramidal lesions, asphyxia, kernicterus, raised intracranial pressure, meningitis, cerebral palsy
	Hypotonia	Lower motor neurone lesions, prematurity, cerebellar lesions, myopathies, metabolic and chromosomal abnormalities
	Clasp-knife rigidity	Upper motor neurone lesion
	Cog-wheel rigidity	Extrapyramidal lesions, cerebral palsy
	Neck stiffness	Meningeal irritation
	Opisthotonus	Meningitis, cerebellar lesions, tetanus
	Myoclonus	Upper motor neurone lesions
	Brisk tendon reflexes	Upper motor neurone lesions, thyrotoxicosis, anxiety, tetanus
	Diminished tendon reflexes	Peripheral neuropathies, hypothyroidism, syringomyelia, lower motor neurone lesions
	Muscle fasciculation	Lower motor neurone lesions, muscular dystrophies, hypocalcemia, thyrotoxicosis, depolarizing drugs

(Continued)

Table 8.8 Common physical signs and their possible causes—cont'd

System	Sign	Possible causes
	Athetosis	Kernicterus, juvenile Huntington's chorea, Wilson's disease, Lesch–Nyhan syndrome, basal ganglia or extrapyramidal lesions, drugs
	Chorea	Ataxia–telangiectasia, Angelman syndrome, Cockayne syndrome, cerebellar or brainstem lesions, drugs (including alcohol and antiepileptics), vestibular neuronitis
	Intention tremor	Cerebellar or brainstem lesions, Friedreich's ataxia, mercury poisoning
	Postural tremor	Anxiety, thyrotoxicosis, alcohol, Wilson's disease, cerebellar lesions, drugs
	Dysdiadochokinesia	Cerebellar lesions
	Asterixis	Encephalopathy, liver failure, metabolic disease
	Meningomyelocele	Maternal folate deficiency, fetal teratogenicity, chromosomal abnormality
	Encephalocele	Meckel–Gruber syndrome
Locomotor	Scoliosis	Congenital vertebral anomaly, developmental abnormality, disc prolapse, Marfan syndrome, Coffin–Lowry syndrome
	Buffalo hump	Cushing disease, steroid therapy
	Short limbs	Chondrodysplasias, osteogenesis imperfecta, fetal varicella syndrome
	Cubitus valgus	Turner syndrome
	Fixed flexion deformities	Arthrogryposis multiplex congenita usually due to oligohydramnios sequence
	Joint erythema	Septic arthritis, inflammatory arthropathy, rheumatic fever
	Joint hypermobility	Familial, enthesopathy, Marfan syndrome, Ehlers–Danlos syndrome, acromegaly
	Myotonia	Myotonic dystrophy, hyperkalemia
	Muscular atrophy	Lower motor neurone lesions, muscular dystrophies, prolonged immobilization
	Muscular hypertrophy	Duchenne's muscular dystrophy
Hands and feet	Finger or toe clubbing	Chronic cardiac, respiratory or gastrointestinal disease, congenital cyanotic heart disease, tumors, suppurative disease
	Koilonychia	Iron deficiency anemia
	Nail pitting	Eczema, psoriasis, chronic paronychia, alopecia areata
	Thickened nail	Psoriasis, chronic paronychia or fungal infection, lichen planus
	Onycholysis	Trauma, fungal infections, eczema, psoriasis, diabetes, drugs
	Splinter hemorrhages	Infective endocarditis, blood dyscrasias, eczema, psoriasis, trauma
	Arachnodactyly	Marfan syndrome
	Brachydactyly	Down syndrome, Ellis van Creveld syndrome
	Camptodactyly	Edward syndrome
	Clinodactyly	Down syndrome, other chromosomal abnormalities
	Polydactyly	Familial, Patau syndrome, other chromosomal abnormalities
	Syndactyly	Acrocephaly–syndactyly syndrome, various chromosomal abnormalities
	Thumb hypoplasia	Thrombocytopenia–absent radius syndrome, Fanconi anemia, Holt–Oram syndrome
	Single transverse palmar crease	Normal, chromosomal abnormality
	Wrist drop	Radial nerve lesion, peripheral neuropathy, muscular dystrophy
	Talipes equinovarus	Positional, oligohydramnios sequence, muscular dystrophy, chromosomal abnormality
	Pes cavus	Familial, Friedreich's ataxia, spina bifida, sacral dermoid
	Pes planus	Physiological lax ligaments, tarsal coalition, cerebral palsy, polio
	Peripheral edema	Cardiac failure, venous thrombosis, hypoproteinemia, nephrotic syndrome, renal failure, prolonged immobilization
	Carpopedal spasm	Hypocalcemia
Reproductive	Gynecomastia	Puberty, obesity, thyrotoxicosis, pituitary–adrenal–gonadal disease, liver disease, drugs
	Galactorrhea	Normal in some newborns, pituitary–adrenal tumors, hormonal therapy, thyroid disease, pregnancy and nursing
	Ambiguous genitalia	Congenital adrenal hyperplasia, hermaphroditism, Prader–Willi syndrome, other chromosomal abnormality
	Cryptorchidism	Delayed testicular descent, causes of ambiguous genitalia
	Testicular mass	Hydrocele, hernia, tumor, orchitis

ASD, atrial septal defect; CHARGE (syndrome), ocular coloboma, heart defects, atretic choanae, retarded growth or development, genital hypoplasia, and ear anomalies; DIC, disseminated intravascular coagulopathy; ITP, idiopathic thrombocytopenic purpura; PDA, patent ductus arteriosus; SLE, systemic lupus erythematosus; VATER, vertebral defects, imperforate anus, tracheo esophageal fistula, and radial and renal dysplasia; VSD, ventricular septal defect.

Table 8.9 Eponymous signs

Eponymous sign	Sign description	Possible causes
Austin Flint murmur	Murmur at apex, onset with third heart sound and loudest at mid-diastole	Aortic regurgitation
Argyll Robertson pupil	Small unequal pupils that react to convergence but not to light	Neurosyphilis, diabetes
Battle's sign	Retromastoid bruising behind ears	Petrous bone fracture
Beau's ridges	Transverse ridging of nail plate	Hypoalbuminemia, steroid therapy, cytotoxics, severe illness
Brushfield spots	Focal areas of iris stromal hyperplasia giving appearance of white spots	Down syndrome
Charcot joint	Severely disorganized, arthritic joint that is pain-free	Tabes dorsalis, diabetic neuropathy, leprosy, myelomeningocele
Cheyne-Stokes respiration	Respirations that decrease in frequency, then stop temporarily before restarting and building up again	Damage to cerebral respiratory center terminal stage
Corrigan's sign	Vigorous pulsation of major head and neck arteries causing head or ears to move	Aortic regurgitation, PDA, VSD
Cullen's sign	Spontaneous umbilical bruising	Hemoperitoneum
Dance's sign	Right iliac fossa depression in distressed infant	Intussusception
Epstein's pearls	Epithelial inclusions along midline of hard palate	Normal in neonates
Erb's palsy	Arm held adducted and internally rotated, extended at elbow, with forearm and palm pronated	C5/6/7 damage
Gottron's sign	Scaly patches over dorsal finger joints, with subungual erythema and cuticular telangiectasia	Polymyositis, dermatomyositis
Graham Steel murmur	Soft, high-pitched murmur in second left intercostal space in early diastole	Pulmonary regurgitation from pulmonary hypertension
Harrison's sulcus	Chest deformity with subcostal groove along attachment of diaphragm	Chronic asthma, rickets
Henoch-Schönlein purpura	Extensive purpuric and ecchymotic lesions on extensor surfaces of limbs	Idiopathic, post-streptococcal, drug-induced
Hoffmann's reflex	Foot dorsiflexion causes calf muscle pain	Calf thrombophlebitis or cellulitis
Jacobsen-Holdsnedt phenomenon	Mediastinum displaced away from affected side during expiration on X-ray	Unilateral obstructive emphysema, e.g. foreign body inhalation
Janeway lesion	Small purplish nodules on palms or soles	Infective endocarditis
Kayser-Fleischer ring	Green-brown ring at outer edge of cornea	Wilson's disease
Kehr's sign	Left shoulder tip pain with acute abdomen	Splenic rupture
Koplik spots	Gray spots in the mucous membranes of the mouth	Measles
Kussmaul breathing	Deep sighing respirations	Diabetic ketoacidosis, uremia, other metabolic acidosis, neurogenic hyperpnea
Murphy's sign	Pain and interruption of inhalation during palpation of right upper abdominal quadrant	Cholecystitis

PDA, patent ductus arteriosus; VSD, ventricular septal defect.

separate charts available for children with Down syndrome, Turner syndrome and sickle cell disease. Growth standards of exclusively breast-fed babies have also recently been published by the World Health Organization.<sup>14</sup> A single measurement of weight or height is rarely helpful. Compare current growth parameters with any previously recorded. Assess whether the growth velocity has been satisfactory.

In infants, weight should ideally be measured in electronic scales with the baby completely undressed. Older children should stand on scales and should have their shoes and outdoor clothing off. The method

by which parent and child are weighed together and the parent's weight is then subtracted to get the child's weight is not reliable. Weight should be measured and recorded in kilograms.

In newborn babies, weight loss of up to 12 per cent is normal in the first 5 days of life, but birth weight should be regained by 10 days of age. Thereafter weight gain is approximately 200 g/week with birth weight doubled by 5 months and tripled by 1 year. In children, the expected weight in kg can be estimated by the formula:  $2 \times (\text{age in years} + 4)$ . However constitutional and ethnic variations in weight should be appreciated.

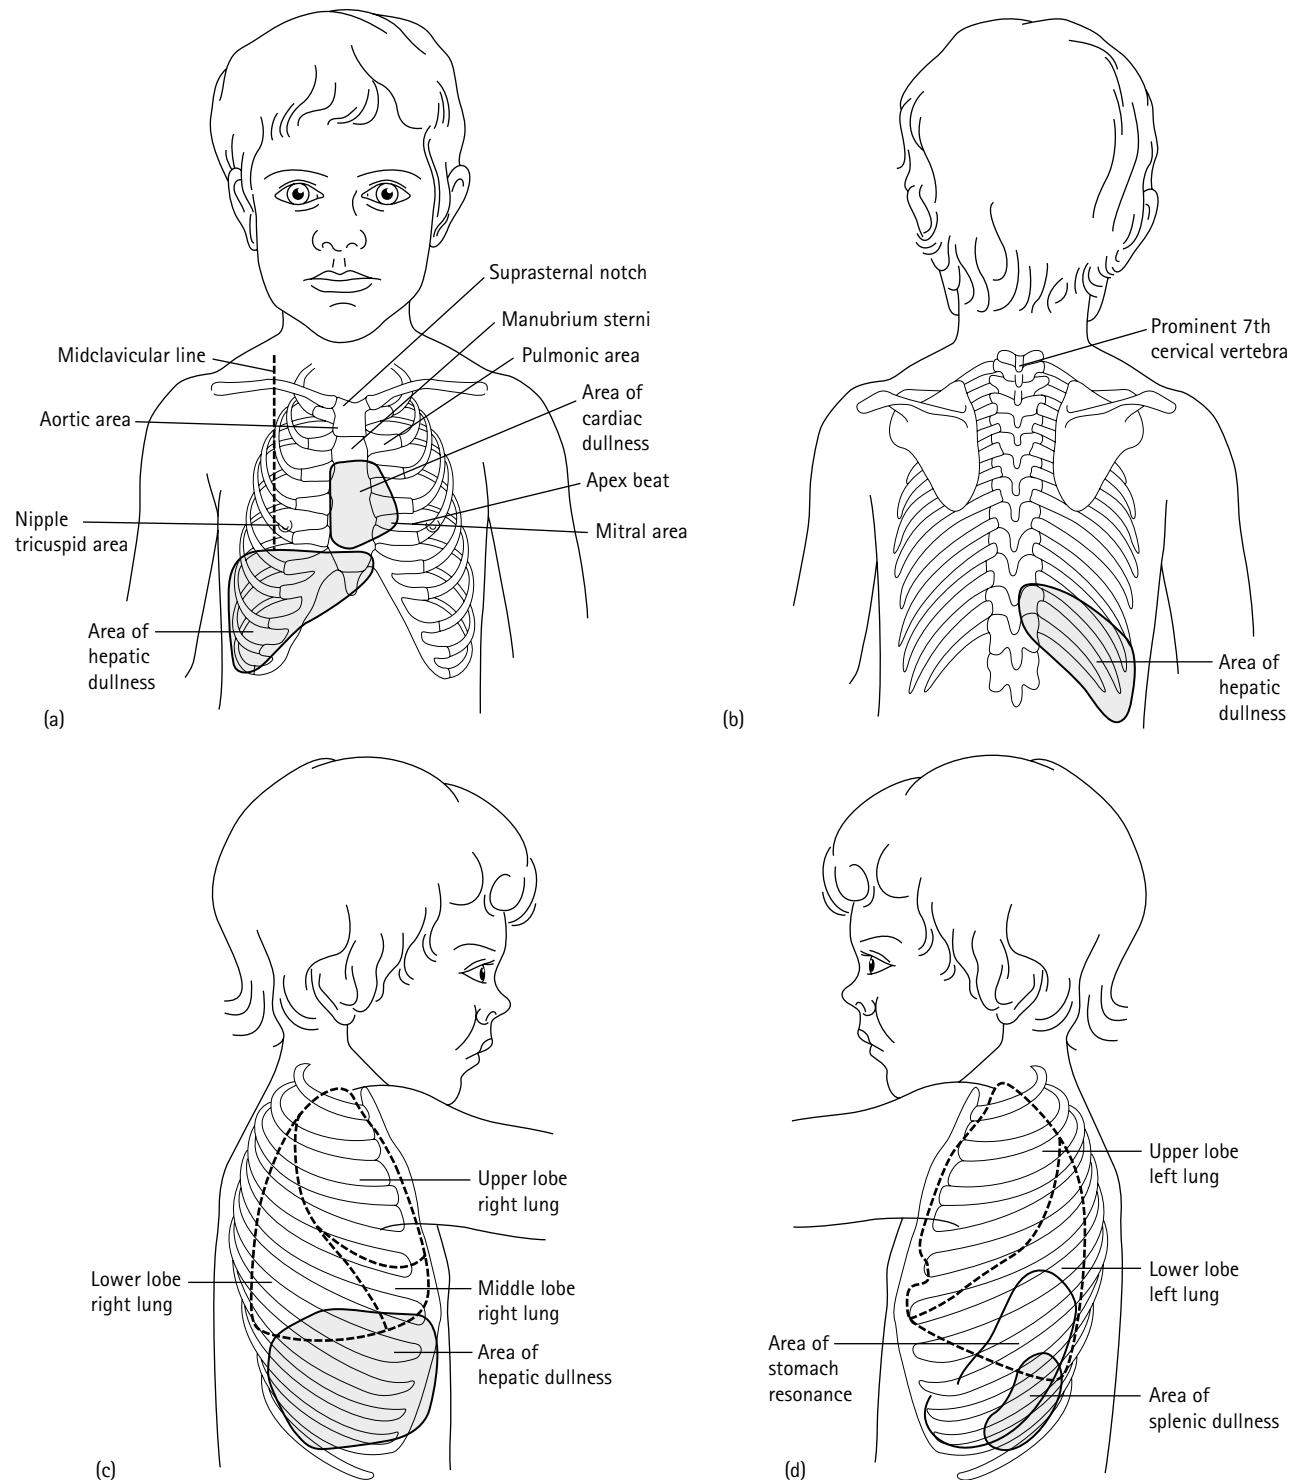

Fig. 8.2 Landmarks in a child's chest: (a) anterior, (b) posterior, (c) right lateral, (d) left lateral.

Crown–heel length is measured in infants lying supine and fully extended on a stadiometer. It should be recognized that this method of measurement is relatively inaccurate due to variation in the 'stretchiness' of a child due to stress, well-being and the time of day, with children similar to adults in being 1 cm taller on average in the morning. In children older than 1 year of age and who are able to stand, standing height should be measured with shoes off on a measuring wall ruler. Height should be measured and recorded in centimeters. At birth length is approximately 50 cm, increasing to 75 cm at 1 year of age and 100 cm

by 4 years. An infant grows on average 14–16 cm/year, a pubertal child 7–12 cm/year and in the mid-childhood years, growth is around 4–6 cm/year. Height velocity charts may be useful in plotting speed of growth around puberty. Remember that body proportions change with age (Fig. 8.3).

Body mass index (BMI) or weight in relation to stature ( $\text{weight}[\text{kg}]/\text{height}^2[\text{m}^2]$ ) may be a more useful measurement of body fat mass in children over 2 years.<sup>15</sup> Both the UK government and the American Academy of Pediatrics have recently advocated the routine monitoring

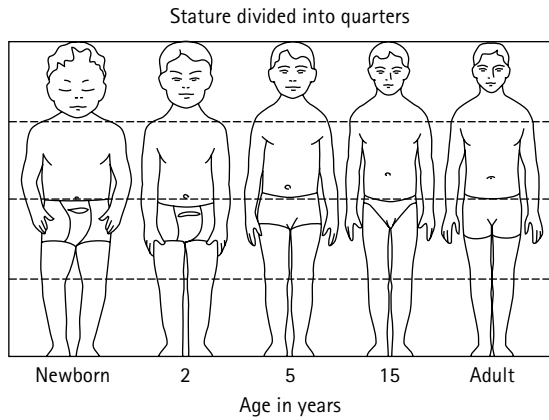

Fig. 8.3 Body proportions at different ages.

of BMI in schoolchildren to identify those who are, or who are at risk of, becoming obese (BMI >97th centile for age).<sup>16,17</sup>

Occipitofrontal circumference (OFC) is the largest circumference around the forehead and occiput. It should be measured with a disposable nonstretch tape and is measured in centimeters to the nearest millimeter. Measure it three times, and then record the largest measurement. The OFC in a term baby is approximately 35 cm, and should enlarge by 12 cm in the first 12 months of life and a further 2 cm by the second year. The subsequent annual increase is 0.5 cm from 2 to 7 years and 0.3 cm from 8 to 12 years. Centile charts are available through childhood and adulthood.

Other signs of adequacy of nutrition should be sought. Children who are failing to thrive will have loose skin folds with a lack of subcutaneous fat. Nutritional deficiencies may manifest as angular stomatitis, glossitis, skin rashes, anemia, bleeding gums, bruises or bowing of the legs. Dissociation between growth parameters may indicate underlying disease such as hypothyroidism, malnutrition, obesity or Marfan syndrome.

## TEMPERATURE

Temperature can be measured at various sites (rectal, sublingual, axillary or tympanic) and with a variety of different devices (mercury thermometer, digital thermometer, tympanic infrared thermometer or color-change chemical thermometer). Rectal, sublingual and tympanic temperatures correlate with core temperature better than axillary temperature.<sup>18-20</sup> Axillary temperatures are accurate in neonates and are representative of sublingual or rectal temperatures, detecting pyrexia with a sensitivity of 98%.<sup>21,22</sup> However in older infants and children, axillary temperatures perform less well and detect pyrexia with sensitivity of only 47%.<sup>22</sup> One degree Celsius should be added to the axillary temperature for any child older than 1 month of age.<sup>21</sup> Forehead liquid crystal strips are even less accurate than axillary temperature.<sup>21</sup>

Tympanic membrane thermometry is a newer development that has been evaluated for use in infants, including well preterm infants.<sup>23</sup> Temperature should be measured in degrees Celsius. The normal core temperature should be 36.5–37.5°C.

## EXAMINATION OF INDIVIDUAL SYSTEMS

### MORPHOLOGY

Examine the head, face, neck, eyes, ears, mouth, hands and feet for signs of abnormal morphology (Table 8.8). Different head shapes are shown in Figure 8.4. Examine the ears for position, size and shape. A normally positioned ear should have its upper third above a horizontal line at eye level, with the helix joining the skull at a horizontal plane through both inner canthi. The presence of low-set ears may be supportive of a chromosomal anomaly, particularly when associated with other dysmorphism. The distance between the eyes can be measured in terms of innercanthal, midpupillary or outer-canthal measurements. Normograms for these and for ear length are available in textbooks of morphology.<sup>24</sup>

### SKIN, MUCOUS MEMBRANES AND LYMPH NODES

Examine the skin for rashes, bruises, skin integrity and birthmarks. Common lesions are detailed in Table 8.8. Lesions can be documented in a diagram or by photographs where necessary.

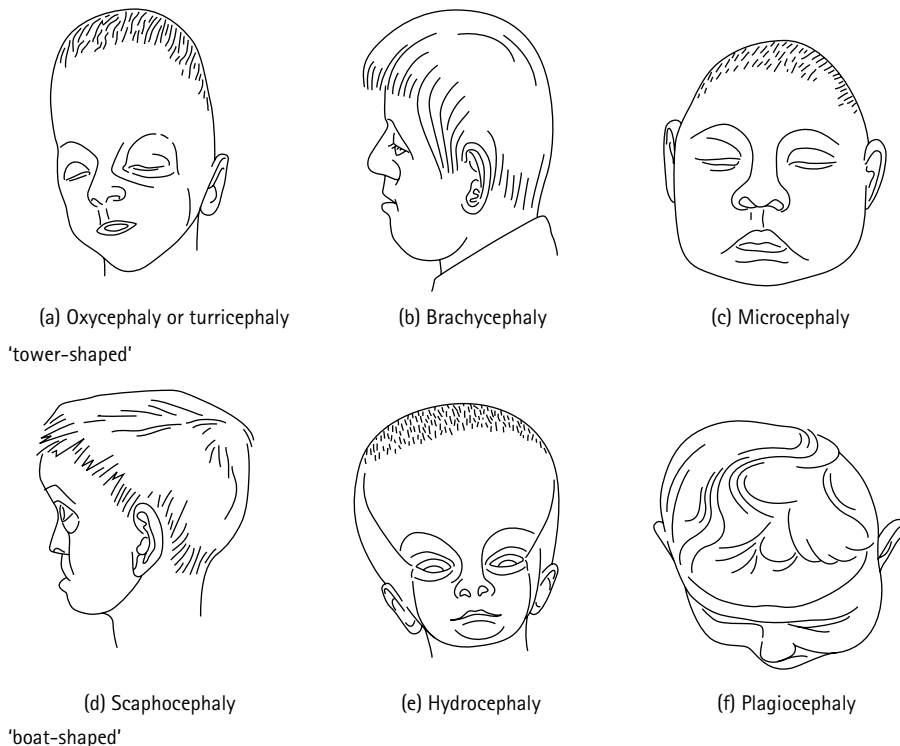

Fig. 8.4 Head shapes.

Rashes should be described in terms of color, distribution, size, nature (macules, papules, vesicles, pustules), ability to blanch under pressure, and whether it is itchy or not. Look for the presence of atopic dermatitis characterized by pruritic, erythematous papules and vesicles with serous discharge and signs of skin trauma from scratching. Seborrheic dermatitis (cradle cap) on the other hand is not itchy and the salmon-colored greasy scales characteristically affect the scalp but also commonly the face, neck, groin and axillae.

There may be jaundice or excessive pallor. Hypercarotenemia may be seen in infants who consume large amounts of carrot and squash, and can be distinguished from jaundice by the absence of orange–yellow discoloration of the sclerae. Assess the mucous membranes for central cyanosis and signs of hydration. Observe in the mouth for gum disease and dental caries.

Examine for lymphadenopathy in the neck, groin and axilla. Multiple, palpable, nontender and generally small, shotty nodes are common in children following upper respiratory infection. The size, number, and consistency of palpable lymph nodes should be documented as well as any associated erythema and tenderness. Remember to check the surrounding area for presence of any infection or inflammation that may have resulted in lymphadenopathy.

## CARDIOVASCULAR SYSTEM

### Inspection

Examine the hands for:

- palmar erythema;
- cyanosis;
- finger clubbing – in cyanotic heart disease usually only after 6 months of age;
- nail bed hemorrhages – rare, seen in infective endocarditis.

Examine the face for:

- dysmorphic features – heart disease is more common in children with other congenital abnormalities or syndromes;
- central cyanosis or pallor;
- sweating.

Examine the precordium for:

- signs of respiratory distress;
- scars – usually a sternotomy scar or a left thoracotomy but be aware that modern advances in laparoscopic surgery may result in lack of traditionally recognized scars;
- a hyperdynamic precordium from a ventricular impulse;
- count the respiratory rate and look for signs of respiratory distress;
- check the oxygen saturations using a pulse oximeter;
- assess general level of nutrition and ease of activity.

### Palpation

Feel whether the child is warm and well-perfused. There may be prolongation of the capillary refill time. This may be an indicator of shock if it is very prolonged, but as a sign it has notoriously poor inter-rater agreement.<sup>25</sup>

Examine the pulse. In infants measure the brachial pulse; in older children measure the radial pulse. Remember that the pulse rate will vary with temperature, activity and stress.

### Rate (Table 8.10)

#### Rhythm

Sinus arrhythmia, where the rhythm and volume of the pulse varies with respiration, is common in children.

#### Volume

Volume is small in circulatory collapse and aortic stenosis and increased in high-output states such as anemia, patent ductus arteriosus and fever. Following a Blalock–Taussig shunt procedure volume may be decreased or absent.

The jugular venous pressure is often difficult to assess in younger children but prominent pulsation may be seen in tricuspid regurgitation and cannon waves in heart block.

Palpate the femoral pulses. Absent or reduced femoral pulses are suggestive of coarctation of the aorta as is radiofemoral delay, which may be difficult to appreciate in faster heart rates.

Palpate the precordium for the position of the apex beat, usually located in the 4th or 5th intercostal space in the midclavicular line. Note any parasternal heave from a ventricular impulse or a thrill from a palpable murmur. Feeling in the suprasternal notch for a thrill can be uncomfortable for children and should only be checked if aortic stenosis is suspected.

Palpate the abdomen for an enlarged liver and spleen. Assess any lower limb edema. Both hepatosplenomegaly and limb edema are late signs of heart failure.

### Auscultation

Auscultate at the apex to identify the heart sounds. The first sound tends to be single and the second sound split with variation during respiration, splitting increasing with inspiration. A third heart sound at the apex is common in infants and younger children. Listen for the murmurs in the positions shown in Figure 8.5 with the bell and then diaphragm of the stethoscope.

Assess and describe any murmur.

Timing	–	systolic, diastolic, continuous
Phase	–	early, mid, late
Duration	–	short, pansystolic
Loudness	–	Grades 1–2 – very soft
		Grade 2 – soft
		Grade 3 – easy to hear, no thrill
		Grade 4–6 – loud with a thrill
		Grade 5 – heard with a stethoscope held off the chest
		Grade 6 – heard without stethoscope

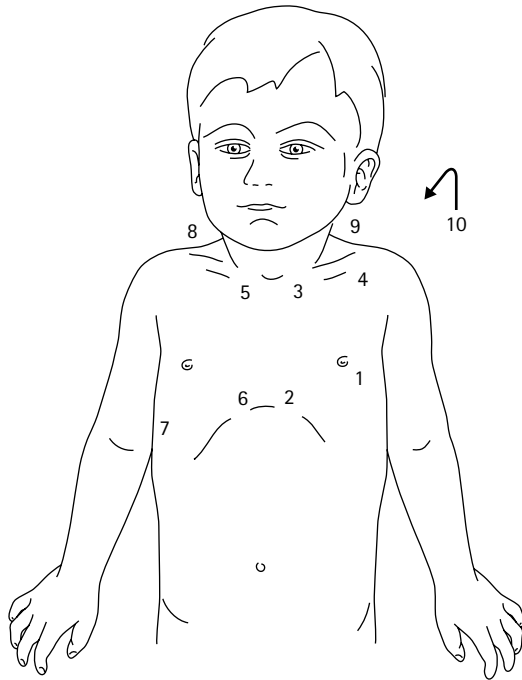

Site of maximal intensity

Radiation	–	examples: to neck in aortic stenosis to back in aortic coarctation/ pulmonary stenosis to right axilla in atrial septal defect
-----------	---	--

Innocent murmurs are common in children and are characterized by being soft, short, midsystolic, localized, and varying with position and respiration. They are commonest at the lower left sternal edge. They are usually musical or vibratory, do not conduct and are not associated with other signs of heart disease. A venous hum is caused by blood flow in the great veins and is heard as a low-pitched machinery-type murmur in the upper right side of the chest that varies with position, becoming louder when sitting up. It may be eliminated by gentle pressure on the neck. Characteristics of a significant murmur are shown

Table 8.10 Normal ranges or values for physiological variables across different ages

Sign	Preterm neonate	Term neonate	Up to 1 year	1–5 years	10 years
Heart rate (beats per min)	120–160	100–140	80–120	70–100	60–80
Blood pressure (mmHg)					
Systolic	Mean BP at least numerically equivalent to gestational age		80	85	95
Diastolic			50	55	60
Respiratory rate (breaths per min)	40–60	30–50	20–40	20–30	15–20

**Fig. 8.5** Auscultation positions. 1, apex; 2, left lower sternal edge; 3, left upper sternal edge; 4, left infraclavicular; 5, right upper sternal edge; 6, right lower sternal edge; 7, right midaxillary line; 8, right side of neck; 9, left side of neck; 10, posteriorly. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall).

**Table 8.11** Characteristics of a significant murmur

Pansystolic or diastolic
Heard best at the upper left sternal edge
Harsh quality
Abnormal 2nd heart sound
Early or mid-systolic click

in [Table 8.11](#).<sup>26</sup> Murmurs with a thrill and those that are diastolic are always significant. All significant murmurs should be referred to a pediatric cardiologist.

### Measure the blood pressure

Practice in pediatric blood pressure measurement has been found to vary widely in the UK with further variation in what are regarded as acceptable limits for normal blood pressure.<sup>27,28</sup> Further difficulties arise due to discrepancies in measurements between devices.

The gold standard for blood pressure measurement is invasive continuous intra-arterial waveform monitoring. This method allows trend evaluation of the blood pressure as well as observation of the waveform, and may indicate pathology. Non-invasive methods include the manual auscultatory method and also automatic oscillometric and Doppler methods. Although non-invasive oscillometric measurements have been found to be reliable in healthy settled neonates,<sup>29</sup> they may be less reliable in critically ill infants.<sup>30</sup> Pulse oximetry waveform systolic blood pressure measurement is a newer development that has been found to be more accurate than oscillometric devices in both postoperative children and sick neonates.<sup>31,32</sup> This method may be particularly useful in patients on transport.<sup>33</sup>

In neonates, the mean blood pressure should be at least numerically equivalent to the infant's gestational age in weeks.<sup>34,35</sup> A guide to normal blood pressure values in older children is given in [Table 8.10](#). A rough guide to remembering expected blood pressure values in children is:

- Systolic BP = 100 mmHg at 6 years. After 6, BP rises by around 2.5 mmHg a year
- Diastolic BP = 60 + age in years

Blood pressure measurements should be considered with respect to the child's size and gender as well as age and pediatric normograms are available.<sup>36-38</sup> Although there are limitations to using an absolute cut off in children, hypertension is generally defined as an average systolic and/or diastolic blood pressure  $\geq 95$ th percentile for age and sex with resting measurements obtained on at least three different occasions.<sup>38</sup>

### Technique for manual auscultatory method (korotkoff's method<sup>39</sup>)

Explain the procedure to the child before you start. The child should be relaxed, as pressures recorded during crying or struggling are unreliable. The child should be sitting with the right arm exposed and resting on a surface at the level of the heart.

Select the largest cuff that will fit the child's arm comfortably. The cuff should encircle the arm and cover around 75% of the distance between the shoulder tip and elbow. A cuff that is too small will give artificially high readings. Doppler, oscillometric and ultrasonic machines will measure the blood pressure automatically. The cuff should be inflated to around 20 mmHg above the point at which the radial pulse disappears. The cuff should be deflated slowly at a rate of about 3 mmHg/s while light auscultation of the brachial artery is performed. The systolic blood pressure is measured as the pressure at which the pulse is first heard. Continue deflation until the sounds become muffled or disappear; this is the diastolic blood pressure. The blood pressure should be measured and recorded in millimeters of mercury (mmHg).

## RESPIRATORY SYSTEM

### Inspection

Observe and listen for signs of respiratory disease:

- measure respiratory rate ([Table 8.10](#)) and observe the pattern of breathing;
- cyanosis (measure SaO<sub>2</sub> with a pulse oximeter, if necessary);
- inspiratory stridor;
- expiratory wheeze;
- grunting;
- nasal flaring;
- cough – may be barking in croup, or moist and wheezy in bronchiolitis;
- tracheal tug;
- use of accessory muscles: intercostal and sternocleidomastoid;
- retractions: subcostal, intercostal, supraclavicular, suprasternal (tracheal tug) or sternal;
- ease of speech and feeding;
- nasal discharge, snuffliness, upper airway secretions;
- posture and level of activity;
- finger clubbing – seen in chronic suppurative conditions such as cystic fibrosis;
- examine any sputum.

Look at the chest for scars, asymmetry and shape. The chest may be barrel-shaped in asthma and a Harrison's sulcus from diaphragmatic tug may be present in poorly controlled asthma and chronic lung disease of prematurity.

Observe for paradoxical respirations with sternal recession and abdominal distension during inspiration and the reverse during expiration. A degree of abdominal breathing is common in infants but excessive use of the abdominal muscles may indicate respiratory distress.

Children over the age of 5 may be able to generate a peak expiratory flow rate. This measurement is commonly used to assess the severity of asthma and response to treatment. It is measured in L/min and can be compared against normal values for height and sex.

### Palpation

Examining the position of the trachea in the suprasternal notch may cause discomfort to some children and is rarely useful.

Assess chest expansion. With thumbs meeting over the sternum and the hands placed gently around the chest, ask the child to take a deep breath. In normal school-aged children, the thumbs should move apart about 3–5 cm.

Percussion is rarely performed in the infant as it can make the child cry and obscures other signs. In older children, explain what you are going to do prior to percussion. Percuss anteriorly and posteriorly, appreciating any dullness suggestive of effusion or consolidation, and hyper-resonance suggestive of a pneumothorax. Always make symmetrical comparisons.

Palpate the abdomen for downward displacement of the liver.

### Auscultation

Use the diaphragm of the stethoscope. Listen anteriorly, posteriorly and in the axillae. Assess equality of air entry bilaterally. Listen to the quality of the breath sounds, which may be harsh, high pitched or bronchial. Harsh breath sounds from the upper airways are easily transmitted to the upper chest in young children. Bronchial breath sounds are higher-pitched than vesicular breath sounds and both inspiration and expiration are equal in length. Listen for any added sounds such as crackles (crepitations), wheeze or pleural rub. Crackles are discontinuous moist sounds from the opening and closing of the bronchioles. Wheeze is the high-pitched expiratory sound from distal airway obstruction. Remember that in infants significant lung disease may be present in the absence of signs on auscultation.<sup>40</sup>

### GASTROINTESTINAL SYSTEM

The child should lie supine. In small infants, examination may take place with the child lying in the parent's arms.

#### Inspection

Assess nutritional status. Look at the eyes for jaundice and anemia. Check for finger clubbing, which may be present in chronic inflammatory bowel disease. Look in the mouth for angular stomatitis, glossitis and mucosal ulceration or bleeding.

Look at the abdomen for distension, visible bowel loops or masses and scars. If there is any swelling, note the site and size of this. Generalized distension may occur with fat, fluid, feces or flatus. Distinguish true distension from the normal protuberant 'pot belly' seen in pre-school children. There may be swelling in the flanks if there is ascites. Gross ascites may lead to eversion of the umbilicus. Localized swellings may be due to enlarged organs, a distended bowel loop, intra-abdominal masses or herniae. Umbilical herniae are common in the infant and usually resolve by 18 months of age. In intestinal obstruction, peristalsis may be visible. It may be relevant to examine the stool and urine.

#### Palpation

Ensure the child is comfortable and relaxed. Ask about any tenderness. Warm your hands. Palpation often provokes giggling in tickly children. Distract the child by asking him questions about school or a favorite toy. Using the child's hand to palpate may help. If the child is unable to settle, bending the child's knees will relax the stomach muscles. In a crying baby, palpate during inspiration or later during sleep. Gently palpate in all four quadrants to assess tenderness and guarding, observing the child's face for signs of pain throughout. Assess any organomegaly, masses and tenderness (Fig. 8.6).

#### Liver

The liver is normally felt 1–2 cm below the costal margin in the mid-clavicular line in children up to the age of 3 years. In pathological conditions it enlarges towards the right iliac fossa and will move with respiration. Palpate from the right iliac fossa, using the tips of the fingers or the side of the index finger. Remember that in respiratory disease the liver may be pushed down by a flattened diaphragm, giving

Fig. 8.6 Palpation: (a) liver, (b) spleen, (c) kidney.

the impression of hepatomegaly. Therefore always percuss the upper edge of the liver and measure the full size in centimeters with a tape measure.

#### Spleen

A spleen is sometimes palpable under the costal margin in normal young children – usually after a minor viral infection. The spleen enlarges towards the right from the left costal margin, although in small infants, extension towards the left iliac fossa is more usual. Laying the child slightly on the right side may allow easier palpation of this organ. Features that distinguish an enlarged spleen from the left kidney are the presence of a notch, inability to feel above it, dullness to percussion and that it is not ballotable. Measure the extent below the costal margin in centimeters with a tape measure.

#### Kidneys and bladder

Although a kidney may be felt in the newborn infant, it should not be palpable in older infants and children. An enlarged kidney may be felt on deep palpation with one hand but a bimanual approach is easier, with one hand underneath the child and one on the abdomen. Kidneys move on respiration, have a smooth outline and can be accessed from the area above them. Feel for tenderness in the flanks posteriorly. A full bladder may be palpable.

#### Other

If ascites is suspected, check for a fluid thrill and percuss for shifting dullness. Percuss the child's abdomen to outline areas of dullness and tympany. Ask the child to roll onto his side and after 1 min, percuss again, noting any shift in the area of dullness, which may suggest ascites. Assess

the size, shape and characteristics of any masses. Check in the groins for swellings suggestive of a hernia, lymph nodes or gonads. Inguinal herniae, in contrast to an umbilical hernia, are always pathological and require referral to the surgeons. The anus should be inspected where guided by the clinical history. Rectal examination is seldom necessary and is discussed later.

### Auscultation

Bowel sounds may be hyperactive in intestinal obstruction and acute infective diarrhea or absent in peritonitis or ileus.

## GENITOURINARY SYSTEM

If the genitals require examination, ensure that a parent or chaperone is present and that this is recorded in the notes. If sexual abuse is suspected the child should be assessed by a child protection specialist.

### Boys

Examine the penis for size and ensure that the urethral meatus is at the tip. In hypospadias the meatus is on the ventral surface of the penis (head, shaft or perineum) and in epispadias, it is positioned on the dorsum. Although a phimosis is common in infancy, by 4 years of age the foreskin can be retracted in most uncircumcised males. Examine the scrotum. Ensure both testes are palpable. If a testis is unable to be felt, determine whether it is truly undescended or simply retractile by asking the child to squat. This will abolish the cremasteric reflex and a retractile testis will be felt. It may be relevant to measure the size of the testes, in which case, use an orchidometer. Feel for other scrotal masses and if found, transilluminate the swelling with a pen torch. Fluid will transilluminate and the commonest cause is a hydrocele. An inguinal hernia is another common scrotal mass and will not transilluminate. Inguinal herniae require surgical referral, particularly if irreducible, in which case it should be treated as an emergency.

### Girls

Look for the size of the clitoris and the labia, the position of the vagina and the presence of any vaginal discharge. The differentiation of notches and clefts in the hymen may be important in suspected child sexual abuse.<sup>41</sup>

## SEXUAL MATURATION

The age at development of the secondary sexual characteristics varies greatly. On average, the onset of puberty is 1–2 years earlier in girls than boys. Breast and pubic hair development may begin as early as 8 years whereas testicular development in boys starts at around 9–10 years. The adolescent growth spurt occurs around 12 years in girls and 14 years in boys.

In girls, growth of pubic hair and breast development are assigned a sexual maturity rating as established by Tanner in 1962 (Fig. 8.7).<sup>42</sup> In boys, a similar rating is used to document the growth of pubic hair and the development of the penis, testes and scrotum (Fig. 8.7).<sup>42</sup>

## RETICULOENDOTHELIAL SYSTEM

Symptoms and signs of dysfunction of the reticuloendothelial system are typically nonspecific and although examination is important in guiding investigations, the diagnosis is usually made on examination of blood count and film, and sometimes the bone marrow.

### Inspection

Look for evidence of weight loss and general indices of nutrition. The child may be lethargic or listless. Look for pallor, jaundice, bruises, mucosal bleeding, petechiae and skin rashes. There may be angular stomatitis and glossitis on examination of the mouth. Take the child's temperature and inspect for signs of infection, remembering to look for candida. Look for evidence of marrow hyperplasia with overgrowth of the frontal and maxillary bones. Examine the gums

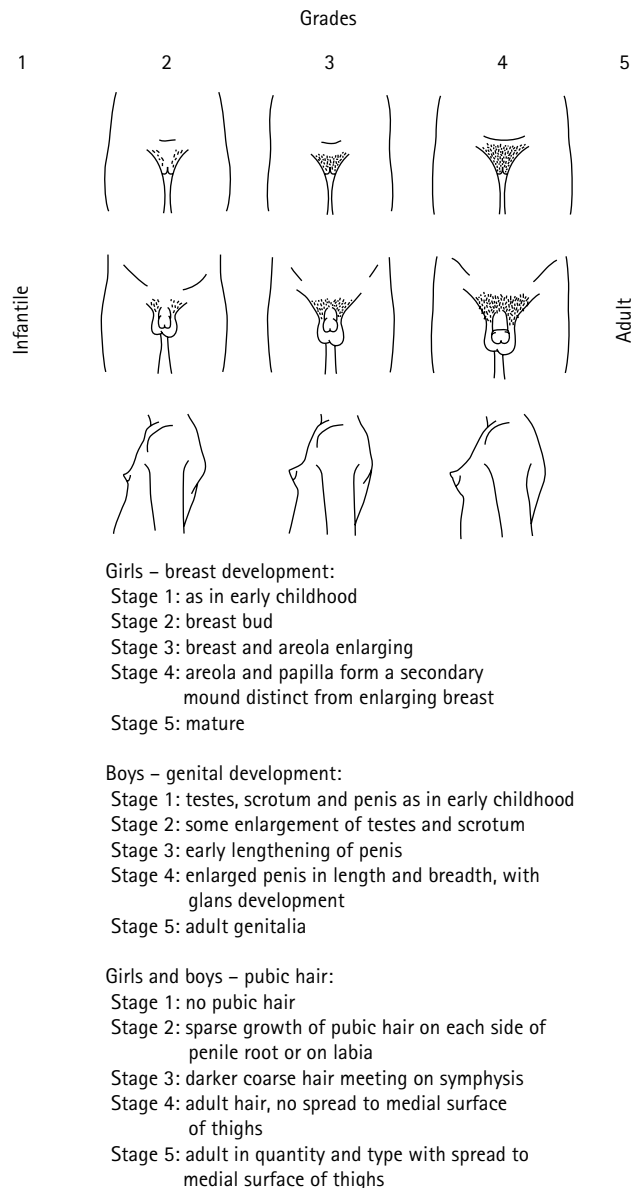

Fig. 8.7 Pubertal development grading. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall)

for hypertrophy. Observe for breathlessness or other signs of respiratory distress.

Look at the abdomen for any distension, dilated superficial veins and scars suggestive of a splenectomy.

### Palpation

Palpate for enlarged lymph nodes in the neck, axillae and groin. Palpate the abdomen for enlargement of the liver and spleen.

### Auscultation

Listen to the heart sounds, noting any tachycardia and the presence of a flow murmur, which may be present in anemia.

## NERVOUS SYSTEM

Although in older children a full detailed neurological examination can be carried out as in adults (Table 8.12), observation and clinical history will allow a reasonable assessment of neurological function in smaller children. Some useful neurological tests are listed in Table 8.13. Neurodevelopmental examination is detailed in Chapter 7.

**Table 8.12** Schema for neurological examination in children

Assessment of level of consciousness and mental state
Inspection – size and shape of head, dysmorphic features, neurocutaneous lesions
Meningeal signs – if prompted by symptoms
Motor system – tone, power, reflexes
Sensation – if prompted by symptoms
Cerebellar function – gait, balance and coordination
Cranial nerves

### Inspection

Assess the level of consciousness and mental state. Observe the child's posture for asymmetry, unusual posture of limbs (such as scissoring of the legs, hemiplegia or windswept posture) and involuntary movements. Look for any neurocutaneous stigmata such as café-au-lait spots, shagreen patches, depigmented macules and facial capillary hemangiomas. Examine the child's head for size, shape and any unusual

facial features. Observe any muscular fasciculation, particularly in the tongue.

Watch the child move around, looking for paucity or weakness of movement, balance and general tone.

In babies, feel the fontanelles and the cranial sutures, noting whether they are open or closed. The anterior fontanelle measures approximately 0.5–2.5 cm in diameter at birth, although the size may vary considerably depending on the degree of molding. It should close by 18 months. The posterior fontanelle measures around 0.5 cm across and closes shortly after birth. The cranial sutures may be overriding at birth due to molding in the birth canal. Feel the sutures for premature fusion (craniosynostosis) or separation, which may indicate hydrocephalus or raised intracranial pressure. If an arteriovenous malformation is suspected, auscultation over the skull may yield cranial bruits.

### Meningism

The classical signs of meningism (neck stiffness, photophobia and in infants, a bulging fontanelle) develop relatively late in the course of

**Table 8.13** Neurological and locomotor tests

Test name	Test description	Possible causes
Babinski's sign	Stroking lateral plantar surface from heel to toes causes extension of great toe	Normal in infants, upper motor neurone lesions
Barlow's test	With one hand stabilizing pelvis, the other hand abducts infant's hip. Pressure is then applied backwards and outwards with the thumb on the inner upper thigh while abducting same hip in an attempt to dislocate an unstable hip	Unstable hip
Bragaard test	Dorsiflexion of foot following straight leg raising causes pain in leg and lumbar region	Sciatic nerve root impingement
Brudzinski's sign	Flexing head causes legs to be drawn up	Meningeal irritation
Chvostek's sign	Tapping facial nerve lightly causes contraction of ipsilateral facial muscles	Hypocalcemia
Gower's maneuver	Child getting up from floor by walking hands up legs	Duchenne muscular dystrophy
Kernig's sign	With hip flexed, any attempt to straighten knee results in hamstring or lumbar spasm	Meningeal irritation
Lachman's test	With knee almost fully extended, tibia can be moved forward on femoral condyle	Anterior cruciate ligament laxity or rupture
McMurray test	Flex hip and knee to 90 degrees. Grasp heel with one hand and steady knee with other. Slowly extend knee using heel movement, while palpating joint line. Do with tibia in external and internal rotation. A clunk indicates displaced cartilage	Cartilage displacement in knee
Moro reflex	See <a href="#">Table 8.16</a>	
Ortolani's test	With one hand stabilizing pelvis, abduct hip and press forward with middle finger on greater trochanter. A dislocated hip can be felt to slip forward into joint again with a 'clunk'	Congenital dislocation of the hip
Romberg's sign	Closing eyes while standing with feet together causes severe swaying or falling over	Proprioceptive or vestibular deficit, posterior column lesion, intoxication
Simmond's test	With patient lying prone, squeezing calf results in absence of plantar flexion of foot	Ruptured Achilles tendon
Thomas test	With patient supine, place one hand between lumbar spine and couch. Flex normal hip to limit to straighten lumbar spine. Opposite leg will rise off couch if fixed flexion deformity present	Flexion deformity of hip
Trendelenburg's test	While standing, pelvis tilts down towards side on which leg is lifted. Opposite side is impaired	Congenital dislocation of the hip, muscular dystrophy
Trousseau's sign	Circumferential pressure of limb causes carpopedal spasm	Hypocalcemia, alkalosis, Bartter syndrome

meningitis. Early symptoms of bacterial meningitis include leg pains, cold peripheries and skin mottling.<sup>43</sup> There may be a history of poor feeding, vomiting and irritability. If the history is suspicious of meningitis, look for neck stiffness. However, this is an unreliable sign in children and can also be present in tonsillitis or in a generalized flu-like illness. A child who has true neck stiffness will not move his neck actively and may even lie in an extended position. Ask him to touch his chin to his chest and each shoulder, and then ask him to look up above. Gently flex the neck while watching the child's face for signs of pain and feeling for resistance. With the child lying supine, flex the child's leg at the hip and knee. Straighten the leg at the knee, observing for neck pain and resistance to extension (Kernig's test).

Ask about photophobia and observe the child's response in a well-lit room and to a bright light shone in the eyes. In infants, assess the tension of the anterior fontanelle remembering that crying and struggling babies will have a bulging tense fontanelle too.

**Tone**

Tone is defined as the resistance to passive movement felt across a joint and should always be assessed with the head in the midline. Observe the posture. A child with generalized hypotonia will lie in a frog-like posture and will 'slip through your hands' when holding him upright. Hypertonic children may lie in a hyperextended position, with arching of the neck and fisting of the hands. Truncal tone can be assessed on pulling to sit or holding prone in the younger child and in the ability to sit in older children. Assess tone in the limbs, checking for spasticity and clonus or untoward floppiness. This is best assessed in children while they are distracted with another activity. Increased tone in the lower limbs may result in scissoring of the legs when a child is held upright. In children who are walking, heels should touch the ground. Increased tone may lead to joint contractures whereas floppiness may result in hypermobile joints or even dislocations.

**Power**

Power is the measure of strength of muscle groups and can be graded as follows:

**Grade**

- 0 – no movement
- 1 – minimal movements present
- 2 – movements but not against gravity
- 3 – voluntary antigravity movements
- 4 – movements against resistance
- 5 – normal strength

The symmetry of active movements should be noted. Assess muscle bulk. Pseudohypertrophy is the fatty infiltration of weak muscles seen in Duchenne muscular dystrophy.

In children who are not yet walking, a useful test of gross motor function is the 180-degree test:

- With the baby lying supine, observe anti-gravity movements and whether he can roll from supine to prone.
- Pull the baby by the hands to the sitting position, assessing head lag.
- Does the baby sit unsupported? What head control does the baby have? Are there protective righting reflexes, present from 5–6 months? The baby puts one arm out to right himself when gently pushed over to one side.
- With hands under the axillae, stand the baby on a flat surface. Does he weight bear?
- Lift the baby upright, assessing tone and posture of the legs.
- Watch for the protective parachute reflex, present from around 6–9 months, as you lay the baby prone. The baby will extend his arms to protect himself.
- With the baby prone, observe head lifting and whether the baby is able to support himself on flexed or extended arms and lift his chest off the bed.
- Observe rolling from prone to supine.

In children who are walking, assess gross motor function in a range of activities including running, jumping, hopping, squatting and climbing steps. Fine-motor power can be assessed as in adults.

**Deep tendon reflexes**

Examination of the deep reflexes includes biceps, triceps, pronator, knee and ankle. In small infants, percussion of the reflexes can be done using a brisk tap with the fingertips; in older children a tendon hammer should be used. Explain to the child before you start the examination what it entails as some children find it alarming. A few beats of clonus in the ankle reflex are normal in small infants but in conditions with increased tone, clonus is exaggerated and sustained.

**Sensation**

Formal assessment of sensation is laborious and difficult to carry out in infants and in small children who lack cooperation. It is not part of the routine examination. In younger children, stroking or tickling may result in withdrawal of the limb and may be a useful screening tool. If suspicious symptoms are present, formally assess sensation in all dermatomes (Fig. 8.8). Explain the procedure clearly to the child and

Fig. 8.8 Cutaneous nerve segments. (From Geigy<sup>112</sup> with permission).

let him know what response is expected of him. Demonstrate the test with the child's eyes open initially. The child should subsequently have his eyes shut. Assess the child's responses to light and deep touch, pain, temperature, vibration and proprioception.

### Cerebellar function

Formal assessment of cerebellar function requires cooperation and is not recommended in infants and younger children. Older children may enjoy the different tasks:

1. Assess the child walking for broad-based features.
2. Listen to the child's speech – slow, slurred speech is characteristic of cerebellar disease.
3. Observe tongue movements – small spastic tongue is classical of cerebellar pathology.
4. Assess balance with one-legged standing, heel-toe test and the Romberg test. The Romberg test involves getting the child to stand with the eyes shut while gently pushing his shoulders from side to side to push him off balance. Explain before the test what it entails and reassure any worried child that you will catch him if he falls.
5. Stand the child with eyes shut and arms outstretched in front, palms facing downward. Push the wrist quickly downward and observe the returning movement. In cerebellar disorders the hand may shoot up past its original position.
6. Examine the eye movements for nystagmus. In cerebellar disease, the nystagmus is typically of large amplitude and low frequency.

7. Heel–shin coordination test – repetitive sliding of the heel of one foot up and down the shin of the other leg. Watch for inaccuracy of placement and 'wobbliness'.
8. Finger–nose test. Get the child to touch your finger then touch his nose repetitively while you move your finger into random positions within his reach. Watch for past-pointing, where the child's finger overshoots the target, and tremulous intent, where attempt at accuracy of the action is associated with increased tremor.
9. Fine motor movements of the fingers – 'playing the piano' and quick repetitive opposition of thumb with each finger.
10. Test for dysdiadochokinesis – ask the child to clap one hand repetitively with the alternating palm and dorsum of the other hand.

### Cranial nerves

Testing of the cranial nerves in children requires practice, patience and ingenuity. Much information can be gathered from watching a child's facial expression and eye movements, observing him eating and listening to him talking. Most children will be only too delighted to stick their tongue out at you! Parental concerns about hearing and vision should be taken seriously and usually warrant specialist referral. Smell and taste are not tested routinely in children.

Detailed assessment of the cranial nerves can be performed in older, cooperative children (Table 8.14). Ophthalmoscopy is described in detail in Chapter 3.1.

Table 8.14 Testing of cranial nerves

	Cranial nerve	Test for integrity
I	Olfactory nerve	Before testing, check each nostril is patent. Test the sense of smell in each nostril, by occluding one at a time. Present common odors such as coffee, chocolate, soap and orange peel
II	Ophthalmic nerve	Test the visual fields, and visual acuity (with glasses on if normally worn) with a Snellen or Logmar chart in school-age children. Charts that use shapes instead of letters are available for younger children. Examine the fundi
III IV VI	Oculomotor nerve Trochlear nerve Abducent nerve	Test the eye movements, looking for nystagmus, squint, head tilting and dysconjugate movements. Ask if he has double or blurred vision during the examination. Examine the pupils for shape and symmetry. Test the direct and consensual papillary reflexes to light and the accommodation reflex
V	Trigeminal nerve	With the child's eyes closed, test facial sensation in ophthalmic, maxillary and mandibular areas with a piece of cotton wool or your fingers. Test sensation over the anterior part of the tongue with an orange stick. The corneal reflex can be unpleasant to test. Touch a piece of damp cotton wool to the lower lateral quadrant of the eye while the child is looking upwards. Check for blinking. Ask the child to bite down hard and test the bulk of the masseter muscle. Test for a jaw jerk by gently tapping the chin with a tendon hammer while the mouth is loosely open
VII	Facial nerve	Test the muscles of facial expression by asking the child to look angry, happy, surprised and to show his teeth. Ask him to pretend to blow up a balloon. Look for asymmetry and feel for weakness. Test common tastes such as sugar, salt, lemon juice on the anterior part of the tongue
VIII	Vestibulocochlear nerve	Test the hearing and balance. Hearing can be tested crudely by distraction testing
IX X	Glossopharyngeal nerve Vagus nerve	Test common tastes such as sugar, salt, lemon juice on the posterior part of the tongue. Testing pharyngeal sensation is unpleasant and should be reserved for those children with swallowing difficulties. Use an orange stick and gently test sensation on both sides. Ask the child to say the sounds 'aah', 'c' and 'g' and watch the movement of the palate. Test the gag reflex if there are swallowing difficulties
XI	Accessory nerve	Inspect and palpate the sternocleidomastoid and trapezius muscles for bulk. Holding the chin on one side, ask the child to turn the head to that side against resistance thus testing the power of the sternocleidomastoid muscle on the opposite side. Test the power of the trapezius muscle by asking the child to shrug his shoulders as you exert downward pressure
XII	Hypoglossal nerve	Ask the child to stick out his tongue and waggle it from side to side. Look for deviation and fasciculation. Ask him to push his tongue against the inside of each cheek, while you assess power from the outside

## LOCOMOTOR SYSTEM

### Inspection

Watch the child as he moves around. In infants observe how he reaches for objects and crawls or bottom-shuffles. In older children observe the gait while walking, running, jumping, hopping and climbing stairs. Observe any unusual positioning, guarding and swelling. Look for erythema or any contractures around a joint. Look at the soles of the child's shoes for asymmetry of tread and scuffing.

### Palpation

Ascertain any tenderness before you start and watch the child's face throughout the examination. Remember that pain may be referred, such as hip pathology presenting as pain in the knee. Examine the upper and lower limbs and then the joints for swelling, tenderness, heat, crepitus and range of movement. Find out the extent of voluntary active movement before manipulating a joint passively.

Examine the spine for sacral sinuses, nevi, swellings and tufts of hair. Check the spine for scoliosis, kyphosis and lordosis with the child standing erect initially. True scoliosis can be demonstrated if an apparent hemithoracic convexity persists on bending over forwards. Some useful locomotor tests are detailed in Table 8.13. Measurement of limb lengths may be relevant and normograms are available in textbooks of morphology.<sup>24</sup>

## INVASIVE EXAMINATIONS

Invasive examinations are not part of the routine examination and should be performed only when guided by relevant information in the clinical history. Such examinations usually cause distress or discomfort and should be performed at the end of the examination.

### EXAMINATION OF AUDITORY CANAL

The ears are best examined in younger children with the child held sideways in the parent's lap. The parent should be shown how to hold the head to prevent trauma if the child wriggles (Fig. 8.9).<sup>42</sup> Use an appropriately sized attachment of the otoscope. Hold the pinna with one hand and insert the otoscope into the external ear canal. Note the integrity and color of eardrum and any discharge.

### EXAMINATION OF OROPHARYNX

If unable to cooperate, the child should be positioned on the parent's lap facing the examiner with the parent's hand firmly on the forehead to prevent the child lunging forward (Fig. 8.10).<sup>42</sup> Using a light source and a tongue depressor inspect the tonsils and pharynx. The size of the tonsils in children may be considerable and usually is of no clinical significance. Note any erythema, ulceration, exudates or palatal petechiae. Candidal infection of the oropharynx leads to white adherent mucosal plaques. The mucosa will bleed if the plaque is scraped off in contrast to milk residue, which is also common in babies. It is useful to be prepared and take a swab for microbiological investigation if warranted, rather than repeat the procedure. Use this opportunity to inspect the condition of the gums and the teeth for caries. Although this examination is a usual procedure in suspected upper respiratory infection, beware of the toxic, febrile child with drooling and stridor. This child may have acute epiglottitis and inspection of the pharynx in this way may precipitate acute respiratory obstruction.

### RECTAL EXAMINATION

This may be necessary to assess fecal impaction and check for anal fissures or trauma. It may also be required when child sexual abuse has been suggested, when it should be performed by a child protection specialist. Its usefulness in assessing pain in acute appendicitis is debatable.<sup>44</sup> Explain to the child what you are about to do. Ask the child to lie on his side with his legs drawn up to his chest. Note the appearance of the anus and the

Fig. 8.9 Method of holding a child for otoscopy. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall)

Fig. 8.10 Examining the oropharynx in an uncooperative child. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall)

presence of any threadworms, excoriation or bleeding. On spreading the buttocks apart, a fissure may be seen, commonly at 6 and 12 o'clock positions. Use lots of lubricant on a gloved little finger. The anal tone may be increased in anal stenosis or decreased (patulous) in spinal cord lesions. The specificity of the reflex anal dilatation test for recurrent anal abuse has been questioned.<sup>41</sup> Appreciate any tenderness and feel for any masses. Examine the appearance of rectal contents on withdrawal of your finger.

### VAGINAL EXAMINATION

Vaginal examination may be necessary in cases of suspected child abuse and in this case should be performed by a clinician skilled in this

procedure. Small children may have vaginal discharge secondary to a self-inserted foreign body. This generally requires exploration under sedation.

## SUMMARY

Summarize the key problems and the list of differential diagnoses. Decide whether any investigations are required to firm up the diagnosis. Formulate a management plan, which may be a period of observation or a therapeutic intervention. Decide on a date for review if necessary and/or whether referral to other specialties is required.

Provide verbal information for the family and include the child where appropriate in the discussion. Support the information by written information, in the form of a note or entry in the parent-held records, a published pamphlet or sending a copy of the clinic letter. Some conditions are best explained with diagrams. Although the Internet is a rich source of information, it may be wise to explain the limitations of this resource.

The likely outcome should be made clear but parents should also know what to do or who to contact if things do not progress as expected. Parents should be clear about arrangements to be seen again. It is often useful to ask parents to recount the information they have been given to ascertain they have understood the plan of action. Ensure your findings are documented accurately and that your notes are dated and signed.

## THE NEWBORN

History and examination of the newborn is a well-established element of routine screening in many countries and takes place usually within the first 3 days of birth. In the UK it is a standard part of child health surveillance.<sup>45</sup> There is no evidence supporting the most optimal time for the examination but traditionally it has been postponed until after the first 24 h of life so that the murmur of a patent ductus arteriosus has disappeared and the infant has had some time to establish feeding. It is recommended in the UK that each infant should be examined before 72 h of age.<sup>46</sup> There is no evidence to support a second neonatal examination,<sup>47</sup> but in the UK this examination is repeated in the primary care setting at around 6 weeks of age.

The purpose of the newborn examination is to identify congenital abnormalities, exclude disease where possible, and establish a baseline for future comparison in that child (Table 8.15). As well as reassuring the majority of parents that their child appears healthy, it also provides an opportunity for health promotion. Recording of information also serves a wider purpose of informing on population health by providing data on weight and head circumference.

Congenital anomalies are present in 9% of newborns,<sup>48</sup> but many may be difficult to identify at this early stage or may be missed by inexperienced staff. The newborn examination therefore has important limitations. Many conditions are asymptomatic in the first days or weeks of life and signs and symptoms evolve over time. Some conditions such as hypoplastic left heart and metabolic conditions will evolve over the first days of life, others such as ventricular septal defect only become apparent at a few days or weeks when pulmonary vascular resistance drops and the murmur of a left-to-right shunt becomes audible. Infants with antenatally occurring brain damage may appear neurologically normal at birth and take many months to show signs of spasticity and

neurodevelopmental delay. It is important to remember, therefore, that the findings of the newborn examination are specific to that particular point in time.

As well as looking for congenital anomalies, the doctor should ascertain that the baby is well, feeding adequately and behaving appropriately. The pediatrician should have a working knowledge of the effects of the intrauterine environment on the fetus, the physiological changes that occur during and after birth, and an understanding of feeding behavior. Although 'baby checks' are usually carried out by a relatively inexperienced member of pediatric staff, it is important that this doctor has an appreciation of the wide spectrum of normality in the newborn as well as a familiarity with the common pathologies. The junior pediatrician must have ready access to senior advice.

Many women are emotionally labile in the postpartum period. Some mothers may have undergone difficult and traumatic labors; others will never have handled a baby before. Most will have had little sleep in the preceding days or weeks. Remember that even minor problems such as an innocent murmur, jaundice or positional talipes can provoke intense anxiety in the parents and should be discussed sensitively and patiently. Never be judgmental or patronizing.

The newborn examination is also an important opportunity to discuss with the mother any concerns about her baby and his feeding as well as offering reassurance that the examination has not detected anything abnormal. Health promotion such as advice about breast-feeding, immunizations and prevention of cot death can be offered at this time. In addition, parents may seek advice on getting their baby to sleep, what to do when their baby is crying and how to manage sibling rivalry. Written information on these subjects may be available in hand-held records or in leaflet form but the doctor should be prepared to discuss these topics and offer sensible advice. Time taken to provide parents with such health care information may enhance parental satisfaction with the newborn examination.<sup>49</sup>

## NEONATAL HISTORY

As with the pediatric history and examination, all information should be recorded accurately and legibly, and signed and dated by the clinician. It is always good practice to check through maternal notes beforehand as parents may fail to disclose important information or realize its relevance.

Introduce yourself and ask the names of the people present and their relationship to the baby. Observe the maternal interaction with her baby. The following important details of the history should be ascertained from the patient records and the mother.

## MATERNAL HISTORY

- Maternal age
- General health and pre-existing medical or psychiatric conditions
- Previous obstetric history including miscarriages and fetal losses
- Inherited conditions, including those on her partner's side, particularly developmental dysplasia of the hip and congenital heart disease
- Social circumstances, including occupation, home support and when she hopes to go home.

## PREGNANCY HISTORY

- Maternal health during pregnancy – pregnancy-induced hypertension, diabetes, thyroid disease etc.;
- Antenatal concerns about the fetus – poor growth, abnormal serum screening, results of amniocentesis or chorionic villous sampling, excessive or inadequate amounts of liquor and antenatally diagnosed anomalies;
- Antenatal incidents – infections, hemorrhage, trauma and episodes of reduced fetal movements;
- Smoking, alcohol and use of recreational drugs during pregnancy should be sensitively discussed;
- Prescribed medications.

Table 8.15 Role of the newborn examination

To detect congenital anomaly
To exclude disease
To record baseline information for future health surveillance
To reassure parents
To provide health education through anticipatory guidance and supporting parenting skills
To inform population statistics

## LABOR AND DELIVERY

- Onset of labor – spontaneous, induced or no labor
- Duration of rupture of membranes
- Mode of delivery
- Medications during labor, including spinal anesthetics and antibiotics
- Presentation of the baby
- Problems during labor – meconium, failure to progress, fetal distress, bleeding, pyrexia
- Condition of the baby at delivery and need for resuscitation.

## INFANT HISTORY

- Gender
- Gestation
- Birth weight
- Current parental concerns
- Feeding history.

Although the management and assessment of breast-feeding has traditionally been the role of midwifery staff, it is important that the pediatrician is also able to assess the adequacy of lactation:

- Is the baby waking for feeds regularly without stimulation?  
A newborn infant typically wants to breast-feed 8–10 times a day in the first few days of life.
- Is the baby rooting and attaching well to the breast? The mouth should be wide-open, with the lower lip rolled down, the chin pressed into the breast and the nose free. The mother should not feel pain if the baby is optimally attached.
- Is the sucking rhythmic and sustained? At the beginning of a feed the baby takes short shallow sucks followed by long deep sucks and audible swallowing.
- Is the baby passing adequate amounts of stool and urine? Most babies will pass meconium (green–black) for the first 2 d of life with changing stool (yellow–brown) appearing by days 3–4. The first stool should be passed within 48 h and urine within 24 h.
- Is weight loss excessive? Most babies lose weight following birth but the majority has regained their birthweight by around 10 d. If a breast-fed infant has a weight loss of greater than 10–12%, consideration should be given to excluding hypernatremic dehydration secondary to lactation insufficiency.<sup>50</sup>

## NEONATAL EXAMINATION

As with the pediatric examinations, this should be carried out where possible with the parents present, in a well-lit, warm and quiet room, where privacy can be respected and interaction between the mother and baby can be observed. It is advisable to examine the baby between feeds and for the examination to be guided by the infant's clinical condition.

It is essential that good hand hygiene is observed at all times and that any equipment is cleaned before and after examination. Although all organ systems must be examined fully, the newborn examination is often opportunistic as babies become cold quickly when undressed and fretful when disturbed. Uncomfortable procedures such as examination of the hips or elicitation of the Moro reflex should be deferred to the end of the examination. Through time and practice each pediatrician will develop their own system for examination, which should be thorough and accurate. A top-to-toe assessment, rather than a system-orientated approach, is useful. Speaking soothingly to the infant may help to calm him and the mother.

### Inspection

The baby should be observed lying supine for general assessment before touching or undressing. Observe the following points:

- General wellness – does the baby look well?
- Level of alertness – the rousability, consolability and nature of the baby's cry should be noted.
- Nutrition – the weight and head circumference (OFC) of the baby should be plotted on a growth chart appropriate for gender and

race. In term infants the weight should be 2.9–4.1 kg and the OFC should measure 33–37 cm. An assessment of skin folds and fat stores can be made through examination. An assessment of gestational age can be made if there is doubt as to the infant's maturity (see Chapter 12).

- Posture and movement – a normal full-term baby should lie in a flexed position and make many random gross movements of his limbs, trunk and head. The presence of asymmetry should be noted. Jitteriness is common and is seen in almost half of all babies in the first few days.
- Color – jaundice, cyanosis, plethora, pallor, meconium staining.
- Work of breathing – respiratory rate, nasal flaring, tracheal tug, tachypnea, grunting.
- Observe the facies for any dysmorphic features.

### Skin

Observe the skin color:

- Plethora may be due to vasodilatation or an increase in circulating red blood cells.
- Pallor may be due to anemia or vasoconstriction.
- Jaundice is common, affecting 30% of newborns between 2 and 4 d of age. It is always an abnormal finding in the first 24 h of life and should prompt investigation for hemolytic disease of the newborn.
- Acrocyanosis where the baby has blue peripheries but is centrally pink is normal in the first 2 weeks of life.
- Central cyanosis is best assessed on the tongue and if present, requires urgent investigation. Cyanosis can be difficult to assess in very pale babies or in those with racial pigmentation. Plethoric babies or those with facial congestion or bruising often appear cyanosed even when well oxygenated. If in doubt carry out pulse oximetry.
- Meconium staining of the skin is often a feature in post-mature infants who have passed meconium in utero some days before delivery. It is most commonly seen around the nails and umbilical cord.
- A harlequin color change is an uncommon episodic but usually benign manifestation of vasomotor instability in the newborn period. When the baby is lying on his side the dependent part appears red but the nondependent part is pale. It is commonest in the low-birthweight infant and may be associated with systemic infection in the unwell infant.

Birthmarks should be noted. Capillary hemangiomas over the eyelids, glabella and nape of neck ('stork marks') are common and fade quickly with time. Cavernous hemangiomas are usually not present at birth but develop over the early weeks and months and typically involute completely by school age. Although often alarming in size and swelling, they require no treatment unless excessively large, when they can be associated with platelet consumption and heart failure, or unless interfering with vision or obstructing the airway. A capillary nevus or port-wine stain, however, is permanent and when located in the distribution of the trigeminal nerve, is often associated with an underlying vascular malformation in the meninges that can interfere with brain development and cause seizures (Sturge-Weber syndrome). Mongolian blue spots are areas of bluish pigmentation, usually over the lower spine and buttocks that are present usually but not invariably in non-Caucasian infants. These also fade over the first year.

The skin in post-mature babies may appear dry and cracked, especially on the feet. This resolves over the ensuing days without treatment. More rarely ichthyosis may be indicative of a more chronic skin condition.

Erythema toxicum is a common benign eruption in full-term babies. Typically the lesion is a red macule with a pale yellow papule in the center. It is occasionally vesicular. The rash is widespread and typically waxes and wanes over the first 2 weeks of life. Although not performed as a diagnostic test, skin scrapings reveal eosinophils. It should be distinguished from staphylococcal infection, which requires antimicrobial treatment. Such infection usually results in a more localized distribution of frankly erythematous pustules.

Milia are tiny white blocked sebaceous glands on the nose and forehead that resolve over a few weeks.

Subcutaneous fat necrosis secondary to local trauma during labor and delivery presents as hard lumps under the skin that initially may be red and painful. These subside with time but there may be residual palpable calcification. Document any bruising or other signs of trauma.

Engorgement of the mammary tissue secondary to placental transfer of maternal hormones may be present in both boys and girls. Rarely neonatal mastitis due to bacterial infection may cause erythema and swelling of the mammary tissue.

Palpable lymph nodes are found in around one third of normal newborn infants and are usually of no clinical significance. They often persist into later infancy.<sup>51</sup>

## Head and neck

Note the shape of the head according to [Figure 8.4](#). Examine the size of the anterior fontanelle, which may vary between 1 and 5 cm across. Normal tension should be noted. Bulging of the fontanelle in a baby who is calm and settled warrants investigation. Palpate the posterior fontanelle, which should be open and usually smaller than the tip of your finger. Palpate the sutures, which in the newborn are commonly overlapping (moulding). Premature fusion (craniosynostosis) or excessive separation of the sutures should be investigated.

Note any signs of trauma from delivery such as scalp lacerations from electrodes, or bruising from forceps or vacuum extraction. A cephalhematoma is a subperiosteal hemorrhage confined within the margins of the skull sutures. Occasionally it may be bilateral. A caput succedaneum is a soft boggy swelling, usually over the vertex, which represents diffuse edema secondary to pressure during birth. Rarely this is associated with a rapidly enlarging hematoma under the aponeurosis causing a subgaleal hemorrhage. This should be taken seriously as it is life threatening. Facial congestion or petechial hemorrhages in the distribution of the superior vena cava are common and resolve spontaneously.

An encephalocele occurs in the midline usually in the occipital region and contains meninges with or without brain tissue. Rarely it may be located anteriorly.

Cutis aplasia is a congenital absence of an area of scalp that may be isolated or have syndromic associations. It is often oval shaped and occurs in the midline at the vertex. It is usually associated with a halo of alopecia.

Examine the neck for presence of developmental anomalies such as branchial fistulae and sinuses. These may occur bilaterally in the newborn and the external opening, which may secrete mucous, usually found in the lower third of the neck anterior to the sternocleidomastoid muscle. Palpate at the back for an extra fold of nuchal skin, which is characteristically seen in Down syndrome, and look for webbing of the neck, which may suggest Turner syndrome. Palpate for any swellings such as the soft fluctuant swelling of a cystic hygroma or the firm restrictive 'tumor' caused by hemorrhagic fibrosis in the sternocleidomastoid muscle. This sternomastoid 'tumor' may result in torticollis of the neck to the affected side. The clavicles should be palpated for fractures.

## Ears

Examine for shape and position. Folded ears are common and result from in utero positioning. These are usually only temporarily deformed. Where there is true underdevelopment of the helix and antihelix ('bat ear'), successful correction of the deformity with splinting may avoid surgery. Low-set ears are found in a number of syndromes and chromosomal anomalies. Look for pre-auricular tags or pits. If isolated, they are usually only of cosmetic significance but warrant assessment of hearing. They may occasionally be associated with abnormalities of the genitourinary tract in infants who have coexistent anomalies.

## Eyes

Note the size and shape of the eyes. Note any slanting of the palpebral fissures, epicanthic folds, colobomata (keyhole-shaped pupil secondary to a defect of the iris, associated with other congenital anomalies) and Brushfield spots (white flecks on the iris characteristic of Down syndrome).

Subconjunctival hemorrhages are common following delivery but the cornea should be otherwise clear or icteric in the presence of hyperbilirubinemia. Discharge from the eyes and the presence of conjunctivitis should be noted. Impaired lacrimal drainage is common in the newborn period and may cause 'sticky eyes'. Copious purulent discharge and erythema of the surrounding eyelids requires microbiological investigation and treatment as it may be due to the gonococcus in the first few days or Chlamydia a little later.

The red reflex is a reflection of light from the retina when an ophthalmoscope is shone through the iris. Puffiness of the eyelids may make this examination difficult in the first couple of days of life. Absence of the red reflex suggests a cataract, corneal opacity or rarely a retinoblastoma and always warrants further investigation. Although congenital cataracts are present in around 3/10 000 live births, routine newborn examination only detects around 35% of these.<sup>52</sup> Infants of nonCaucasian origin may have retinal pigmentation that alters the appearance of the classical red reflex. Isolated retinal hemorrhages are common after birth and are of no significance.

## Nose

Both nostrils should be patent and this can be ascertained by occluding each nostril separately with a finger whilst the mouth is closed. 'Snuffliness' is relatively common due to congestion of small nasal passages and should clear over the first couple of days. Excessive sneezing may indicate drug withdrawal.

## Mouth

Observe any asymmetry of the mouth and nasolabial folds suggestive of facial nerve palsy. Note any micrognathia, if present. A cleft lip may be unilateral, bilateral or midline. Assessment of the mouth includes both digital examination and visual inspection of both the soft and hard palate to exclude both submucosal and overt clefts. Palatal clefts may be unilateral, bilateral or midline and may involve the alveolus. A high-arched palate may be present as part of a syndrome such as Pierre Robin syndrome or cranial deformities.

Cyst-like thickenings of the oral epithelium are called 'Epstein's pearls' and may be found on the gums. They are usually but not always in the midline and are of no clinical significance. Congenital teeth are rare but represent the first deciduous teeth and should not be removed unless loose. A bluish swelling on the floor of the mouth is likely to be a mucous retention cyst (ranula) originating from the sublingual or submandibular salivary ducts and requires no treatment. White deposits on the tongue and buccal mucosa may be secondary to milk deposits or from *Candida albicans* infection. Milk deposits are easily scraped away but *Candida* is adherent and tends to bleed on scraping.

The presence of a sublingual frenulum is common but true tongue-tie, where the frenulum is short and restrictive, is rare and may result in feeding difficulties if present.

## Hands and feet

Check for a full complement of fingers and toes and for normal palmar creases. Although a single palmar crease is present in 4% of the Caucasian population, it may be associated with chromosomal abnormalities. Ensure there is no syndactyly (joined digits) or polydactyly (extra digits). Polydactyly may be pre-axial (on the radial side) or postaxial (on the ulnar side). Both fused and extra digits are commonly familial but may be associated with dysmorphic syndromes. Rocker-bottom feet may be found in Edwards syndrome (trisomy 18) and other syndromes. Puffiness of the hands and feet ('lymphedema') with hypoplastic nails is seen in Turner syndrome.

## RESPIRATORY EXAMINATION

Assess the respiratory rate before handling the infant ([Table 8.10](#)). The pattern of respiration in the newborn infant is often irregular with alternating short pauses and relative tachypnoea (periodic breathing). Observe for signs of respiratory distress including subcostal and sternal

retractions. Listen for grunting (an expiratory sound and a nonspecific sign of respiratory distress) or stridor (an inspiratory sound indicating a congenital laryngeal problem such as laryngomalacia, tracheal stenosis, webs or cleft, or rarely compression of the larynx by a vascular ring).

Observe any chest deformity. Percussion is never helpful and may distress the baby. Auscultation rarely yields extra information in the absence of respiratory symptoms. Auscultate the chest with the diaphragm of the stethoscope, anteriorly, laterally and posteriorly for symmetry of breath sounds. Crepitations may be present in the hours following birth due to retained lung liquid but should rapidly clear.

## CARDIOVASCULAR EXAMINATION

Congenital heart defects affect 7–8 per 1000 live-born infants and account for 3% of all infant deaths and 46% of deaths due to congenital malformations. Early detection can improve the outcome of congenital heart defects,<sup>53</sup> but many infants with significant cardiac defects have normal cardiovascular examinations in the first week of life.<sup>54</sup> Moreover, while the newborn examination identifies around 45% of congenital cardiac disease; one third of affected infants will present with symptoms or noncardiac abnormalities before this examination.<sup>55</sup>

Observe the color of the baby for cyanosis, which may be difficult to see under normal lighting conditions. If in doubt measure the oxygen saturation with a pulse oximeter. Assess perfusion, remembering that it is normal for the hands and feet of a newborn baby to be cold and appear blue (acrocyanosis). Remember that cardiac disease, particularly cardiac failure, may cause tachypnea.

Palpate the precordium for the apex beat, which should be present in the fourth intercostal space around the mid-clavicular line. A parasternal heave and thrill is best felt by the palm of the hand and not the fingers. A heave may lift your hand, and a thrill may be palpable as a vibration.

Auscultate the chest. Measure the heart rate (Table 8.10). Remember that the heart rate varies in response to physical activity and level of alertness. In a newborn baby it may vary between 80 bpm in deep sleep and 160 bpm when crying and active. Listen for heart sounds and murmurs in the suggested positions shown in Figure 8.5.<sup>42</sup> Use both the bell (for low-pitched sounds) at the apex and the diaphragm (for high-pitched sounds) in all positions. Describe the quality and any splitting of the heart sounds as well as any additional heart sounds or murmurs. The second sound is often loud and single shortly after birth but splitting can be detected by around 48 h in most infants. Around 60% of newborn infants will have murmurs in the first few hours of life but many are transient and not related to cardiac pathology. Around 20–54% of murmurs will have structural cardiac disease on echocardiography but many are small ventricular septal defects that close spontaneously in the first few months of infancy.<sup>54,56,57</sup> Innocent murmurs are characterized by a normal clinical examination, normal pulses, soft 1–2/6 systolic murmur heard at the left sternal edge and normal heart sounds with no clicks.<sup>58</sup>

Gently extend the hips and palpate the femoral pulses in each inguinal crease over the femoral triangle with the thumbs. Remember that this may upset a baby and should be left until the end. In restrictive left output conditions such as aortic coarctation or valvular stenosis, femoral pulses may be reduced in volume or difficult to feel. If so, it is mandatory to perform a four-limb blood pressure and refer urgently to a cardiologist. Remember a baby with coarctation may have normal femoral pulses in the first few days due to the presence of a patent ductus arteriosus.

The abdomen should be palpated and the size of the liver measured in the midclavicular line.

Non-invasive measuring of the blood pressure is difficult and often inaccurate in healthy newborn infants. It is seldom part of the routine examination. In sick newborns, intra-arterial blood pressure can be measured accurately.

## ABDOMINAL EXAMINATION

The abdomen should be inspected for distension. Mild distension due to recent feeding or swallowed air from crying is not unusual. Owing to lax abdominal musculature, visible bowel loops and diastasis of the rectus sheath are common features. The xiphisternum at the caudal end of the sternum is often clearly visible.

The cord should be inspected to ensure it is clean with no surrounding erythema. The cord separates at around 10 d of age but may still be adherent until 14 d. The three umbilical vessels (one vein and two arteries) may be seen shortly after birth. An isolated single umbilical artery is associated with a marginal increase in the incidence of renal anomalies. However these are almost universally mild and self-limiting, and imaging investigations should only be pursued in the face of other congenital anomalies.<sup>59</sup> An umbilical hernia is common and of little clinical significance. It should be distinguished from an omphalocele, where there is herniation of the abdominal contents through the umbilicus within a sac of peritoneum, and gastroschisis, where an anterior abdominal defect usually to the right of the umbilicus allows protrusion of the gut and intra-abdominal contents. A flare of erythema around the cord may indicate infection (omphalitis).

Superficial and then deep palpation of the abdomen with warmed hands may reveal the presence of masses such as enlarged liver or spleen. If the baby has just fed, be careful not to provoke vomiting. A liver edge up to 2 cm below the costal margin is a normal finding in this age group.

The spleen is not often palpable but in some infants with lax abdominal muscles it may be felt under the ribcage. The spleen of the newborn expands down the left flank rather than towards the right (Fig. 8.11).<sup>42</sup>

The kidneys are often palpable and are best examined using a finger and thumb encircling the flank (Fig. 8.11).<sup>42</sup>

The anus should be patent and not positioned anteriorly. Any nappy dermatitis should be noted. Stool should be inspected if available. Rectal examination is not a part of the routine examination. If clinically indicated it should be carried out by the examiner's well-lubricated fifth finger.

## GENITALIA

### Boys

Examine the penis for shape and size. It is common for babies to have a degree of phimosis and attempts should not be made to retract the foreskin at this age.

Fig. 8.11 Palpation of the infant spleen/kidney. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall)

The position of the urethral meatus should be noted and should be at the tip of the penis. In hypospadias the meatus is positioned on the ventral surface of the penis. It may be associated with a tethering of the foreskin known as 'chordee'. In epispadias, the urinary outlet is situated on the dorsum of the penis. Abnormal meatal position usually requires surgery and parents should be cautioned not to arrange circumcision, as the foreskin may be required during reconstruction. Ask about or if possible, observe the urinary stream. A poor stream may warrant further investigation for meatal stenosis or posterior urethral valves.

Examine the scrotum and testes. The scrotum should be inspected for evidence of pigmentation. Although common in infants of darker skin color, consideration should always be given to the diagnosis of congenital adrenal hyperplasia. Both testes should be palpable in the scrotum or high in the scrotum outside the inguinal canal. Some testes will be retractile and move from the scrotum to the inguinal canal on stimulation. These can be gently milked along the inguinal canal to the scrotum. The right testis descends later than the left. A unilateral undescended testis is present in 5% of male infants and should descend by around 3 months of age. Bilateral undescended testes warrant further investigation. Testicular torsion, suggested by bluish black discoloration of the scrotum with a hard tender testis, requires urgent surgical attention. A hydrocele may be present after birth. Containing fluid, a hydrocele will transilluminate and may extend superiorly, communicating with the abdominal cavity. It usually resolves over the coming months. Indirect inguinal hernias are also common and warrant surgical referral, particularly where irreducible, when urgent surgical repair is required.

## Girls

The labia majora and minora should be separate and not fused. In term infants, the labia minora should be covered by the labia majora and should meet at the anterior aspect of the clitoris. In preterm infants, the labia majora may be underdeveloped and retracted laterally, causing the labia minora to appear more prominent. Labial swellings may indicate the presence of testes. Clitoral enlargement or pigmentation is suggestive of congenital adrenal hyperplasia. Vaginal tags are small remnants of mucosal tissue protruding from the posterior end of the vagina. These are of no clinical significance and regress over the ensuing months. A white mucoid discharge is normal. It is common at the end of the first week of life for a small amount of blood to be passed in response to the withdrawal of maternal hormonal influence (pseudomenses).

## NEUROLOGICAL ASSESSMENT

The nervous system of the newborn is in a rapid state of development and any examination must allow not only for any pathological variations but also for the state of maturity of the infant.

Listen to the quality of the cry and assess the consolability of the infant. The infant's behavioral state should be noted.

The posture of a term infant should be flexed and symmetrical, with the knees tucked under the pelvis when prone. A frog-legged posture with abduction of the hips suggests generalized hypotonia. Abnormal posturing of the feet and hands should be noted, e.g. fisting, thumb adduction, big toe extension. Nerve palsies caused by a traction injury during birth may affect the upper roots of the brachial plexus (C5, C6) leading to an Erb's palsy with internal rotation and adduction of the arm with the hand held in a 'waiter's tip' position. Less commonly, the lower roots (C8, T1) are damaged, resulting in a Klumpke's palsy. This affects innervation of the small muscles of the hand and causes weakness of the wrist and finger flexors. A facial nerve palsy may present with asymmetry of the facies, particularly when crying, failure of eyelid closure and difficulty in feeding. Feeding support and lubrication of the eye may be required while the palsy resolves. Most palsies resolve over the ensuing weeks.

All assessments of tone must be performed with the head in the midline so as to avoid elicitation of the asymmetric tonic neck reflex (Fig. 8.12).<sup>42</sup> Tone may vary with the level of alertness and with relation to

Fig. 8.12 Tonic neck reflex. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall)

feeds. Small-for-gestational-age infants may be relatively hypertonic and hyperalert at birth. Recoil of the limbs may give information about tone. Head lag on arm traction in the pull-to-sit maneuver should be assessed. On sitting supported, the baby should have a curved back and intermittently raise his head. When held prone, some flexion of the limbs against gravity should be present, the head is lifted intermittently in line with the body and truncal tone should be evident. Infants with Down syndrome are almost universally hypotonic. Back and neck arching (opisthotonus), limb extension and stiffness may be features of an intracranial pathology such as meningitis, asphyxia, hemorrhage or kernicterus.

General quality and quantity of spontaneous movements should be observed. The baby should exhibit frequent generalized fluent and alternating movements when awake. Antigravity movements of all limbs should be present, as should strong resistance to passive movement. Intermittent lifting of the head when prone is normal. Around a half of all newborn babies exhibit jitteriness<sup>40</sup> but if this is excessive, it may indicate drug withdrawal, metabolic disturbance or intracranial pathology.

Although not performed routinely, deep tendon reflexes of the knee, ankle and biceps can be elicited in the newborn infant and may be warranted in the face of other neurological abnormality (Table 8.16). These can be performed with a sharp tap of the middle finger or a small patella hammer. The presence of clonus should be noted. Although muscular fasciculation is rare in the newborn infant, it may be visible in the tongue in the presence of anterior horn cell disease.

Sensory examination is limited to withdrawal from tactile stimuli. Painful stimuli should not routinely be inflicted on the normal newborn infant. Vision can be assessed crudely. A baby should open his eyes in a darkened room and screw up his eyes when exposed to bright light. In the first week of life a newborn baby will fix on a human face or red ball at a distance of around 15–25 cm and can follow it horizontally and vertically over a short arc. An intermittent divergent or convergent squint is common in the full-term infant. Roving eye movements, persistent nystagmus and the sun-setting sign are always abnormal. A crude assessment of hearing is the observation that a baby will startle at a loud noise and may be consoled by a quiet calming voice. Universal newborn hearing screening, by elicitation of auditory brainstem-evoked responses or evoked otoacoustic emissions, has recently been introduced across the UK.

Table 8.16 Neonatal reflexes

Primitive reflexes Cranial nerve reflexes (relevant cranial nerves)	How elicited	Time of appearance	Usual time of disappearance of those reflexes that are time limited	Possible significance if abnormal
Sucking (IX, X, XII)	On feeding	Birth	When voluntary control of feeding achieved at 6–9 months	General neurological depression, hypotonia, immaturity or bulbar palsy
Swallowing (IX, X, XII)	On feeding	Birth	When voluntary control of feeding achieved at 6–9 months	General neurological depression, hypotonia, immaturity or bulbar palsy
Rooting (V)	On light contact with infant's cheek the infant turns towards the point of contact	Birth	9 months	General neurological depression, hypotonia, immaturity or bulbar palsy
Glabella (V, VII)	A sharp tap on the glabella produces momentary tight closure of the eyes	Birth	Variable persistence	Apathy or facial palsy if absent; accentuated in hyperexcitability
Head turn to light (II)	With infant supine light from a diffuse source is allowed to fall on one side and then on the other side of the infant's face and he turns his head to the light (the infant must be in a quiet relaxed state)	Several weeks	—	General neurological depression, hypotonia, ?impaired vision
Pupillary (II, also III and V)	Shade one eye with the hand for a moment or two and then withdraw it	Birth	—	General neurological depression, ?impaired vision
Optic blink (II)	Shine a bright light suddenly at the eyes	Birth	—	General neurological depression, ?impaired vision
Doll's eye (III, IV, VI)	Turn head slowly to right or left watching position of eyes (normally eyes do not move with head)	Birth	2 weeks	Ophthalmic muscle palsies (ophthalmoplegia)
Acoustic blink (VIII)	Clap the hands about 30 cm from the infant's head. Avoid producing an air stream across the face. Rapid habituation – no response to test – normally achieved	After a few days	—	?Impaired hearing
Labyrinthine (rotation) (VIII, also III, IV, VII)	(a) Hold baby upright with examiner's hands under infant's arms. Spin round so that baby turns with examiner, first one direction then the other (the head should turn towards direction in which baby is being turned)  (b) Baby similarly held but head held firmly by examiner's forefinger and middle finger which, on each side, are extended upwards against the side of the baby's head. Similar rotation (the baby's eyes should turn towards the turning direction)	Birth	—	Disturbed vestibular function or ophthalmoplegia  Disturbed vestibular function or ophthalmoplegia
Gag (IX, X, XII)	Touch posterior pharynx, e.g. with spatula	Birth	—	General neurological depression or bulbar palsy
Cough (IX, X, XII)	Generated spontaneously on irritation of the respiratory passages	Weak for several weeks after birth	—	General neurological depression

(Continued)

Table 8.16 Neonatal reflexes—cont'd

Primitive reflexes Cranial nerve reflexes (relevant cranial nerves)	How elicited	Time of appearance	Usual time of disappearance of those reflexes that are time limited	Possible significance if abnormal
<b>Cutaneous reflexes</b> Palmar/foot grasp	Place the examiner's forefinger in the palm/sole of the infant's hand/foot, which then closes round the examiner's finger, maintaining a grip	Birth	2–3 months (palmar), 7–8 months (foot)	General neurological depression, hypotonia: hemisyndromes, Erb palsy or clavicular fracture. May persist beyond normal time in spastic cerebral palsy
Abdominal	Stroke a pin or thumbnail from the side to the center of the abdomen (a response is only possible if muscles are fully relaxed)	7 d	—	Absence does not necessarily imply abnormality
Anal	Contraction of the external anal sphincter when the skin round it is stroked with a pin	Birth	—	Damage to sacral cord (e.g. spina bifida)
Cremaster	Stroking the medial side of the thigh with a pin or thumbnail results in pulling up of the testes	10 d	—	Absent in spinal cord lesion
Withdrawal	On pricking the sole of the foot with a pin there is rapid flexion of the hip, knee and foot	Birth	—	Hemisyndromes; absent or weak in spina bifida and after breech delivery with extended legs
Plantar (Babinski)	Stroking the foot along the lateral side with pin or thumbnail produces dorsal flexion of the big toe and spreading of the other toes in infancy (and plantar flexion of the other toes in older children who are walking). Do not mistake a grasp reflex of the foot for a flexor plantar response	Birth	—	Defects of lower spinal cord, hemisyndromes
<b>Extensor reflexes</b> Asymmetrical tonic neck	With baby in supine position rotate the head to one side. This produces increased tone in, and partial extension of, the arm and leg on the side to which the head is rotated, and there may be flexion of the arm and leg on the contralateral side	1 month	3–5 months	Medullary or spinal cord damage. Readily elicited in immature infant. May persist beyond normal time in cerebral palsy
Crossed extensor reflex	Passively extend one lower limb pressing the knee down, and with a pin stimulate the sole of the foot of this fixated leg. Flexion and slight abduction of the unstimulated lower limb normally occurs	A few days after birth	1 month	Absent in lesions of spinal cord and weak in peripheral nerve damage
Trunk incurvation (Galant)	Stroke a pin or thumbnail along the paravertebral line about 3 cm from the midline from the shoulder to the buttock (the back should curve with the concavity to the stimulated side)	5–6 d	7–8 d	Hemisyndromes; spinal cord damage – with indication of segmental level
Perez	Elicited as for Galant but by stroking over central vertebral spines (the infant arches backwards, the buttocks rise and the anus dilates)	5–6 d	—	As for trunk incurvation reflex
Moro	Hold baby in supine position with shoulders and back supported on left hand and arm of the examiner and head (occiput) on the right hand. Allow the head to fall back suddenly (catching it again with the right hand after it has fallen a short distance) while the rest of the body remains supported. The arms rapidly abduct and come together again with an embracing movement and the legs flex	Birth	2–3 months	General neurological depression, hypotonia. Prolongation of tonic phase of response in immaturity. Hemisyndromes, fractured clavicle or humerus. May persist beyond normal time in cerebral palsy

(Continued)

Table 8.16 Neonatal reflexes—cont'd

Primitive reflexes Cranial nerve reflexes (relevant cranial nerves)	How elicited	Time of appearance	Usual time of disappearance of those reflexes that are time limited	Possible significance if abnormal
Hand opening	Stroke the dorsum of the hand	Birth	2–3 months	General neurological depression; hemisyndrome
<b>Progression</b>				
Walking/stepping	Hold infant in standing position and place foot on a flat surface. The leg extends to take the infant's weight (supporting reaction), the opposite leg flexes then extends, and as it takes weight the original leg flexes	4 d	2 months	General neurological depression, hypotonia; paresis of lower limbs
Placing	With the baby held upright between the hands of the examiner the dorsal part of the foot is brought lightly in contact with the edge of the table. Normally the baby flexes knee and hip and places foot on the table	4 d	5–9 months	General neurological depression, hypotonia; paresis of lower limbs
Crawling	Infant prone. Crawling movements may occur spontaneously but can be reinforced by the examiner pressing his thumb gently into the sole of the infant's foot (the crawling reflex is more easily elicited in the immature infant than the walking reflex)	4 d	4 months	General neurological depression, hypotonia; paresis of lower limbs
<b>Tendon reflexes</b>				
Jaw jerk	Sharp tap on the examiner's index finger placed on patient's chin below the lip	2 d	—	Absent in brainstem lesions or 5th cranial nerve damage; exaggerated in hyperexcitability, e.g. hypocalcemia
Biceps	A tap on the examiner's finger placed on the biceps muscle causes contraction of the muscle	2 d	—	Absent in general neurological depression and hypotonia; exaggerated in hyperexcitability
Knee jerk	A tap on the patellar tendon with the knee in the flexed position produces quadriceps contraction	2 d	—	Absent in general neurological depression and hypotonia; exaggerated in hyperexcitability
Ankle	With infant prone, knee slightly flexed and the fore part of the foot held lightly in the examiner's hand a tap over the tendo Achillis produces plantar flexion of the foot (response better felt than seen)	Birth	—	Absent in general neurological depression and hypotonia; exaggerated in hyperexcitability
Ankle clonus	Rapid dorsiflexion of the foot with the examiner's hand on the distal part of the sole produces a succession of rapid contractions of the calf muscle (only briefly sustained in a normal infant)	Birth	—	Absent in general neurological depression and hypotonia; exaggerated in hyperexcitability

### Primitive reflexes

The primitive reflexes are detailed in Table 8.16. The value of examination of the primitive reflexes lies in their asymmetry, absence or persistence in certain pathological conditions. Although it is not necessary to conduct the full battery of the reflexes at each newborn examination, it is important to have a working knowledge of the characteristics of each in case of suspected abnormality during examination. Generally, the feeding reflexes (root and suck responses), Moro, pal-

mar and plantar and vestibular reflexes should be assessed at each examination.

### Spine and locomotor system

The spine should be inspected with the infant prone, checking that it is straight with no curvature. Examine for evidence of a midline defect such as a meningocele or signs of spina bifida occulta, e.g. midline swelling, dimples, nevi and tufts of hair. Sacral dimples are usually

blind-ending pits at the base of the spine that are rarely of significance.<sup>61</sup> A sacral sinus, in persistent communication with the spinal cord, is usually lateral to the midline above S2 and warrants further investigation as it carries a risk of meningitis and may overlie spinal defects.

The limbs should move spontaneously and against gravity. Muscle mass should be appropriate for gestation. Owing to the restriction of movement in utero both the elbows and the knees may have a 30-degree limitation of extension that corrects over the first week. If there is a history of difficult delivery or shoulder dystocia, there may be reduced movement of the arm or callus formation over the clavicle at a few days of age. Babies who were in extended breech position in utero may have fully extended knees for some days after birth.

Examine the hips for developmental dysplasia (DDH). Incidence of this condition varies depending on the screening and classification methods used<sup>62</sup> and is probably around 1.2/1000 live births in the UK. The issues of screening and treatment of DDH are complex and have been reviewed in detail on behalf of the American Academy of Pediatrics.<sup>63</sup> Lay the baby supine on a firm surface (Fig. 8.13).<sup>42</sup> Keep the baby calm and relaxed if possible. If the baby is active or distressed, there will be muscular contraction around the hip that will limit examination. Look at the thighs for symmetry of the creases. Examine each hip separately. Hold the knee and hip flexed and adducted with the middle finger on the greater trochanter and the thumb on the medial aspect of the thigh. Stabilize the pelvis with your other hand. Exert gentle downward and lateral pressure. A clunk may be heard as the hip dislocates out of the acetabulum (Barlow maneuver). The dislocation may reduce spontaneously with relief of downward pressure but may also be reduced with the Ortolani maneuver. In this maneuver, the greater trochanter of the already dislocated hip is relocated into the acetabulum with forward pressure of the middle finger while the hips are being abducted. Established dislocation may also present with limitation of hip abduction. Ligamentous clicks related to the presence of maternal hormones are common and must be distinguished from true instability. Ultrasound screening of the hips is available in some centers but evidence is as yet lacking for its use in universal screening of the newborn.<sup>64</sup>

Examination of the feet for talipes (equinovarus, plantar flexion with medial rotation or calcaneovalgus, lateral rotation of the foot) should be performed. Most cases of talipes are postural deformities only and will resolve with or without gentle manipulation. Talipes may be a result of in utero 'squashing' and can be associated with positional scoliosis, plagiocephaly, 'bat ear' and developmental hip dysplasia.<sup>65</sup> In some cases

the deformity cannot be corrected with manipulation and will require orthopedic assessment.

## SUMMARY

The quality of information obtained from the newborn examination depends on the skill and diligence of the examiner. This takes practice and patience to achieve. All information should be recorded clearly at the end of the examination and any abnormal findings reported in a simple and sensitive manner to the parents, with supportive written information where possible. A clear plan for follow-up, treatment or specialist referral should be documented and implemented.

## GENERAL PRINCIPLES OF COMMON INVESTIGATIONS

### INTRODUCTION

Modern medicine has become dominated by the introduction of ever-more sophisticated and expensive tests. Although these may be vital in securing a diagnosis, their sensible use and safe interpretation are crucially dependent on good basic clinical skills. After reaching a hypothesis suggested by careful history taking and thorough examination, the clinician must decide whether laboratory tests or imaging will help in confirming the diagnosis suggested by the signs and symptoms. The decision to order such tests will be influenced in part by the probability and utility of the possible outcomes of the test, which may be invasive or costly.

The probability of the test is the likelihood it will be positive or negative in that particular patient or situation and is usually based on strong clinical research studies. All diagnostic tests can produce false negatives and false positives. The accuracy of a test to diagnose a particular condition can be expressed in terms of its sensitivity and specificity. Sensitivity is the percentage of the test population who has the index condition and are test positive. A very sensitive test will detect most people with the disease but may produce abnormal findings in healthy individuals (false positives). Specificity is defined as the percentage of the test population who are healthy and who test negative. A very specific test may miss the diagnosis in affected patients (false negatives) but is likely to be very accurate when the test is positive.

The utility of a test refers to the worth or value of the outcome and can be objective (measured in monetary terms or expected years of life) or subjective (stated in relation to the anticipated value to the patient or society). Other factors influencing the ordering of investigations will be the availability of the necessary technology and the expertise required to perform and/or interpret the test.

Tests may be reported in terms of qualitative (e.g. yes or no, blood groups) or quantitative results. Quantitative test results are usually referenced against a range produced from results of the same test in the normal healthy population. Such results usually fall within a normal distribution and the normal range represent two SDs either side of the mean, that is, 95% of the population. A healthy member of the normal population will have a 5% chance of a test result that falls outwith this reference range (false positive). Disease populations also have a distribution of test results and sometimes these may overlap with one or other extreme of the normal healthy population (false negative). The larger the difference between the test result and the limits of the normal population, the greater the chance that the test will be truly positive. Indiscriminate testing should be avoided as an increased number of tests will result in more likelihood of a false-positive result being generated. Be guided instead by clinical acumen. A constellation of positive signs and symptoms will increase the prior probability that a chosen test will be abnormal. Therefore the value of a test is determined by the prevalence of the condition in the test population (Baye's theorem). Bayesian analysis dictates that the value of a test is at its best when there is an intermediate pre-test probability of a disease. Although clinicians seldom have such exact statistics available they must be aware

Fig. 8.13 Hip examination. (From Laing & McIntosh<sup>42</sup> with permission of Baillière Tindall)

of the importance of the integration of clinical information with diagnostic tests.

Samples for investigations should be collected appropriately and responsibly to ensure that test results are an accurate representation of that specific patient. Children particularly will have limited understanding or tolerance of clinician error if a sample has to be repeated.

## HOW TO MINIMIZE SPURIOUS RESULTS

- Use the correct container.
- Fill it with the recommended volume.
- Do not shake samples, just mix.
- Label the container with the correct patient details.
- Avoid unnecessary delays in reaching the laboratory.

The following section outlines some of the more common investigations of blood, cerebrospinal fluid and urine; more specialized tests and implications of abnormal results will be discussed in detail in the relevant chapters. All reference ranges are given in Appendix.

## Blood

### Full blood count and film

Normal blood count values are given in Appendix.

The full blood count and film provide information about:

- red blood cells (number, size, volume, hematocrit, hemoglobin, Hb concentration, morphology);
- white blood cells (number, type, morphology);
- platelets (number and morphology).

Results depend not only on the quality of sampling, as small clots within the sample can affect all parameters, but also on the site of sampling: compared to venous blood, capillary samples tend to overestimate hemoglobin levels, hematocrit and white cell counts, and underestimate platelet counts.<sup>66</sup>

### Red blood cells

1. Hemoglobin (Hb): the normal Hb concentration varies through childhood, reaching adult values by 12 years of age. A newborn infant has an Hb concentration of between 150 and 240 g/L. This higher concentration may be caused by the high circulating red cell volume necessary in the relatively hypoxic conditions in the womb. The Hb drops to a nadir of 90–130 g/L after delivery at around 8–12 weeks and gradually increases over the first year of life. The subsequent Hb range in childhood is between 110 and 150 g/L. A similar trend is seen in hematocrit and mean cell volume (see Appendix).
2. The hematocrit (Hct) or packed cell volume (PCV) is a measure of the blood volume occupied by red blood cells. In most laboratories the Hct will be calculated by an automated analyzer. Manually measured hematocrits may still be performed in some centers. As this latter method uses centrifuge to separate the blood into layers of plasma, red cells and white cell/platelets, the hematocrit will always be slightly higher than automated hematocrits, as the degree to which the blood can be separated is limited.
  - In the newborn, a high Hct (a venous Hct > 65%) exists in conditions where there is an excess of red cells secondary to endogenous production (intrauterine growth restriction, infant of a diabetic mother, chromosomal disorders) or to exogenous transfusion (excessive blood transfusion, twin–twin transfusion syndrome, delayed cord clamping).
  - In older children, polycythemia is seen in dehydration, cyanotic heart disease, chronic hypoxia, following renal transplant and in association with some rare tumors (pheochromocytoma, cerebellar hemangioblastoma). Polycythemia vera (primary polycythemia) is very rare in children.
  - A low Hct may be due to dilution, blood loss, increased destruction or decreased production of red cells.

3. The 'mean cell volume' (MCV) is the average volume of the cells, measured in femtoliters (fl). Apart from in early infancy, where the size of the red blood cells is larger (90–125 fl), the mean cell volume in childhood is around 75–90 fl. Anemia may be classified as microcytic or macrocytic depending on this value.
  - Anemia with a low MCV suggests failure of Hb synthesis, commonly secondary to iron deficiency anemia but may also be due to chronic disease or hemolysis. Measurement of serum iron, transferrin and ferritin may help to distinguish between these causes.
  - Anemia with a high MCV suggests failure of DNA synthesis and is seen in conditions resulting in B<sub>12</sub> or folate deficiency.

### White blood cell count

The total white cell count (WCC) is a summation of the various white cell subgroups including neutrophils, lymphocytes, basophils, eosinophils and monocytes. It is measured in the number of cells per liter. Neutrophils and lymphocytes make up around 90–95% of the total white cell count but the relative proportion of each of these subgroups varies throughout childhood. The WCC is high at birth, with a predominance of neutrophils, and falls to normal values of  $6\text{--}15 \times 10^9/\text{L}$  in the subsequent days. Lymphocytes decrease during the first few days of life and then increase until the second week. Thereafter the lymphocyte is the predominant white cell, making up 60% of the total white cell population until mid-childhood, when the neutrophil is predominant. An excessive increase of any of the white cell subgroups may indicate a hematological malignancy:

- A raised neutrophil count is indicative of bacterial infection and is rarely secondary to stress or leukemia. Steroids may also increase circulating neutrophils.
- Neutropenia is commonly seen in viral infections, but may also be seen in severe sepsis, cyclical neutropenia and bone marrow suppression. In the newborn period it is observed in infants with severe intrauterine growth restriction and in growing premature infants.
- A lymphocytosis may be seen in viral infections, pertussis and leukemias.
- Eosinophils are typically raised in allergic conditions and parasitic infections.
- An increase in monocytes is seen in chronic inflammation and in granulomatous diseases.

### Platelet count

Platelets are measured as the number per liter. The platelet count is constant throughout life at around  $150\text{--}450 \times 10^9/\text{L}$ .

- Thrombocytosis (platelet count >  $450 \times 10^9/\text{L}$ ) is a feature of infection, hemorrhage, Kawasaki disease, malignancy (lymphoma, neuroblastoma, acute megakaryocytic leukemia), anemia (iron/vitamin E deficiency) and also occurs post-splenectomy.
- Thrombocythemia is a sustained platelet elevation over  $800 \times 10^9/\text{L}$ . The principal stimulation of platelet production, thrombopoietin, is raised in inflammatory disorders as part of the acute phase reaction, and thrombocythemia is a common feature of such conditions. Essential or primary thrombocythemia is very rare in children.
- Thrombocytopenia is defined as a platelet count of less than  $100 \times 10^9/\text{L}$ . The commonest cause is a clot in the sample or poor sampling technique. Always repeat the sample before treatment if the result is unexpected. Any patient with a confirmed thrombocytopenia should have a coagulation profile measured. Thrombocytopenia may be due to blood loss, increased destruction (infection, disseminated intravascular coagulation, immune thrombocytopenia), decreased production (infection, congenital platelet disorders, asphyxia, drugs or marrow infiltration) or sequestration (hypersplenism). In the infant with intrauterine growth restriction, thrombocytopenia may occur secondary to decreased production (lineage steal<sup>67</sup>) or increased platelet consumption (placental vascular disease<sup>68</sup>).

### Blood film

Microscopic examination of a film will inform about cell morphology and may reveal:

- abnormal cell forms such as Howell-Jolly bodies (damaged or absent spleen);
- sickle cells (HbS hemoglobinopathy);
- spherocytes (autoimmune hemolytic anemia, hereditary spherocytosis, sepsis);
- Heinz bodies (enzyme deficiencies);
- target cells (iron deficiency, hemoglobinopathies, post splenectomy)
- schistocytes and fragments (burns, prosthetic heart valves, disseminated intravascular coagulation (DIC), microangiopathy) coarse basophilic stippling of red cells (lead poisoning);
- reticulocytes (immature red blood cells seen in response to hemorrhage or hemolysis).

Occasionally films will be stained specifically to look for parasites such as malaria and microfilaria.

### Coagulation screen

The clotting cascade and abnormalities thereof are described in detail in Chapter 23. Reference values for newborn infants and older children are given in Chapter 39, Appendices. Attention to optimal sampling is important, as activation of clotting during traumatic or lengthy sampling is common and samples taken from indwelling lines are frequently contaminated with heparin. A routine coagulation screen consists of measurements of the prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen and fibrin degradation products (FDPs) or D-dimers. An abnormal coagulation screen may prompt further tests such as the thrombin time, bleeding time and levels of specific factors. Both the PT and APTT are compared against simultaneous control samples using the same methodology. The PT and PTT remain normal until factor levels drop to about 25–40% depending on the reagents used.<sup>69</sup> The PT and PTT measure the time to fibrin clot formation and as such, neither test will detect even severe deficiency of factor XIII, which is responsible for covalent cross-linking of the fibrin mesh.

**Prothrombin time.** The PT

- measures the generation of thrombin after the addition of tissue factor *in vitro*;
- tests the integrity of the extrinsic and common pathways (factors I, II, V, VII, X);
- may also be used to monitor warfarin therapy and assess liver damage.

**Activated partial thromboplastin time.** The APTT

- measures the generation of thrombin after the addition of contact-activating factor (e.g. kaolin, silica);
- tests the integrity of the intrinsic and common pathways (factors I, II, V, VIII, IX, X, XI, XII);
- can be used to monitor treatment effects of heparin.

In prolongation of the APTT, a 'mix' is often performed to distinguish between the presence of an 'inhibitor' (such as heparin or other anticoagulant) and a factor deficiency. The patient's plasma is mixed 50:50 with normal plasma. If the abnormality of APTT does not disappear, the patient's plasma is likely to contain an inhibitor. If the mix results in at least partial correction of the APTT, a factor deficiency is more likely.

**Fibrinogen.** Fibrinogen (Factor I) is a protein synthesized in the liver and normally has a concentration between 1.5 and 4.0 g/L. Low levels are seen in liver disease, in disseminated intravascular coagulation and in preterm infants. As fibrinogen is required in the final stage of coagulation, in converting thrombin (IIa) to fibrin (Ia), a low fibrinogen (0.6–0.8 g/L) will also result in prolonged PT and APTT.

**Fibrin degradation products (FDPs) or D-Dimers.** Both types of fragments result from the breakdown of a cross-linked fibrin mesh by plasmin and are increased in DIC and in the presence of large thromboses. An abnormal coagulation screen may be due to:

1. poor sampling;
2. decreased or abnormal factor production:

- vitamin K deficiency, malabsorption, liver disease, warfarin;
  - hemophilias A, B and von Willebrand disease.
3. antagonism – heparin, lupus anticoagulant;
  4. consumption or blood loss – DIC (including hemolytic uremic syndrome), sepsis, large thrombosis or hemorrhage.

### Blood cultures

Blood cultures should always be taken as a sterile procedure to minimize contamination with skin commensals. In the newborn, the optimal specimen volume is around 1 ml, as lower volumes may be inadequate to detect low colony-count sepsis.<sup>70</sup> In extremely low-birth-weight infants however, consideration must be given to whether improved blood culture yield justifies the risk of a relatively large blood sample. In older children, 2–10 ml blood is desirable, although it is always worth culturing smaller volumes because high levels of bacteremia (>1000 CFU/ml of blood) are found in some infants. In blood-borne infections, there is seeding of bacteria at a fairly constant rate. In other infections, transient seeding of organisms from a focus of infection, such as an abscess, is followed around 45 min later with pyrexia. Organisms grown from blood that has been sampled from intravascular catheters may represent commensals instead of true line infection.

Blood should be collected into a bottle with specific media for growing aerobic and non-aerobic organisms. The bottle is then incubated for 48 h. In modern systems, colorimetric carbon dioxide sensors measure microbial growth and an alarm is activated. The sample can then be Gram stained, cultured on appropriate bacteria medium and sensitivity to various antibiotics is assessed. Some bacteria such as *Mycobacteria* require specialist and prolonged culture.

### Urea, electrolytes and creatinine

Fluid and electrolyte disturbances are detailed in Chapter 17. Assessment of urea and electrolytes should be made in association with other parameters of hydration and renal function including clinical signs of hydration, blood pressure, measures of end-organ perfusion (level of consciousness, temperature, urinary output, assessment of skin perfusion), weight and acid-base status. Supplementary information from paired urinary and plasma osmolality, urinalysis and urinary electrolytes may be useful. It is important to have an appreciation of the age-dependent variations in body water distribution and renal function.

### Sodium

Sodium is predominantly an extracellular cation. The plasma sodium is a measure of body water as well as intravascular sodium, particularly in the newborn infant, where plasma sodium is a proxy of hydration. Sodium diffuses freely between the body compartments but the activity of the Na<sup>+</sup>/K<sup>+</sup> ATPase transport mechanism means that it remains mainly in the extracellular compartment. The regulation of plasma sodium is closely related to water, which is regulated by antidiuretic hormone acting on the renal collecting ducts. Control over absorption and excretion of sodium is primarily by the renin-angiotensin system prompted by changes in perfusion pressure at the renal juxtaglomerular apparatus. Plasma sodium values are influenced by poor sampling technique: hemolyzed samples will have artificially low sodium.

Hyponatremia (Na < 135 mmol/L) may be due to:

- decreased total body sodium (congenital adrenal hyperplasia, diarrhea, vomiting);
- normal total body sodium and increased body water (syndrome of inappropriate antidiuretic hormone, water intoxication, excessive hypotonic infusions, acute renal failure);
- increased total body sodium and greater retention of water (cardiac failure, nephrotic syndrome, cirrhosis).

It may be difficult to determine which of these causes is responsible and the child will need careful clinical assessment with weighing, acid-base balance, paired urine and plasma electrolytes and osmolality (Table 8.1.7).

Hypertatremia (Na > 150 mmol/L) may be due to:

- sodium loss with greater loss of water (dehydration due to vomiting, diarrhea);

Table 8.17 Additional tests in the investigation of hyponatremia

	Renal failure	Adrenocortical failure	Inappropriate ADH	Hemodilution	RTA
Serum K (mmol/L)	> 5.5	> 5.5	<4	<4	<4
Urine osmolality (mosm/L)	-	-	high	low	low
Blood osmolality (mosm/L)	-	-	low	low	n
Urine/blood osmolality	< 1.1	> 1.1	>2	<1.1	-
Urine Na (mmol/L)	> 20	> 20	n or ↑	n or ↓	↑
Urine Na/K	> 1.5	> 1.5	n	n	n
Blood pH	-	-	-	-	< 7.2
Urine pH	-	-	-	-	> 5.6

RTA, renal tubular acidosis; ADH, antidiuretic hormone.

- normal total body sodium with water loss (fever, radiant heaters, diabetes insipidus, poor breast-feeding);
- increased total body sodium (hyperosmolar feeds, excessive sodium supplementation).

### Potassium

Potassium is also freely diffusible across cell membranes but the active transport mechanism means that it is predominantly an intracellular cation. Plasma potassium may not reflect total body levels, as there may be considerable flux between the body compartments. For example, insulin and alkalosis may result in low plasma potassium due to an intracellular influx, whereas the reverse is seen in acidosis and drugs such as digoxin and beta-blockers. Despite its mainly intracellular presence, small changes in plasma potassium concentration can have major changes in membrane excitability. Renal excretion of potassium is dependent on renal tubular function, urine flow rate and aldosterone.

Hypokalemia ( $K^+ < 3.5$  mmol/L) occurs with:

- persistent vomiting, diarrhea, or alkalosis;
- diabetic ketoacidosis;
- rarely due to diuretic therapy, renal tubular defects and endocrine disturbances such as Cushing disease and hyperaldosteronism.

Hyperkalemia ( $K^+ > 6.5$  mmol/L) may be factitious due to in vitro hemolysis. True hyperkalemia where there is elevation of total body potassium occurs:

- in renal failure (decreased excretion);
- following increased load (crush injuries, hemolysis, gastrointestinal hemorrhage or tumor lysis syndrome);
- occasional causes include massive hemolysis, congenital adrenal hyperplasia and drugs such as spironolactone, and angiotensin-converting inhibitors.

### Urea

Urea is a nontoxic substance made by the liver as a means of clearing ammonia from protein metabolism. Urea is filtered by the glomerulus. If the glomerular filtrate is flowing slowly through the proximal tubule, urea tends to be passively reabsorbed and returns to the bloodstream. By itself it is a poor marker of renal excretory function.

Uremia may be due to:

- increased protein catabolism from high protein diets, severe physiological stress or gastrointestinal bleeding;
- impaired kidney function: pre-renal (underperfusion of the kidney), renal (intrinsic renal tubular or glomerular pathology), or post-renal (obstruction to urinary flow);
- contraction of the extracellular compartment in dehydration.

Laboratory differentiation of these causes is detailed in Chapter 17.

A decreased plasma urea is seen in:

- low protein states (e.g. starvation, malabsorption);
- severe liver disease;
- overhydration.

### Creatinine

Creatinine is the most commonly used way of assessing the excretory function of the kidneys. This breakdown product of creatine and phosphocreatinine is released from skeletal muscle at a steady rate. Serum creatinine correlates with the percentage of skeletal muscle mass and as such may be higher in boys than girls. Creatinine is filtered freely by the glomerulus, and a small amount is also secreted into the glomerular filtrate by the proximal tubule. However due to this tubular secretion, creatinine will overestimate glomerular filtration rate (GFR) at low filtration rates and as such elevated serum creatinine alone is an insensitive index of decreased GFR. More accurate estimations of renal function in children can be derived from various formulae that use height, creatinine and a constant to calculate the GFR.<sup>71,72</sup>

In children, increased creatinine is seen commonly in:

- impaired kidney function;
- massive tissue trauma, e.g. crush injuries and burns.

Ingestion of cooked meat and vigorous exercise may cause a temporary increase in creatinine.

### Glucose

The normal range of blood glucose concentration is lower in the newborn compared to the child. The newborn infant undergoes a process of extrauterine adaptation during which the brain relies on ketones and lactate for fuel while glycogenolysis and gluconeogenesis are switched on. As such newborn infants appear to tolerate lower levels of hypoglycemia than older children. The exception may be those infants whose ketogenic potential may be impaired due to growth restriction or prematurity, or where ketogenesis is switched off due to hyperinsulinism. Although controversy exists as to the definition of neonatal hypoglycemia that requires treatment ('operational threshold'), it has been shown that at levels below 2.6 mmol/L, acute alteration of cerebral physiology may occur.<sup>73</sup> However, many healthy full-term infants appear clinically asymptomatic when hypoglycemic. There is little information about the long-term sequelae of transient neonatal hypoglycemia to dictate acute management. Clinicians should be guided by the infant's clinical status and the potential of a particular child to generate alternative brain fuels.<sup>74</sup> In the older child, blood glucose concentrations between 4.5 and 6 mmol/L indicate good glucose homeostasis.

Plasma or serum is the preferred sample for laboratory measurement whereas whole-blood methods are used in point-of-care testing. However whole-blood samples may be affected by hematocrit or skin-cleansing agents, and are generally 10–18% lower than plasma samples.<sup>75</sup>

Hypoglycemia is seen in:

- hyperinsulinism (exogenous insulin, islet cell adenomas or hyperplasia, oral hypoglycemic agents, infant of a diabetic mother);
- decreased glucose production (inherited metabolic conditions);
- decreased fuels and fuel stores (fasting, malnutrition, malabsorption, small-for-gestational age infants);

**Table 8.18** Normal blood gas values in children (see Chapter 12 for newborn values)

	pH	pCO <sub>2</sub> (kPa)	pO <sub>2</sub> (kPa)	Base excess (mmol/l)	HCO <sub>3</sub> <sup>-</sup> (mmol/l)
Arterial blood	7.38–7.45	4.5–6.3	11.3–14.0	+2.5 to –2.5	23–27
Venous blood	7.35–7.40	6.0–7.6	Variable	+2.5 to –2.5	24–29

- inadequate counter-regulatory hormones (growth hormone or cortisol deficiency);
  - increased fuel demand (fever, exercise).
- Hyperglycemia (> 7 mmol/L after a 4-hour fast) is seen:
- commonly in children with diabetes mellitus;
  - in high-stress conditions, e.g. in sepsis and following cardiovascular collapse;
  - in the extreme preterm infant receiving i.v. nutrition (hyperglycemia may be due to decreased insulin production and impairment of end-organ sensitivity).

### Blood gas analysis

Acid-base balance in the newborn is discussed in Chapter 12 and in older children in Chapter 17. Normal values in well children are shown in Table 8.18. Blood gas analyses are usually performed on arterial or capillary samples.

Hydrogen ion concentration is precisely regulated by three systems that act to prevent excessive changes in pH:

1. the chemical acid–base buffer systems of the body fluid that combine with acid or base. The bicarbonate buffer system is the most important, but others include the phosphate and the protein (important intracellularly) buffer systems;
2. the respiratory center that regulates removal of CO<sub>2</sub>, and therefore H<sub>2</sub>CO<sub>3</sub>;
3. the kidneys, which can excrete acid or alkaline urine.

Low pH values indicate acidosis, and high values, alkalosis. Both these extremes may have respiratory or metabolic causes (Table 8.19). pCO<sub>2</sub> and pO<sub>2</sub> values indicate the success of gas exchange at the alveolar–capillary interface. The metabolic component (the base excess or bicarbonate level) is calculated by allowing for the effect of pCO<sub>2</sub> on the pH, i.e. any change unexplained by the pCO<sub>2</sub> indicates a metabolic abnormality.

Metabolic acid is any acid in the body except carbonic acid. Such acids are not respirable and need to be neutralized, metabolized or excreted via the kidney. The base excess (BE) refers to the amount of acid required to return the blood pH to normal (pH 7.38–7.45) and is measured in mmol/L. The relationship between bicarbonate and metabolic acidosis is not consistent or linear and therefore the base excess is considered the best measure of the metabolic disturbance.

Metabolic acidosis may be due to loss of base or gain of acid. Calculation of the anion gap may help to differentiate the two. The anion gap represents the difference between serum anions and cations and is calculated by the following equation:

$$\text{Anion gap} = (\text{Na}^{++} \text{K}^{+}) - (\text{Cl}^{-} \text{and HCO}_3^{-})$$

The difference is usually 12 mmol/L (range 8–16 mmol/L). In metabolic acidosis secondary to bicarbonate loss, the anion gap will be normal as Cl<sup>-</sup> rises proportionately. An acidosis secondary to accumulation of an anion such as lactic acid will have an increased anion gap (Table 8.19).

**Table 8.19** Causes of acid–base disturbance

	Acidosis (pH <7.35)	Alkalosis (pH >7.45)
Respiratory	pCO <sub>2</sub> > 6.5 kPa Respiratory failure – severe asthma – pneumothorax – blocked airway – pulmonary edema – poor respiratory drive	pCO <sub>2</sub> < 4.5 kPa Hyperventilation – hysteria, excessive crying – iatrogenic – early salicylate poisoning – brainstem dysfunction Hyperammonemia
Metabolic	BE < –4 mmol/L <u>Increased anion gap</u> Lactic acidosis – hypoxia – prolonged exercise – poor tissue perfusion due to sepsis, hypovolemia, anaphylaxis – primary lactic acidosis, defects of gluconeogenesis, fatty acid oxidation Ketoacidosis – diabetes mellitus – organic and branched chain amino acidemias Impaired renal handling of H <sup>+</sup> – renal failure – renal tubular acidosis type 1 Ingestion of excess salicylate, ethanol, methanol, ethylene glycol <u>Normal anion gap</u> Loss of bicarbonate – diarrhea – renal tubular acidosis type 2 – intestinal fistulae	BE > + 4 mmol/L Loss of acid (e.g. H <sup>+</sup> , K <sup>+</sup> ) – pyloric stenosis – recurrent vomiting – diuretic therapy Gain of bicarbonate – secondary to over-replacement in metabolic acidosis

## Cerebrospinal fluid

As sampling of the cerebrospinal fluid (CSF) is an invasive procedure with risks of infection and cardiorespiratory compromise, it is essential that consideration is given to the extent of investigations required to confirm the suspected diagnosis, so that repeat punctures are not required. Prior liaison with microbiologists and biochemists may be advisable if unusual conditions are suspected. Traumatic taps are common, affecting at least 15–20% of all pediatric lumbar punctures and can make interpretation of findings difficult.<sup>76</sup> Trauma may be caused to the lumbar veins by introducing the needle too far during the procedure. Having an experienced assistant to hold the child as well as a skilled clinician performing the procedure may optimize the chances of obtaining noncontaminated CSF.

### Color

The color of normal CSF is clear. Yellow discoloration (xanthochromia) is seen in the presence of old hemorrhage and in hyperbilirubinemia. Blood from a traumatic puncture may contaminate the initial drops of CSF, or uniformly blood-stained CSF may be due to intracranial hemorrhage. The color may be hazy, turbid or frankly purulent in meningitis.

### Glucose

The CSF glucose level should be at least 60% of the simultaneous blood glucose level. If it is lower, this indicates that glucose is being utilized by constituents within the CSF such as bacteria, or white and red cells. It is characteristically very low in tuberculous meningitis and often normal in viral meningitis. Normal glucose levels do not rule out infection, because up to 50% of patients who have bacterial meningitis will have normal CSF glucose levels.

### Protein

Protein in the CSF is dependent on age (it may be as high as 2500–3000 mg/L in the newborn), the presence of blood (intracranial hemorrhage, traumatic tap) or other cells (white cells, bacteria, liquefying brain tissue). Normal childhood values are around 150–450 mg/L after infancy.

### Microscopy

Microscopic examination of the CSF will ascertain the number of white cells and red cells in the sample of CSF and whether there are any organisms present. It is important to remember however that the CSF may be normal in early infection. Do not try and distinguish bacterial and viral meningitis on the basis of clinical or preliminary CSF findings. If CSF findings are suggestive of viral meningitis, treat with antibiotics until it is proven 'culture-negative'.

White cells should be less than 5/mm<sup>3</sup> but in the full-term newborn on the first day of life, values of up to 30/mm<sup>3</sup> may be normal. Preterm infants may have white cell counts in excess of 30/mm<sup>3</sup>. An excess of white cells is suggestive of infection. Cytospin and subsequent staining may give information as to the subgroup of white cell present. Although neutrophils predominate in bacterial meningitis, lymphocytes may be the predominant cell in the newborn period, and in partially treated meningitis or *Listeria monocytogenes* meningitis.

Increased numbers of red and white cells are commonly seen in a traumatic tap and following intracranial hemorrhage. As many as 20% of pediatric lumbar punctures may be traumatic. As such it is conventional to correct the number of white cells depending on the number of red cells seen: 1 white cell allowed for every 500 red cells in the CSF.<sup>77</sup> The accuracy of this method is disputed however, as the ratio may vary depending on the peripheral white cell count. Taking this into consideration, some assume that the ratio of white blood cells to red blood cells in the peripheral blood remains constant when peripheral blood is introduced into the subarachnoid space. Therefore, the expected or predicted CSF white cells can be calculated on the basis of the peripheral blood count and the CSF red cells. This predicted white cell value can then be subtracted from the actual or observed CSF WBC. A true increase in CSF

white cells exists when the observed CSF white cell count is greater than the predicted count. Debate exists as to whether or not this is any more reliable as a predictor of the presence or absence of infection. In fact some have found a reduction in the observed white cell count compared to the predicted, and have postulated that white cells may adhere to the meninges or may undergo lysis on transport.<sup>78</sup>

Morphology and Gram staining characteristics will give a clue as to the nature of any organism, but the Gram stain can be affected by laboratory techniques and expertise, as well as bacteria load. The CSF Gram stain has a sensitivity of between 60% and 92% in children not treated previously with antibiotics.<sup>79,80</sup> Cytospin may increase the ability to detect bacteria, especially in partially treated or very early meningitis, when numbers of bacteria may be low. Culture of the organism is required for definitive diagnosis but antibiotic treatment prior to lumbar puncture can decrease the sensitivity. The common central nervous system pathogens are Group B *Streptococcus* (Gram-positive coccus), *Streptococcus pneumoniae* (Gram-positive coccus), *Neisseria meningitidis* (Gram-negative diplococcus), *Haemophilus influenzae* (Gram-negative bacillus), *Escherichia coli* (Gram-negative bacillus) and *Listeria monocytogenes* (Gram-positive bacillus).

The polymerase chain reaction (PCR) has superseded latex agglutination techniques in the diagnosis of meningitis. PCR is fast, has high sensitivity and specificity for many central nervous system infections, and requires only small volumes of CSF. PCR has been especially useful in the diagnosis of viral meningitis, where it has a very high sensitivity for herpes simplex virus type 1, Epstein Barr virus, cytomegalovirus, varicella zoster virus and enterovirus.<sup>81,82</sup> In bacterial meningitis, PCR is in common usage for diagnosis of *N. meningitidis*, *H. influenzae*, Streptococci, *Listeria* and *E. coli*.<sup>83,84</sup> particularly when antibiotics have been started prior to lumbar puncture.

## Urine

Urine for culture should be collected by an optimal method:

- Clean catch and mid-stream specimens and suprapubic aspiration of urine are the methods least likely to be contaminated by organisms from the perineum.
- The bag method is highly prone to contamination and the bag is uncomfortable to remove. It should therefore never be used for culture and only for collection of urine for metabolic analysis, output measurements or for estimation of electrolytes.
- Urine for microscopy must be refrigerated. If it cannot be examined promptly; delays of more than 2 h between collection and examination often cause unreliable results.

### Microscopy

Microscopy of urine yields important information as to the presence of cells, casts, crystals and micro-organisms.

### Leucocytes

Counts of fewer than 3 white cells/mm<sup>3</sup> of uncentrifuged urine or 5 white cells/high power field of centrifuged urine are normal. Usually, the cells are granulocytes. Higher numbers (pyuria) may be present in urinary tract infection but are also common in any pyrexial illness and in the presence of renal calculi. In 30% of urinary tract infections, there are no or only a few white blood cells in the urine. Most of these are in children with recurrent infections.

### Red cells

Normal values are fewer than 3 red cells/mm<sup>3</sup> of uncentrifuged urine or 2 red cells/high power field of centrifuged urine. As well as identifying red cells, microscopy may also reveal red cell casts and dysmorphic red cells that have odd shapes because of their passage through an abnormal glomerulus. Such odd-shaped erythrocytes suggest glomerular disease. Hematuria may be microscopic only or macroscopic, and may originate from anywhere in the renal tract. Glomerular and tubular causes are often associated with significant proteinuria, whereas infection, tumors and calculi are less so. Exercise-induced hematuria is

relatively common, benign and self-limiting. Red cells may also be found following bladder procedures.

### Epithelial cells

Epithelial cells originating from the renal tubule are usually present in the urine in small numbers. However, in nephrotic syndrome and in conditions leading to tubular degeneration, they are seen in greater quantity and typically contain oval fat bodies.

### Casts

Casts in the urinary sediment may help to localize disease to a specific location in the genitourinary tract. Urinary casts are formed only in the distal convoluted tubule or the collecting duct during periods of urinary concentration or stasis or when the urinary pH is very low. The proximal convoluted tubule and loop of Henle are not locations for cast formation. The predominant cellular elements determine the type of cast:

- Hyaline casts are composed primarily of a mucoprotein (Tamm-Horsfall protein) secreted by tubule cells. It is found in pyelonephritis and chronic renal disease, but may be a normal finding, especially in pyrexial illnesses or following exercise;
- Red blood cell casts – indicative of glomerulonephritis or severe tubular damage. May be present following strenuous activity or renal trauma;
- White blood cell casts are most typical for acute pyelonephritis, but they may also be present with glomerulonephritis. Their presence indicates renal inflammation because such casts will not form outside the kidney;
- Granular casts – seen in acute and chronic renal failure;
- Epithelial casts – suggest tubular damage and are found in acute tubular necrosis, interstitial nephritis and nephritic syndrome;
- Fatty casts – lipid-laden renal tubule casts found in nephritic syndrome.

### Crystals

Occasional crystals of triple phosphate, uric acid or calcium oxalate are common and usually of no significance. However they may be present in larger amounts in hyperuricemia, cystinuria or in *Proteus* infection. More unusually, crystals such as cystine (in urine of neonates with congenital cystinuria), tyrosine (congenital tyrosinosis) or leucine (maple syrup urine disease) may be seen. All of these rare forms may be observed in the urine of children with severe liver disease.

### Bacteria

Bacteria are not an unusual finding in urine because of the large number of commensals around the urethral meatus in both boys and girls. Bacteria in urine specimens will also rapidly multiply in room temperature. Gram stain of uncentrifuged urine has a sensitivity of 93% and specificity of 95% for urinary tract infection on a recent meta-analysis:<sup>85</sup>

- The presence of any organism from a suprapubic aspirate should be considered significant.
- Culture of urine should follow microscopy of urine.
- Generally, more than 100 000/ml of one organism is defined as significant bacteriuria.
- Mixed organisms are suggestive of contamination.

### Urinalysis

Urinalysis is performed by a variety of bedside testing methods. Dipsticks will test a sample of urine for specific gravity, pH, glucose, blood, protein, ketones, leukocyte esterase and nitrites. Dipstick testing is notorious for false negatives and false positives in the presence of specific medications and various urinary characteristics.<sup>86</sup>

### Specific gravity

Specific gravity (SG) is the ratio of the weight of a volume of urine to a similar volume of water. Because of their weight, glucose and protein

can affect the SG. The SG of urine is a proxy for its osmolality and should be between 1005 and 1030. As well as reflecting the hydration of the patient, it is also a measure of the concentrating ability of the kidneys. Dipsticks estimate SG poorly and more accurate estimation requires visualization of urine on a refractometer.

Lower SG values indicate dilute urine and may be due to:

- high fluid intake;
- diabetes insipidus;
- diuretics;
- impaired renal function.

High SG values indicate concentrated urine and are found in:

- dehydration;
- syndrome of inappropriate secretion of antidiuretic hormone;
- glycosuria.

### Urinary pH

The normal pH of urine is 4.6–8.0 depending on diet and acid-base status. Acidification takes place in the renal tubule and the collecting ducts.

Alkaline urine (pH > 8) is found in:

- *Proteus* or *Pseudomonas* urinary tract infections;
- respiratory alkalosis;
- renal tubular acidosis (RTA);
- normokalemic metabolic acidosis.

Acidic urine (pH < 4.6) is found in:

- other urinary tract infections;
- respiratory and metabolic acidosis (not RTA).

### Glycosuria

Plasma glucose is filtered in the glomerulus but almost all of it is reabsorbed in the proximal convoluted tubule, such that less than 0.1% of glucose normally filtered by the glomerulus appears in urine (<130mg/24h). Glycosuria is found when the filtered glucose is in excess of the reabsorptive capabilities of the tubule:

- in hyperglycemia (commonly diabetes mellitus);
  - in the premature infant who typically has a low renal threshold for glucose;
  - in Fanconi's syndrome where there is proximal tubule dysfunction.
- Dipsticks employing the glucose oxidase reaction for screening (Clinistix) are specific for glucose but can miss other reducing sugars such as galactose, lactose, pentose and fructose. These sugars are best detected with the Clinitest (a modified Benedict's copper reduction test) but positive results may also be obtained in the presence of glucuronates, cephalosporins and vitamin C. In the case of a positive result, chromatography will confirm the presence and type of sugar.

### Hematuria

A positive dipstick for blood may indicate hematuria, myoglobinuria or hemoglobinuria. Microscopy is required to distinguish hematuria from other conditions.

### Proteinuria

Only low-molecular-weight plasma proteins are filtered at the glomerulus and most are reabsorbed by the renal tubule. However, a small amount of filtered plasma protein and protein secreted by the distal tubule (Tamm-Horsfall protein) can be found in normal urine. Dipsticks are impregnated with tetrabromophenol blue, which changes color according to the amount of protein present in the urine. This reagent is sensitive to albumin but may not detect low concentrations of gamma globulins and Bence Jones proteins, which require other diagnostic methods. Alkaline and highly concentrated urines may result in false positives whereas acidic, dilute urines may prove to be falsely negative.

Normal total protein excretion does not usually exceed 4 mg/h/m<sup>2</sup> in the child in any single specimen. More than 150 mg/d is defined as 'proteinuria'. Proteinuria more than 40 mg/h/m<sup>2</sup> is severe and known as 'nephrotic syndrome'. The majority of patients with proteinuria on dipstick testing will not have significant renal disease.

Proteinuria may result from:

- increased glomerular permeability (glomerulonephritis, congenital nephrosis);
- impaired tubular reabsorption (Fanconi syndrome, acute tubular necrosis, interstitial nephritis);
- orthostatic or postural proteinuria – a benign condition that results from prolonged periods of standing; it is confirmed by obtaining a negative urinalysis result after 8 h in supine position;
- transient proteinuria may be found in pyrexial illness and following vigorous exercise;
- dipstick tests for trace amounts of protein yield positive results at concentrations of 5–10 mg/100 ml – lower than the threshold for clinically significant proteinuria. A result of 1+ corresponds to approximately 30 mg of protein per 100 ml and is considered positive; 2+ corresponds to 100 mg/100 ml, 3+ to 300 mg/100 ml, and 4+ to 1000 mg/100 ml.

Although dipsticks are sensitive in detecting proteinuria, accurate measurement requires a 24-hour urine collection. In small children this may not be practicable and a random single sample estimation of urinary protein/creatinine ratio may give useful information more easily.<sup>87</sup>

### Ketones

Acetone, acetoacetic acid and beta-hydroxybutyric acid resulting from either diabetic ketosis or other forms of calorie deprivation (starvation), are easily detected with dipsticks containing sodium nitroprusside.

### Leukocyte esterase and nitrites

Leukocyte esterase (LE) is an enzyme produced by neutrophils and a positive test indicates pyuria. Pyuria occurs in a variety of conditions including infection, inflammation, pyrexial illness and malignancy. Nitrites are formed in the urine from the conversion of nitrates by bacteria. A positive result indicates bacteria present in amounts of  $10^4$ /ml or greater but a negative result does not rule out infection. Negative results are common in infants where frequent voiding may preclude bacterial nitrate reduction and in infections with non-nitrate-reducing organisms. A recent meta-analysis of pediatric articles concluded that LE and nitrites in combination have a sensitivity of 88% and specificity of 96% in the detection of urinary tract infection, and perform nearly as well as Gram staining of urine.<sup>85</sup>

## PRINCIPLES AND PRACTICALITIES OF DIAGNOSTIC IMAGING

Imaging of the pediatric patient is performed to detect congenital abnormality, diagnose disease or injury, assess response to treatment and locate the position of foreign bodies such as surgically placed lines. Although more sophisticated modalities such as magnetic resonance and radioisotope imaging have revolutionized the specialty, the mainstay of pediatric radiology continues to be conventional X-ray imaging and ultrasonography. This section details the principles of the various imaging techniques; the application of these techniques to the various body systems is discussed in the relevant chapters of this textbook.

### RADIATION PROTECTION

The scientific measurement of radiation dose (the 'effective dose') is the millisievert (mSv). Because the body tissues have differential sensitivity to radiation exposure, particularly in childhood, the actual dose to different tissues and organs varies. The stated 'effective dose' is an average value of effect on the entire body. Background exposure from natural environmental sources is around 2–3 mSv/year but varies depending on location.

Children are particularly sensitive to radiation, with specific risks to the thyroid gland, breast tissue, bone marrow and gonads. This means that a similar radiation dose per gram of tissue has a greater potential for developing fatal cancer.<sup>88</sup> Furthermore, children have a longer

lifespan in which to manifest radiation-related cancer. Radiation for older adults and the elderly does not carry the same cancer risk, as many radiation-induced cancers will not become evident for many decades. Consequently children are recognized as being twice as likely to develop late manifestations of detrimental radiation effects than adults for the same effective dose.<sup>89</sup> Table 8.20 shows the effective dose of an X-ray examination in childhood and the lifetime risk of fatal cancer secondary to that examination.<sup>90</sup> In the Ionizing Radiation (Medical Exposure) Regulations,<sup>91</sup> children are recognized therefore, as warranting special consideration.

The aim of a good pediatric radiology department is to have agreed protocols and diagnostic pathways, standardized techniques, comparable diagnostic image quality and dose within the published reference ranges. Minimization of dose can be achieved in four key areas:

1. justification: benefit must outweigh harm;
2. optimization: adequate diagnostic quality at the lowest achievable dose;
3. evaluation: availability of quality criteria references for a diagnostic image;
4. radiation protection:
  - equipment and techniques should comply with national regulations;
  - doses should be recorded for each patient and should comply with standard diagnostic reference levels.<sup>92–94</sup>

## CONSIDERATIONS FOR A PEDIATRIC RADIOLOGY DEPARTMENT

The correct and optimal use of imaging depends on close teamwork between the clinician and the radiologist. This applies not only to the planning of initial investigations but also to prompt feedback about results and whether secondary investigations are required. Investigation should proceed along recognized flow channels, beginning with the least invasive procedure. Many hospitals have interdepartmental meetings that promote education and collaboration.

Gaining a child's trust and cooperation is essential for optimizing image quality, thereby reducing radiation exposure and investigation times. It is highly desirable that radiology staff have training in communicating with and managing children. Clear and simple explanations of the planned procedure should be available to the parent and, where appropriate, to the child prior to the examination. The department should be friendly and clean, with books or toys available in the waiting area. Waiting times should be minimized. Praise for the child's cooperation is important and reward in the form of stickers or certificates can be useful. Simple and safe restraints and supports should be on hand for immobilization of particular body areas. A variety of sizes of shields for gonad protection should be available. A chest X-ray should never include ovaries and an abdominal X-ray should never include testes.

Policies for safe sedation and anesthesia should be in place and undergo regular review. The IRR99 advises a quality assurance program in each department to ensure optimal diagnostic images are produced at the lowest possible exposure to the child.<sup>95</sup>

Table 8.20 Lifetime risk of developing a fatal cancer following X-ray exposure in childhood<sup>90</sup>

Examination	Effective dose (mSv)	Lifetime risk of fatal cancer
Chest	0.01	1/million
Spine	0.07	1/150 000
Abdomen	0.1	1/100 000
Micturating cystourethrogram	1.0	1/10 000
CT head	2	1/5000
CT body	10	1/1000

## CONVENTIONAL X-RAYS

X-rays are high-frequency electromagnetic waves that are radiated through a patient. The emergent X-ray beam excites a fluorescent screen that produces light exposure on the photographic film. The image produced by X-ray depends on the density of the tissues through which the radiation passes. These are normally bone, soft tissue, air and fat. The different body tissues absorb the X-ray variably, with bone and calcified structures absorbing most radiation and air absorbing least. The absorption differences between tissues can be enhanced by the administration of contrast such as barium, or iodine in a water-soluble form.

Barium is a safe, dense and inert medium and is used exclusively in gastrointestinal studies. When supplemented with bicarbonate, the resultant barium/air interface will detail mucosal irregularities such as ulceration and polyps. Non-ionic water-soluble contrasts are now used routinely for i.v., intra-arterial and intrathecal examinations. Owing to a relatively low osmolality, non-ionic contrast media are ideal for investigation of gastrointestinal pathology such as gastro-oesophageal reflux and aspiration, tracheo-oesophageal fistula and bowel obstruction. Although low osmolar non-ionic contrast is regarded as safer than other media, any use of contrast poses risks over and above that of the plain X-ray, due to potential allergic and nephrotoxic effects.<sup>96</sup>

X-rays are typically the primary imaging modality for investigation of suspected fractures, chest pathology and bowel obstruction or perforation. X-rays may also be performed to monitor response to therapy such as healing of a fracture, drainage of a pleural effusion or antimicrobial treatment of pneumonia. They are regularly used to locate the position of endotracheal, feeding tubes and indwelling vascular catheters. Because most X-rays are performed by radiographer, a clinician will commonly see the film before a radiologist is able to report it. As such, clinicians must be able, not only to assess any abnormality, but also to have an appreciation of the normal radiological appearances and the quality of the film. A standard approach is shown below.

### Standard approach to assessing an X-ray

1. Use good viewing conditions, i.e. a light box in a darkened room.
2. Check that the child's name, date of birth and date of examination are correct.
3. Note the orientation of the X-ray, e.g. anterior–posterior film, posterior–anterior film, lateral, sagittal, coronal, transverse etc. and check which sides are marked 'left' and 'right'.
4. Assess the quality of the X-ray:
  - is the child in an optimal position or was the film taken with the child rotated laterally, or in a scoliotic or lordotic position? Rotation in an infant's chest X-ray can be assessed by comparing symmetry of the anterior ends of the ribs; in an older child compare the symmetry of the medial ends of the clavicles;
  - has the area of interest been fully imaged, e.g. in a chest X-ray, are the apices and costophrenic angles of the lungs shown?;
  - is the X-ray adequately penetrated? In a chest X-ray, the vertebral bodies should be visible through the heart shadow;
  - in a chest X-ray, was the X-ray taken during inspiration? If so, there should be eight ribs visible above the hemidiaphragm;
  - are there artefacts from overlying or underlying equipment or clothing that obstruct the view of the area of interest?
5. Comment on any foreign bodies such as indwelling lines, endotracheal or nasogastric tubes. Foreign bodies may be in front of the child, inside the child or behind the child;
6. Describe any abnormalities of:
  - the soft tissues: localized or generalized swelling, calcification, foreign bodies, trauma;
  - the bones: density, deformity, fracture, inflammatory change;
  - the organs: detailed in individual chapters.
7. Summarize the positive findings.

Fluoroscopy is a technique by which dynamic X-rays are recorded and viewed in real-time. The X-ray beam is projected through a patient to a fluoroscopic screen and this image is coupled to an intensifier and

video camera, allowing images to be viewed instantaneously. It is particularly useful in barium studies, urography and during interventional procedures.

## ULTRASOUND

Ultrasonography (USS) is an established non-ionizing bedside tool that has become the first-line imaging modality in many conditions in children. A transducer sends high-frequency (between 3 and 12 MHz) sound waves through a tissue. A coupling gel is used to enhance transmission by improving contact between the transducer and the skin. The sound wave is partially reflected from the interface between different tissues and returns to the transducer as an echo. These echoes are converted into electrical pulses that are processed and transformed into a digital image. High-frequency sound waves have a short wavelength, and such images have a high resolution. However, the attenuation of the sound wave is increased at higher frequencies, so in order to have better penetration of deeper tissues, a lower frequency (3–5 MHz) may be used.

USS is portable and easy to use, and patients rarely require sedation. It has disadvantages in being dependent on the technology of the system and the knowledge and skills of the operator. Sound waves pass poorly through bone so examination of the brain is limited to infancy. Reflection of sound waves by gas can make examination of the chest and abdomen difficult. Although no known risks have been recorded *in vivo*, ultrasound is a form of energy and there remains concern about its safety, especially at higher power levels that can cause significant heating in tissues. Consideration should be given to keeping acoustic power, pulse amplitude and examination time to a minimum. The greatest risk of USS is sometimes considered to be erroneous diagnosis in the hands of unskilled operators.

Although used therapeutically in adults in lithotripsy, phacoemulsification and thrombolysis, the uses of USS in pediatrics are diagnostic and for image guidance in interventional radiology. Newer developments in USS technology have allowed three-dimensional (3D) and more recently, four-dimensional (real-time 3D) imaging. These tools offer more accurate assessment of fetal morphology, in particular the face, heart and extremities.<sup>97</sup>

Echocardiography is used widely for the detection of abnormalities of the heart and surrounding vessels. M-mode (1D) and 2D echocardiography inform anatomy and movement of the heart muscle and valves, while Doppler ultrasound gives information of blood flow direction and velocity. The information retrieved by Doppler can be portrayed as a spectral graph of frequency or velocity versus time, or as an image using color Doppler (directional Doppler). Color Doppler processes frequency shift and phase information, allowing blood cells to be coded in color depending on their direction and speed. Conventionally, red shows blood flow towards the transducer, blue indicates flow in the opposite direction and a red–blue mosaic indicates turbulence of blood flow. The color image, superimposed on the grayscale background of the 2D image has revolutionized the diagnosis of congenital heart disease. Doppler may also be used to measure flow and hemodynamic disturbances elsewhere in the circulation, namely in and around aneurysms, thromboses and stenoses. Altered blood flow in the brain secondary to increased intracranial pressure or impaired cerebral autoregulation is manifest as a change in the resistance or pulsatility index, as measured by Doppler USS.<sup>98,99</sup>

Contrast-enhanced USS with injected microbubbles of air improves ultrasound signal backscatter and is used in both echocardiography and urography.

## COMPUTERIZED TOMOGRAPHY

This technique was introduced into clinical practice in 1972 and offers high-quality cross-sectional views of the body. A large series of 2D images is taken around a single axis of rotation and these are processed by digital geometry to generate a 3D image of internal anatomy. Various structures can be delineated based on their ability to block the X-ray beam. Tissues that most attenuate the beam appear white (bones), and

tissues that cause less attenuation appear darker (air-filled lungs, fat). Although historically images were generated in an axial plane, modern scanners have allowed the data to be reformatted in alternative planes and even in 3D forms.

Major advances in CT systems, computer technology and reconstruction algorithms have resulted in a dramatic reduction in the acquisition speed such that a modern scanner can reconstruct a 1000-image study in less than 30 s. Spiral or helical techniques have reduced movement artefacts, particularly those related to breathing and gastrointestinal motility. Such systems have reduced the need for sedation and anesthesia in children.<sup>100</sup> The shorter imaging times makes it easier for children to lie still and hold their breath during critical parts of the examination.

Compared to conventional X-rays, CT improves low contrast resolution of soft tissues and can distinguish tissues that differ in density by less than 1%. However this high resolution is at the expense of a highly absorbed radiation dose (Table 8.20).<sup>90</sup> European guidelines advise on quality criteria for a CT examination that will provide the required clinical information in its optimal form, with minimum dose to the patient.<sup>101</sup>

CT is particularly useful in the diagnosis of bony abnormalities, particularly craniofacial injuries, in the imaging of the chest parenchyma and in acute abdominal trauma. CT also detects blood and calcification easily. Compared to MRI however, soft tissue contrast is relatively low and this can be a problem in the brain, where the differences between white and grey matter are small. Contrast will enhance tissue differentiation and is particularly useful in the evaluation of tumors and lymphadenopathy, although MRI remains a more sensitive tool.

## MAGNETIC RESONANCE IMAGING

This technique depends on the ability of nuclei within a tissue to resonate under certain conditions in the presence of a magnetic field. The nuclei first align themselves in a parallel or anti-parallel direction in response to a strong magnetic field. The tissue is then briefly exposed to pulses of electromagnetic energy (radiofrequency [RF] pulses), which causes some of the nuclei to assume a temporary high-energy state. As the high-energy nuclei relax and realign, they emit energy at rates that are recorded to provide information about their environment.

Generally, image contrast is created by using a selection of image acquisition parameters that weights signal according to the different phases in the relaxation processes that establish equilibrium following the RF pulses (T1, T2 or T2\*). In the brain, T1 weighting causes axons (white matter) to appear white, congregations of neurons to appear gray, and cerebrospinal fluid to appear dark. The contrast of white matter, gray matter and cerebrospinal fluid is reversed using T2 or T2\* imaging.

Different strengths of magnet are available. The low-strength magnets (0.18–0.23 T) are usually of an open configuration and as such are less claustrophobic. Mid-strength magnets of up to 2 T are of a tunnel configuration and are noisier and more expensive. The high-strength systems have the advantage of faster image acquisition and better resolution.

The time for data acquisition by MRI is relatively long, with several periods of acquisition lasting up to 10 min each. This may be difficult for the young or poorly cooperative child and sedation or even anesthesia may be necessary.

MRI is now used in fetal imaging in the delineation of congenital anomaly and acquired damage.<sup>102</sup> It has been important in the identification and classification of many congenital brain abnormalities<sup>103</sup> and in the documentation of the development of the premature brain.<sup>104</sup> It has been evaluated as an alternative to postmortem, where it performs relatively poorly but may be useful where consent has not been granted for pathological examination.<sup>105</sup>

Diffusion-weighted imaging (DWI) measures diffusion of water molecules within a tissue and can demonstrate impairment of this diffusivity, particularly within the brain, where DWI has high sensitivity

for detecting infarction within minutes of occurrence. In the newborn, abnormal signaling in the brain on DWI predicts outcome following hypoxia-ischemia.<sup>106</sup>

Diffusion tensor imaging (DTI) makes use of the assumption that water molecules within a tissue do not exhibit Brownian motion but instead move in a particular direction, e.g. along an axon with the nervous system. DTI has been pioneering in producing maps of fiber directions within the brain to examine connectivity.<sup>107</sup>

MR spectroscopy allows study of the biochemistry of the brain by providing information about the relative concentrations of certain metabolites in specific areas of the brain. Contrasts with specific magnetic properties (such as gadolinium) may be required to delineate areas of interest.

The advantage of MRI technology is that, as far as we know today, it is harmless to the patient, using non-ionizing radiation that is in the radiofrequency range. While a CT scan may have good spatial resolution (i.e. the ability to differentiate two structures that are a small distance apart), MRI has better contrast resolution (i.e. the ability to distinguish between two structures that are similar but not identical) and provides excellent soft tissue differentiation apart from in the chest, where CT remains superior. MRI is poorer in depicting bone or blood compared to other imaging modalities.

The presence of pacemakers and other metallic implants is a contraindication to MRI as they may cause arrhythmias, trauma due to movement of the object, thermal injury from induction heating or failure of the implanted device. Owing to the construction of many scanners, children may feel claustrophobic during the examination. In addition, the loud noise and vibration resulting from rapidly alternating magnetic gradients interacting with the main magnetic field can be highly disturbing. Children may be distracted from the excessive noise by listening to music or a story through earphones but some still find it distressing that they are unable to hear their nearby parents.

## NUCLEAR MEDICINE

Nuclear medicine uses radioactive isotopes for the diagnosis and treatment of patients. Where conventional radiology provides information mostly on structure, nuclear medicine provides complementary data on function.

The most commonly used radionuclide is <sup>99m</sup>Tc but <sup>123</sup>I, <sup>131</sup>I, <sup>133</sup>Xe and <sup>81m</sup>Kr are occasionally used. The dose of radionuclide is calculated from the weight and surface-area of the child. The radiation dose is usually less than that received through equivalent X-rays. Radionuclides are absorbed by healthy tissue at a rate different from tissue undergoing a disease process. The tissue, having absorbed the radionuclide, emits gamma radiation that is detected by a camera. A deviation in normal rates of absorption may be an indication of abnormal metabolic activity.

The use of nuclear medicine in pediatrics is primarily diagnostic:

- detection of congenital abnormalities such as Meckel's diverticulum, lung anomalies, biliary atresia;
- diagnosis of inflammation/infection – white cell scans;
- assessment of swallowing and gastro-esophageal reflux;
- assessment of differential renal function and vesico-ureteric reflux;
- assessment of pulmonary perfusion;
- investigation of bony pathology – tumors, infection, trauma, avascular necrosis.

Nuclear medicine is a common therapeutic option in adults, utilized in the treatment of thyroid disease, neural crest tumors and the palliation of metastatic bone pain. In children monoclonal antibodies such as metaiodobenzylguanidine (MIBG) have been labeled with large doses of <sup>131</sup>I and successfully used in the treatment of neuroblastoma.<sup>108</sup>

## SINGLE-PHOTON EMISSION COMPUTERIZED TOMOGRAPHY (SPECT)

Single-photon emission computerized tomography (SPECT) is an allied nuclear medicine blood flow technique where a gamma camera rotates

around the body at the time of examination, collecting data from all angles. A series of axial images of the internal anatomy is generated, which allow more precise localization of activity. SPECT can be used to observe biochemical and physiological processes, as well as the size and volume of structures. The main use of SPECT in children has been in the identification of epileptogenic foci in the brain prior to neurosurgical removal<sup>109</sup> and in the diagnosis and monitoring of areas of abnormal bone metabolism such as spondylolysis<sup>110</sup> and tumors.

## INTERVENTIONAL RADIOLOGY

The field of interventional radiology is expanding rapidly with radiologists now performing many procedures that were previously the responsibility of surgeons. In children because of their small size and sensitivity to radiation, ultrasound rather than CT is the usual choice for image guidance. Commonly performed procedures include vascular and enteric access, biopsy (liver, kidney, tumor), aspiration and drainage (abscess, effusion), stenting procedures (esophageal, ureteric, biliary), angiography, nephrostomy and sclerotherapy of lymphatic or vascular malformations. Many children will require sedation or anesthesia during the intervention but in general such procedures are easier than in adults, even accounting for difficulties in vascular access. Image-guided central venous access has the advantages of a very high success rate, the ability to access innovative vessels (collaterals or recanalization of occluded veins), optimization of tip position and the opportunity to combine it with other image-guided procedures such as biopsy.

## GENERAL PRINCIPLES OF COMMON PRACTICAL PROCEDURES

### INTRODUCTION

The process of obtaining informed consent, specific for various tests and procedures has become arguably more important with the public's wish and expectation that they should be involved in medical decisions. In requesting consent for a test or procedure from a child, parents or other health professionals, it is important to know what is involved in that procedure. Parental understanding will allow the child to be better prepared and will ensure optimum benefit is provided to the patient from each procedure. Even relatively simple medical words and phrases are difficult for most parents and children to understand, and innocent words can sound extremely frightening (murmur, tumor, anesthetic, etc.) Children and parents may be reluctant to ask for a 'translation' when the explanation is theoretically in their own language. Help them by considering the words you will use, in what context and how they might be misinterpreted. If you are explaining procedures to someone in whom your language is not his mother tongue, use a translator (do not rely on relatives if this is an important procedure or one that carries significant risk). In general:

1. Know how to explain procedures to parents and children. Do not explain a procedure if you are not fully aware of what will be involved: go and find out about it. Consider:
    - Why is the procedure necessary?
    - When and where will it take place?
    - What grade of staff will be performing it?
    - What problems might be encountered and what risks are possible?
    - Ensure that you are able to explain the balance of risk versus benefit of the procedure *in that child*.
  2. Local variation in procedures will be present. Try and find out how the procedures vary and give up-to-date information.
  3. Be able to appreciate the hazards associated with procedures for both patients and staff, and therefore how to avoid them.
  4. Do not perform procedures for which you are not adequately trained.
- In this section common procedures are explained and their benefits, risks and hazards discussed. There will be local variation in how procedures are performed, so find out how these differ in your locality. This will be important from the perspective of clinical governance.

## PREPARING PATIENTS FOR PROCEDURES

### Informed consent

Consent should usually be obtained by the person doing the procedure or at least by someone who is capable of doing it. Issues with regard to consent are dealt in Chapter 10. Remember that issues of consent apply to both parents and children.

### Talking to children about procedures<sup>111</sup>

Misconceptions exist that delaying or not explaining procedures to children protects them from pain and fear. Such mistaken beliefs often arise because staff and/or parents fail to appreciate the level of understanding of the child or because they have little ability to adapt their communication to language that the child will understand. If parents do not wish to have a procedure explained to their young child, then those wishes should generally be respected, though parents should understand the procedure and not try to protect themselves by not telling the child. The parents should be made aware of the consequences of not discussing an important procedure with their child. Even if parents are present during a procedure, the child should be the focus of explanation. Do not ignore the child hoping they will pick up information given to the parents.

When talking to a child, introduce yourself and take account of the cognitive level of the child and his language. Don't patronize, and consider throughout the consultation whether you retain his interest and understanding. In your introduction, recognize (as the child will) your authority as an adult, but be respectful of the child's status. Give a clear introduction to the topic or plan to be discussed and be careful not to make promises you will not be able to keep (e.g. confidentiality etc.) Communicate on the same physical level, and begin the conversation with a nonthreatening topic. Warn the child the main topic to be discussed is a serious one, and enquire as to what the child understands about that topic already. Always give adequate time for the child to respond or ask questions and listen carefully to his response, but do not pressurize the child into giving a response. Do not attempt to anticipate his answers. Go at the child's pace and check the child has understood. Any explanation should be a clear and simple, optimistic (but realistic) narrative of the events. There is a tendency to overestimate what information has been conveyed and how much has been understood, and a tendency to underestimate what the child has acquired from other sources.

The child will often give clues as to when he feels the conversation is over. If the procedure is complex, then it is often not possible to cover everything at one meeting and a further time can be arranged. End by summarizing what has been discussed, including the child's viewpoints; offer a plan. Explain that you are available to discuss the procedure and how the child and parents can contact you.

### Use of play specialists

Play specialists are a well-trained and respected part of the pediatric team in any hospital. They have knowledge of infant and childcare, nursing and teaching. They may be able to advise doctors and nurses of a particular child's needs. The play specialist is able to introduce different types of play and activities to individual children based on their age and development. Children use play as a medium to express feelings. Familiar play helps children to normalize a clinical environment, with reduction in their anxiety and stress.

Hospital play specialists have a significant role in preparing children for procedures during their stay in hospital. Preparation can be achieved by use of photo books and role playing. Children can also be given the opportunity to touch and play with medical equipment in a safe and controlled environment, i.e. syringe painting, dolls fitted with cannulae, nasogastric tubes etc. As a familiar face to the children, play specialists can have a significant effect in relaxing them during procedures by using distraction methods.

### Procedural pain

The management of pain during procedures is described in detail in Chapter 38.

The management of procedural pain in children should be by the simplest effective technique, multimodal, pre-emptive where possible, and frequently reassessed and titrated to the child's needs.

Pre-emptive pain control helps to minimize fear and anxiety associated with the procedure, reduces the stress response, prevents the 'wind up' phenomenon of central nervous system sensitization to noxious stimuli and tissue release of pain mediators. Pain prevention should be tailored to the individual child's needs using a combination of nondrug techniques, local anesthetic, simple analgesics and opioids, and sedation where appropriate. By using a multimodal approach the required doses of stronger agents can be reduced and in turn this reduces the incidence of adverse effects. Management of pain requires regular pain assessment and this must be linked to appropriate action.

### Nonspecialist practical procedures

Clinical governance dictates that procedures should only be carried out by those who have had fully supervised training. The descriptions provided here are insufficient to enable you to perform these tasks, but they should provide enough information for you to be familiar with what is involved so that you can describe them adequately to parents and patients. Techniques for more specialist procedures are discussed in the relevant chapters.

#### **Title.** Peripheral venous sampling

**Procedure.** The most common form of blood sampling takes blood from a peripheral vein. In children, the veins in the arm (brachial) and back of the hand are most frequently used.

**Complications.** Localized hematoma (bruise) may occur, which will disappear in a few days. Tourniquets will produce elevation of plasma calcium estimation.

**Hazards.** In children, separate needle and syringe are still used more frequently than closed needle systems. These are more hazardous to users and patients in terms of needle stick injury. Needles with the hub broken off should not be used under any circumstances. Neonatal venepuncture needles are now available. Gloves should be worn during all blood-taking procedures.

#### **Title.** Peripheral capillary sampling

**Procedure.** This method of blood sampling is satisfactory for assessing arterialized carbon dioxide and pH in the peripheral blood. It can also be used for complete blood counts and glucose estimation. In the neonate the side of the heel is used and in older infants and children the finger tip. The procedure is quick and although some centers use an anesthetic cream for such intervention, this may cause blood vessel constriction that can reduce the amount of sample. A spring-loaded lancet reduces damage to skin and is least painful. A capillary tube collects the sample from the skin, which is sometimes smeared with Vaseline to help localize the blood. The area is compressed with cotton wool following the procedure to stop bleeding.

**Complications.** Biochemical tests on capillary samples may have errors, especially elevation of potassium and calcium measurements. In neonates, very deep stabs on the heel have been rarely associated with osteomyelitis.

**Hazards.** Automated spring-loaded lancets need to be disposed of in a similar way to other 'sharps'. Blood sampling should be performed wearing gloves.

#### **Title.** Peripheral arterial sampling

**Procedure.** This is required for measurement of arterial oxygen, and also carbon dioxide and pH. Transcutaneous oxygen and saturation monitoring has reduced the need for frequent arterial sampling to estimate arterial oxygen. The most common site for an arterial sample is the radial artery but the posterior tibial artery is sometimes used in the neonate. Other arteries can be used as long as an adequate alternative arterial supply can be demonstrated to that area of tissue. Fixed sampling syringes are now in common use and contain heparin to stop the sample clotting. Arterial sampling can be painful (use local anesthetic cream, or subcutaneous local anesthetic injection without adrenaline). The pulse is identified and the needle inserted at a 45-degree angle. Pressure will need to be applied to the site for up to 5 min after removal of the needle before bleeding stops.

**Complications.** Hematoma frequently forms during arterial sampling, either because of insufficient pressure applied to the overlying skin once the needle is withdrawn, or because the needle pierces the artery at an oblique angle, limiting blood drawn but damaging the vessel wall. Occasionally, arterial spasm can severely limit arterial supply to the limb peripheral to the sampling site: this should correct over a few minutes, though occasionally an arterial vasodilator, such as topical nitroglycerin ointment may have to be applied.

**Hazards.** Sharps need to be disposed of appropriately. Gloves should be worn, and because of the possible spray of arterial blood users may wish to use protective eyewear.

#### **Title.** Peripheral venous access

**Procedure.** A peripheral venous cannula is frequently placed in children. In neonates, veins may easily be seen but may be too small to cannulate; in toddlers veins may be difficult to see because of subcutaneous fat. At all ages, knowledge of the distribution of large subcutaneous veins is valuable. Local anesthetic cream should be used where possible. A tourniquet may be applied to help fill veins, though it is often helpful to have a second person to apply a tourniquet with their hand (ensuring that little wriggles don't ruin your attempts to site the cannula). Parents should be warned that this technique is difficult and even in experienced hands several attempts may be required. In very young children with poor venous access, a scalp vein may be the most sensible option, though many parents may find it particularly distressing because hair in the region has to be shaved to enable fixation. Peripheral venous cannulation represents a standard technique to most doctors, yet is associated with significant stress to many parents. Children may need securing to ensure a quick and relatively painless procedure. The cannula should be secured effectively to ensure the child does not remove it as soon as it is in place.

**Complications.** Hematoma formation is common. Occasionally, particularly when using scalp veins, an artery may be mistaken for a vein during cannulation. Any pulsatility of flow during cannulation is arterial and the cannula should be withdrawn (using 5 min of pressure) immediately.

**Hazards.** Sharps must be disposed of appropriately. Gloves should be worn.

#### **Title.** Peripheral venous cutdown access

**Procedure.** This procedure is used when no veins can be identified for percutaneous cannulation. Children needing this procedure are commonly in extremis, but every attempt should be made to ensure adequate explanation and pain relief. The sterile procedure usually cannulates the long saphenous vein just above the ankle, by making an incision in the skin and dissecting back the tissues until the vein is identified. A small slit in the vein then allows the cannula to be inserted. The catheter is sutured in place.

**Complications.** Bleeding at the site may occur when circulation is re-established if sutures are not secure enough.

**Hazards.** This is a sterile surgical procedure with full protection against blood biohazard.

#### **Title.** Intraosseous needle insertion

**Procedure.** This is an emergency procedure used when no veins can be identified for peripheral cannulation. In a shocked child with hypotension, this procedure should be performed after no more than two quick attempts at peripheral cannulation. The tibia is the most common site for insertion, though the femoral head and other sites are possible. The child is frequently in extremis and pain relief may not be possible without access in an unstable child. The position of insertion is just below the tibial tuberosity on the anteromedial aspect of the tibia. The needle is screwed steadily into bone until the outer cortex is felt to give way. The bone marrow that can be aspirated can be sent for blood glucose and electrolyte concentration, in addition to blood culture. All i.v. preparations can be given via intraosseous needle. Though the needle is fairly secure within the bone, it should be attached with tapes. When circulation is re-established, i.v. access should be obtained and the intraosseous needle withdrawn.

**Complications.** Leak of instilled fluid into the skin around the site of the needle may occur if the needle is not properly sited. The needle can occasionally exit the bone on the opposite side and this should be checked for before fluid is instilled.

**Hazards.** When dropped, intraosseous needles tend to fall on the handle exposing the needle upright: great care is needed to alert others in the vicinity if the needle is dropped. Sharps need to be disposed of appropriately. Gloves should be worn.

**Title.** Peripheral arterial access

**Procedure.** This is only needed if a child requires intensive care. In older children the radial or femoral arteries are typically cannulated. In neonates the radial and posterior tibial are most commonly used. As far as parents are concerned, the procedure is similar to peripheral venous cannulation. In practice, arterial cannulation is more difficult, particularly as the arterial pulse can sometimes be difficult to localize precisely, and the elastic wall of the artery and arterial spasm may impede cannulation. In small infants, a cold light transilluminator may help to locate the radial or posterior tibial artery. The small risk of peripheral ischemia following insertion of an arterial catheter should be balanced against the benefit of continuous arterial access (and the availability of continuous direct arterial blood pressure). Local anesthetic should be used for insertion. The artery can be cannulated in a similar way to venous cannulation. Some prefer to transfix the artery with the cannula needle, withdrawing slowly until the end of the needle is within the artery, shown by a flashback into the hub of the cannula. The cannula, once in place, needs careful and continued observation for signs of peripheral ischemia and localized hematoma or leak. Arterial spasm and peripheral ischemia are discussed in the section on arterial sampling (see earlier).

**Complications.** Peripheral ischemia; blood loss from puncture site or misconnected blood pressure monitoring circuit.

**Hazards.** Sharps need to be disposed of appropriately. Gloves should be worn. Arterial lines should be labeled clearly so that i.v. drugs are not infused inadvertently.

**Title.** Lumbar puncture

**Procedure.** A lumbar puncture enables access to the cerebrospinal fluid (CSF) surrounding the spinal cord. It is performed safely in the majority of children, however caution is needed if there is a question of raised intracranial pressure (i.e. meningism, headache, vomiting). In children younger than 1 year of age with a soft patent anterior fontanelle the procedure is considered safe. In children without a patent anterior fontanelle, it is not possible to reliably identify raised intracranial pressure by fundoscopy alone and so a cranial CT may be required, or, if the index of suspicion of meningitis is high, then i.v. antibiotics can be started and a lumbar puncture performed at a later time. Children with coagulopathy or respiratory instability are also at risk from the procedure. Children and infants usually lie on their left side for the procedure, with oxygen saturation and heart rate monitoring. Occasionally an upright flexed sitting position may be used. Local anesthetic cream should be used if time allows, but in suspected meningitis, risks of delaying antibiotic administration outweigh the benefits of analgesia. Complete aseptic technique should be used, including gown and sterile gloves. The key to success is having the back well flexed and perfectly perpendicular to the edge of the bed. An assistant who will maintain the position when the needle enters the back is very important. The needle is placed in the lower back, between L3 and L4 (the space directly below the superior iliac crest when the child is lying on his side). Pressure estimation with a manometer may be warranted prior to removal of approximately 2 ml of CSF for biochemical and microbiological examination. Two or three attempts may be required to find the spinal fluid space, particularly if the child is active. Following removal of enough fluid, the central portion of the needle is replaced and the needle withdrawn; a sealant spray or liquid is quickly applied to close the puncture hole and a dressing or sticking plaster is placed over the site.

**Complications.** Occasionally a blood vessel close to the spine may be hit by the needle and the sample will be heavily blood stained; these samples should still be sent for culture. If this occurs then a further attempt one intervertebral space higher may be attempted. Headache is a common side effect following lumbar puncture, and should settle with simple pain relief over 48 h. Occasionally continued seepage of CSF may require firm pressure with a sterile dressing until leakage stops. In children with raised intracranial pressure a lumbar puncture may result in 'coning', where the base of the brain is pushed down into the base of the skull, depressing the respiratory center and other autonomic control centers; this is a neurological emergency requiring urgent intensive care support. Prior scanning by CT or MRI may detect increased pressure and advise against lumbar puncture.

**Hazards.** Sharps are used and should be disposed of appropriately. CSF should be considered an infected biohazard.

**Title.** Clean-catch urine sampling

**Procedure.** This is performed in children suspected of having a urinary tract infection (bag urine collection is frequently contaminated, and the result sets off a whole series of unnecessary investigations). The child should be well hydrated and be sat on a parent's knee with no nappy (diaper). The genitals should be cleaned with sterile water (not disinfectant) and left to dry. The hands of the person collecting the sample should be washed prior to collection. A small sterile container should be held ready, waiting for the child to pass urine and a sample (approximately mid-stream), obtained as soon as the event occurs. Good observation and rapid reflexes are required, as the opportunity may not arise again for many more hours.

**Complications.** None

**Hazards.** Hands should be thoroughly washed after sample collection as they may be contaminated with bodily fluids.

**Title.** Suprapubic urine sampling

**Procedure.** This technique enables a rapid and clean sample of urine to be obtained. It is particularly useful if children are unwell with a suspected urinary tract infection and antibiotics need to be started. The bladder is an abdominal organ in the baby but becomes more and more pelvic as the infant grows. As such, the procedure is most easily performed in children younger than 18 months of age. The child needs to be lying supine with legs kept still. Local anesthetic cream should be used for analgesia. The bladder should be palpated (or percussed), or alternatively can be identified on ultrasound: in an emergency the bladder can be sampled without these, but may contain no urine (a 'dry' tap). The suprapubic area should be cleaned with antiseptic fluid and then a small needle attached to a syringe is inserted perpendicular to the skin in the midline just above the symphysis pubis in the infant: in the older child the needle may need to be directed more into the pelvis. Urine is withdrawn into the syringe and the needle removed. Pressure need only be applied to the area for a short time and then the area left without dressing if there is no bleeding.

**Complications.** 'Dry' tap: knowledge of when the infant/child last passed urine and good clinical practice should minimize the number of these. Ultrasound may confirm the presence of urine in the bladder. Hematuria may be noted for a short period after the procedure. The child may void during skin preparation; have a container ready to catch the stream. Occasionally adjacent bowel can be punctured; this typically does not cause a problem as the hole created is small and self-healing.

**Hazards.** Care should be taken as the child may move during the procedure if not correctly nursed, causing needlestick injury. Sharps should be disposed of carefully.

Excretion	160		

## INTRODUCTION

Prescribing for children encompasses a number of knowledge-based skills and practical considerations. These include knowledge and understanding of inter- and intraindividual variation relating to age, body composition, differential maturation of body organs, and state of health.

Pharmacokinetics is the mathematical expression of the drug handling processes of absorption, distribution, metabolism and excretion which determine a medicine's disposition in the body. Pharmacodynamics describes what the medicine does to the body and therefore the processes linking the concentration of a drug in a body fluid with pharmacological effect. This is essentially the interaction of a drug with a receptor at the site of action.

## DRUG HANDLING PROCESSES

Unless they are administered directly into the vascular system, all medicines need to be absorbed. Most will depend on absorption from the gastrointestinal tract.

## GASTROINTESTINAL ABSORPTION

The rate and extent of gastrointestinal absorption is affected by gut pH and flora, gastric contents and emptying time, gut motility and absorptive surfaces. All vary somewhat according to age and with certain disease processes. After the neonatal period, there are a few differences with age and gastrointestinal absorption of medicines is usually predictable in rate and extent. The unpredictability of the newborn period relates to reduced gastric acid secretion, reduced gastric emptying time, and reduced intestinal motility and biliary function. The oral route is preferred for drug administration generally.

## OTHER ROUTES OF DRUG ABSORPTION

Absorption from **muscle** is unpredictable. Drugs which are not water soluble tend to precipitate with resultant delayed or decreased absorption. The rate and extent is also compromised by poor perfusion in serious illness.

Absorption through **skin** is more important with regard to toxicity than benefit. Preterm skin represents much less of a barrier than that of a full-term baby and hexachlorophene, aniline dye, and steroid toxicity have been reported. However, the same characteristics afford a potential for drug delivery via topical creams and patch formulations although these are limited in application.

## DISTRIBUTION

The composition of body water compartments, protein binding, regional blood flow and membrane permeability are important determinants of drug distribution in the body. The relatively large total and extracellular body water compartments in the newborn and infancy period largely account for the greater drug distribution volumes in young children.

Drug distribution is also affected by the extent and characteristics of protein binding. The lower protein binding for drugs in particular in the newborn and infant probably relates to the amount of albumin available, different affinity, and competitive displacement by endogenous substances (e.g. bilirubin; free fatty acids). The greater free fraction at this age contributes to a larger distribution volume and increase in clearance. Although albumin is the major drug-binding protein, lipoproteins and alpha-1 acid glycoprotein are important and their concentration is influenced by age, nutrition and disease processes.

## METABOLISM

Removal of a drug from the body occurs as soon as it is absorbed. The process of removal for many drugs includes biotransformation into more water-soluble compounds so facilitating elimination through the kidney or in bile. For most drugs, this process makes them less active or completely inactive although some 'parent' drugs are converted from active to other active compounds (theophylline to caffeine and morphine to morphine-6-glucuronide) and in some cases to more active compounds (carbamazepine to its 10'11 epoxide metabolite).

Most biotransformation processes occur in the liver although some occur in the intestine. There are two phases of metabolism, both occurring mainly within the hepatocyte. Phase I reactions are enzymatic and involve oxidation, reduction, hydroxylation or hydrolysis; Phase II reactions are mainly those of conjugation with glucuronide, sulfate or glycine.

The cytochrome P450 mixed function oxidase system is the most important biotransformation system incorporating many enzymes and isoenzymes. In general, these enzyme systems are immature at birth and particularly so in premature newborns. There is therefore relatively slow clearance of most metabolized drugs in the first 2 or 3 months of life. Between 2 and 6 months, clearance is more rapid than in adults and even more so for most drugs from 6 months to 2 years. From 2 to 12 years, somewhat faster clearance rates than in adults are maintained but after 12 years, adult values are the norm (Table 9.1).

**Table 9.1** Approximate elimination half-life ( $t_{1/2}$ ) and total clearance (Cl) for drugs in children relative to adult values for different elimination pathways (from published literature database)

		Preterm newborn	Full-term newborn	1 week–2 months	2 months–6 months	6 months–2 years	2 years–12 years	12 years–18 years
All drugs	$t_{1/2}$	3.8	1.85	1.8	1.1	0.75	0.95	1.05
All drugs	Cl	0.5	0.7	0.75	1.2	1.7	1.35	1.0
Renally cleared drugs	$t_{1/2}$	2.7	2.6	1.1	0.75	0.6	1.1	–
Metabolized drugs								
Cytochrome P450 Isoenzyme 1A2 (caffeine, theophylline)	$t_{1/2}$	–	9.1	4.0	1.2	0.6	0.6	–
Metabolized drugs								
Cytochrome P450 Isoenzyme 3A	$t_{1/2}$	5.1	1.9	1.75	0.35	0.5	0.75	0.75
Metabolized drugs								
Cytochrome P450 All isoenzymes	$t_{1/2}$	4.4	1.75	3.5	1.25	0.6	0.75	0.95
Phase II glucuronidation drugs	$t_{1/2}$	4.2	2.8	2.1	0.9	1.15	1.3	1.5

## EXCRETION

Glomerular filtration of drugs depends on renal blood flow, protein binding and the functionality of the glomeruli. The relatively low glomerular filtration rates in premature and full-term newborns result in the half-lives of renal cleared drugs being approximately two to three times longer than those in adults, and this difference is maintained up to 1–2 weeks age. Thereafter, rates are similar in infants and adults up to 2 months. Half-lives are subsequently faster until about 2–3 years.

## PHARMACOKINETICS

Pharmacokinetics refers to the mathematical expressions of drug changes in the body. **Bioavailability** describes the fraction (percentage) of drug reaching the systemic circulation of that presented to the body. For intravenously administered drugs, this is considered to be 1 (100%). For other routes of administration, values are usually somewhat less than 100% and this amount (and the rate of absorption) depends on a number of physicochemical properties of the drugs and other factors related to the patient. Reduced blood flow to the gut in intestinal and systemic illness tends to slow the rate and extent of absorption but food in the gut only tends to delay absorption.

**Volume of distribution** describes an apparent hypothetical volume within which a drug is distributed. It tends to be larger in babies, infants and young children than in adults. The relationship between dose (bioavailable dose = FD), volume of distribution ( $aV_d$ ), and concentration (c) is given by the equation:

$$c = FD/aV_d \quad \text{Equation 1}$$

In simplistic terms, it is like achieving a pink volume of liquid (c) when an amount of red dye (D) is put into a bucket of water ( $aV_d$ ). In clinical terms, it determines what loading dose, either initially ( $c \times aV_d$ ) or during maintenance therapy ((desired – measured concentration)  $\times aV_d$ ) is required, e.g. to stop fitting using phenytoin.

The **(elimination) half-life ( $t_{1/2}$ )** describes the time it takes for a drug concentration in any body fluid to reduce by half. It most frequently refers to blood. Mathematically its value is given by dividing 0.693 by the slope of the terminal portion of the log concentration–time ‘curve’ or elimination rate constant ( $k_e$ ):

$$t_{1/2} = 0.693/k_e$$

**Clearance** is the volume from which drug is removed per unit time. The concept of renal clearance is well understood. Drug clearance

usually refers to total body clearance (Cl) and is the product of apparent volume of distribution and the elimination rate constant:

$$Cl = K_e \cdot aV_d \text{ or } Cl = (0.693/t_{1/2}) \cdot aV_d$$

## PRESCRIBING PRINCIPLES

**Choice of drugs** depends on a number of factors. Of course, the benefit–risk assessment has to be positive, and the drug delivery needs to be practically feasible. This will depend on an assessment of handling, kinetics and formulation availability. For antibiotics the choice is further determined by the likely or known causal organism, the minimum inhibiting concentration (MIC), and the ability to reach the site of action.

In considering the **administration route** for most drugs, the oral route is preferred but is inappropriate if there is significant vomiting and when gut perfusion is compromised by systemic illness. Gut pathology and immaturity (first week or two of life) are significant and important considerations. The intramuscular route only serves the purpose of ‘one-off’ administration because of pain and unpredictable bioavailability. The skin route is more of a toxicity consideration but some benefit is afforded in the newborn and for a small but increasing number of drugs available as patches. Inhalation of antibiotics in cystic fibrosis, and steroid and/or beta-2 agonists in asthma are established examples for this route. The rectal route is more unpredictable than the oral route but affords possibilities in vomiting, ‘nil by mouth’, and upper gut pathologies. Rectal administration is well established in some acute situations (benzodiazepines in continuing fits) and in situations where skilled personnel are not available, e.g. home use of diazepam, paracetamol and antiemetics. More recent use of intranasal or buccal delivery has proved efficacious for midazolam as sedation and in stopping fits.

Some drugs are not stable when administered orally but most drugs are and therefore should be given by this route. Liquids are most rapidly absorbed giving shorter times to peak concentrations. Tablets that require disintegration and dissolution are more slowly absorbed as a result. **Choice of formulation** is also important because of variation in palatability.

**Dose determination** is especially difficult given the wide inter- and intraindividual variability of pharmacokinetic parameters with age. Pharmacodynamic and receptor variability are less well worked out but are likely to be of similar or even greater importance. For drugs where there is only a small difference between appropriately effective and toxic concentrations (drugs with low or

narrow **therapeutic indices**), individualization of dosage is even more important.

If there is a clear endpoint of efficacy (e.g. blood pressure lowering; stopping fits) and if there is a wide therapeutic index, titration with increasing doses is appropriate. For some problems and drugs, plasma concentration therapeutic ranges are established and doses are then determined by the target concentration. Pharmacokinetic knowledge determines dosage in these situations. For example, and using the rearranged Equation 1, the required single dose is the product of target concentration and apparent volume of distribution. For phenytoin use in a child who continues to convulse, the equation for an infant of 3 months could be:

$$\text{i.v. dose (mg/kg)} = aV_d(0.75\text{L/kg}) \times \text{desired concentration} \\ (20\text{ mg/L}) = 15\text{ mg/kg.}$$

The repeated doses that are necessary are determined by a drug's clearance; the frequency of dosing by its half-life (for drugs for which there is a relationship between concentration in blood and clinical effect). The dose is given by:

$$\text{Dose} = \text{concentration (mg/L)} \times \text{clearance (L.kg.h}^{-1}\text{)} \times \text{dose interval (h).}$$

The **frequency of dosing** will not result in wide fluctuation between doses if the dose interval approximates the half-life.

Many of these considerations relate to knowledge about the kinetics of the drug, and the recommended dose regimens in prescriber reference sources are based on these and other factors where such knowledge exists.

**Therapeutic drug monitoring** whereby drug concentrations are measured to determine dose regimens is not practically useful for drugs (the majority) which have clearly defined and easily measured clinical effects or endpoints. For the remainder, drug level monitoring is potentially useful but established therapeutic ranges are available for only a few. Phenytoin and gentamicin are the best known examples. Concentration monitoring is especially useful in potential drug-drug interaction scenarios, where the therapeutic index is narrow, and in situations of therapeutic failure or potential noncompliance.

Practical conditions for measurement include: 'steady state' concentrations (at least five elimination half-lives should have elapsed since starting therapy in chronic situations); time of likely peak concentration; whether measurement is primarily for efficacy or toxicity (peak or trough [pre dose] concentrations may be more related to one or the other).

**Length of treatment** is determined by published data related to the condition treated and individual patient response. **Compliance** with therapy in chronic situations may frequently be no more than 50% of that prescribed or intended. Its relevance in the assessment of therapeutic failure should not be underestimated.

## DRUG INTERACTIONS

Drugs primarily interact with food and other drugs. However, for most drugs, food is not of major clinical significance.

Interactions with other drugs – the effects of one drug changed by another – are important if they lead to toxicity or reduced efficacy. Drug absorption interactions are relatively unimportant. However, other pharmacokinetic interactions based on protein binding or drug clearance are potentially of much greater clinical relevance. Drugs which are more than 90% protein bound and with relatively low volumes of distribution are those for which interactions should be considered although changes arising from displacement of one drug from protein binding sites by another and so increasing the amount of 'free drug' are rarely of clinical importance because of the transient nature of this effect.

Drugs which influence the metabolism of others by inhibiting or inducing the mixed function oxidase system are frequently of clinical concern. Rifampicin, carbamazepine, phenytoin and phenobarbital are examples of enzyme-inducing drugs which lower the concentration of some other drugs. Cimetidine, erythromycin and sodium

valproate are enzyme-inhibiting drugs which increase the concentrations of those other drugs dependent on similar mechanisms for clearance.

## DRUGS IN BREAST MILK

The context of consideration should always be 'which drugs should not be used or deserve special consideration in breast-feeding mothers?' rather than 'should mothers be allowed to breast-feed when taking these drugs?' Few drugs require particular consideration. These are listed with effects and special considerations in [Table 9.2](#). In general, the following considerations are relevant:

- Is a drug really necessary? If it is, a discussion between the pediatrician and mother's doctor is necessary.
- If a drug is needed, choose one which is the safer of alternatives, e.g. warfarin rather than phenindione; paracetamol rather than aspirin.
- Consider the benefit of measuring the drug concentration in the baby.
- Drug exposure may be reduced by taking medication just before a baby's long sleep, or just after breast-feeding.

## UNLICENSED MEDICINES AND USE OF LICENSED MEDICINES FOR UNLICENSED APPLICATIONS

More than 30% of medicines used in hospital practice are either unlicensed, or are used outwith the license indications. The Joint Standing Committee on Medicines of the Royal College of Paediatric and Child Health and the Neonatal and Paediatrics Pharmacists Group has recognized the need for those who prescribe for children to prescribe unlicensed medicines, or use medicines 'off label' and has provided the following information and guidance:

- Those who prescribe for a child should choose the medicine which offers the best prospect for the child, with due regard to cost.
- The informed use of licensed medicines for unlicensed applications and unlicensed medicines is necessary in pediatric practice.
- Health professionals should have ready access to sound information on any medicine they prescribe, dispense or administer, and its availability.
- In general, it is not necessary to obtain explicit consent of parents, carers or child patients to prescribe or administer licensed medicines for unlicensed applications, or to prescribe unlicensed medicines.
- *Those with administrative responsibilities* should support therapeutic practices that are advocated by a respectable, responsible body of professional opinion.

## WHAT PARENTS AND CHILDREN NEED TO KNOW ABOUT MEDICINES

The prescriber needs to recognize the need for information provision and the following is an appropriate and basic check list:

- Medicine generic/brand name;
- How the medicine is expected to help. What results are expected? How long it takes to start working;
- How much to take at one time and how often;
- For how long the medicine will need to be taken;
- When to take the medicine. Before or after meals? At bed time? At special times?;
- How to take the medicine. Can it be diluted? With juices? With food?;
- Other medicine, foods, drinks which shouldn't be taken with the medicine;
- What restriction on activities is necessary?;
- Possible side-effects. When might they occur? Can they be reduced? Will they go away by themselves?;

Table 9.2 Drugs and breast milk

Problem area	Drug	Effect
Cytotoxics	Cyclophosphamide Ciclosporin Doxorubicin Methotrexate	Possible immunosuppression; unknown effect on growth or association with carcinogenesis
Abuse/social	Amfetamine Cocaine Heroin Phencyclidine	Irritability, poor sleeping Irritability; vomiting; seizures Tremors; restlessness; poor feeding Potent hallucinogen
Radiopharmaceuticals (cessation of breastfeeding according to time of effect)	Copper 64 ( <sup>64</sup> Cu) Gallium 67 ( <sup>67</sup> Ga) Iodine 123 ( <sup>123</sup> I) Iodine 125 ( <sup>125</sup> I) Iodine 131 ( <sup>131</sup> I) Technetium 99m ( <sup>99m</sup> Tc)	Radioactive 50 h (3 d) Radioactive 2 weeks (2 weeks) Radioactive 30 h (2 d) Radioactive 12 d (2 weeks) Radioactive 2–14 d (2 weeks) Radioactive 15 h–3 d (3 d)
Other drugs to be cautious about	Atenolol Clemastine Ergotamine Lithium Phenindione	Cyanosis; bradycardia Drowsiness; irritability; high-pitched cry (1 case) Vomiting; diarrhea; fits Half therapeutic concentration Increased prothrombin time and partial prothrombin time

- When to seek help if problems occur;
- What to do and how long to wait if things don't get better;
- How to keep the medicine safely and in what storage provision;
- Expiry date;
- How to renew the medicine by prescription.

### INTRODUCTION

Everyone involved in the care of children has a duty of care that requires them to promote the best interests of the child. Decisions or recommendations made on behalf of children, as well as being medically appropriate, must be consistent with both ethics and law. To the fullest extent possible they should be joint decisions involving all of those with a legitimate role in the partnership of care and they must respect the human rights of everyone whose lives may be affected by them. In most everyday clinical situations the options available are relatively straightforward, the communication is harmonious and everyone involved agrees on the appropriate course of action. However, when situations are more complex major difficulties can arise.

The actions of health professionals are subject to external scrutiny more than ever before. Highly publicized enquiries into standards of practice in relation to postmortem examinations, organ retention, research conduct and children's cardiac surgery (see [Appendix](#)) have tested the trust of the public in the medical profession. Doctors need to become comfortable with the fact that their recommendations may be questioned rather than accepted uncritically, both at the time they are made and in retrospect once the outcome of a clinical situation is known. Practicing medicine under these circumstances requires familiarity with ethical reasoning, legal issues and the professional standards of behavior expected by regulatory bodies as well as with technical medical information. The aim of this chapter is to provide basic guidance in these matters. The same broad principles governing conduct apply wherever medicine is practiced but legal matters vary significantly by jurisdiction. The legal issues discussed here represent the position in UK jurisdictions. Guidance on professional matters can be found on the General Medical Council website (see [Appendix](#)).

### CHILDREN'S RIGHTS

The UN Convention on the Rights of the Child<sup>1</sup> was endorsed by the UK Government in 1991. Although it influenced subsequent legislation, it was not directly translated into law, unlike the European Convention on Human Rights,<sup>2</sup> which became fully incorporated into UK law in October 2000 following the enactment of the Human Rights Act 1998.<sup>3</sup> The impact of this legislation on medical professionals is that their decisions will be tested against human rights norms and jurisprudence, as well as professional considerations. Up-to-date information about

developments in the application of this new legislation can be obtained from the British Medical Association website (see [Appendix](#)). The rights of one individual can often conflict with the rights of another and determining which right carries most importance in a given situation can be difficult. Clinicians are encouraged to seek legal advice if they are in doubt in these matters.

As far as health issues are concerned, the main rights that are likely to affect medical practice are the right to life (article 2 of the Convention), the right not to be subjected to inhuman or degrading treatment (article 3), and the right to private and family life (article 8). Some other rights may be relevant, including the right to marry and found a family (article 12), which may affect fertility questions and the right not to be subjected to discrimination (article 14). The precise effect of these rights in the health context is not yet settled, but human rights arguments have already been taken into account in a number of important cases involving treatment decisions. At this stage, however, it must be pointed out that the human rights guaranteed in the Convention are not absolute (with the exception of article 3). Individual states benefit from what is called a 'margin of appreciation', which allows them to interpret the rights in a way that suits their own social and cultural principles.

### CHILDREN AND CAPACITY – COMMUNICATION AND CONSENT

Honest, open communication is an essential foundation of ethical practice. Many differences of opinion originate from misunderstandings or inadequate information. The input of time required for optimal communication is substantial but the investment is usually repaid in the form of greater trust and confidence on the part of patients and parents. Communication is a two-way process and, where possible, should involve substantial listening as well as talking. When information has been shared and decisions or recommendations have been made openly there are greater grounds for confidence in their validity. However, there are issues associated with communicating with children that need to be specifically addressed, and these will vary with the age of the child.

### THE VERY YOUNG CHILD

It is self-evident that very young children are not able to receive information, nor to express an opinion about proposed medical treatment. In this situation, parents have both the right and the responsibility to make

decisions on behalf of their child, but they must act in the child's best interests (this will be considered in more depth later). For the moment, it is worth noting that parents, if they are to meet this standard, need access to accurate and clear medical information. Additionally, where there is a clear medical recommendation it should be made. Parents will generally wish to be guided by expert clinical recommendations, although they may not always agree with them. In some cases, it may be appropriate to offer to arrange for a second opinion, and of course interpreters can assist in overcoming language barriers. Discussion with the family's religious adviser may give an insight into the background to specific moral standpoints, although this should only be done with the consent of the family so as to avoid problems with confidentiality. There is an ongoing need to re-visit information and decisions with families to maintain confidence and to ensure the continued validity of the consent.

## THE OLDER CHILD

Although the age of majority (the time at which a child becomes an adult) is set by law,<sup>4,5</sup> children become more mature as they age, and it is clear that children under the age of majority may have legal authority to make their own medical decisions. Great care should be taken in assessing whether or not a young person is sufficiently mature when they express an opinion about their treatment, but it should not simply be assumed that a child is not competent merely because they reject the medical recommendation.

A valid consent may, therefore, be given by a child under the age of 16, provided that the nature and implications of the treatment can be understood. Whether or not a child has the capacity to consent depends, then, on the maturity of the individual and on the complexity of the issues that have to be decided. A comparatively young child may be able to give consent to an uncomplicated procedure with no long-term implications for health (minor surgery, for example, or the administration of an antibiotic to combat an infection) whereas it will clearly require considerably greater understanding to consent to procedures involving greater risk. The law does not, and cannot, set out precise criteria for determining capacity: this will entail an assessment of the facts of each case. Once a child is deemed competent to consent to treatment (and this is a decision generally left to the attending doctors) it is not necessary to have parental consent as well. Only a single valid consent is required to enable treatment to proceed legally. The child should be encouraged to involve the parents, but this choice belongs to the competent child. A parental refusal of consent cannot override the consent of a competent child.

Once the child is seen to be capable of acting autonomously, there is no need for a proxy decision maker. Although it may seem logical from this position that a child who is competent to consent to medical treatment should also be competent to refuse it, courts have deemed young people who refuse medical treatment where a parent has consented not to be competent and have allowed treatment to proceed against the wishes of the child. In the English case of *Re W*,<sup>6</sup> a 16-year-old girl refused treatment for anorexia nervosa in spite of the grave threat that the illness posed to her health. Although she was legally entitled to consent to treatment, the court ruled that this did not imply a correlative authority to refuse it, and that parental consent in such circumstances would override the child's opposition until such time as the child reaches the age of majority (18 years in England and Wales). This means that provided that parental consent is obtained, treatment in the best interests of the child may be imposed even if the child satisfies legal criteria of competence. This is justified on the grounds that there is a difference between consent to treatment and its refusal; the latter requires greater maturity and understanding than the former. Ultimately, the need to preserve life may override other considerations. However in Scotland, where a young person acquires full decision-making capacity at 16 years of age, the courts would have no right to interfere with their decision, and arguably Scots law gives more rights to children under the age of 16 than does the law in England and Wales.<sup>7</sup>

Although children may be permitted to consent to treatment under the age of majority, this too may be ignored in the face of more important considerations. In *Re M*,<sup>8</sup> for example, the court authorized a heart transplant operation in the case of a 15-year-old girl who expressed strong objections to further treatment. This was done on the explicit grounds that the need to preserve her life outweighed the risks entailed and in the face of the possibility that she might in the future resent her wishes being ignored. A Human Rights Act challenge to this position is conceivable. Both article 3 and article 8 of the Convention provide some protection for the realm of private decision-making. It could be argued that subjecting a competent child to a strongly resisted procedure constitutes inhumane treatment, although this would have to be balanced against parental rights under article 8 to make decisions relating to family life. It is unlikely, though, that a court would allow a child to embark on a life-threatening course of action (even with parental approval). The law is prepared to be paternalistic in relation to the decisions that children make. Certainly autonomy may be encouraged, but courts have sometimes regarded it as a negation of the principle of respect for autonomy to allow choices that would prevent the development of the full autonomy that usually comes with adulthood.

However, maximizing children's autonomy is a worthwhile goal, and will depend in part on the quality of the communication with the child. Communication should always be truthful and realistic. Information about risks and benefits should reflect local experience as well as the outcomes described in the medical literature. In cases of possible medical error patients and parents should be informed and this should be documented. It may occasionally be justifiable to withhold information but only if disclosing it would cause serious harm to the patient or another person. The General Medical Council publication *Good Medical Practice* outlines professional standards on which continuing medical registration is dependent.<sup>9</sup> 'If a patient under your care has suffered harm, through misadventure or for any other reason, you should act immediately to put matters right, if that is possible. You must explain fully and promptly to the patient what has happened and the likely long- and short-term effects. When appropriate you should offer an apology... In the case of children the situation should be explained honestly to those with parental responsibility and to the child, if the child has sufficient maturity to understand the issues.'

Sometimes parents and professionals may feel that giving a child full details is not in their best interests, but this should be the exception rather than the rule.

## BEST INTERESTS OF CHILDREN

At the center of issues relating to the care of children is the requirement to safeguard the best interests of the child. A person's best interests are not definable in simple terms of physical health. A complex interaction of physical, emotional and social factors is involved. The health gains of a procedure alone may not, therefore, be sufficient to determine a clear best interest. If the child does not wish to be treated or investigated it may not be justifiable to do so. The negative impact on the child – and on relationships with the child – of performing a procedure against their wishes may outweigh any health benefit obtainable. On the other hand, while adults are free to make choices that to others might seem unwise and to take actions that place themselves at risk of harm, children who are in the process of developing competence or capacity as decision makers do not enjoy the same degree of autonomy. Until they become competent, others have rights and responsibilities to decide on their best interests for them. When a child's best interests are judged by a proxy decision maker it is, however, important to separate the interests of the child from those of the decision maker.

There are many reasons why caregivers and parents or young people may evaluate best interests differently. Health care professionals tend to be enthusiasts for positive action in response to health problems. They are strongly motivated to improve outcomes and tend to believe that scientific advances will help them to do so. If treatments are not working there is a natural urge to look for alternatives and a reluctance to accept

failure. This so-called technological imperative<sup>10</sup> could lead a clinician to favor using treatments that a patient, or a different clinician, might not wish to agree to. The converse is also true. Experienced clinicians can sometimes be more pessimistic than parents or young people about what the future might hold.<sup>11</sup> It is important for clinicians to analyze whether their personal beliefs may affect the advice or treatment that they offer patients and to be open about this in order that patients can see another professional if they wish.

The values and experiences of parents and young people are also highly variable. Where the child is very young, and cannot express an opinion, parents may seek to impose their own views on the child. For example, people with particular religious beliefs may wish to reject certain treatments for their child (such as blood transfusion) that doctors believe to be vital – even life-saving. From the parents' point of view, the child's best interests are served by following their religious tenets; for doctors, their best interests are more likely to be concerned with continuing to live. Where such disputes arise, clinicians should seek legal advice and this may ultimately mean that the decision for the child is made by a court of law. This decision may not agree with the parents' views, of course, but the right of parents to be involved in their child's treatment decisions was recently reinforced by the European Court of Human Rights in the case of *Glass v United Kingdom*.<sup>12</sup> This case involved a serious (and ultimately violent) dispute between a family and the doctors caring for their son. Although it is authority for the right of parent(s) to be involved in the treatment plan for incompetent children, it should be treated with some caution. The legal finding against the health care professionals concerned was made directly because there were options for resolution – that is seeking a declaration from the High Court – that they had not taken. In that sense, it is of limited relevance, but it is an important case in establishing both the need to negotiate with families (and where this proves unsuccessful, to seek legal authority) and in its reinforcement of the family's rights in decision-making for incompetent children.

In the case of older children, it is important that their views are heard and, where appropriate, accommodated. We have already seen that decisions to reject recommended treatment can be overcome by the court or by the parents in England and Wales (even after the young person has reached the age of 16). In Scotland the position is different. At 16, a child becomes an adult for these purposes and his/her decisions cannot be interfered with by parents. In addition, the right of children under the age of 16 to make their own decisions (if they are sufficiently mature) about medical treatment is clear, and it has long been assumed that this includes the right to refuse treatment. The terms of s. 2(4) of the Age of Legal Capacity (Scotland) Act 1991<sup>5</sup> establish that a child under the age of 16 in Scotland can indeed make his or her own decisions if sufficiently mature. That this might include the right to refuse treatment seems to be clarified by the case of *Re Houston*.<sup>13</sup> In this case, a young man who suffered from mental illness was deemed competent to refuse medical treatment. It should be noted, however, that *Houston* is the only case that has been considered in Scotland on this ground, and it is a decision of one of the lower courts. It would not, therefore, be binding in a more senior court. The legislation does not specifically mention refusal, but it does seem clearly to give decision-making authority to competent people under the age of 16. What is important to bear in mind is that, in the case of older children, it is not their chronological age that necessarily is of importance; rather it is their understanding and maturity.

## WITHHOLDING/WITHDRAWING TREATMENT

It is clear from the medical literature that it is common practice for life-prolonging treatment to be withdrawn. Discussions with parents about limitation and possible withdrawal of treatment may occur in up to 70% of deaths in UK neonatal units<sup>14</sup> and between 43% and 72% of deaths in pediatric intensive care units.<sup>15</sup> Since many of the issues raised by life-and-death dilemmas are ethical/legal and not medical, some commentators, notably philosophers and lawyers, believe that doctors and

parents are not competent to make such decisions on their own and that the law should dictate this process. However, not every decision needs to be made by a court, and indeed it would be impossible for medicine to function if doctors were constantly required to seek legal endorsement of their clinical decisions. At the same time, the protection of human life is a matter of central concern for the law, and therefore any medical and parental decisions must be made against a background of certain legal limits as to what is permissible. Within these limits, there remains considerable room for nuanced and sensitive decisions to be made by those most intimately involved in the life of the child and his or her medical care. When this process fails, however, courts will likely become involved as the ultimate arbiter of the child's best interests.

The starting point of any discussion of this issue is the stark proposition that any deliberate act intended to bring life to an end normally amounts to the crime of murder. This is the case even if the person carrying out the act acted with the motive of ending the victim's suffering (assisted suicide or euthanasia). Although there have not been many convictions of doctors in the UK for killing their patients with this motive in mind, this is more because of the difficulty of getting juries to convict in such cases than of any ambiguity in the law. A recent attempt to change the law in the UK has been put on hold, and seems unlikely to succeed. Euthanasia is legal under some circumstances in the Netherlands, Belgium and the Northern Territory of Australia, where the State law was overruled by Federal legislation. Physician-assisted suicide is also explicitly permitted in the US state of Oregon, and is widely tolerated in Switzerland. The legal prohibition of assisted dying within the UK does not, however, prevent the appropriate and medically indicated use of pain-killing drugs that will have the incidental effect of shortening the life of the patient. This is justified by the doctrine of double-effect, which holds that pursuing a legitimate goal (in this case, pain relief) is justified even if this will have the inevitable effect of causing an undesirable event (the death of the patient). The fact that death is foreseen is not, in terms of this doctrine, the same as it being intended, although in other areas of law this description of the event has been challenged. For example, it was said in the case of *R v Woollin*<sup>16</sup> that where an outcome was foreseen as inevitable it must also be regarded as intentional. In other words, in the medical context, if a significant increase in analgesia predictably results in death, then the doctrine of double-effect may not be sufficient to avoid criminal charges.

Assisted dying is one thing, but the withdrawal or denial of treatment is regarded as quite different. It has long been accepted that it is lawful to withdraw life-prolonging treatment if it is no longer in a person's best interests and that it is lawful to withhold treatment for the same reason. This has been established in a series of cases in which the courts have considered the circumstances in which it is proper to withdraw support for infants and young children for whom the prognosis is bleak. In most of these cases the courts have recognized that where a child's suffering would be intense and where no reasonable quality of life could be achieved, then it is futile to continue with treatment. An example of such a decision is *A National Health Service Trust v D*<sup>17</sup>, in which the child in question had been born with chronic and worsening lung disease and suffered in addition from heart failure, hepatic and renal dysfunction as well as severe developmental delay. There was a difference of opinion in this case between the parental and medical views as to whether resuscitation should be attempted in future; the court endorsed the medical conclusion of futility. In reaching its conclusion, the court addressed arguments based on European Convention rights. In particular, the court said that the decision not to resuscitate was compatible with article 2 of the Convention (the right to life). It also expressed the view that such a course of action was in accordance with article 3, which requires that a person should not be subjected to inhuman or degrading treatment; undue prolongation of life through excessively zealous treatment could infringe the right to die with dignity. This decision is significant, in that it demonstrates that human rights provisions will not be interpreted in such a way as to oblige doctors to provide treatment in those circumstances where their clinical and indeed human judgment suggest otherwise.

The practice of withholding or withdrawing life-prolonging treatment is acknowledged and endorsed by the British Medical Association<sup>18</sup> and by the Royal College of Paediatrics and Child Health.<sup>19</sup> There is presently no legal requirement for the involvement of the courts in medical decisions of this nature, unless, as we have seen, there is a dispute that cannot otherwise be resolved. It is desirable, however, that decisions of such gravity, made on behalf of dependent individuals, are not taken by a single person but reflect the views of a body of people with an intimate involvement in the situation. This can provide a safeguard against the possibility that a decision could be overly influenced by the polarized views or values of one person. Openness should promote better decision-making. Clear documentation of the issues being addressed, the individuals involved and their viewpoints is an important part of this. Nor should decisions of this nature be rushed. In emergencies where the appropriate course of action is unclear and a plan has not been documented, trainee doctors should administer life-sustaining treatment until a senior and more experienced doctor arrives. With these safeguards in place it is reassuringly uncommon for parents to think later that the wrong decision was made.<sup>20</sup> It is not essential for there to be unanimity of views on the part of the medical team. There should be substantial consensus and the weight attributed to individual dissent will depend on the experience and knowledge of the person expressing it.

Withdrawal of life-prolonging treatment does not imply withdrawal of care. Care that is directed at maintaining the comfort and dignity of the patient (palliative care) is always required. The clinical team should continue to consider the child's physical, emotional and spiritual needs. Food and fluid should usually be offered (but not forced) on a regular basis. The role of assisted feeding by nasogastric tube or gastrostomy can be a source of difficulty. There is a spread of opinion as to what circumstances determine whether this is a life-prolonging medical treatment, a comfort measure or a basic necessity. In some circumstances such as the persistent vegetative state it may be seen to be in a person's best interests for feeding or i.v. fluids to be withdrawn. It is important to consider whether these measures are benefiting the patient. These issues must be handled sensitively, taking into account the views of the family and the staff.

Where consideration is being given to withdrawal of treatment there may be a number of treatments in use, such as mechanical ventilation, antibiotics, analgesics or sedatives and paralyzing agents. It is not appropriate to wait for the effect of the medications to wear off before withdrawing the ventilation. This would effectively amount to giving one futile treatment because you were already giving another. Analgesics should be continued after the withdrawal of ventilation. The primary intention of administering analgesics is to control pain and distress, and this has a clear benefit to the patient. A side effect of opioids may be that they suppress breathing and could shorten life; however this is not the purpose for which they are being administered. Subject to the caveat discussed earlier, the principle of double-effect is recognized and accepted in law.<sup>21</sup> The situation is a little more finely balanced in the case of paralyzing agents. If ventilation is withdrawn in a paralyzed patient, death will certainly follow shortly afterwards. These agents are generally being given to facilitate ventilation in a critically ill patient with severe cardiopulmonary failure. Under these circumstances death is inevitable after withdrawal of ventilation whether paralyzing agents are being used or not. Paralyzing agents may therefore reasonably be continued up to the point that ventilation is withdrawn but should not be administered after extubation. In the absence of cardiopulmonary failure, paralyzing agents are unlikely to be in clinical use and should not be given to patients who are not going to be ventilated.

The Ethics Advisory Committee of the Royal College of Paediatrics and Child Health published guidance for professionals about withdrawing or withholding life-sustaining treatment from children.<sup>19</sup> This is available online ([http://www.rcpch.ac.uk/publications/recent\\_publications/Withholding.pdf](http://www.rcpch.ac.uk/publications/recent_publications/Withholding.pdf)). The guidance highlights a number of axioms on which ethical decision-making about the withholding or withdrawal of life-prolonging treatment may be based:

1. There is no significant ethical difference between withdrawing (stopping) and withholding treatments, given the same ethical objective.
2. Optimal ethical decision-making concerning children requires open and timely communication between members of the health care team and the child and family, respecting their values and beliefs and the fundamental principles of ethics and human rights.
3. Parents may ethically and legally decide on behalf of children who are unable, for whatever reason, to express preferences, unless they are clearly acting against the child's best interest or are unable, unwilling or persistently unavailable to make such decisions on behalf of their child.
4. The wishes of a child who has obtained sufficient understanding and experience in the evaluation of treatment options should be given substantial consideration in the decision-making process.
5. The antecedent wishes and preferences of the child, if known, should also carry considerable weight given that conditions at the time for action match those envisaged in advance.
6. In general, resolution of disagreement should be by discussion, consultation and consensus.
7. The duty of care is not an absolute duty to preserve life by all means. There is no obligation to provide life-sustaining treatment if: (1) its use is inconsistent with the aims and objectives of an appropriate treatment plan or (2) if the benefits of that treatment no longer outweigh the burden to the patient.
8. It is ethical to withdraw life-sustaining treatment if refused by a competent child, or from children who are unable to express wishes and preference when the health care team and parent/carers agree that such treatment is not in the child's best interests.
9. A redirection of management from life-sustaining treatment to palliation represents a change in beneficial aims and objectives and does not constitute a withdrawal of care.
10. The range of life-sustaining treatments is wide and will vary with the individual circumstances of the patient. It is never permissible to withdraw procedures designed to alleviate pain or promote comfort.
11. There is a distinction to be drawn between treatment of the dying patient and euthanasia. When a dying patient is receiving palliative care, the underlying cause of death is the disease process. In euthanasia, the intended action is to cause death.
12. It follows that use of medication and other treatments that may incidentally hasten death may be justified if their primary aim is to relieve suffering. The Ethics Advisory Committee of the Royal College of Paediatrics and Child Health does not support the concept of euthanasia.
13. Legal intervention should be considered when disputes between the health care team, the child, parents and carers cannot be resolved by attempts to achieve consensus.

The guidance document outlines five situations where it may be ethical and legal to consider withholding or withdrawal of life-sustaining medical treatment from children:

1. **The Brain-dead Child.** In the older child where criteria of brainstem death are agreed by two practitioners in the usual way it may still be technically feasible to provide basic cardio-respiratory support by means of ventilation and intensive care. It is agreed within the profession that treatment under such circumstances is futile and the withdrawal of current medical treatment is appropriate.
2. **The Permanent Vegetative State.** The child who develops a permanent vegetative state following insults, such as trauma or hypoxia, is reliant on others for all care and does not react or relate to the outside world. It may be appropriate to withdraw or withhold life-sustaining treatment in these circumstances. In England and Wales, withdrawing such treatment requires the authority of the courts.<sup>22</sup> In Scotland, no such permission is demanded, although the Lord Advocate has indicated that only in those cases where it has been obtained will there be a guarantee of no prosecution.

3. **The No Chance Situation.** The child has such severe disease that life-sustaining treatment simply delays death without significant alleviation of suffering. Treatment to sustain life in this case is inappropriate.
4. **The 'No Purpose' Situation.** Although the patient may be able to survive with treatment, the degree of physical or mental impairment will be so great that it is unreasonable to expect them to bear it.
5. **'The Unbearable Situation'.** The child and/or family feel that in the face of progressive and irreversible illness further treatment is more than can be borne. They wish to have a particular treatment withdrawn or to refuse further treatment irrespective of the medical opinion that it may be of some benefit.

The document concludes that:

'In situations that do not fit with these five categories, or where there is uncertainty about the degree of future impairment or disagreement, the child's life should always be safeguarded in the best way possible by *all* in the health care team, until these issues are resolved.'

Decisions about withdrawing or withholding life-prolonging treatment are likely to be based on probabilities rather than on certainties. Parents need to be prepared for what might follow. Death may take minutes or hours or may not occur at all. Protracted deaths are particularly stressful for parents and may cause them to doubt the wisdom of the decision. There is a danger that withdrawing or withholding treatment in a child who goes on to survive may mean that the eventual outcome is worse than would otherwise have been the case. Unexpected survivors need ongoing support, evaluation and respect.

Disputes about where the balance between the views of doctors and parents should lie are at their most acute when the outcome of following one or the other would result in the death of a child. Again, in these cases, it is wise to seek legal advice and the ultimate decision may become that of the courts.

Several UK cases have involved this situation. In *Re C (a minor)*,<sup>23</sup> a decision of the Family Division of the High Court of England and Wales, there was a difference of opinion between the parents and the doctors of a 16-month-old child suffering from spinal muscular atrophy. The medical view was that further ventilation in the event of a collapse was futile, a view that was not shared by the parents who, for religious reasons, believed that everything possible should be done to save human life. The court declined to endorse the parental view. In *R v. Cambridge District Health Authority, ex parte B*,<sup>24</sup> the father of a child requiring treatment with a limited chance of success challenged the decision of the area health authority that this treatment was not justified. This was unsuccessful, the Court of Appeal accepting that decisions have to be made about the allocation of resources and that parents could not upset such hard decisions, provided that they were reasonably reached by those making them.

Parental wishes were at the center of two further life-or-death cases: *Re T (a minor) (wardship: medical treatment)*<sup>25</sup> and, more recently, *Re A (children)*.<sup>26</sup> In *Re T* a parental decision to refuse a liver transplant for a child suffering from biliary atresia was upheld, even although medical opinion was that this could add several years to the child's life. This was an exceptional case and in *Re A (children)*, the highly publicized conjoined twins case, parental opposition to surgery to separate the children was overruled.

More recently two further cases have highlighted the complexities of these decisions. In the case of Charlotte Wyatt, who was born with multiple life-threatening pathologies, the views of the clinicians caring for her were that she would be best served by being allowed to die. In their view, aggressive treatment was not appropriate; indeed, it was essentially futile. Her parents, however, wanted treatment to continue and were determined that she should receive every assistance to live. In the event, Charlotte lived for many months longer than her doctors would have predicted, although it is impossible to judge objectively the quality of her life.

In October 2004, the High Court in England declared that Charlotte's best interests, in the event that she suffered from an infection which

led, or might lead, to a collapsed lung, would be served by providing 'all suitable medical care including antibiotics'.<sup>27</sup> Should, however, she require intubation and/or ventilation, it would be lawful for her doctors to decide not to provide this treatment. Her doctors could also lawfully decide that it was appropriate to administer continuous positive airway pressure (CPAP), but if she were 'visibly distressed' by this, it would also be lawful to withdraw it. Finally, it would be lawful for her doctors to use symptomatic relief to make her more comfortable, even if that might depress her efforts to breathe (double-effect). In December 2004, the judge made three further declarations, and the case was heard again in January 2005, when the court instructed that further experts should be engaged to discover whether or not Charlotte's condition was improving, as her parents insisted it was. Later in 2005, in the High Court, the judge lifted an order saying that doctors would not be acting unlawfully if they decided not to give Charlotte artificial ventilation in a life-threatening situation, and indicated that her parents should reach agreement with the doctors about their daughter's treatment if a crisis arose. However, in February 2006, Charlotte's condition had worsened, and in his latest ruling Mr Justice Hedley said that Charlotte's deterioration meant that circumstances had changed. She had developed a cough, probably caused by a viral infection, and was having difficulty breathing. Mr Justice Hedley therefore agreed that doctors could lawfully decide not to resuscitate her if they feel it would not be in her best interests to do so.

The second case is referred to as *Re MB*.<sup>28</sup> In this case, the child was found to have a degenerative, inherited condition that would ultimately require him to be artificially ventilated before his inevitable death. The parents wished all treatment – including artificial ventilation – to be used; the clinicians, on the other hand, believed that the child's best interests would not be served by imposing painful, distressing and ultimately futile treatment. The court acknowledged that the views of each were important, but that its task was objectively to establish the best interests of the child. In the event, the judge declared that it was in the child's best interests for current treatment (including continuous pressure ventilation) to be continued. However, should interventions such as cardiopulmonary resuscitation (CPR) or the i.v. administration of antibiotics be required, it would be in his best interests to withhold them. However, if parents and doctors are in agreement that treatment should be continued, then the Law will not need to be involved. Should parents wish no treatment to be given and the doctors disagree, again they should seek legal advice. In one such case, the court allowed parents to refuse treatment even although the doctors believed that it would be life-saving, showing just how complex this situation can be.<sup>29</sup>

## PARENTAL RESPONSIBILITY

Broadly the obligations of parents are to care for the child and to raise him or her to moral physical and emotional health. This is the fundamental task of parenthood and the only justification for the authority that it confers. This is enshrined in The Children Act 1989,<sup>30</sup> which applies in England and Wales, and the Children (Scotland) Act 1995,<sup>31</sup> which is the equivalent Scottish legislation. Having said that, parental decisions that are not in the best interests of their children can be overridden by the courts, as has been reported. However, given that parents have the primary rights and responsibilities in respect of their children under these Acts, it is important to discover who actually has parental rights, bearing in mind that in an emergency, where treatment is necessary to prevent serious deterioration in a child's condition or to save its life, treatment can proceed without consent.

### Who is a parent?

The biological parents are the legal parents unless a child has been adopted; however biological parenthood does not necessarily confer parental responsibility under the Acts (except where parental rights have been acquired following a surrogacy arrangement in terms of s.30 of the Human Fertilisation and Embryology Act 1990.<sup>32</sup> The mother has parental responsibility, and so does the father, provided that he was married to the mother at the time of the conception or the birth, or if he marries her after

the birth. Once a parent has obtained parental responsibility, it is not lost in the event of divorce. It is possible that the Human Rights Act could be used by unmarried fathers to establish their parental responsibility on the basis of their right to enjoy family life if the mother of the child is not permitting their involvement, but the outcome of any such challenge is unclear.

Of course, a parent is not always available. The person who has care of the child under these circumstances (e.g. a grandparent or carer) has a responsibility under the Children Act to do 'what is reasonable in all the circumstances of the case for the purposes of safeguarding or promoting the child's welfare. This could in theory include giving consent to medical treatment, but carers should not give consent if they know that the parent is likely to object.

In England, Wales and Northern Ireland if the parents are not married, the father can gain parental responsibility by entering into a parental responsibility agreement with the mother and registering it in the Principal Registry of the Family Division of the High Court. A father can also be granted parental responsibility by a court. Adoptive parents have parental responsibility. The courts can grant parental responsibility to others such as a guardian or a local authority where the child is made the subject of a care order or a residence order. The parental responsibility that accompanies these orders lasts for the duration of the order. The court itself can also give consent to treatment on behalf of a child and can make specific issue orders or prohibited steps orders limiting parental responsibility in specified circumstances. The High Court can make the child a ward of court, which requires all important decisions about the welfare of the child to be referred to the Court. In an emergency the High Court is available at all hours and, if appropriate, a duty judge can be obtained through the security officer at the Royal Courts of Justice. The judge may deal with the issue by telephone or in person. A medical adviser should be available to speak to the judge in such circumstances.

In Scotland, unmarried fathers can gain parental responsibility through a voluntary parental responsibility agreement with the mother, registered in the Books of Council and Session. Fathers can also apply to the Sheriff Court or the Court of Session for an order granting them parental responsibilities and rights. Adults can gain parental responsibility by being appointed as guardians or on the order of a court. The Court of Session can give consent on behalf of a child who is not competent but, as we have seen, probably cannot override the refusal of a competent young person, although this has not been tested. As in the rest of the UK, the courts are available at all hours, if necessary, and can respond promptly. Both the Sheriff Court and the Court of Session can make decisions about medical issues. Contact should be made with the local Sheriff Court or with the Keepers office and if appropriate a Sheriff or Judge Depute will be contacted. As before, a medical advisor should be available via telephone or in person to answer any questions. The court can make specific issue orders or prohibited steps orders. One further arena for welfare-based decisions is the Children's Hearing System. If someone believes that a child requires compulsory measures of supervision, an official called a 'Reporter' will investigate and decide whether a ground for referral to a children's hearing is established, e.g. that the child is likely to suffer serious impairment in his health or development due to a lack of parental care. If such a ground is established a hearing is arranged. If the young person and the parents accept the ground for referral the hearing can then decide on the case and issue an appropriate order. If the ground is not accepted then the case must be determined by a Sheriff Court. If the Sheriff decides that the ground is valid the case is returned to the Children's Hearing, which can make supervision decisions; otherwise it is dismissed.

Under the Adoption and Children Act (2002)<sup>33</sup> in England and Wales and the Family Law Scotland Act 2006,<sup>34</sup> unmarried fathers now automatically gain parental responsibility if they are named as the father on the birth certificate.

## CONFIDENTIALITY

Adults should be able to assume that health care professionals dealing with personal information about them will maintain confidentiality.

Confidentiality may be broken but only when consent (express or implicit) is given for disclosure or where it becomes necessary to breach confidence to protect others from a risk of serious harm. When children have been deemed competent their right to confidentiality must be respected, as long as this is judged to be in their best interests. (This was established legally in the case of *Gillick v. West Norfolk and Wisbech Area Health Authority*.<sup>35</sup>) When serious issues are being considered, the competent child should be encouraged to involve their parents but the choice belongs to the competent child. Less mature children may also wish for matters to remain confidential. They too should be encouraged to share information with their parents voluntarily and their confidence should not be broken lightly. If the information involves serious matters relating to the health or well-being of the incompetent child, the health care professional will have to disclose the information but they should not do so without informing the child of their intention and explaining their reasons for disclosing the information. In cases of abuse or neglect there is a responsibility to disclose information to the social services to protect the child from possible harm. It may be justifiable not to inform the child of your intention to disclose this information but only if doing so would introduce a serious risk to their health and well-being.

Medical records are confidential, which means that parents may not see the medical records of their competent child without their permission. Children have a right of access to their own records under the Access to Health Records Act 1990<sup>36</sup> provided that the child is capable of understanding the nature of his or her application for access (s. 4 of the Act). This right of access to the record may also be exercised by the parent or guardian on behalf of the child. As in the case of an application by an adult to see medical records, information can be withheld when the person holding the record believes that disclosing it will cause serious harm to the patient or another person.

Where personal health information potentially attributable to an individual is published or presented, consent should be sought for the disclosure, although under section 60 of the Health and Social Care Act 2001<sup>37</sup> the nonconsensual use of identifiable patient information for the purposes of research and the improvement of treatment services may be authorized in certain circumstances. In the normal case, consent for the use of identifiable patient information should specify the ways in which the information will be disclosed. When such information is disclosed for research purposes to others who are not directly involved in the care of the patient, consent should also be sought. Anonymized information is not protected in the same way, and considerable benefit is obtained from clinical improvement activity and research work in which clinicians analyze their patient information databases and the anonymized databases of others. Such work would become impracticable if individual patient consent was required and there would be a potential for considerable loss of health benefit to patients.

Since the Caldicott Report,<sup>38</sup> within the UK each health care organization must appoint a Caldicott Guardian. This is usually a senior health professional responsible for safeguarding the confidentiality of patient information.

## DUTY OF CARE OF THE HEALTH PROFESSIONAL

The clinician has an ethical and legal duty of care to protect the life and health of his or her patients. Treatment decisions should be consistent with the basic ethical principles of beneficence and nonmaleficence, which require that the benefits must outweigh the burdens. In the UK, doctors alone have the right to decide whether a treatment is medically appropriate and patients have no right to insist on treatment from a doctor if that doctor does not consider it to be in their best interests. Similarly, parents have no right to obtain such treatments for their children. The courts cannot oblige doctors to undertake any specific medical intervention, even if parents wish to insist on it – although courts may agree with parents that treatment is appropriate, as we have already seen.

If the clinician is being pressed to administer a treatment deemed inappropriate, all efforts should be made to resolve the situation through

further discussion. If these efforts do not succeed, the clinician should go to reasonable lengths to find an alternative clinician for the family, although if good decision-making practices have been followed there may not be one easily identifiable. If these measures do not succeed and the clinician has the support of his colleagues then he cannot be forced to treat. However, the parents should be informed of their right to obtain judicial review if they wish. Following the *Glass* judgement,<sup>42</sup> it is clear that parents have this right. However, it would be for the parents in this situation, rather than the doctors, to initiate any such action as the doctor's actions are regarded as appropriate professionally. If the medical reasoning has been sound and the clinician's colleagues support him then there is a strong prospect that the decision not to treat will be upheld. If a doctor refuses to give a treatment then this decision may later be challenged legally on the grounds that it amounts to a failure to discharge the duty of care owed to the patient. If there has been such a failure, then this may amount to negligence, the presence of which is determined by applying the test of whether the doctor has acted in accordance with the practice accepted by a responsible body of medical practitioners skilled in that particular art, and that his decision was logical. In other words, a specialist must practice with the ordinary skill of his speciality.<sup>39,40</sup>

Doctors have no legal authority to institute treatment in the absence of consent but they have a duty of care and an ethical responsibility to institute emergency treatment deemed to be in the child's best interests. If there is doubt as to the best interests in an emergency, then this same duty should compel them to act on the presumption that the child would want to be saved, at least until there has been time for further consideration. Under these circumstances, if the action satisfied the legal test described earlier, it is highly likely (even if not absolutely certain) that the courts would support it.

If the patient or parents refuse consent to important but non-urgent treatment, attempts should again be made to resolve the dispute through further communication. A second opinion, particularly from an acknowledged expert, may help. If these measures do not succeed and the clinician has support for his position from his colleagues, judicial resolution should be sought. Again the sharing of the information with colleagues and presence of their support will increase the chances that the court will endorse the doctor, but if the decision-making process has lacked balance then the court will rightly support the alternative position. One viewpoint is that seeking a judicial resolution might take the pressure off the relationship between the family and the clinician. In reality it probably just relocates the conflict from the consulting room to the courtroom without substantially changing the individuals involved, the balance of power or the nature of the conflict.<sup>41</sup>

## GENETIC TESTING

Recent progress in elucidating the genetic basis of disease has been beyond all expectation and continued progress is likely. This carries great potential to improve health through new approaches to the diagnosis, treatment and prevention of illness. Further progress must be made before gene therapy becomes widespread but diagnosis and screening are already widely established. This gives rise to a number of ethical issues.<sup>42</sup> Rare and serious diseases that affect the health of children can be detected and this has obvious potential benefit to children. The new science also offers increasing capacity to detect predisposition to illnesses or even behavioral traits that may affect individuals only in adulthood. The results of such tests may have marked adverse effects on a child and on their future potential. As well as the person being tested, genetic tests also affect many others who are related to them. They may influence parental reproductive decisions. They may cast doubt on parenthood. They may raise similar issues for siblings. False-positive and false-negative results can cause considerable anxiety. Genetic tests should therefore only be used with caution, informed consent and adequate counseling. In general, tests on children should only be performed when a direct benefit to the child is anticipated during childhood. If the test will give information that will not have great relevance to the child

until adulthood, then it should be deferred until the child is competent to decide for him- or herself whether or not to agree to testing. This cautious approach to the genetic testing of children has been endorsed in the UK by the Government's Advisory Committee on Genetic Testing and by its successor body, the Human Genetics Commission (see [Appendix](#)).

Consent to genetic testing raises questions that have yet to be firmly settled. In the case of routine nongenetic tests carried out in a clinical context, all that is required is that there should be consent to the necessary medical procedures (by the competent child or by the parent or guardian). It is not necessary to explain the implications of every biochemical test, for example, that will be carried out on a sample. Where, however, the test has particular significance (such as a human immunodeficiency virus [HIV] test), the person giving consent should know the nature of the test being proposed. Genetic tests have special features that should be explained in general terms to the patient. In particular, genetic tests may have implications for other family members, and if this is the case then this should be discussed with the parent (and with the child, if the child is sufficiently mature to understand what is entailed by the information). Further questions are raised by multiplex testing, which may involve testing for a number of different genetic characteristics through devices capable of detecting numerous DNA sequences. It may be unrealistic to expect a full explanation to be given of everything that such a test may do, and for this reason consent should be valid if it is explained to the patient that a number of genetic characteristics may be revealed by the test and that this information may be retained on the record. Obviously this must be done sensitively, as nothing will be gained by giving complicated explanations that may serve only to alarm the patient unnecessarily. In respect of consent to testing, all that the law requires is that the doctor should give the patient that amount of information that is reasonable in the circumstances. A sound sense of current professional consensus on these issues is probably as good a guide as any as to how the matter should be approached.

Paternity testing may be requested by parents. This should not be performed without the involvement of both parents unless authorized by a court. Courts usually determine that testing is in the interests of the child. The child and family may need a lot of support and counseling. Guidelines on this subject are now available (see [Appendix](#)).

## RESEARCH

There is no doubt that medical research can be in the best interests of children. Without it, medicine would be unable to progress, ineffective treatments would not be discarded, effective new treatments not introduced, and dangerous ones not identified. Carrying on in ignorance where properly conducted research could determine the optimal path is unethical. However, while research may benefit society it can sometimes be of little benefit to the individual under study. This may be irrelevant in the case of competent adults, who can consent to participate in ethical research even if it is of no therapeutic benefit to them. The involvement of children in research is more problematic. Research that is of potential therapeutic benefit to the child is acceptable, and can be consented to by the parent on behalf of the child. Nontherapeutic research, however, is of no benefit to the child, unless, possibly, the child has a sibling or other close relative who suffers from the condition that is the subject of research. In such a case, it is possible to argue that the child benefits from helping to advance knowledge of a condition that affects him or her through the family link. There are other ways in which participation might be in the best interests of the child. Patients enrolled in studies tend to experience some improvement in their clinical outcomes when compared with similar patients who are not being studied.<sup>43</sup> This inclusion benefit may relate to the closer supervision necessary to perform successful research. Where there is no such justification, then it must be asked whether it is either ethical or legal to involve children in nontherapeutic research.

One further constraint on the involvement of children in research relates to the question of risk. There is widespread agreement that it is ethical to use children in medical research provided that the research

in question involves a negligible risk of harm to the child. There is a range of views as to how this risk is to be assessed. The legal position on this issue is more complex. It has been suggested in the past that the Law prevented participation by children even in nonrisky research on the grounds that parental consent, which would be needed, cannot be given in respect of anything that is not in the best interests of the child. On this view it would be impossible, then, for a parent ever to agree to something from which the child would not benefit. However, the view has also emerged that a parent may consent to that which does not actually threaten the child's interests. This would mean that nontherapeutic research on children is permissible, with parental consent, as long as the risk is negligible. It is not yet settled whether this latter view would be taken by the Law, particularly given the best interests requirement that predominates judicial decision-making in this area.

It should be stressed that if the child is old enough to have views on involvement, these views should be taken into account (even if the child does not have the capacity to consent in general). If a research procedure involves discomfort, and the child objects, then it would be unethical to continue with the procedure. From the legal point of view it would clearly not be in the child's best interests to proceed with unwelcome procedures.

In 2000, The Ethics Advisory Committee of the Royal College of Paediatrics and Child Health published guidelines for the ethical conduct of medical research involving children.<sup>44</sup> Six principles were outlined:

1. Research involving children is important for the benefit of all children and should be supported, encouraged and conducted in an ethical manner.
2. Children are not small adults; they have an additional, unique set of interests.
3. Research should only be done on children if comparable research on adults could not answer the same question.
4. A research procedure that is not intended directly to benefit the child subject is not necessarily either unethical or illegal.
5. All proposals involving medical research on children should be submitted to a research ethics committee.
6. Legally valid consent should be obtained from the child, parent or guardian as appropriate. When parental consent is obtained, the agreement of school-age children who take part in research should also be requested by researchers.

In 2005, the Additional Protocol to the Convention on Human Rights and Biomedicine, Concerning Biomedical Research (Council of Europe)<sup>45</sup> also considered research on incompetent people, and proposed the following guidelines:

#### ARTICLE 15 – PROTECTION OF PERSONS NOT ABLE TO CONSENT TO RESEARCH

1. Research on a person without the capacity to consent to research may be undertaken only if all the following specific conditions are met:
  - i. the results of the research have the potential to produce real and direct benefit to his or her health;
  - ii. research of comparable effectiveness cannot be carried out on individuals capable of giving consent;
  - iii. the person undergoing research has been informed of his or her rights and the safeguards prescribed by law for his or her protection, unless this person is not in a state to receive the information;
  - iv. the necessary authorization has been given specifically and in writing by the legal representative or an authority, person or body provided for by law, and after having received the information required by article 16, taking into account the person's previously expressed wishes or objections. An adult not able to consent shall as far as possible take part in the authorization procedure. The opinion of a minor shall be taken

into consideration as an increasingly determining factor in proportion to age and degree of maturity;

- v. the person concerned does not object.
2. Exceptionally and under the protective conditions prescribed by law, where the research has not the potential to produce results of direct benefit to the health of the person concerned, such research may be authorized subject to the conditions laid down in paragraph 1, subparagraphs ii, iii, iv, and v above, and to the following additional conditions:
  - i. the research has the aim of contributing, through significant improvement in the scientific understanding of the individual's condition, disease or disorder, to the ultimate attainment of results capable of conferring benefit to the person concerned or to other persons in the same age category or afflicted with the same disease or disorder or having the same condition;
  - ii. the research entails only minimal risk and minimal burden for the individual concerned; and any consideration of additional potential benefits of the research shall not be used to justify an increased level of risk or burden.
3. Objection to participation, refusal to give authorization or the withdrawal of authorization to participate in research shall not lead to any form of discrimination against the person concerned, in particular regarding the right to medical care.

The UK has not yet ratified this Convention, but it is likely that these guidelines will be seen as persuasive, and they should certainly be taken into account in the interests of best practice.

The same basic principles apply when consent is obtained for research studies as when consent is obtained for treatment or examination. The person must be given adequate information to enable them to understand the nature and purpose of the research and weigh up its risks and benefits, otherwise it will be invalid. However, consent can be difficult to achieve when the individual is already heavily burdened with complex information,<sup>46</sup> and even when people have given written consent they do not always remember that they did so.<sup>47</sup> Recollection of the information that they were given is often poor and their understanding of what they consented to may be incorrect.<sup>48</sup> For these reasons researchers should regard the process of seeking consent as ongoing throughout the duration of their involvement with any patient. They should maintain the child's and the parents' awareness that they are enrolled in a study, explaining any procedures, tests or treatments that are being used and making clear whether they are part of standard care or are being performed specifically for the purposes of the study.

Wherever possible, a reasonable amount of time should be allowed between informing a family about a research study and obtaining consent. This can be impracticable in some studies where interventions are performed under pressure of time, e.g. in the immediate newborn period. The child and family should be aware that they are free to withdraw from a study at any time without penalty. Important details about the study should be given in the form of a printed information sheet that the patient can keep, as well as being communicated verbally. Financial rewards should not be offered to families other than reasonable expenses. Pressure should not be exerted. If the child and family wish to know the final results of the research then these should be made available to them as soon as is practicable. There may be considerable delay in this if long-term follow-up requires blinding to be maintained.

Poorly designed research is unethical research. Peer review and statistical advice should be sought during study design. Often the results of studies can be disappointing, with no positive finding. It is still important to attempt to publish these studies to avoid others repeating the work and burdening future participants unnecessarily. Failure to publish negative results is an important source of bias in the literature. This has been made difficult by the competition for publication in a limited amount of journal space. With advances in technology this should lessen as electronic publishing will provide the space for studies that cannot compete successfully for mainstream scientific journal exposure.

A great deal of research is commercially sponsored.<sup>49</sup> As well as potentially affecting the outcomes of future patients, the results of such studies are economically important to individuals or companies. Clinicians entering into agreements to organize such studies should not do so if they are not given a say in the study design, access to the full data and freedom to publish the data, even if the results are not flattering to the product in question. At the time of submission for publication, authors should disclose all financial interests between themselves and others that might influence their work.

## MENTAL HEALTH CARE

When treating people for mental illness the same ethical principles apply as when treating others. The Mental Health Acts<sup>50,51</sup> describe statutory powers that allow patients to be detained in hospital and treated for mental illness in the interests of their own health. There is no specific statutory authority to treat physical disorders of those receiving treatment under the Mental Health Acts. Psychiatric treatment can proceed without consent where a patient has been compulsorily admitted under the relevant Act. Children or young people who have been detained under the Mental Health Acts have the right to a hearing either before a tribunal or, in Scotland, the Sheriff Court. The tribunal, or court, may order the discharge of a detained patient if the patient is found not to have a mental disorder of a nature or degree justifying detention in hospital. Alternatively, even if a disorder is present, discharge may be ordered if the detention is not justified in the interests of the patient's health or safety, or in order to protect others.

## A ROLE FOR ETHICS COMMITTEES?

Given the uncertainty faced by many caregivers in complex ethical and legal situations, some consider that there may be a role for institutional ethics committees to provide advice, education and support.<sup>52</sup> Doctors and nurses do not express widespread support for a decision-making role for such committees<sup>53</sup> and neither do parents.<sup>54</sup> In the UK, any medical decision made would remain the legal and professional responsibility of the doctor concerned. More work is required to establish the value of these committees. There is however, a clear need for better education of health care staff in the ethical and legal matters.<sup>53</sup> Further information about existing committees can be obtained from the UK Clinical Ethics Network website (<http://www.ethics-network.org.uk>).

## CONCLUSION

Treating children is a particularly complex area of the medical enterprise. Care should be taken to identify the child's best interests, to communicate carefully with the child (where possible) and the parents, and – where the child is sufficiently mature – serious and appropriate weight should be given to their views. The legal trend is increasingly to prioritize and respect autonomy, but children's autonomy and their best interests may sometimes appear to conflict. Resolving this tension requires careful and sensitive communication. In the event that no agreement can be reached, it may be necessary to seek legal advice, and even to involve the courts.

Report of the Independent Review Group on Retention of Organs at Post-Mortem, Edinburgh: Stationery Office; 2001

### GENERAL MEDICAL COUNCIL

Standards of practice on which ongoing professional registration within the United Kingdom depend are outlined on the General Medical Council web-site at <http://www.gmc-uk.org>. This site covers a broad range of issues including, duties of a doctor, good medical practice, medical research guidance, withholding and withdrawing treatment, confidentiality, consent, and guidance for doctors asked to circumcise male infants.

### BRITISH MEDICAL ASSOCIATION

Up-to-date information about the impact of the European Convention on Human Rights on medical practice within the UK can be obtained from the BMA web-site at <http://www.bma.org.uk>.

### HUMAN GENETICS COMMISSION

<http://www.hgc.gov.uk/Client/library.asp> Includes: 'Whose hands on your genes?' (November 2000) – A consultation document on the uses of human genetic information, followed by a report on this subject (May 2002).

### PATERNITY TESTING

Code of Practice and Guidance on Genetic Paternity Testing Services (Department of Health Guidance Document). This can be found on the Department of Health policy and guidance section <http://www.dh.gov.uk/PolicyAndGuidance/fs/en> website.

### PUBLICATION ETHICS

Guidelines on good publication practice have been published by the Committee on Publication Ethics. <http://www.publicationethics.org.uk>.

## PRENATAL SCREENING AND DIAGNOSIS OF CONGENITAL ABNORMALITIES

Congenital abnormalities occur in 3–4% of newborn infants and are responsible for between 10 and 15% of perinatal deaths and 30–40% of postneonatal deaths.<sup>1</sup> Even if not lethal, many congenital abnormalities cause significant long-term morbidity. The benefits of prenatal diagnosis include enhanced parental and neonatal preparedness and optimization of delivery. For those anomalies likely to be associated with death and/or significant disability, parents can be offered pregnancy termination. Antenatal screening for trisomy 21 receives much attention, but structural malformations account for 63% of therapeutic pregnancy terminations for fetal abnormalities.<sup>2</sup>

## MATERNAL SERUM SCREENING

Maternal serum screening (MSS) for trisomy 21 is carried out with a combination of maternal age and biochemical analytes. Measurements of alpha-fetoprotein (AFP) and human chorionic gonadotrophin (hCG) in the second trimester constitute the double test; the addition of unconjugated estriol ( $\mu\text{E3}$ ), or  $\mu\text{E3}$  and inhibin A make the triple and quadruple tests, respectively. The detection rates for trisomy 21 with the double (60%), triple (68%) and quadruple tests (79%) are all substantially greater than using maternal age alone. These test characteristics are based on a false-positive rate (FPR) of 5% and a threshold for offering invasive testing of 1 in 200–250.

More recently, pregnancy-associated plasma protein-A (PAPP-A) and hCG have been used as first trimester serum markers, with a detection rate of 63%. Combined first and second trimester serum screening (the serum integrated test) has been reported to give detection rates of about 85% with a false-positive rate of 2.7%.<sup>3</sup>

## ULTRASOUND

### FIRST TRIMESTER

#### Structural anomalies

First trimester anatomy screening identifies 32–65% of major structural abnormalities in low-risk populations, and 57–74% in high-risk cases. The anomalies that have been detected in the first trimester include anencephaly, holoprosencephaly, cystic hygroma, multicystic kidneys, megacystis and anterior abdominal wall defects.

#### Nuchal translucency

Screening with nuchal translucency (NT), measured as the maximum thickness of the subcutaneous tissue overlying the cervical spine at 11–14 weeks, identifies 74–82% of fetuses with trisomy 21 for a FPR of 5%. NT also acts as a marker for other trisomies (18, 13), sex chromosome abnormalities, syndromic disorders and structural abnormalities including cardiac defects (Table 11.1); in one large study 56% of the major cardiac anomalies occurred in fetuses with a NT above the 95th centile at 10–14 weeks' gestation.<sup>4</sup> Others have demonstrated that the prevalence of major cardiac defects in euploid fetuses with NT > 3.5 mm is 5–6%. However, the sensitivity of NT screening for cardiac abnormalities is low (15%). The overall chance of delivering a healthy infant declines with increasing NT; 86% at 3.5–4.4 mm, 77% at 4.5–5.4 mm, 67% at 5.5–6.4 mm, and less than 31% for an NT > 6.5 mm.<sup>5</sup>

Other first-trimester ultrasonographic markers for T21 include absence of the nasal bone, increased impedance to flow in the ductus venosus and tricuspid regurgitation. The incorporation of one or more of these markers into a screening program for T21 increases the first trimester detection rate to about 92–94%, for a FPR of about 2–3%.

Strategies incorporating first trimester ultrasonography have the additional benefits of providing parents with early reassurance and

**Table 11.1** Anomalies associated with nuchal translucency in euploid fetuses

Cardiac	Other structural
Tetralogy of Fallot	Diaphragmatic hernia
Hypoplastic left heart	Pentalogy of Cantrell
Transposition of the great arteries	Exomphalos
Coarctation of the aorta	Body stalk anomaly
Aortic stenosis or atresia	Caudal regression
Ventricular and atrioventricular septal defects	Achondrogenesis
Other complex cardiac defects	
Genetic syndrome	Other conditions
Mucopolysaccharidosis type VII	Homozygous alpha-thalassemia
Zellweger	Twin-twin transfusion syndrome
Spinal muscular atrophy	Parvovirus infection
Noonan	
Robinow	
Cleidocranial dysplasia	
Jarcho-Levin	

the early detection of nonviable and multiple pregnancies. It is perceived that termination of pregnancy in the first, as compared to the second trimester, is safer and less likely to result in psychological sequelae. Termination prior to 15 weeks of pregnancy can be carried out by suction aspiration, obviating the need for a medical procedure involving vaginal expulsion of the conceptus. However, recent evidence suggests that the emotional responses to termination for an abnormal fetus are independent of the gestational age and method of termination.<sup>6</sup> Other potential problems with early pregnancy screening include the narrow time interval for screening and diagnosis, the higher loss rate of chorionic villus sampling compared with amniocentesis, lack of pathological confirmation of diagnosis, and the high spontaneous loss rate in abnormal pregnancies (particularly trisomies and cystic hygroma).

## SECOND TRIMESTER

### Structural anomalies

Ultrasound screening between 18 and 20 weeks of pregnancy identifies 61–85% of fetal anomalies in low-risk populations.<sup>7–11</sup> The sensitivities for individual anomalies are shown in Table 11.2. Although one large trial<sup>12</sup> reported very poor detection rates (17%), subsequent analysis indicated that the low sensitivities were due in part to poor sonographer training. A recent meta-analysis of eight studies showed that, when compared with selective examination, routine second trimester screening is associated with earlier diagnosis of twin pregnancy and a reduced incidence of induction of labor for post-term pregnancy,<sup>13</sup> but no apparent benefit in terms of perinatal mortality. It is likely that this result is explained by the rarity of perinatal deaths (10 per 1000), variable detection rates, and some parents opting to continue their pregnancy even when a lethal anomaly is diagnosed.

### Markers of chromosomal anomalies

Many aneuploid fetuses exhibit major structural anomalies and/or minor findings of little or no functional significance (soft markers). For each soft marker, a likelihood ratio for aneuploidy is calculated from the ratio of the frequencies in affected and normal fetuses. Likelihood ratios (LRs) for potential ultrasound markers associated with trisomy 21 are shown in Table 11.3. Maternal age is used for the prior risk, and the risk factors applied sequentially when more than one is present. A normal scan without anomalies or soft markers reduces the risk for trisomy 21 by about 40–45% (i.e. LR 0.6).

CCAM, congenital cystic adenomatoid malformations.

## COMBINED SERUM AND ULTRASOUND SCREENING

### COMBINED TEST

Screening with a composite-adjusted risk derived from measurement of NT and maternal serum PAPP-A and hCG in the first trimester is known as the *combined test*. The detection rate for trisomy 21 is increased to about 85–89% for the same FPR of 5%. This test retains the perceived benefits of first trimester ultrasonography and early diagnosis.

**Table 11.3** Ultrasound markers for trisomy 21

Sonographic feature	Likelihood ratio for trisomy 21
Nuchal fold 6+ mm	10.0
Echogenic bowel	5.5
Short femur	2.5
Mild pyelectasis	1.5
Choroid plexus cyst	1.5
Sandal gap	1.5

## INTEGRATED TEST

The combination of multiple first and second trimester ultrasonographic and serum markers for trisomy 21 is known as the *integrated test*. Typically, this involves a composite adjusted risk based on first trimester NT, as well as first and second trimester serum screening. The multiplicity of markers involved in this form of screening is associated with test characteristics that are better than with any other form of screening; the detection rate for trisomy 21 is 95% for a FPR of 5%. Alternatively, FPRs can be reduced to <1% while maintaining sensitivity at ~85%.<sup>3</sup>

This screening strategy is referred to as *non-disclosure sequential screening*, and involves withholding results from women until the second trimester serum markers have been measured. There are, however, concerns that pregnant women and clinical staff might find the non-disclosure of high-risk first trimester results to be unacceptable, and a breach of patient autonomy by the denial of the perceived benefits of first-trimester screening.

## CONTINGENT SCREENING

These concerns about non-disclosure screening have led to the development of an alternative form of sequential screening, in which a first trimester test is used to triage the screened population into three groups: one group (high-risk screen positive) that is immediately offered a diagnostic test, a second group (screen negative) that receives no further screening, and a third group (intermediate risk) in which the first trimester results are reused in the second trimester as part of a subsequent integrated test. Theoretical modeling suggests that first-trimester completion is achievable in about 75% of women for a 30% early detection rate and a 55% second trimester detected rate (net 85%) with a false-positive rate only 0.1% above that achievable by the Integrated test.<sup>14</sup>

Contingent screening retains the perceived benefits for a substantial proportion of screened women, but there are concerns about the complexity of the test, and whether or not the real-life performance characteristics will match those demonstrated in modeled scenarios.

## SAFETY OF ULTRASOUND

Ultrasound induces the thermal effects and gas bubble formation (cavitation). There is no evidence of teratogenesis in humans despite the widespread use of prenatal ultrasound for more than 20 years. Newnham et al<sup>15</sup> reported that mothers exposed to five or more third-trimester ultrasound examinations delivered babies weighing about 25 g less than controls. These results have not been confirmed in other studies. Case-control or randomized, controlled studies have shown small but significant increases in speech problems, dyslexia, abnormal grasp, and non-right handedness.<sup>13</sup> However, there is little consistency between these studies, which are all prone to methodological problems including errors due to chance in multiple hypothesis testing.

## MANAGEMENT OF PRENATALLY DETECTED STRUCTURAL ANOMALIES

### PRINCIPLES OF MANAGEMENT

The prenatal diagnosis of a fetal malformation should prompt referral to a clinician with expertise in the antenatal management of such conditions. Regional fetal medicine centers have been established with core teams of experts specialized in ultrasonography, invasive assessment and intrauterine therapy. The initial management includes a detailed characterization of the malformation, as well as a thorough search for associated anomalies. Many structural anomalies are associated with an increased risk of chromosome abnormalities, and the management will usually include the offer of prenatal karyotyping. Parents are provided with considerate, empathetic and knowledgeable counseling based, wherever possible, on relevant prenatal literature. The prognosis

for lesions diagnosed during pregnancy is often very different from those diagnosed after delivery. A single clinician leads and coordinates this process, which often includes colleagues in genetics, neonatology and neonatal surgery. Decisions regarding further testing, surveillance during pregnancy, and the time and place of delivery are individualized according to the underlying problem.

Termination of pregnancy (TOP) in the UK is allowable at any gestation if there is a substantial risk of serious handicap. The interpretation of risk and handicap, and by implication the decision to offer termination of pregnancy, is presently at the discretion of the clinician(s) involved with the case. The Royal College of Obstetricians and Gynaecologists has issued guidelines recommending fetocide for TOPs after 22 weeks' gestation.<sup>16</sup>

## CENTRAL NERVOUS SYSTEM

### Ventriculomegaly

Ventriculomegaly (ventricular width  $\geq 10$  mm) describes dilatation of the lateral ventricles whereas hydrocephalus refers to a pathological increase in intracranial cerebrospinal fluid, which is usually associated with increased intracranial pressure and enlargement of the fetal head. Ventriculomegaly occurs in 0.05–0.3% of all pregnancies.

The causes of ventriculomegaly include constitutional increase in size, obstruction to the flow of fluid through the ventricular system, other central nervous system (CNS) anomalies (e.g. neural tube defects, hemorrhage, or migration defects), infection (cytomegalovirus, toxoplasmosis, adenovirus), genetic disorders and karyotype abnormalities (trisomies 21, 18 and 13, as well as triploidy and translocations). Associated anomalies are found in 70% of cases. Additional investigations should include fetal echocardiography, an infection screen, and the offer of invasive testing to determine the fetal karyotype. Consideration should be given to magnetic resonance imaging (MRI), which at gestations beyond 23 weeks has been claimed to provide additional information – particularly in the evaluation of the posterior fossa, midline structures (corpus callosum) and cortex. Examples of alterations to the diagnosis after MRI in cases with apparently nonspecific hydrocephalus include aqueductal stenosis, agenesis of the corpus callosum, migrational abnormalities, or late presenting Chiari II malformations.<sup>17,18</sup> There is uncertainty about the amount of useful additional information from MRI following ultrasonography by experienced specialists.

In general, the prognosis for fetuses with ventriculomegaly and other abnormalities is very poor. However, quantification of individual risk for adverse outcome when the underlying diagnosis is unclear can be difficult. The management and prognosis for fetuses with isolated ventriculomegaly are influenced by the severity of the ventricular dilatation.

### Mild/moderate ventriculomegaly

Ventricular widths between 10 and 15 mm are often subdivided into mild (ventricular width 10–12 mm) and moderate (12.1–14.9 mm) ventriculomegaly. About 2–3% of fetuses with apparently isolated mild/moderate ventriculomegaly will have a karyotype abnormality. If all investigations are normal, about 93–97% of surviving fetuses with mild ventriculomegaly will have a normal outcome,<sup>19</sup> but the chance of a normal outcome with moderate ventricular dilatation decreases to about 75–80%. It has been reported that neonatal survival to 2 years of age in fetuses with the antenatal diagnosis of moderate ventriculomegaly is about 80%.<sup>20</sup> Serial scans are undertaken throughout pregnancy to monitor the ventricular size. Resolution of the ventriculomegaly occurs in about one third of cases and increases the chance of a normal outcome.

### Severe ventriculomegaly

For severe ventriculomegaly (ventricular width  $\geq 15$  mm), the incidence of chromosome abnormalities is ~10%. With apparently isolated severe ventriculomegaly the neonatal/infant mortality rate is ~50%, with about 50% of surviving infants exhibiting abnormal neurodevelopment.<sup>21</sup> Where severity has been reported, about 20% were mildly affected and 80% moderate to severe. Postnatal ventriculoperitoneal

shunting is required in 60% of cases. For parents continuing their pregnancy, serial scans should be undertaken to monitor ventricular size. In cases with rapidly progressive disease and/or hydrocephalus, delivery should be considered as soon as fetal maturity can reasonably be assumed. There is no benefit from routine Cesarean section, but the macrocephaly can be severe enough to preclude vaginal delivery. In utero ventriculoperitoneal shunting does not improve outcome, and frequently results in intracranial hemorrhage with in utero demise. Cephalocentesis may be justified to avoid traumatic delivery but also has a very high mortality rate.

### Spina bifida

The incidence of neural tube defects in the UK has declined from 5.5 to 1.0 in 1000 over the last 20 years. Part of this reduction might be due to periconceptual folate supplementation, which reduces the incidence of neural tube defects by 75%.<sup>22</sup> The ultrasound features include widening of the spinal posterior ossification centers (dysraphism), a sacular protrusion and/or a defect in the overlying skin. Virtually all cases of myelomeningocele manifest cranial features including microcephaly, scalloping of the frontal bones (lemon sign), ventriculomegaly, obliteration of the cisterna magna and/or an absent or abnormally shaped cerebellum (banana sign) as a consequence of the Arnold–Chiari malformation. Associated anomalies occur in most other systems, but the commonest are urogenital anomalies (9%) including renal agenesis, horseshoe kidneys and ureteral duplications. Karyotype abnormalities, mainly trisomy 18, occur in 2% of apparently isolated cases.

There is a wide spectrum of outcomes for newborns with spina bifida – with the upper level of the lesion being the greatest determinant of eventual neurologic function. Infants with the prenatal diagnosis of a thoracic lesion are rarely ambulatory, whereas 90–100% of infants with a sacral or lower lumbar (L5) defect are ambulatory most of the time.<sup>23</sup> Mid-lumbar lesions are associated with ambulation in about 50% of cases.

The majority (60–70%) of infants with spina bifida will have a normal IQ, and even more (about 85%) will attend high school and/or college. Intellectual restriction in children with spina bifida is usually associated with complications of shunt placement, but recent data indicates that shunt placement is carried out less frequently than previously. About 70% of infants with sacral lesions require a shunt, with rates rising to about 90% with a lumbar, and 100% with thoracic lesions.

Continence problems are common, but about 75–85% of patients with spina bifida will achieve social continence using techniques such as clean intermittent catheterization.

There is concern that the counseling of parents following the diagnosis of spina bifida has been unduly pessimistic.<sup>24</sup> It is certainly true that some children will experience devastating sequelae, but many more will go on to have normal intelligence, reasonable ambulation and social continence.

### Agensis of the corpus callosum

Agensis of the corpus callosum (ACC) is found in 1 in 19 000 unselected autopsies and 2.3% of children with mental retardation. The corpus callosum can be identified with coronal ultrasound views after 20 weeks' gestation. However, these views are not part of the standard ultrasound scan, and it is likely that many cases are unrecognized. In low-risk cases, the diagnosis will only be made through identification of associated anatomic alterations including mild ventriculomegaly, absence of the cavum septum pellucidum, and enlargement or upward displacement of the third ventricle.

In total, 80% of cases are associated with other anomalies including hydrocephalus, Dandy–Walker syndrome, neuronal migration disorders and aneuploidy (trisomies 13 and 18). Normal outcome occurs in 85% of cases with apparently isolated ACC and in 13% of cases with additional scan abnormalities.<sup>25</sup>

### Holoprosencephaly

Holoprosencephaly is characterized by failed septation of the midline forebrain structures, and is frequently accompanied by midfacial abnor-

malities. The forebrain abnormalities are subdivided into lobar, semilobar, and alobar types according to increasing degree of failed septation. Population-based studies suggest a prevalence of 1.1 to 1.2 cases per 10 000 pregnancies.<sup>26</sup> Associated syndromic (including Smith–Lemli–Opitz, Hall–Pallister, pseudotrisomy 13, and Meckel) and structural anomalies are common. Trisomy 13, the most commonly identified cause, and other chromosomal abnormalities (trisomy 18 and rearrangements or deletions) account for nearly 50% of cases.

The prognosis is very poor; overall, about 70% of affected infants die within 1 year, and all diagnosed infants exhibit developmental delay, which is often severe. It is possible that individuals with subtle forms of undiagnosed lobar holoprosencephaly exist with little or no neurological abnormality. Even when a case of holoprosencephaly appears to be sporadic, the recurrence risk (13–14%) remains higher than with other major malformations. The high incidence of syndromic and subtle familial cases and the high recurrence rates emphasize the importance of full investigation and detailed postnatal counseling.

### Dandy–Walker malformation

Dandy–Walker malformation (DWM) describes agenesis or hypoplasia of the cerebellar vermis with communication between the fourth ventricle and the cisterna magna. Chromosome abnormalities are present in 15–45% of cases and around 45% have other CNS anomalies, including holoprosencephaly, ventriculomegaly and neuronal migration defects. Non CNS structural and syndromic anomalies are present in two thirds of cases. Prenatal series report a 40% risk of fetal or neonatal death and almost all reported survivors are symptomatic with developmental/motor delay, seizures and spasticity. It is possible that isolated DWM is associated with a lower risk of neurodevelopmental problems, but very few genuinely isolated cases have been reported.

## URINARY TRACT

### Hydronephrosis

Renal pelvic dilatation (RPD) is usually defined as an anteroposterior diameter of the renal pelvis of  $\geq 5.0$  mm in the second trimester and/or  $\geq 7.0$  mm in the third trimester. It affects 1% of pregnancies and is commoner in male fetuses. Using a threshold of 4 mm at 20 weeks of pregnancy increases the sensitivity for detecting significant nephrouropathy from 53% to 76% but increases the false-positive rate. Antenatal RPD can be a variant of normal or can be secondary to urinary tract pathology (pelviureteric junction obstruction [PUJO], vesicoureteric reflux [VUR], vesicoureteric junction obstruction, posterior urethral valves and obstruction in a duplex system).<sup>27</sup> Bladder and/or ureteric dilatation suggest the presence of lower urinary tract uropathy, but their absence does not exclude this possibility. The presence of caliectasis and parenchymal thinning is associated with an increased likelihood of obstruction.

### Mild/moderate renal pelvic dilatation

Mild second trimester RPD (5–10 mm) resolves during pregnancy in 66–80% of cases.<sup>27</sup> Significant nephrouropathies are more likely if RPD persists in the third trimester (40%) than if it resolves (12%)<sup>28</sup> and therefore a follow-up scan should be performed at 32 weeks' gestation. Progression from mild to severe ( $\geq 15$  mm) dilatation is uncommon (< 5% of cases). Most cases of pathology have a third trimester RPD  $\geq 10$  mm (sensitivity 80%, specificity 93%) with the exception of VUR, which occurs in 10–15% of cases even with mild RPD. Where RPD persists at 32 weeks, an ultrasound scan should be performed 3–7 d after delivery unless prenatal ultrasound findings suggest lower urinary tract obstruction where an earlier scan (24–48 h) is indicated.<sup>27</sup> Many units recommend antibiotic prophylaxis, as well as investigation for VUR for those babies with prenatal RPD because postnatal ultrasound is an unreliable modality for the detection of VUR. However reflux associated with mild RPD is usually low grade, found more often in males and has a high probability of resolving spontaneously. Increasingly the weight of published evidence suggests that routine micturating cystourethrography is no longer justified.<sup>27</sup> Few (< 3%) fetuses with fetal RPD < 15 mm will ultimately require surgery.<sup>27</sup>

### Severe Renal Pelvic Dilation (RDP)

Almost all fetuses with severe RPD (> 15 mm) will have significant renal pathology, most commonly PUJO. There is a relationship between severity of prenatal RPD and differential function in the obstructed kidney as assessed by MAG3 isotope renography. The requirement for pyeloplasty (based on differential function) increases with the extent of fetal RPD; 7% at 15–20 mm, 29% at 20–30 mm, 65% at 30–50 mm and 100% at > 50 mm.<sup>27</sup> The overall prognosis for fetuses with isolated unilateral dilatation is usually excellent. A more cautious approach needs to be taken with bilateral disease. Reduction or absence of amniotic fluid suggests severe renal dysfunction and a very poor prognosis. Serial scans should be undertaken to assess the degree of dilatation and amniotic fluid volume. Progressive dilatation and/or diminution of amniotic fluid volume near term (37 weeks) are indications for delivery.

### Renal agenesis

Unilateral renal agenesis occurs in 1 in 1000 pregnancies, and bilateral renal agenesis 1 in 4000. Bilateral renal agenesis is always associated with severe oligohydramnios from about 15 weeks' gestation. Earlier in pregnancy, a large proportion of the amniotic fluid originates from the fetal membranes. The differential diagnosis of severe oligohydramnios includes other causes of impaired urine production (bilateral multicystic kidney disease, urinary tract obstruction), fetal growth restriction and amniorrhesis. The sonographic demonstration of kidneys and bladder is very difficult in the absence of amniotic fluid. Transvaginal and color Doppler sonography may help but a definitive diagnosis often requires amnioinfusion and occasionally infusion of fluid into the fetal abdomen.

### Low urinary tract obstruction

Posterior urethral valves (PUVs) are the most common cause of severe lower urinary tract obstructive uropathy, occurring in 1 in 5000–8000 male fetuses. Ultrasonographic appearances include a dilated thick-walled bladder, a dilated posterior urethra, and oligohydramnios. The obstruction is classified as complete when there is anhydramnios, or incomplete when the amniotic fluid volume is normal or slightly reduced. The most important differential diagnosis is severe bilateral VUR producing the megacystis–megaureter association. However, with reflux, the bladder is often thin-walled and the liquor volume is normal. Urethral atresia can also lead to severe bladder dilatation and has a worse prognosis because of the associated cloacal anomalies. Associated abnormalities are seen in 43% of fetuses and include cardiac anomalies, bowel rotation, imperforate anus and vesicorectal fistula. Karyotype abnormalities occur in up to 8% of cases.

The prognosis for PUV is dependent on the degree of obstruction and the extent of renal dysplasia.

### Complete obstruction

Complete obstruction is associated with anhydramnios and a very poor prognosis as a consequence of renal dysplasia and pulmonary hypoplasia. Decompression of the dilated bladder with a vesicoamniotic shunt can increase amniotic fluid volume and protect the fetus from pulmonary hypoplasia. Shunt placement is only worthwhile in fetuses with satisfactory residual renal function, as assessed with ultrasonography and measurement of urinary electrolytes after vesicocentesis. Kidneys with bilateral cystic change will always be severely dysplastic. Normal ranges have been established for fetal urinary sodium, calcium, phosphate, osmolality and beta 2-microglobulin. In borderline cases, analysis of fresh urine from a repeat vesicocentesis after 2–3 d can provide more definitive results. With appropriate case selection, survival rates of 67% have been reported after vesicoamniotic shunt procedures.<sup>29</sup> A recent systematic review and meta-analysis concluded that bladder shunting improves perinatal survival in fetuses with lower urinary tract obstruction, particularly those with poor predicted prognoses.<sup>30</sup> The quality of evidence leading to this conclusion was, however, noted to be poor. The complications of shunt placement include chorioamnionitis, anterior abdominal wall defects, and fetal demise; the overall procedure-

related fetal loss rate is about 5%. Even when the shunt works satisfactorily, many fetuses develop renal dysplasia requiring renal support within the first year of life. A multi-centre randomized controlled trial comparing intra-uterine vesico-amniotic shunting vs. not shunting in the treatment of congenital bladder outflow obstruction is currently underway.

### Incomplete obstruction

Fetuses with no or mild oligohydramnios throughout pregnancy are protected from pulmonary hypoplasia and are very likely to survive. Some degree of renal dysplasia is common, but the severity is highly variable and difficult to predict. Vesicocentesis might be indicated in those fetuses with borderline amniotic fluid volume. Management during pregnancy should include serial scans to monitor amniotic fluid volume and renal appearances.

### Cystic kidney disease

Multicystic renal dysplasia is the commonest form of cystic kidney disease diagnosed in utero. Bilateral disease occurs in 23% of cases, and is characterized by paraspinal cystic masses, a nonvisible bladder, and severe oligohydramnios. Pulmonary hypoplasia is invariable resulting in neonatal death. The prognosis for unilateral disease is dependent on the presence of contralateral renal anomalies, which occur in up to 39% of cases and include renal agenesis, renal hypoplasia, pelviureteric junction obstruction and VUR. Reflux occurs in 15% of cases, but is not always apparent prenatally. If the contralateral kidney appears normal, and there are no apparent systemic anomalies, the prognosis is excellent. A further ultrasound scan should be carried out in the third trimester of pregnancy to monitor the size of the diseased kidney. Postnatal investigations should include a renal scan and a micturating cystourethrogram with antibiotic cover.

Autosomal recessive and dominant renal cystic disease are usually only diagnosed in cases with a family history. The management is individualized according to the underlying pathology and degree of in utero renal dysfunction as assessed from amniotic fluid volume. Specialist neonatal nephrologic advice is required.

## ABDOMINAL WALL

### Exomphalos

Exomphalos is an incomplete return of the abdominal contents into the abdominal cavity, which is complete by 11–12 weeks' gestation. The incidence is 1–3 per 1000 pregnancies. The lesion is highly variable in size and appears as an anterior extrusion of abdominal contents contained within a sac, which occasionally ruptures. The umbilical vein will be seen coursing through the sac, in contrast to a gastroschisis, where the cord insertion is intact. Other abnormalities are common. Cardiac malformations are seen in up to 50%, limb abnormalities in 30%, and karyotype abnormalities in 28–36%, mainly trisomy 18. The smaller umbilical hernias, and lesions diagnosed early in pregnancy (<15 weeks) are associated with even higher rates of aneuploidy. Associated genetic anomalies include the Beckwith–Wiedemann and de Lange syndromes.

Survival rates for isolated lesions are in excess of 90%, but some babies will require staged repairs and need to be in hospital for many weeks. Larger lesions are associated with reduced survival rates (~75%), as is the presence of additional abnormalities. Periodic ultrasound surveillance should be undertaken, but the incidence of complications such as bowel constriction is low. There is no merit in routine Cesarean section, but this might be justified for the very extensive lesions where the fetal liver is completely extruded.

### Gastroschisis

A gastroschisis is a herniation of the intra-abdominal contents through a defect in the abdominal wall, usually just to the right of the cord insertion. The ultrasonographic features include free loops of bowel floating in the amniotic fluid, associated with an intact cord insertion. Gastroschisis is not usually associated with other anomalies, but some studies have reported cardiac anomalies in up to 5% of cases. About

50% of fetuses will be small for gestational age (SGA), and there is an increased risk of hypoxic intrauterine death. Intestinal atresias or stenosis secondary to intestinal ischemia are reported in up to 30% of cases. Survival rates for isolated cases without liver herniation approach 95%. Management should include periodic surveillance during pregnancy to establish fetal size, growth, placental function and bowel status. Bowel luminal diameters of 11–17 mm have been associated with an increased incidence of bowel complications at surgery. Delivery should be in a unit with neonatal surgical facilities. There is no merit in routine Cesarean section.

## THORAX

### Diaphragmatic hernia

Left-sided congenital diaphragmatic hernia (CDH) is usually suspected when the fetal heart is displaced to the right side of the chest, and/or the stomach is seen in the thoracic cavity. If neither of these signs is evident, the diagnosis is often missed. The prenatal diagnosis of a right-sided CDH is especially difficult; the echogenicity patterns of the fetal lung, liver and small intestine are very similar. About 60% of CDHs evade prenatal diagnosis. Associated anomalies occur in 30% of cases, and include abnormalities of the cardiovascular, genitourinary, musculoskeletal, and central nervous systems, as well as aneuploidy (mainly trisomy 18) in 10–15% of cases. Reported survival rates for isolated lesions diagnosed in utero are 50–60% but this falls to 10% when there are coexistent anomalies. The prognosis is dependent on contralateral lung development, but ultrasound assessment of lung size and growth is imprecise. Early diagnosis, the presence of liver in the chest, hydramnios and hydrops are associated with a worse outcome. The ratio of fetal lung area to head circumference ratio (LHR) measured with ultrasonography at 22–28 weeks appears to be predictive of survival, but only in fetuses without intrathoracic herniation of the liver – ranging from 58% with a LHR < 1.0, to 89% with a LHR > 1.6.<sup>31</sup>

Management should include fetal echocardiography and ultrasound scans every 2 weeks during the third trimester to look for hydramnios and hydrops. Delivery should be in a unit with specialist neonatal and pediatric surgical facilities. There is no contraindication to vaginal delivery. The extent to which outcome can be improved with prenatal surgery remains to be determined.

### Cystic adenomatoid malformation

Congenital cystic adenomatoid malformations (CCAMs) are classified on the basis of ultrasound appearances as macrocystic (type 1), mixed (type 2) or microcystic (type 3). Microcystic lesions appear predominantly echogenic, whereas macrocystic lesions contain one or more unilocular cysts. The differential diagnosis includes CDH, pulmonary sequestration, and bronchial atresia. In difficult cases, intrathoracic instillation of fluid helps differentiate a CDH. Doppler color flow imaging may visualize a direct vascular connection to the aorta in sequestration. Associated anomalies are rare but hydrops can occur as a result of distortion of the thoracic great arteries/veins, or myocardial dysfunction.

The prognosis for a CCAM in the absence of hydrops is very favorable. In about 20–30% of cases, there is partial or apparently complete resolution of the lesion in utero. Ultrasound scans should be performed every 4 weeks to exclude hydrops, but this rarely develops if it is not present at diagnosis. The place of delivery can be decided according to the size of the lesion. The prognosis for fetuses with hydrops is much less favorable. However, even when hydrops is present in early pregnancy, serial scans have documented apparent shrinkage and resolution of the lesion with disappearance of the hydrops.

## GASTROINTESTINAL ABNORMALITIES

### Duodenal atresia

Duodenal atresia affects 1 in 5000 pregnancies. The typical ultrasonographic appearances include a 'double-bubble', with the stomach and dilated duodenum forming similarly sized and connected fluid-filled

structures, and hydramnios, which can predispose to premature labor. The diagnosis is not usually evident before the end of the second trimester. Associated anomalies include vertebral defects, imperforate anus, tracheoesophageal fistula with esophageal atresia, and radial and renal dysplasia (complex) (VATER) association and trisomy 21, which is present in 30% of cases. The prognosis for fetuses with isolated duodenal atresia is very good. Regular ultrasound surveillance should be carried out to monitor amniotic fluid volume. Hydramnios can be severe and warrant amnioreduction.

### Other bowel obstruction

The appearance of multiple fluid-filled bowel loops suggests small bowel obstruction. Precise localization of the obstruction is not possible, but the greater the number of dilated bowel loops and the greater the dilatation, the more distal the atresia. Conversely the greater the volume of amniotic fluid, the more proximal the obstruction. Associated anomalies external to the gut are uncommon. The prognosis is usually excellent, but the outlook needs to be more guarded when multiple atresias are suspected. Serial ultrasound scans are performed to monitor amniotic fluid volume. Amnioreduction is occasionally required.

### Meconium ileus

Meconium ileus should be suspected when the bowel is dilated and hyperechogenic. Virtually all cases are due to cystic fibrosis, which can usually be confirmed with parental and fetal genotyping. About 98% of the cystic fibrosis gene mutations have been characterized and can be identified with DNA studies. The immediate prognosis for meconium ileus is good, but the longer term prognosis is determined by the underlying condition.

## CARDIAC ABNORMALITIES

Congenital heart disease occurs in 0.4–1.0% of live births and accounts for 35% of infant deaths secondary to congenital disease. Screening using the four-chamber view of the fetal heart will detect about 20% of cardiac abnormalities. Sensitivity is increased by incorporating views of the arterial connections. Chromosomal anomalies have been reported in up to 30% of fetuses with prenatally detected heart disease; trisomy 18 is detected as frequently as trisomy 21, with Turner syndrome the next most common. Karyotype analysis should include a search for microdeletions localized to the long arm of chromosome 22 (22q11), which result in DiGeorge syndrome.

A detailed discussion about the diagnosis and management of the individual cardiac abnormalities amenable to prenatal diagnosis is outwith the scope of this chapter. Interested readers are referred to Allan et al.<sup>32</sup> The prognosis for malformations detected with prenatal ultrasonography is usually worse than for those first seen after delivery. Counseling should be undertaken by clinicians specializing in the field of prenatal echocardiography.

## SKELETAL DYSPLASIAS

The commonest lethal skeletal dysplasia seen prenatally is thanatophoric dysplasia with an incidence of 1 in 10 000 births. Other lethal dysplasias include achondrogenesis (1 in 40 000 births) and osteogenesis imperfecta (1 in 55 000). The prenatal diagnosis of skeletal dysplasias is complex and beyond the scope of this chapter. Interested readers are referred to Griffin.<sup>33</sup> Frequently the precise diagnosis is not made until after delivery or autopsy. The lethal anomalies can usually be identified by either severe micromelia (long bone lengths > 4 SDs below the mean for gestation), narrow chest dimensions, or associated anomalies.

## INVASIVE PROCEDURES AND FETAL SURGERY

The commonest indication for invasive testing is to establish the fetal karyotype in situations of high risk such as advanced maternal age,

abnormal MSS or the ultrasonographic visualization of anomalies or soft markers. The number of monogenic disorders amenable to prenatal diagnosis by polymerase chain reaction (PCR) analysis of DNA is increasing rapidly, and has virtually replaced diagnosis by enzyme assay. Other indications include suspected fetal infection and alloimmunization.

All invasive procedures should be performed with real-time ultrasound guidance by appropriately trained and experienced operators. The Royal College of Obstetricians and Gynaecologists has recently issued guidelines suggesting that operators should undertake a minimum of 30 amniocenteses a year in order to maintain skills.<sup>34</sup>

## AMNIOCENTESIS

Amniocentesis can be carried out from 15 weeks' gestation onwards. Early (11–14 weeks) amniocentesis is more hazardous than either chorionic villus sampling (CVS) or second trimester amniocentesis.<sup>35</sup> The cells in the amniotic fluid are mostly in interphase, and are prepared for metaphase analysis by culture in flasks for 2–3 weeks. More rapid culture on cover slips reduces reporting time to 7–10 days, but is more costly. Rapid detection of trisomy 21 and other trisomies is possible with quantitative PCR, but the information provided is probe specific.

The only randomized, controlled study of pregnancy outcomes following amniocentesis reported a procedure-related loss rate before viability of 1%.<sup>36</sup> Procedure-related losses occur up to 6 weeks after the test, but the maximal risk appears to be within 1–2 weeks. Experienced operators have lower complication rates; those undertaking < 50 procedures in 3 years had a single pass success rate of 82% compared with 93% for those carrying out > 50 procedures.<sup>37</sup> It is likely that the majority of losses occur as a result of infection.

## CHORIONIC VILLUS SAMPLING

CVS in the first trimester of pregnancy can be performed transabdominally or transcervically using biopsy forceps or aspiration. Direct chromosome preparations from the cytotrophoblast provide provisional information about the fetal karyotype within 48 h. Rapid culture of the mesenchymal core allows full cytogenetic analysis using G-banding and also obviates diagnostic errors due to mosaicism in the fetus and/or placenta (see later). Chorionic villi are also an excellent source of DNA, supplying sufficient amounts for most molecular genetic techniques without prior culture. It is recommended that CVS is performed after 10 weeks of pregnancy when there is no increased risk of severe limb deficiencies and the hypoglossia/hypodactyly syndrome. Transabdominal placental sampling can also be performed in the second and third trimesters, but is more prone to failure as a result of reduced mitotic activity of the cytotrophoblast.

Meta-analysis of three randomized trials<sup>38</sup> showed pregnancy loss rates before viability to be significantly greater following first trimester CVS compared to midtrimester amniocentesis (odds ratio [OR] 1.37, 95% confidence interval [CI] 1.18–1.60.) However, a large number of the CVS procedures were carried out using a transcervical approach, which is associated with a higher incidence of procedure-related miscarriage.

Diagnostic errors can occur due to confined placental mosaicism (CPM), where aneuploid cells (mosaic and rarely nonmosaic) occur in the placenta but not in the fetus. In one large series, mosaicism was present in 30 (1.2%) of 2483 CVS cases.<sup>39</sup> Confined placental mosaicism within the cytotrophoblast will be apparent in the direct preparation, but not the longer term mesoderm culture. For those cases where the long-term culture confirms the mosaicism, or shows mosaicism not found on direct analysis, further investigation is warranted with either detailed ultrasonography, amniocentesis, fetal blood sample or skin biopsy. The input of genetics experts is essential to the management of couples in this very difficult situation.

## FETAL BLOOD SAMPLING BEFORE LABOR

Fetal blood can be obtained from the umbilical vein, the intrahepatic vein, or the heart from about 18 weeks' gestation onwards. The main

indications for fetal blood sampling are urgent fetal karyotyping after 18 weeks and measurement of hematologic parameters in fetuses at risk of alloimmune anemia or thrombocytopenia. Other indications include suspected fetal infection, later pregnancy DNA analysis, and investigation of mosaic results from either amniocentesis or CVS.

The post-procedure pregnancy loss rate following fetal blood sampling is about 1%. Loss rates are related to the indication for sampling; in one study loss rate was 1.5% for prenatal diagnostic procedures, 14% for fetuses with suspected placental dysfunction and 25% for fetuses with fetal hydrops.<sup>40</sup>

## OTHER TISSUE BIOPSIES

Fetal skin biopsies are performed for suspected dermatological disorders such as harlequin ichthyosis or congenital bullous epidermolysis. Skin biopsies are also potentially useful in the investigation of fetuses with a suspected mosaic karyotype. Fetal liver and muscle biopsies have also been reported, but there are few indications.

## FETAL SURGERY

Despite many advances in prenatal diagnosis, the fetus remains inaccessible. Established in utero therapeutic procedures include transabdominal intravascular transfusion of red cells or platelets, as well as placement of pleuroamniotic and vesicoamniotic shunts. The transplacental route is used for the delivery of antiarrhythmic agents for the treatment of complex cardiac arrhythmias.

The desire to perform more complex surgical treatments led to the development of open fetal surgery for conditions such as CDH, sacrococcygeal teratoma, CCAM of the lungs and obstructive uropathies. In severe form these conditions have a very poor prognosis due in part to progressive organ damage throughout the second trimester. In open surgery, the fetus is partially extracted, undergoes surgery, and is then returned to the amniotic cavity. Success rates have been severely limited by the high incidence of preterm labor, premature rupture of membranes and placental abruption. The median interval between surgery and delivery is 4 weeks with a median gestational age at delivery of only 25 weeks.

Endoscopic fetal surgery is less traumatic to the uterus and membranes, and is associated with fewer complications. In a series of 15 fetal endoscopic tracheal occlusion (FETO) procedures for severe CDH, only two mothers (13%) delivered within 2 weeks of surgery.<sup>41</sup> Prenatal tracheal occlusion obstructs the normal egress of lung fluid, increases transpulmonary pressure, leading to enhanced lung growth. The ability to predict outcome by measurement of the lung:head ratio (LHR) in fetuses with severe CDH has been used to select cases more likely to benefit from FETO; in a recent series, neonatal survival following FETO when the LHR was < 1.0 was 57%, as compared with 11% with an expectant approach.<sup>42</sup>

Other possible indications for endoscopic fetal surgery include amniotic bands and obstructive uropathies. Fetal surgery is an intriguing future development, but rigorous assessment is required before these techniques become more widely available.

## ASSESSMENT OF FETAL SIZE AND WELL-BEING

### DEFINITIONS

Perinatal mortality and morbidity are linked not only to gestational age but also to fetal growth. Screening previously focused on the detection of the small fetus but obstetricians now appreciate the differences between size and growth. Size is an endpoint, typically weight at birth, whereas growth is the process by which this endpoint is reached. Size is determined by a combination of local factors in tissues and organs, together with systemic nutritional and endocrine factors. Genetic influences, which are the primary determinant of fetal size, probably act primarily at the local level.

'Small for gestational age' refers to a fetus that is below a specific weight or anthropometric threshold. The commonly used thresholds for clinical and ultrasonic measurements are the 10th and 5th centiles. Approximately 40% of SGA infants are growth restricted as assessed by morphometric measures of wasting (ponderal index, midarm to head circumference [MAC:HC] ratio, skinfold thickness). These fetuses have failed to achieve their genetically programmed growth potential usually because of placental dysfunction and/or maternal disease. The remainder of SGA infants are thought to be constitutionally small.

SGA fetuses are at greater risk of stillbirth, acidemia at birth, low Apgar scores, neonatal complications, neurodevelopmental impairment as well as non-insulin-dependent diabetes and hypertension in later life. They are therefore the single largest group of fetuses tested for well-being. The reason that studies of SGA infants have shown poor perinatal outcome is likely to be due to the high incidence of true fetal growth restriction (FGR) in this group. Morbidity is much commoner in SGA infants with evidence of wasting and there is little evidence that small infants who reach term without evidence of growth restriction are at increased perinatal risk.<sup>43</sup>

### ETIOLOGY OF FETAL GROWTH RESTRICTION (FGR)

The etiology of FGR is diverse but can be broadly classified according to the site of the primary pathology (Fig. 11.1). Some factors (e.g. maternal smoking) may affect fetal growth through several mechanisms. Genetic alterations associated with FGR can be divided into chromosomal anomalies, CPM and syndromes. Overall 4–7% of SGA fetuses will be aneuploid, the commonest abnormalities being triploidy and trisomies 13, 18 and 21. In CPM two or more cell lines with different karyotypes are present, both being derived from the same zygote. Cytogenetic abnormalities restricted to the placenta that have been associated with FGR include trisomy 16, trisomy 22 and trisomy 9. Growth restriction is also part of the phenotype of a large number of syndromes, some of which involve a primary disturbance of bone growth (e.g. osteogenesis imperfecta) and others associated with generalized (proportionate) reduction in body growth (e.g. Silver–Russell syndrome).

Congenital viral infection probably accounts for up to 5% of FGR. A causal relationship is clear for cytomegalovirus and rubella virus but probably also exists for varicella-zoster and human immunodeficiency viruses.

Abnormalities of uteroplacental perfusion and stem artery structure underlie a significant proportion of preterm FGR. Failure of extravillous trophoblast invasion and spiral artery transformation, leading to

placental ischemia, is generally associated with maternal pre-eclampsia. However identical changes can be seen in the myometrial spiral arteries of 60–80% of growth-restricted fetuses born to women without hypertension.

### SCREENING AND DIAGNOSIS OF SGA/FGR

#### Clinical assessment

Methods of detecting SGA fetuses include antenatal clinical examination, measurement of symphysis-fundal height (SFH), fetal anthropometry and ultrasound estimated fetal weight (EFW). All measurements require an accurate estimation of gestational age based on fetal crown–rump length prior to 13 weeks' gestation or fetal head circumference between 16 and 24 weeks' gestation (95% prediction interval  $\pm$  5 d).

Abdominal palpation remains a routine part of obstetric examination, despite the fact that the sensitivity for detection of a SGA infant is only 20–30% and the positive predictive value (PPV) no greater than 40%. Measurement of SFH is an alternative but a systematic review, which identified only one controlled trial which showed that SFH measurement did not improve perinatal outcome.<sup>44</sup> Serial SFH measurements may improve sensitivity and specificity as may the use of customized SFH charts. The customized antenatal growth chart displays computer generated curves for fetal weight and SFH, adjusted for physiological variables (maternal height, weight at booking, parity and ethnic group). One controlled trial has shown that use of customized charts improved detection rate of SGA infants (48% versus 29%, OR 2.2 [95% CI 1.1–4.5]) and reduced the number of women admitted (OR 0.6, 95% CI 0.4–0.7).<sup>45</sup> SFH should be measured at each antenatal assessment after 24 weeks of pregnancy. Ultrasound assessment is indicated if the SFH falls below the 10th centile.

#### Ultrasound anthropometry

A large number of ultrasonic anthropometric measurements have been used to predict fetal size but abdominal circumference (AC) and EFW are the most accurate.<sup>46</sup> Fetal AC is measured at the level of the hepatic vein. Fetal weight can be calculated from a variety of formulae incorporating routine ultrasonic anthropometric measurements (AC, BPD, HC and femur length [FL]). Systematic review suggests that an AC < 10th centile has the highest sensitivity, predicting 84% of SGA infants in high-risk women with an overall OR of 18 (95% CI <10–34).<sup>46</sup> Reported sensitivities for EFW < 10th centile are lower and more variable (33–89%) although the overall OR is higher (39 [95% CI 29–52]). FPRs are comparable (20–25%) but can be reduced by the use of customized

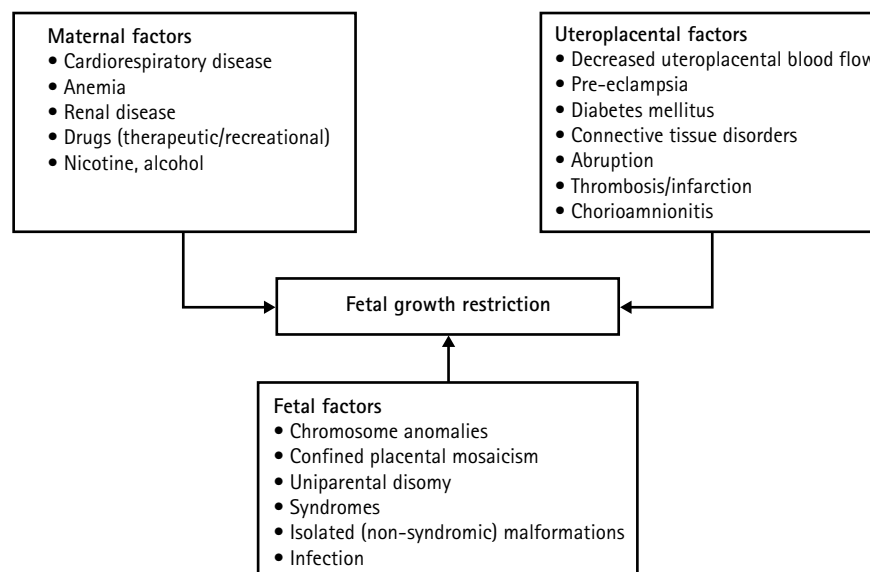

Fig. 11.1 Etiology of fetal growth restriction according to site of primary pathology.

ultrasound charts which adjust for physiological variables; in one study 27.5% of cases classified as SGA using an unadjusted EFW < 10th centile were reclassified as appropriate for gestational age (AGA) using the customized cut-off.<sup>47</sup> Fetuses identified as small by customized charts are more likely to suffer adverse perinatal outcome; the OR for stillbirth was 6.1 (95% CI 5.0–7.5) for fetuses classified as SGA by customized charts but AGA by population charts compared with 1.2 (CI 0.8, 1.9) for those classified as SGA by population charts but normal by customized charts.<sup>48</sup> Fetal anthropometric ratios (e.g. HC:AC and FL:AC) are less predictive of SGA than AC or EFW and there is no evidence that disproportion adds to the prognostic significance over and above the severity of growth restriction.

Despite the evidence that ultrasound anthropometry is effective at detecting small fetuses, there is no evidence that routine late pregnancy ultrasound in low-risk or unselected women confers benefit to mother or baby; systematic review of seven randomized trials (25 000 women) suggests that, while screened women are less likely to deliver post-term (OR 0.69 [95% CI 0.58–0.81]), perinatal mortality is no different (OR 1.12 [95% CI 0.75–1.68]).<sup>49</sup> Most of these studies investigated the value of a one-off measurement of size rather than the trend (reflecting growth) and none included umbilical artery Doppler (see later).

Reference charts of AC and EFW, derived from longitudinally collected measurements, can be used to assess fetal growth. Several studies have confirmed that serial measurements of AC and EFW are superior to single estimates in the prediction of wasting at birth and perinatal morbidity; a change in EFW SD (z) score of  $\geq -1.5$  detects 80% of babies with an abnormal MAC:HC ratio (OR 14.6 [95% CI 2.8–76.5]) and 54% of babies with suboptimal neonatal outcome (OR 3.6 [95% CI 1.3–9.5]).<sup>50</sup> Where growth restriction is suspected, measurements of size should be performed every 2 weeks as shorter intervals increase the FPR.

### Uterine artery doppler

Because of the association between abnormal placentation and FGR, there has been considerable interest in the ability of uterine artery Doppler to predict FGR. Uterine arteries can be readily identified trans-abdominally with color flow Doppler and reproducible waveforms obtained by pulsed Doppler. A positive test (defined as an abnormal waveform ratio and/or a diastolic notch) between 20 and 24 weeks predicts pre-eclampsia, FGR and perinatal death in low- and high-risk populations. A recent systematic review of 74 studies found a sensitivity and specificity for predicting FGR in a low-risk population of 33% (95% CI 26–40) and 91% (95% CI 87–94). Sensitivity increased to 69% (95% CI 54–83) in a high-risk population while specificity fell (69% [95% CI 46–90]).<sup>51</sup> More importantly the test is more predictive of FGR necessitating delivery before 34 weeks' gestation (LRs > 5). In one screening study, 14% of fetuses where the mother had an abnormal uterine artery waveform (pulsatility index > 95th centile) developed FGR (fetal AC < 5th centile) and, of this group, 40% required delivery < 34 weeks.<sup>52</sup>

There is also accumulating evidence that several of the analytes used in maternal serum screening for Down syndrome (e.g. PAPP-A, hCG, AFP and uE3) can also be used to screen for FGR, pre-eclampsia and adverse perinatal outcome. Thus in the future it may be possible to offer multiparameter screening for 'poor placentation' between 12 and 24 weeks.

## ASSESSMENT OF FETAL WELL-BEING

### Principles

Fetal death from hypoxic ischemia may occur acutely, as a result of a sudden insult (e.g. cord accident or placental abruption), or may be the result of chronic placental dysfunction. In the latter case, FGR (but not necessarily SGA) is invariably present. Current understanding of the adaptive responses and consequences of progressive fetal hypoxemia is primarily derived from animal studies but antenatal fetal blood sampling has provided important insights into human FGR. In the face of progres-

sive hypoxemia (fetal  $pO_2$  > 2 SDs below mean for gestation) the fetus makes a number of circulatory and metabolic adaptations to optimize the available oxygen and nutrient supply. With progressive placental insufficiency the fetus becomes acidemic (pH > 2 SDs below mean for gestation) and ultimately suffers end-organ damage prior to death. Up to 40% of severely growth restricted fetuses (AC > 2 SDs below the mean for gestation) are acidemic. This is an important outcome as there is evidence that chronic fetal acidemia is associated with reduced neurodevelopmental outcome as assessed by Griffiths neurodevelopmental quotient at a mean age of 29 (range 12–52) months.<sup>52</sup>

A number of biophysical tests are available to assess fetal well-being. These include fetal Doppler arterial and venous flow velocity waveforms, cardiotocography (CTG), amniotic fluid volume (AFV) and the biophysical profile score (BPS). For many of these tests the relationship between test result and antenatal hypoxemia/acidemia has been defined, thereby obviating the need for fetal blood sampling, which carries a significant risk in FGR. In this context a normal test result implies the absence of acidemia and therefore fetal well-being. As the only effective intervention available to the obstetrician is delivery, the presence of fetal well-being justifies expectant management, at least prior to term, unless there is coexistent maternal disease necessitating delivery. When the test is abnormal, the likelihood of acidemia and the risk of end-organ damage/death with further expectant management have to be balanced against the risks of premature delivery.

### Umbilical artery doppler

Reproducible Doppler velocity waveforms can be obtained from the umbilical artery (UA) using pulsed Doppler. A variety of descriptive indices have been used to characterize the waveform including pulsatility index (PI), resistance index and systolic:diastolic ratio. Mean PI declines during pregnancy with the 95th centile value falling from around 2.0 at 20 weeks to 1.4 at term. Waveform indices are independent of the angle of ultrasound insonation and reflect downstream blood flow resistance. With progressive placental damage and vascular occlusion, PI increases and in some cases this may progress to absent or even reversed end-diastolic velocities (A/R EDV). Between 40% and 45% of fetuses with an elevated PI (but EDV present) are hypoxemic and 20–30% are acidemic. In contrast 80–90% of fetuses with AEDV are hypoxemic and 45–80% are acidemic. Loss of EDV is a key finding, which has a profound impact on outcome and management. Overall perinatal mortality in this group is around 40%,<sup>53</sup> justifying delivery on this finding alone after 32 weeks' gestation and possibly earlier.

Systematic review of randomized trials in high-risk pregnancies (mainly in association with hypertensive disorders and FGR) has indicated that management based on UA Doppler significantly improves important obstetric outcomes, including fewer admissions (OR 0.56 [95% CI 0.42–0.72]) and fewer labor inductions (OR 0.83 [95% CI 0.74–0.93]).<sup>54</sup> There was also a trend to reducing perinatal mortality (OR 0.71 [95% CI 0.50–1.01]). There is also evidence that UA Doppler is superior to CTG and the BPS in predicting outcome in SGA fetuses and that it reduces use of resources.<sup>55</sup> Thus UA Doppler should be the primary mode of fetal monitoring in the high-risk fetus. Screening low-risk fetuses by UA Doppler however does not reduce perinatal mortality or morbidity and is not recommended.

Fetuses with a normal UA Doppler and normal anatomy can be managed as a 'normal small fetus'; in this group twice-weekly monitoring results in earlier deliveries and more inductions of labor than fortnightly monitoring without any difference in neonatal morbidity.<sup>56</sup> Thus, in the absence of maternal hypertension, provided UA Doppler and fetal growth remain normal fortnightly surveillance can be maintained until delivery. Fetuses with abnormal UA Doppler, especially those with A/R EDV, require more intensive surveillance. The average interval between loss of EDV in the UA and the development of a terminal CTG is 7 d, although the range is wide (1 d to more than 4 weeks). Gestational age > 30 weeks, the presence of maternal hypertension and Doppler venous abnormalities are associated with a reduced interval. The optimal monitoring strategy in this group is unclear and may involve targeted fetal

Doppler (arterial and venous), BPS or both. Quality randomized trials are urgently needed in this area.

### Fetal arterial and venous doppler

Redistribution of cardiac output to the cerebral circulation is one of the earliest signs of hypoxemia. This is reflected by an increase in the umbilical artery:middle cerebral artery (MCA) PI ratio to greater than 1 (~95th centile) or a decrease in the middle cerebral artery PI. Despite being a sensitive indicator of hypoxemia, there is no evidence that MCA Doppler is a better predictor of adverse outcome than UA Doppler. However the absence of cranial redistribution may provide better negative prediction in the preterm fetus; when gestational age at first Doppler was less than 32 weeks, the MCA PI had a sensitivity of 95.5% and a negative predictive value of 97.7% (negative LR 0.10) for major adverse outcome (death, neurological complications and necrotizing enterocolitis).<sup>57</sup> Compared to fetuses without cranial redistribution, those with cerebral sparing appear to have no long-term adverse neurodevelopmental effects although larger follow-up studies are needed.

Fetal venous Doppler abnormalities generally follow loss of EDV in the UA and are thought to reflect ventricular function and, to a lesser extent, cardiac afterload. Waveforms from the ductus venosus (DV) show a systolic and a diastolic peak followed by a trough ('a' wave) related to atrial contraction. With increasing hypoxemia, the 'a' wave decreases and then reverses and pulsations may be evident in the umbilical vein (UV); 90% of fetuses with these findings are acidemic and they have the highest sensitivity for perinatal death and serious morbidity.<sup>58</sup> In fetuses with loss or reversal of EDV in the UA, abnormal DV Doppler waveforms and gestational age at delivery show the strongest association with perinatal death.<sup>59</sup> Perinatal mortality in this group is increased by 20–25% in the presence of abnormal DV waveforms.<sup>58,59</sup> Hence many authorities regard reversal of the DV 'a' wave and/or UV pulsations as indications for delivery irrespective of biophysical parameters. As myocardial function worsens, tricuspid valve regurgitation may appear and there may be a loss of brain sparing with normalization of the MCA PI. These are pre-terminal events and fetal death is likely within 48 h.

### Biophysical profile scoring (BPS)

The BPS incorporates CTG, AFV and three dynamic ultrasound variables (fetal movement, fetal breathing and fetal tone). Each component is scored 0 (abnormal) or 2 (normal). A total score of 8 or 10 is normal and excludes acidemia.<sup>60</sup> Perinatal mortality within 7 d of a normal BPS is  $\leq 1$  per 1000 and no test has a lower false-negative rate. Scores of 4 or less are regarded as abnormal; > 90% of fetuses will be acidemic and 50% will have an umbilical vein pH < 7.25. Adverse outcome increases with declining score: perinatal mortality increases from 12.5% with a score of 4 to 100% with a score of 0 without intervention (and 43% despite intervention), while the rate of cerebral palsy increases from ~2 to 25% respectively.<sup>60</sup> A score of 6 is equivocal necessitating repeat testing, usually within 12–24 h. Systematic review of four poor-quality studies (fewer than 3000 subjects) indicates that BPS does not improve perinatal outcome but insufficient data are available to assess the true value of the test.<sup>61</sup> Given the absence of benefit from randomized trials and that the BPS is a time-consuming test, it is not recommended for primary surveillance in high-risk fetuses. However, based on the results of observational studies, BPS may have a role in monitoring preterm fetuses with A/R EDF in the UA when a normal score allows continued expectant management. In the authors' large series of 137 fetuses with growth restriction and A/R EDF monitored with daily BPS, in utero demise in actively managed cases (i.e. where delivery in the fetal interests was offered) was 4%.<sup>62</sup>

CTG and AFV have been used in isolation as tests of fetal well-being although there is little evidence to support this. The CTG records autonomic reflexes superimposed on intrinsic cardiac activity. In addition to the baseline fetal heart rate (FHR) and variability, the CTG records periodic changes (accelerations and decelerations). Two 15 b.p.m. accelerations lasting  $\geq 15$  s in a 20-minute period are regarded as reassuring. Preterm

accelerations are less marked. Unlike the BPS where only 0.7% of tests are abnormal (score  $\leq 4$ ) and 1.7% are equivocal, up to 15% of CTGs will be nonreassuring. This proportion increases as gestation declines. A nonreassuring CTG is a poor predictor of perinatal death within 7 d (< 10%). The features most predictive of acidemia are reduced FHR variability (< 5 b.p.m.) and decelerations (positive predictive value 65% and 75%, respectively). When both are present (so-called 'terminal' CTG), the overall mortality rate is around 45%. Use of CTG in high-risk pregnancies is not associated with better perinatal outcome; in fact systematic review of four randomized trials showed a trend towards increasing perinatal mortality in the CTG group (OR 2.85, 95% CI 0.99–7.12).<sup>63</sup> Computerized analysis of the CTG provides a more objective measure of FHR variability; several parameters have been studied but the short-term variability (STV) appears to be the most useful; around 60% of fetuses with a STV < 3.5 ms are acidemic. Computer systems have been shown to be more accurate predictors of umbilical acidemia than clinical experts but it is unclear whether use of this technology (as opposed to visual analysis) improves perinatal outcome.

There are many definitions for reduced AFV but the two most widely accepted are a maximum vertical pocket < 2 cm or a four-quadrant amniotic fluid index (AFI) < 5 cm. Both correlate very poorly with actual AFV and neither accurately predicts perinatal outcome. Systematic review of 18 studies indicated that an AFI < 5 cm was associated with an increased risk of Cesarean section for fetal distress (relative risk [RR] 2.2, 95% CI 1.5–3.4) and Apgar score < 7 at 5 min (RR 5.2, 95% CI 2.4–11.3),<sup>64</sup> but not with neonatal acidosis. Large observational studies have shown an association between reduced AFV and perinatal mortality but the predictive value is poor (< 10%). There is little evidence to support intervention with isolated oligohydramnios when the UA Doppler is normal.

The sequence and timing of circulatory changes in FGR with progressive hypoxemia/acidemia have been determined and are summarized in Figure 11.2. In a serial study of preterm growth-restricted fetuses, 73% showed this pattern of Doppler deterioration prior to emergency delivery (median gestation of 30 weeks) for a BPS of  $\leq 6$ .<sup>65</sup> In the majority, Doppler deterioration was confined to the week prior to delivery, was most marked for the UA and DV and was complete 24 h before BPS decline. The decline in BPS typically involved cessation of breathing movements 2–3 d before delivery, followed by a decline in AFV and then a loss of fetal movement and tone on the day of delivery.

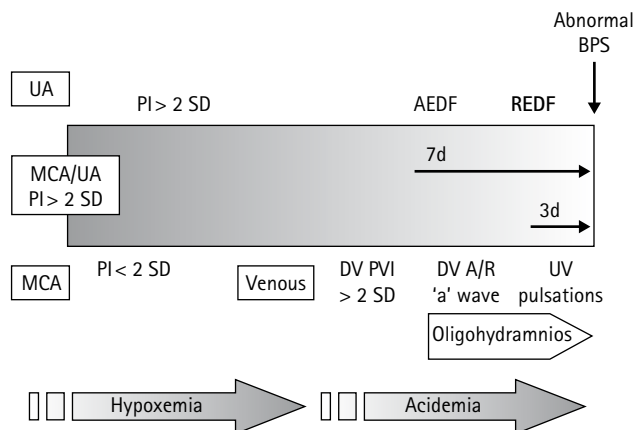

Fig. 11.2 The sequence and timing of Doppler changes in FGR with progressive hypoxemia/acidemia. Doppler changes are usually (but not invariably) preceded by a decline in fetal growth (as assessed by serial changes in abdominal circumference or weight). AEDF, absent end diastolic frequencies; BPS biophysical profile score; d, days; DV A/R, ductus venosus absent/reversed; MCA, middle cerebral artery; PI, pulsatility index; PVI, peak velocity index; REDF, reversed end diastolic frequencies; SD, standard deviation; UA, umbilical artery; UV, umbilical vein.

**Table 11.4** Indications for ultrasound to assess fetal size and well-being

<b>Maternal medical history</b>	<b>Current pregnancy history</b>
Hypertension	SFH < 10th centile
Antiphospholipid syndrome	Pregnancy-induced hypertension
Sickle cell disease	Antepartum hemorrhage
Renal disease	Oligohydramnios
Cardiopulmonary disease	Post-term
Insulin-dependent diabetes mellitus	Abnormal uterine artery Doppler waveforms
	Elevated maternal AFP
<b>Previous obstetric history</b>	
Stillbirth	
Pre-eclampsia	
SGA infant	
Caesarean section for fetal distress	
Placental abruption	

AFP, alpha-fetoprotein; SFH, symphysis–fundus height; SGA, small for gestational age.

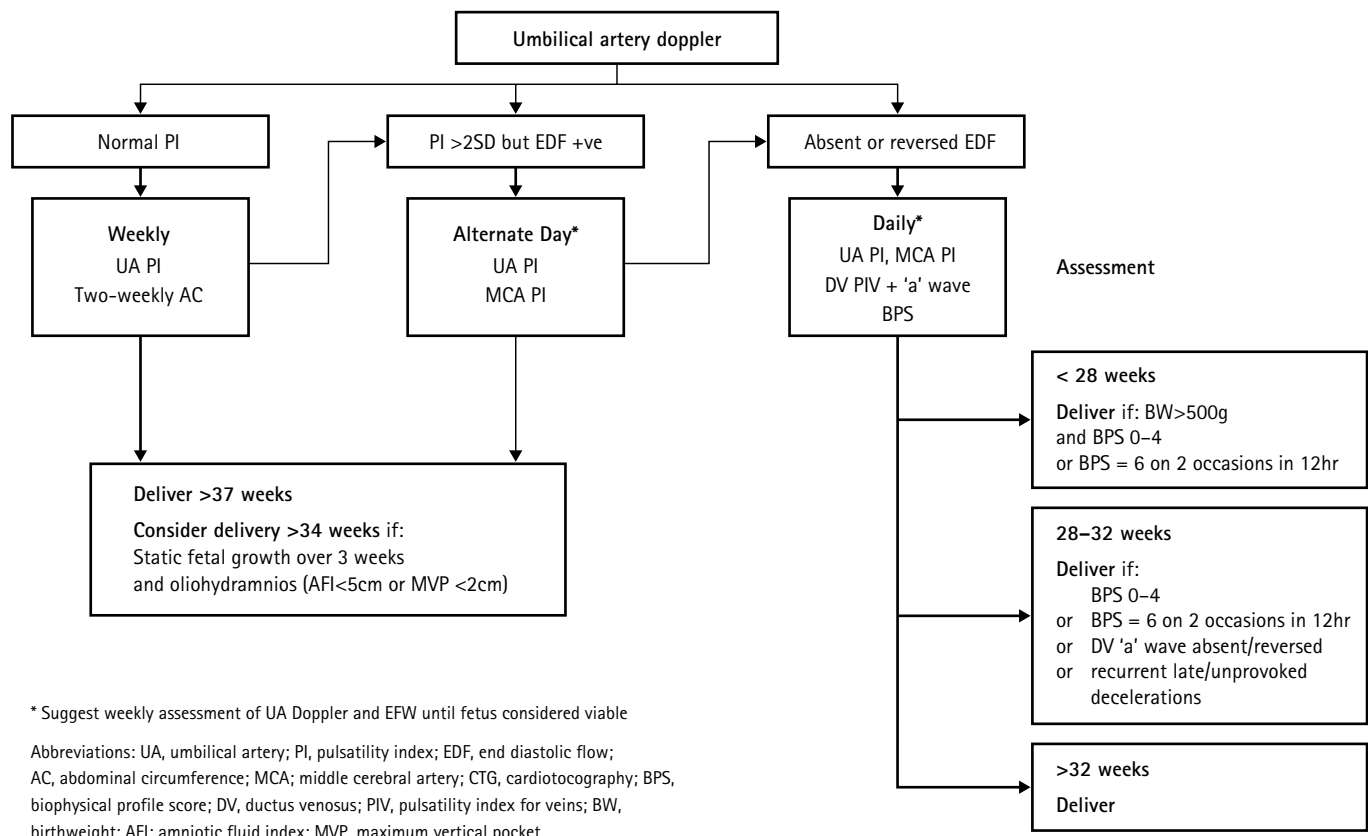

**Organization of screening**

Women with risk factors for FGR and fetal acidemia/perinatal mortality (Table 11.4) should have ultrasound screening for fetal size and well-being by AC and UA Doppler. The timing and frequency of assessment should be determined by the degree of risk and the outcome of uterine artery Doppler screening at 20–24 weeks of pregnancy. In those with a normal uterine artery Doppler, a single screen at 32–34 weeks may be appropriate but where risk is high (e.g. previous stillbirth associated with FGR, abnormal uterine artery Doppler), 2-weekly surveillance from 26 weeks is justified.

The authors' current management guidelines following the initial AC and UA Doppler are shown in Figure 11.3. Where the mother does not have pre-eclampsia and the UA Doppler is normal UA Doppler testing is repeated weekly. This is increased to twice weekly if the UA PI becomes abnormal (but with EDF present). Once there are A/R EDF in the UA this is regarded as an indication for daily BPS and DV Doppler studies and an indication for delivery, irrespective of the results of other monitoring tests, after 32 weeks' gestation. Deterioration of the DV Doppler, with reversal of the 'a' wave, usually heralds a decline in the BPS. Unless parents have made an informed decision not to intervene due to the expected poor prognosis (< 500 g and < 28 weeks' gestation) the authors would deliver when the BPS or DV Doppler became abnormal between 28 and 32 weeks' gestation. Based on the authors' previous experience,<sup>62</sup> the BPS alone is still used to time delivery < 27 weeks. However the benefit of using the BPS rather than abnormalities in the DV waveform to time delivery have not been studied. In this group, the authors routinely offer Caesarean section as in excess of 75% will develop fetal distress if exposed to labor.

**Conclusion**

All SGA fetuses should be monitored with UA Doppler. Several studies have demonstrated that fetuses not identified as SGA have a higher rate of adverse fetal outcome (OR 4.1 [95% CI 2.5–6.8]) than those identified as SGA and monitored with UA Doppler.<sup>66</sup> Widespread use of UA Doppler is also likely, at least in part, to account for the proportionally larger reductions in perinatal mortality and cerebral palsy in very low birth weight (VLBW) growth-restricted infants compared with VLBW infants overall seen over the last 20 years: 67% [95% CI 51–80] in 1983–1987 versus 5% [95% CI 2–13] in 1998–2002 compared to 54% [95% CI 44–64] in 1983–1987 versus 20% [95% CI 15–25] in 1998–2002, respectively.<sup>67</sup>

**Fig. 11.3** Guidelines for management of high-risk fetuses based on ultrasound morphometry and umbilical artery (UA) Doppler. We base the decision to deliver fetuses with absent or reversed end diastolic frequencies (A/R EDF) prior to 34 weeks on the biophysical profile scoring (BPS). Randomized trials are needed to determine if this is a better strategy than using Doppler alone. AC/EFW, abdominal circumference/estimated fetal weight; AF, amniotic fluid; CTG, cardiotocography; DV, ductus venosus; EDF, end diastolic frequencies; SD standard deviation; UV, umbilical vein.

## MULTIPLE PREGNANCIES

### TWINS

#### Perinatal complications

Perinatal mortality in twins is about five times greater than in singletons. The majority of adverse outcomes occur as a result of either preterm delivery, which occurs in 30–50% of twin pregnancies, or FGR. The predominant prenatal prognostic factor for twins is chorionicity. Relative to dichorionic twins, monochorionic twins are at greater risk of fetal loss at 10–24 weeks' gestation (12.2% versus 18.0%), perinatal mortality (2.8% versus 1.6%), preterm delivery < 32 weeks (9.2% versus 5.5%) and birth weight < 5th centile in both twins (7.5% versus 1.7%).<sup>68</sup> The marked increase in the number of second trimester losses is a consequence of the fetoplacental vascular anastomoses that are present in more than 98% of monochorionic pregnancies. Hemodynamic imbalance between the two circulations is responsible for acute and chronic transfusion syndromes.

#### Prenatal ultrasonography in twins

Prenatal ultrasonographic assessment of fetal sex and placental/membrane morphology is highly accurate in predicting chorionicity. The lambda sign, an echogenic chorionic tissue projection into the base of the intertwin membrane, is evident in all dichorionic pregnancies at 10–14 weeks' gestation but disappears by the 20th week in about 7% of dichorionic pregnancies with fused placenta. Monochorionic twins should be scanned every 2 weeks to look for evidence of transfusion pathology. Dichorionic twins with normal biometry, umbilical Doppler values and amniotic fluid levels should be scanned every 4–6 weeks from 24 weeks onwards to monitor growth and well-being.

#### Discordant size and growth

A 20–25% discordance in size between twins is associated with an increased incidence of adverse pregnancy outcomes. The differential diagnosis includes constitutional size difference, uteroplacental dysfunction, and fetal abnormalities as well as twin–twin transfusion syndrome (TTTS) in monochorionic twins. Detailed ultrasonography including Doppler analysis of the umbilical, fetal and uteroplacental circulations will usually determine the etiology. The assessment of fetal well-being is based on the same principles as for singletons, but decisions regarding premature delivery need to consider the outcome of the healthy twin.

#### Twin–twin transfusion syndrome

The TTTS occurs in about 10–15% of monochorionic twins and accounts for 17% of perinatal deaths. The syndrome develops when there is unbalanced shunting of blood from one twin (the donor) to the other (the recipient) through arteriovenous anastomoses in the placenta. The donor twin progressively becomes anemic, growth restricted, and oliguric. The resulting oligohydramnios can be so severe that the donor becomes shrouded in the amniotic membrane ('stuck twin'). The recipient becomes plethoric, polyuric, and can eventually develop cardiomegaly and cardiac failure manifest as hydrops. The polyuria leads to hydramnios, which predisposes to miscarriage and/or extreme prematurity. The wide spectrum of severities is incorporated into a sonographic staging classification, as first proposed by Quintero et al.<sup>69</sup>

**Stage I:** The bladder of the donor twin is still visible, and Doppler studies are still normal.

**Stage II:** The bladder of the donor twin is not visible (during the length of the examination, usually 1 h), but Doppler studies are not critically abnormal.

**Stage III:** Doppler studies are critically abnormal in either twin and are characterized as absent or reverse end-diastolic velocity in the umbilical artery, reverse flow in the ductus venosus, or pulsatile umbilical venous flow.

**Stage IV:** Ascites, pericardial or pleural effusion, scalp edema, or overt hydrops are present.

**Stage V:** One or both twins are dead.

Mortality rates for severe (grade II+) untreated TTTS at < 22 weeks approach 95%. Therapeutic options include serial amnioreduction, endoscopic laser coagulation of placental vascular anastomoses, and selective termination of one fetus with bipolar cord diathermy.

#### Serial amnioreduction

Therapeutic amniocentesis reduces the amniotic fluid volume and/or pressure, thereby reducing the risk of preterm birth and amniorrhexis. The procedure sometimes results in reappearance of fluid in the donor sac. This might reflect alterations in the hemodynamic characteristics of the shunt caused by a reduction in hydrostatic pressure.

#### Endoscopic laser coagulation of placental vascular anastomoses

Endoscopic laser coagulation obliterates the communicating placental vessels between the twins. A combination of ultrasonography and direct vision are used to examine systematically the chorionic plate along the whole length of the intertwin membrane and identify the crossing vessels. The main advantage of this treatment is that the potential for further intertwin vascular shunting is substantially reduced, thereby removing the need for repeated interventions, and theoretically improving the health of surviving twins by reducing cardiovascular instability.

#### Comparison of outcomes following endoscopic laser coagulation or amnioreduction

Data from a recent multicentre randomized, controlled trial indicated that endoscopic laser coagulation for all grades of TTTS – as compared with amnioreduction – was associated with a higher likelihood of one or both twins surviving to 28 d of age (76% vs. 56%) or 6 months.<sup>70</sup> Analysis of data from a large comparative case series confirmed better outcomes following endoscopic laser surgery in pregnancies complicated by stage III/IV TTTS, but the outcomes for stage I/II disease were similar after both forms of treatment.<sup>71</sup>

Detailed long-term follow-up of babies surviving laser surgery for severe TTTS has revealed that up to 11% will experience minor neurologic disability, and a further 11% will develop major neurologic morbidity.

#### Selective feticide

The spontaneous death of one twin is often associated with either loss of the sib, or resolution of the hydramnios. Selective feticide of one twin with a mechanical procedure, such as umbilical cord ligation, has been reported with good short-term results. However, there is concern regarding the potential for acute transfer of blood into the placenta of the demised twin.

#### Single fetal demise

Single fetal death occurs in 0.5–6.8% of twin pregnancies. The earlier twins are diagnosed, the more likely one twin is to demise. The three major factors affecting outcome are the gestational age at death, the cause of death and the chorionicity of the twins. With dichorionic twins, provided the cause of death is intrinsic to the dead twin, complications are unusual. However, the death of a monochorionic twin may be followed by cerebral infarction in the surviving co-twin, as well as renal, hepatic and cutaneous damage. In 13 studies, single fetal death was associated with serious morbidity in 24% of 119 surviving monochorionic children.<sup>72</sup> It is likely that the cause of the neurological damage is acute exsanguination of the surviving twin into the circulation of the dead twin through placental vascular anastomoses.

The optimal management of single fetal death ≥ 36 weeks' gestation is elective delivery. For dichorionic twins remote from term, an expectant approach leads to enhanced maturity and an increased chance of survival. For the survivors of monochorionic single fetal deaths, there is debate as to whether the optimal management is delivery or expectant.

However, delivery is unlikely to improve outcome if the reason for neurological injury is acute hypoperfusion immediately after the demise of the sibling. Thus a conservative approach is usually adopted with serial ultrasound follow-up (and/or MRI) to look for ventriculomegaly, porencephaly, and microcephaly.

### Fetal anomalies

Fetal anomalies are more common in twin pregnancies, particularly monozygous twins, compared to singletons (OR 1.25, 95% CI 1.21–1.28).<sup>73</sup> Even in monozygous twins it is more common for twins to be discordant for anomalies. When ultrasound or genetic studies demonstrate that twins are discordant for a major anomaly, parents are faced with a choice between continuation, TOP, or selective feticide. The risks of selective feticide are dependent on gestation and chorionicity. In dichorionic twins, selective feticide with intracardiac injection of potassium chloride is associated with miscarriage rates varying between 5% at 11–12 weeks and 9% at 16–20 weeks' gestation. The chance of co-twin demise is much reduced if the procedure is carried out during the third trimester after fetal maturity is established, but parents find this option emotionally more difficult.

Selective feticide in monochorionic twins is problematic. Potassium chloride injected into the heart of the abnormal twin might enter the circulation of the normal twin through placental vascular connections. Recent experience with this technique appears to be encouraging; with co-twin survival rates of about 80–85%, and very low rates of immediate neonatal morbidity. However, further investigation is required before definitive conclusions can be drawn regarding the safety of this procedure.

### Monoamniotic twins

About 1% of monozygous twins are monoamniotic. Mortality rates (10–40%) are greater than for all other forms of twins due to the increased incidence of fetal anomalies, cord entanglement, prematurity and trauma during labor. Stillbirths at > 24 weeks are unusual in women admitted to hospital for daily fetal monitoring, but there is no consensus about the optimal technique for monitoring these very high-risk pregnancies. Prophylactic early delivery is usually recommended at about 32–34 weeks' gestation by Cesarean section.

### HIGHER ORDER MULTIPLES

The natural incidence of triplets is 1 in 8000 pregnancies. With assisted reproductive techniques, the incidence has increased to between 1 in 850–2000. The mean gestation at delivery is 33 weeks with a mean birth weight of 1800 g. Preterm delivery at less than 28 weeks' gestation occurs in 7% of cases, and at less than 32 weeks in 28%. Perinatal mortality rates vary from 48 to 151 per 1000 pregnancies. Cerebral palsy occurs in about 3% of long-term survivors. For quadruplets, perinatal mortality rates are between 67 and 104 per 1000, with cerebral palsy occurring in 10% of survivors. The outcomes for higher order multiple pregnancies are even worse.

### Multifetal pregnancy reduction (MFPR)

Although advances in prenatal and neonatal care have resulted in significant improvement in perinatal mortality for higher order multiple pregnancies, there remains concern about long-term morbidity for both the offspring and the family. One option is MFPR, which is usually performed by intrathoracic injection of potassium chloride. Success rates of 100% are typical.

The majority of pregnancies are reduced to twins. This leaves 'margin for error' if there is a problem with a remaining fetus. The frequency of complications, mainly miscarriage or preterm delivery, is a function of the starting number of fetuses (Table 11.5).<sup>74</sup> The outcome for pregnancies reduced to twins is comparable to nonreduced twins. There is general agreement that gestation at delivery (and birth weight) are improved following triplet reduction to twins, but it might be that pregnancy loss rates in centers without a substantial experience of MFPR are greater than those generally reported in the literature. There are no doubts that outcomes are improved following MFPR for quadruplets and higher order multiple pregnancies.

## ALLOIMMUNIZATION

### RED CELL ANTIBODIES

When maternal antibodies to antigens on fetal red cells cross the placenta they can result in hemolysis. The risk of hemolytic disease of the newborn (HDN) requiring treatment is dependent on the red cell antigen (Table 11.6). Transplacental fetomaternal hemorrhage (FMH) is the most common cause of alloimmunization. Heterologous blood transfusion is the second, but is the most common cause of sensitization to the uncommon antigens. Of the five major antigenic loci determining rhesus (Rh) status (C, D, E, c, e), D is the most immunogenic, followed by c. Approximately 85% of the Caucasian population are RhD positive, 45% being homozygous for the D antigen. Routine screening for red cell antibodies is undertaken at booking and around 30 weeks of pregnancy. Alloimmunization is now sufficiently uncommon that all cases at risk of significant hemolysis should be managed by, or in collaboration with, a regional center.

### Anti-D prophylaxis

Anti-D immunoglobulin (Ig) should be given to all nonsensitized RhD-negative women within 72 h of the delivery of a RhD-positive infant. A dose of 100 µg (500 iu) is capable of suppressing immunization by 4–5 ml RhD-positive cells. A Kleihauer test is routinely undertaken to detect larger FMH requiring additional anti-D Ig. Prophylaxis is also given after potentially sensitizing events during pregnancy (e.g. antepartum hemorrhage, invasive prenatal diagnosis) and after therapeutic TOP, ectopic pregnancy, and uterine evacuation of a spontaneous or incomplete abortion. Between 1 and 1.5% RhD-negative women develop anti-D antibodies during a first or subsequent pregnancy due to 'silent' FMH. Evidence from several studies indicates prophylactic anti-D during pregnancy in the early third

Table 11.5 Multifetal pregnancy reduction: pregnancy losses or deliveries as a function of starting number (S) before reduction

	N	Losses			Deliveries		Mean GA

trimester reduces this to 0.2% or less and antenatal prophylaxis is now recommended.

### Management of women with anti-D

Once anti-D antibodies are detected the father's RhD type should be determined. Significant hemolysis does not occur with anti-D concentrations  $\leq 4$  iu/ml and there is no need for intervention. Antibody testing should be repeated monthly to 28 weeks and fortnightly thereafter. Above 4 iu/ml there is a risk of anemia but this is not accurately predicted by anti-D concentration; between 4 and 15 iu/ml mild to moderate anemia, requiring postnatal transfusion, may occur but severe anemia (hemoglobin  $< 7$  g/dl) is uncommon. Above 15 iu/ml, and particularly in the presence of rapidly rising levels, the risk of severe anemia has been reported to be as high as 50%. Where there is a risk of significant hemolysis and the partner is heterozygous for the RhD antigen, the fetal RhD genotype can be predicted using real-time PCR on cell-free fetal DNA within the maternal circulation.

In women with anti-D  $> 4$  iu/ml and an RhD-positive fetus, the risk of fetal anemia is assessed by ultrasonographic measurement of cerebral peak systolic blood flow; the sensitivity of an increased peak velocity of systolic blood flow for severe fetal anemia is  $\sim 100\%$  with a FPR of 12% (positive LR 8.5, 95% CI 4.7–15.6, negative LR 0.02, 95% CI 0.00–0.25).<sup>75</sup> This increase in peak velocity is likely to be a result of increased cardiac output and/or reduced blood viscosity.

The management of increased peak systolic velocity (i.e.  $> 1.5$  Multiples of the Median [MoMs]) at gestations  $< 33$  weeks is cordocentesis to measure the fetal hematocrit (or hemoglobin). The risk of increased sensitization, especially with transplacental passage of the needle, and fetal death suggests that fetal blood sampling should be reserved for fetuses perceived to be at highest risk. Intravascular transfusions are begun when the fetal hematocrit declines below  $> 30\%$  (less than the 2.5th centile after 20 weeks). The timing of subsequent blood sampling in fetuses with a hematocrit  $> 30\%$  is determined by the strength of the positive direct antiglobulin test and the fetal reticulocyte count. Compatible (RhD negative), fresh, leukocyte depleted blood, resuspended in saline to a hematocrit of  $\sim 70$ – $75\%$ , is transfused into either the umbilical vein (at the placental cord insertion) or the intrahepatic vein. The volume of blood required to attain the desired hematocrit (typically 40–50%) can be estimated from the initial fetal and donor hematocrits together with the estimated fetoplacental blood volume. The second

transfusion is arbitrarily undertaken 2 weeks after the first, or at a time when the peak systolic velocities increase beyond the treatment threshold. The timing of subsequent transfusions is then determined from the fall in hematocrit, which becomes more consistent over time (typically  $\sim 1\%/d$ ) as fetal erythropoiesis is suppressed and only donor blood is circulating. Intraperitoneal transfusion is less effective and associated with a greater risk of fetal death compared with intravascular transfusion. Furthermore combining intraperitoneal and intravascular transfusion confers no advantage. The aim with fetal transfusion is to reach a gestational age of at least 36 weeks before delivery.

Mortality rate per intravascular transfusion is  $\sim 3\%$ , with higher rates reported when transfusion is required prior to 20 weeks' gestation and in hydropic fetuses. Overall 84% of fetuses (94% without hydrops and 74% with hydrops) requiring in utero transfusion will survive<sup>76</sup> with  $< 10\%$  suffering developmental problems.<sup>77</sup> Postnatal exchange transfusion is rarely necessary when there have been at least two antenatal transfusions. Top-up transfusions are frequently necessary because of late anemia prior to resumption of normal erythropoiesis.

### Management of women with other alloantibodies

Anti-c antibodies can be quantitated accurately and management of women with anti-c levels  $> 4$  iu/ml follows similar guidelines to anti-D, including fetal genotyping from maternal blood. Antibody levels for other red cell antibodies are measured by indirect antiglobulin test. The reciprocal of the highest dilution of serum that causes agglutination is the titer. Severe hemolysis rarely, if ever, occurs with titers  $\leq 1$  in 32 with the exception of anti-Kell, where severe anemia has been reported with titers as low as 1:2. In Kell disease the main cause of fetal anemia is erythroid suppression rather than hemolysis. Determination of the partner's Kell status is vital as only 9% will be Kell positive, with virtually all being heterozygous. Thus very few fetuses of women with anti-Kell are actually at risk.

### PLATELET ANTIBODIES

In alloimmune thrombocytopenia (AIT), maternal antiplatelet antibodies to a paternally derived platelet antigen, usually PLA1, cross the placenta and destroy fetal platelets. Neonatal AIT occurs in 1 in 2000–5000 births with intracranial hemorrhage (ICH) in 15–20% of cases. Between 30% and 50% of ICH occurs in utero, usually after 30 weeks' gestation. The mother is healthy and her first child is affected in 50% of cases. Recurrence rates are very high ( $> 85\%$ ). Management is controversial, but often based on stratification by the history of previous siblings.

Women with a history of an infant with an ICH during pregnancy are usually treated with i.v. immunoglobulin (1 g/kg/week) from about 12 weeks, followed by fetal blood sampling at 22–24 weeks.<sup>78</sup> If severe thrombocytopenia (platelet count  $< 30 \times 10^9/L$ ) is confirmed the dose of i.v. immunoglobulin can be doubled, or prednisone can be added to the therapy. Because the response is not consistent, repeat fetal blood sampling 2–4 weeks later is necessary. A falling platelet count, particularly to  $< 20 \times 10^9/L$ , is an indication for platelet transfusion. Transfusion raises the platelet count for only a few days and therefore needs to be repeated weekly. Platelet transfusions are more likely to be complicated by fetal bradycardia and death than red cell transfusions and therefore delivery around 34 weeks, usually by Cesarean section, is appropriate. Where the initial platelet count is  $> 50 \times 10^9/L$  it is reasonable to repeat blood sampling 4–6 weeks later.

Women with no prior history of a fetus with an antenatal ICH are often treated with IVIG from about 20 weeks, followed by fetal blood sampling close to 32 weeks. The management thereafter is determined by the platelet count, as described earlier.

### INTRODUCTION

### DEFINITIONS – WORLD HEALTH ORGANIZATION (WHO)

#### GESTATION (INDEPENDENT OF BIRTH WEIGHT)

1. Preterm = less than 37 completed weeks of gestation (258 days).
2. Full-term = between 37 weeks and 42 completed weeks of gestation (259–293 days).
3. Post-term or postmature = more than 42 completed weeks (294 days).

Dates are taken from the first day of the last menstrual period. Conception is presumed to be approximately 2 weeks after this date. Ultrasound

dates are based on conception and have to be altered to fit with the dates estimated from the last menstrual period.

#### BIRTH WEIGHT (INDEPENDENT OF GESTATION)

1. Low birth weight = less than 2500 g.
2. Very low birth weight = less than 1500 g (accepted by convention).
3. Extremely low birth weight (USA – very, very low birth weight) = less than 1000 g (accepted by convention).
4. Impossibly or incredibly low birth weight = (less than 750 g).

#### SIZE FOR GESTATION (Fig. 12.1)

1. Small for gestation (SGA) = less than 10th centile in weight expected for gestation (small for dates).

Fig. 12.1 Size for gestation based on population centiles for birth weight with gestation: LGA, large for gestational age; AGA, appropriate for gestational age; SGA, small for gestational age (less than the 10th centile expected weight for gestation).

2. Appropriate for gestation (AGA) = between 10th and 90th centiles of weight expected for gestation.
3. Large for gestation (LGA) = more than 90th centile in weight expected for gestation.

NB: The expected weight centiles will vary with the population. The terms immature, premature and dysmature should no longer be used.

## AGE

### In utero

1. Less than 1 week = fertilized egg to the formation of the blastocyst.
2. 1–12 weeks = embryo.
3. 12 weeks – delivery = fetus.
4. 24 weeks or more = current period of 'legal' viability in the UK.

In the UK it is uncommon to terminate a pregnancy after 20 weeks of gestation, though it is legal through to term for major fetal anomaly or maternal life-threatening problem (Human Embryo and Fertilisation Act 1990<sup>1</sup>.)

**Abortion** is the expulsion of the dead fetus prior to 24 weeks' gestation (168 days). A dead fetus expelled after this time is a **stillbirth**. Note that a liveborn baby is a baby of *any gestation* that has signs of life (e.g. only a heart beat) at delivery. Many miscarriages before 20 weeks' gestation will show signs of life.

### The neonate

1. Perinatal period = the period from 24 weeks' gestation or the time of the live birth if less than 24 weeks' gestation, to 7 days of postnatal age.
2. Early neonatal period = the first 7 days of life of a liveborn infant of *any gestation*.
3. Late neonatal period = 8–28 days after birth.
4. Neonatal period = the first 28 days of life of a liveborn infant of *any gestation*.
5. Infancy = the first year of life.

## MORTALITY RATES

1. Stillbirth rate = number of stillbirths per 1000 total births.
2. Perinatal mortality rate (PMR) = number of stillbirths + early (up to 7 days) neonatal deaths per 1000 total births.
3. Neonatal mortality rate (NNMR) = number of deaths in the first 28 days per 1000 live births.
4. Infant mortality rate (IMR) = number of deaths in the first 365 days per 1000 live births.

Maternity units should collect the figures for PMR, NNMR and also neonatal deaths before discharge from hospital. Reduction of NNMR simply by postponing the deaths out of the neonatal period is not the ideal of neonatal care. Bronchopulmonary dysplasia, infection and necrotizing enterocolitis are the current problems that lead to late deaths after 28 days. The 'corrected' WHO neonatal mortality rate is the number of deaths in the first 28 days of life (birth weight greater than 1000 g) per 1000 live births.

## THE ECONOMICS OF NEWBORN CARE

### INTRODUCTION

The increasing incidence and improved survival chances of infants of low birth weight and low gestational age, as well as the diffusion of new technologies for mature infants, have increased the demand for specialist neonatal care in many industrialized countries.<sup>2</sup> This has generated considerable debate about the correct level of funding for neonatal care. Economic evaluation provides a framework for assessing the costs and benefits of neonatal care, and for identifying the combination of human and material inputs that maximize health benefits or other measures of social welfare. This section outlines the methods of economic evaluation of health care and, in the process, describes the key economic issues raised by studies of neonatal care.

### STUDY DESIGN

Economic evaluations of neonatal interventions can be conducted on the basis of observational evidence, such as before-and-after studies, case-control studies or ad hoc syntheses of evidence from several sources. However, health economists tend to consider prospective economic evaluations conducted alongside randomized controlled trials as possessing the highest internal validity.<sup>3</sup> A number of trial-based economic evaluations of neonatal interventions has been reported in the literature in recent years, including studies of ultrasonography in the diagnosis and management of developmental hip dysplasia,<sup>4</sup> neonatal extracorporeal membrane oxygenation (ECMO)<sup>5</sup> and indomethacin prophylaxis for patent ductus arteriosus.<sup>6</sup> The randomized controlled trial is considered to act as the primary vehicle for collecting unbiased information on both the costs and consequences of the interventions being evaluated and a means of simulating real world conditions. However, there are many circumstances in which the use of a single randomized controlled trial as a vehicle for economic analysis of a neonatal intervention will provide an inadequate and partial basis for decision making. For example, the sample size of the trial may be inadequate for true differences in outcomes between the experimental and control groups to be recognizable with statistical methods. If this is the case, then the clinical effectiveness estimate might have to be derived from meta-analyses or overviews of the relevant controlled trials in the area, or the cost estimates might have to be derived from several studies.<sup>7</sup> In addition, many randomized controlled trials of neonatal interventions focus upon intermediate outcomes rather than the long term outcomes that might be of interest. For example, a number of trials have shown that giving preterm infants systemic corticosteroids in the first few days of postnatal life improves short term respiratory outcomes, such as reducing oxygen dependency, but also appears to increase the rate of adverse neurological outcomes over the longer term.<sup>8</sup> There are many circumstances, therefore, in which decision-analytic modelling techniques have to be used to extrapolate the relevant data beyond the time horizon of the randomized controlled trial in order to reflect long term outcomes.

### FORM OF ECONOMIC EVALUATION

Four broad forms of economic evaluation have been reported in the literature.<sup>3</sup> *Cost-minimization analysis* is the simplest form of economic evaluation and establishes the least costly method of achieving given outcomes. It is only appropriate if all outcomes are known or found to be identical. Birnie et al<sup>9</sup> performed a cost-minimization analysis of

domiciliary antenatal fetal monitoring in high-risk pregnancies. The investigators found that, compared with in-hospital monitoring, domiciliary monitoring is safe (when measured in terms of a range of neonatal outcomes) and reduces health service costs by one half.

*Cost-effectiveness analysis* compares the costs of health interventions to their consequences where the consequences are measured in natural or physical units. Cost-effectiveness analysis can only be used to compare interventions that produce the same kinds of consequences. It cannot be used to compare an economic evaluation whose primary outcome is cases of necrotizing enterocolitis avoided with an economic evaluation whose primary outcome is days of oxygen dependency avoided. To make these broader comparisons, a common 'currency' for measuring consequences is needed. The common currency is achieved in two distinctly different ways, one leading to *cost-utility analysis* and the other leading to *cost-benefit analysis*. In both cases, by placing a value on the consequences of interventions, either through preference weighting or value weighting, the methods can address questions of allocative efficiency, i.e. the efficient allocation of scarce resources across different areas of neonatal care.

In *cost-utility analysis*, the consequences of health interventions are measured in quality-adjusted life years (QALYs), which attempt to capture the health gains derived from health interventions in a single metric that combines life years gained and enhancement of health-related quality of life.<sup>10</sup> The QALY displays cardinal properties, such that four years of a child's life in a health state judged to be halfway between death and full health would be considered equivalent to two years in full health. The advantage of the QALY metric is that it allows neonatal interventions with diverse consequences to be compared. QALYs have been estimated for a number of neonatal interventions, including predischarge monitoring for apnea of prematurity,<sup>11</sup> neonatal surgery and subsequent treatment for congenital diaphragmatic hernia,<sup>12</sup> neonatal surgery and subsequent treatment for congenital anorectal malformations,<sup>13</sup> alternative models of neonatal intensive care,<sup>14,15</sup> and prophylactic indometacin in very low birth weight infants.<sup>16</sup>

In *cost-benefit analysis*, the consequences of health interventions are measured and valued in monetary units, most commonly by asking relevant individuals how much they would be willing to pay to obtain the consequences. This is most frequently done using the willingness to pay approach. Hence, for a new neonatal screening program, the analyst could describe to potential parents how many life years the program could be expected to add and what the health of the child would be during those years, and then ask them how much they would be willing to pay to obtain those health benefits. In cost-benefit analysis, both the costs and consequences of an intervention are valued in the same units, monetary units, and thus cost-benefit analysis is the only technique that can determine in and of itself that an intervention is worth delivering in economic terms (benefits exceed the costs, thus generating positive net benefit).

## PERSPECTIVES FOR ECONOMIC EVALUATION

Economic evaluations can be undertaken from a number of different perspectives or viewpoints. The broadest, most comprehensive perspective is the societal perspective in which all costs are counted regardless of who incurs the costs. In neonatal care, a societal perspective is often relevant. Low birth weight babies, for example, may require support from social service departments upon their discharge from hospital. The parents of sick neonates may have to forego other productive activities (paid or unpaid work) in order to spend time with them; their transport costs to and from the neonatal unit may be considerable, and care for other children may have to be arranged.<sup>17</sup> Other perspectives can also be adopted in studies, such as the perspective of a particular agency, the entire health care system or the perspective of the family. Recently, the National Institute for Health and Clinical Excellence (NICE) in England and Wales recommended that the most relevant costs for economic evaluation are those incurred by the National Health Service and personal social service providers.<sup>18</sup> Alternative perspectives are often useful as

a means of predicting who will favor a new program and who will not, and thus to help an appropriate implementation strategy.

## DISCOUNTING IN ECONOMIC EVALUATION

Health care interventions often generate streams of costs and consequences that occur over time and into the future. For example, an effective treatment for preterm infants may reduce the number of hospital admissions during childhood and reduce the pool of disabled children that need to be cared for by society. Analysts are not only concerned about the costs and consequences of the intervention during the neonatal period, but also those costs and consequences that occur throughout childhood and beyond. By discounting, all costs and consequences that occur in future years are reduced by a discount factor to their equivalent present values. The discounted amounts, the equivalent present values, are totalled and then all programs can be fairly compared on the basis of their present values. The discount rates applied within economic evaluations of neonatal interventions have varied markedly across jurisdictions and over time. Recently, NICE has recommended that economic evaluations conducted in England and Wales should discount costs and, more controversially, health consequences, at an annual rate of 3.5%.<sup>18</sup> The effect of discounting health consequences as well as costs is that many neonatal screening programs will appear to be penalized as their benefits are often felt over the longer term. When the results are potentially sensitive to the discount rate used, then sensitivity analyses that vary the discount rate between 0% and 6% are recommended in order to assess the impact on the final results.<sup>18</sup>

## COMPONENTS OF ECONOMIC EVALUATION

It is useful to view the various costs and consequences of neonatal programs as building blocks, which can be assembled in an economic evaluation in different ways.

### Costs

The costs of neonatal programs can be calculated using a number of different approaches. The most common alternative approaches are based on cost accounting methods, either using detailed information about resources used by individual patients (the 'bottom up' approach), or by allocation of total costs by unit workload (the 'top down' approach). Many studies, particularly those conducted in countries, such as the United States, where there is a comprehensive system of billing and fee-for-service payment of providers, cite charges for neonatal care rather than costs. However, it is worth noting that health care charges may include elements arising from corporate financial decisions and may therefore be poor proxies for the costs of providing neonatal care. If the study adopts a societal perspective, the impact of the neonatal program on other sectors of the economy and on families and carers should also be considered. Estimation of these broader costs may use a number of methods including time and motion studies, diary methods, work sampling, interviews with key caregivers, case note analysis and patient activity databases.<sup>19</sup>

### Consequences

The consequences of neonatal programs can be described in terms of either: (1) resources saved, or (2) health effects.

### Resources saved

Neonatal programs can save resources for the health sector, for other sectors of the economy and for patients and informal carers. For example, an effective intervention for preterm birth might avoid hospital readmissions, the consumption of special education services, and the time taken off work by parents to care for a disabled child. The methods for measuring these resource savings are identical to those outlined in the section on costs. These resource savings are simply the costs that would have been incurred if the program had not been provided. Indeed, all assessments of costs and consequences within an economic evaluation framework are comparative to an alternative.

### Health effects

In addition to potential resource savings, neonatal interventions will hopefully also directly impact upon the health of the child. These health effects can be measured in natural or physical units (for example, cases of necrotizing enterocolitis avoided) that can then be incorporated into a cost-effectiveness analysis. Alternatively, they can be measured in terms of health state preferences in the construction of QALYs for incorporation into a cost-utility analysis, or in willingness to pay terms for incorporation into a cost-benefit analysis.

**QALYs.** For cost-utility analysis, the quantity and health-related quality of life effects of a neonatal intervention are combined into a composite metric, the QALY. The life years gained component of the QALY metric is relatively uncontroversial. It is ideally calculated through clinical trials of the intervention being evaluated, incorporating long term follow-up of patients and controls. In contrast to the life years gained component of the QALY metric, estimation of the *health-related quality of life* component has generated great interest amongst health economists. Several scaling techniques have been developed with the view to estimating these weights, the most prominent of which are the rating scale, the standard gamble approach and the time trade-off approach. The scaling techniques vary in their strength of foundation in economic theory and health economists are still debating their relative merits.<sup>20</sup>

An alternative approach to measuring the health-related quality of life weight of a health state is provided by multi-attribute utility measures, which are generic health-related quality of life instruments with pre-existing preference weights which can be attached to each permutation of responses. The available multi-attribute utility measures include the EQ-5D<sup>21</sup> and the Health Utilities Index (HUI).<sup>22</sup> Oostenbrink et al<sup>23</sup> compared the EQ-5D with the Mark 3 version of the HUI to value the health states associated with childhood bacterial meningitis. A panel of 28 pediatricians classified seven health state descriptions which included deafness, epilepsy, mental retardation and paresis. They found that HUI Mark 3 preference values were substantially lower than the EQ-5D values for all health state descriptions, although the ranking of the health states was the same. Greatest differences were found in states associated with deafness and mental retardation. This reflects the fact that the EQ-5D does not include dimensions for cognition or sensation, so these aspects of health-related quality of life are only covered by their effects on functional domains such as 'usual activities' or 'anxiety/discomfort'. It should be noted that there are a number of methodological problems that have constrained the application of all multi-attribute utility measures in the neonatal context.<sup>24</sup> Most notably, the measures tend to incorporate a core set of health attributes that reflect human experiences as a whole and ignore attributes that might be considered relevant in the neonatal context, such as health care needs and gross motor mobility. In addition, there is a great deal of uncertainty concerning the appropriate respondents for the preference elicitation tasks.<sup>24</sup>

**Willingness to pay.** An alternative approach to valuing health effects is the willingness to pay approach for incorporation into cost-benefit analysis. The willingness to pay approach is considered to provide values that reflect individuals' strength of preference for health interventions.<sup>3</sup> Willingness to pay questions can be classified in either open-ended or closed-ended form; the latter offers respondents an opportunity to accept or reject a series of price levels for the intervention being valued. Population values may be obtained using a variety of survey techniques, including face-to-face interviews, telephone interviews and postal surveys. As with the various QALY-based approaches, a particular methodological concern when applying the willingness to pay approach in the neonatal context is identifying the appropriate respondent for the task. Valuations might be obtained from clinicians, parents or the general public. The primary justification for using clinicians is that they are knowledgeable about neonatal care and its sequelae and may be more accessible than some patient groups and their families. The primary justification for selecting a sample of parents is that the parents might be considered the final arbiter of the child's best interests, particularly after the child has been discharged from the neonatal unit; parents might have the greatest sense of what the child himself might perceive as

a worthwhile existence, and what the child might view as intolerable. The rationale for measuring the preferences of the general public is related to policy decision-making, i.e. the consideration that decisions pertinent to public policy should be based on public opinion.

### COMPARATIVE ANALYSIS OF COSTS AND CONSEQUENCES

Economic evaluation synthesizes evidence on costs and consequences within an explicit framework, enabling decision-makers to assess whether a neonatal intervention offers good 'value for money'. Data on either costs or consequences, when viewed in isolation, do not provide decision-makers with the information required for value for money assessments.

In cost-minimization analysis, the decision rule for decision-makers is straightforward. If health effects are equivalent, then the cheaper neonatal intervention is preferable. Similarly, in cost-benefit analysis, the decision rule for decision-makers is straightforward. If the monetary valuation of the consequences of a neonatal intervention exceeds the net costs of the intervention, then the intervention should be provided since there is a net gain to society. In cost-effectiveness analysis and cost-utility analysis, however, the decision rule becomes rather more complex, since costs and health effects are expressed in different metrics. In analytical terms, there is a number of possible scenarios that can be summarized in a 'cost-effectiveness plane' (Fig. 12.2). The same scenarios apply whether the health effects are measured in natural or physical units, such as life years gained, for the purposes of cost-effectiveness analysis, or in QALYs for the purposes of cost-utility analysis.

In the cost-effectiveness plane, the difference in health effects between a neonatal intervention and its comparator is plotted along the horizontal axis, whilst the difference in cost between a neonatal intervention and its comparator is plotted on the vertical axis. In the south-east (SE) and north-west (NW) quadrants of the cost-effectiveness plane, one intervention is clearly more effective and less costly than the other and, therefore, this intervention would be a clear winner in cost-effectiveness or cost-utility terms. In the south-west (SW) and north-east (NE) quadrants, however, one intervention is both more effective and more costly, and decision-makers need to assess whether the additional costs are worth the greater effectiveness. Currently, there is very little explicit guidance on what decision-makers are willing to pay for health gains generated by new neonatal technologies. There is some evidence to suggest that NICE holds a willingness to pay threshold of approximately £30 000 for an additional QALY in the general population.<sup>25</sup> However, it is conceivable that members of the general population attach greater weight to health gains made by children, particularly compromised infants, and that decision-makers should weight their decisions in favor of these particular groups.

Fig. 12.2 The cost-effectiveness plane. ICER, incremental cost effectiveness ratio.

## CONCLUSIONS

Economic evaluation provides a means of allocating finite health care resources in an efficient manner. It can inform decision-making processes at many levels, from national decision-making bodies, such as NICE, to decisions by local health care providers. However, it is important to mention some of the limitations of the approach. Although health economists agree about the objectives of economic evaluation, they disagree about a number of methodological issues. For example, some health economists argue that cost-benefit analysis is the optimal form of economic evaluation because of its foundation on welfare economic theory, whilst others promote cost-utility analysis because of its broader acceptance by the research community. Some health economists argue that economic evaluation of health interventions should be limited to a health service perspective, whilst others promote a broader societal perspective. There is also a number of methodological concerns that are unique to economic evaluation of neonatal care, such as the methods for summarizing the consequences of interventions that have a direct impact upon the health of two individuals, the mother and her infant, in a single estimate of cost-effectiveness.<sup>26</sup> Even without these methodological concerns, economic evaluation should not be viewed as a panacea for decision-makers, but rather as an additional strand of evidence that can facilitate evidence-based decision-making.

## THE NORMAL FETAL-NEONATAL TRANSITION

The most vital change immediately after birth is for the lungs to expand to take in air. If lung expansion fails, death will occur quite rapidly and shortly after the umbilical cord is clamped. Almost as important as lung expansion is the change from the fetal type circulation, with the cardiac output bypassing the lungs, to the postnatal pattern where the cardiac output from the right side of the heart will perfuse the lungs and be oxygenated (Fig. 12.3). Less urgent changes in the other organ systems must take place over the next days and weeks in order to ensure a viable post-natal existence.

### THE LUNGS (Fig. 12.4)

The lungs of the fetus in utero are filled with a unique fluid which near term is being produced at a rate of about 3 ml/kg/h. Clearance of this fluid is crucial for successful air breathing and begins during labor. Each uterine contraction has been shown to generate surges of fetal catecholamines which reduce the rate of lung liquid secretion and, as labor progresses, lead to active resorption. Elective delivery of the baby before labor will lead to babies being born with wet lungs which result in transient tachypnea of the newborn (p. 250). Additional lung fluid is dispersed during the second stage of labor by a compression force of up to 160 cm of water and the elastic recoil from this vaginal squeeze may draw up to

Fig. 12.3 Fetal circulation. The circled figures indicate oxygen saturation at various points, e.g. blood 70% saturated at point where inferior vena cava enters right atrium. L.A., left atrium; L.V., left ventricle; R.A., right atrium; R.V., right ventricle.

returns from the lungs; therefore the blood passing from the left atrium to the left ventricle is largely the oxygenated supply from the placenta. Left ventricular contraction powers blood to the aortic arch with its major vessels; thus the coronary and carotid arteries of the fetus, the priority areas, receive blood with the best possible oxygen content. Blood returning from the coronary sinus and the superior vena cava to the right atrium passes to the right ventricle and the pulmonary trunk. The high pulmonary vascular resistance of the fetus and the presence of the patent ductus arteriosus ensure that the right ventricular output predominantly (90%) supplies the descending and abdominal aorta and the viscera. Fifty percent of the abdominal flow goes via the two umbilical arteries to the placental bed where exchange of blood gases and other nutritional and excretory substances occurs (Fig. 12.4). The distribution of blood flow in utero is primarily dependent on the high vascular resistance of the unexpanded fetal lung and the low vascular resistance of the placenta. Fetal pulmonary arterioles have a thick medial muscle layer. The low fetal PaO<sub>2</sub> is thought to keep the vessels constricted. With the first gasps there is a rapid rise in the oxygen tension within the alveoli, and the arteriolar musculature relaxes and pulmonary perfusion occurs. The sudden increase in pulmonary venous return of well-oxygenated blood to the left atrium functionally closes the foramen ovale within minutes or hours of birth and this now well-oxygenated blood [PaO<sub>2</sub> greater than 7 kPa (50 mmHg)] is ejected up the aortic arch from the left ventricle. The closure of the ductus arteriosus is thought to be a result of the increased oxygen content. The ductal muscle in utero is maintained in a relaxed state by the combination of the relative hypoxia and the presence of high circulating levels of prostaglandins produced by the placenta.

The clamping of the umbilical cord raises the systemic vascular resistance and, as a consequence, blood may pass in the reverse direction through the patent ductus. This 'transitional circulation' may revert back to the fetal situation (right to left) if satisfactory oxygenation is not achieved (persistent pulmonary hypertension of the newborn, p. 268). Functional closure of the ductus usually takes place within the first 24 h (and usually much earlier) after birth, but before this a systolic murmur may be present at the base of the heart from transient left to right ductal flow. After birth the pulmonary artery pressure falls from about 3.3–5.3 kPa (25–40 mmHg) on the first day to 2 kPa (15 mmHg) after 6 weeks. During this time there is a rise in the systemic blood pressure from 45–55 mmHg (6–7.3 kPa) to approximately 70 mmHg (9.3 kPa).

## BRAIN AND CENTRAL NERVOUS SYSTEM

The brain and central nervous system develop steadily through fetal life, infancy and childhood. There are no dramatic changes that occur with or because of birth itself although sensory experience following birth is obviously different. At birth the cerebellum is more maturely developed than the cerebrum. Neuronal development and dendritic connections are more evident and myelination is already occurring from the oligodendroglia. Cerebral myelination and dendritic connections are predominantly postnatal events.

Brainstem and higher reflexes develop in late fetal life in an orderly fashion and can be used to estimate gestation. Interruption at any stage will cause damage. The seriousness of ensuing problems will depend on the maturity of the brain at the time the damage occurs.

Some recognition patterns seem innate in the newborn. Immediately after birth many newborns will follow a simple stylized face through 180 degrees, though if the features are scrambled this will not occur. Other experiments show rapid learning ability; for example by the fifth day of life the breast-fed infant will be able to detect his own mother by his sense of smell.

## THE GUT AND DIGESTION

Swallowing is well developed by the fourth month of in utero life. The inability to swallow in utero leads to hydramnios. Sucking develops rapidly after birth; usually the baby increases the number of sucks in a burst from 5–6 on the first day to 30 or more by day 3. Babies born

at 28 weeks' gestation may also suck but the effective coordination of sucking, swallowing and breathing does not occur until 34–35 weeks' gestation. The importance of sucking and swallowing after birth is obvious but these have to be matched by the ability of the rest of the gastrointestinal tract to digest and absorb the food. Intestinal motor activity and the migrating motor complex are developed by 34 weeks' gestation but it is possible that feeding facilitates this development in a baby born earlier.<sup>27</sup> Radiological investigation will show that air usually passes to the large bowel by 2 h of postnatal age, even in the very preterm infant. Most of the intestinal enzymes are present at birth but their full activity and that of the various gastrointestinal hormones are further induced by feeding. Breast milk is undoubtedly and not surprisingly better tolerated than other food and no additional nutritional supplements are required for at least 4–5 months of life in the full-term infant.

Meconium should be passed within 24 h of birth (95%). Should the baby fail to pass meconium, medical staff should be notified as an intestinal atresia, Hirschsprung disease or meconium ileus may be the cause.

## THE KIDNEYS AND RENAL FUNCTION

Dynamic measurements of bladder volume by ultrasound show that the fetus at full term will be producing 7 ml of urine/kg/h; thus glomerular filtration from the full complement of nephrons (present by 35 weeks' gestation) is considerable. Fine control of water balance in utero has been the concern of the placenta, and after birth both glomerular and tubular immaturity mean that fluid and electrolyte insults on the newborn are poorly tolerated. The glomerular filtration rate (GFR) of the term infant is only 10 ml/min/m<sup>2</sup>, increasing to 15 ml/min/m<sup>2</sup> by the end of the first week. Renal blood flow is low at birth and the juxtaglomerular nephrons are preferentially perfused. Sodium resorption is well developed in the full-term infant (though not in the preterm) as the tubules are comparatively mature and the circulating aldosterone levels are high. The maximum urine osmolality is relatively low, not because of the baby's inability to secrete the antidiuretic hormone, arginine vasopressin (AVP), from the posterior pituitary but because the low solute and nitrogen content of breast milk result in a low solute concentration in the interstitial compartment of the medulla. Increasing the protein intake of the infant increases the maximum urine osmolality that is possible.

The renal bicarbonate threshold is low and there may be limited hydrogen ion excretion due to reduced phosphate availability. Both of these may lead to acidosis. The tubular cells are also less able to produce ammonia. This is more marked in preterm infants, particularly with high protein and acid loads, and leads to the late metabolic acidosis of prematurity.

The breast-fed infant receives low solute food with adequate nitrogen and calories: there is little stress on the kidneys. Unmodified cows' milk or solids contain too much solute and nitrogen and can rapidly lead to metabolic difficulties such as cows' milk tetany (p. 373) and hypernatremia (p. 220).

Congenital abnormalities of the kidney and renal excretory systems lead to metabolic upset developing over the first days or weeks of life depending on their severity. The common coexistence of pulmonary hypoplasia with complete renal agenesis (Potter syndrome) ensures this abnormality presents as an acute respiratory difficulty, usually with rapid death.

## LIVER FUNCTION

Immaturity of liver function leads to jaundice (p. 279) and also to the newborn's inability to tolerate drugs which are usually excreted via the biliary tree. The 'gray baby' syndrome is due to increased free and conjugated chloramphenicol levels in the serum leading to vomiting, poor sucking, respiratory distress, abdominal distention, diarrhea and eventually collapse. Liver immaturity may be a factor in the development of hemorrhagic disease of the newborn (p. 295) though damage to the liver from hypoxia and an inadequate supply of vitamin K are likely to be more important components.

## BLOOD

The fetal hemoglobin predominant in the full-term newborn (80%) is ideal for oxygen uptake across the placenta at the low oxygen tensions that are present in utero. After birth this fetal hemoglobin is less able to unload oxygen at the tissues. Red cell 2,3-diphosphoglycerate levels increase rapidly in the newborn period to improve oxygen delivery and release, and the oxygen dissociation curve shows a shift to the right.

The blood volume of the newborn depends on the age at which the umbilical cord is clamped. Clamping within the first 15 s after delivery leads to a blood volume of around 75 ml/kg but delayed clamping increases this, the contracting uterus expelling blood from the sinuses of the placenta to the baby (Fig. 12.5). If the cord is not clamped for 3 min after delivery, the blood volume may be 95–100 ml/kg. In the term baby this is associated with a higher incidence of respiratory problems and jaundice but in the preterm infant, where the hemoglobin and red cell volume at birth tend to be lower, a 30 s delay in cord clamping with the newborn infant lower than the placenta may reduce the respiratory problems and the subsequent requirement for top-up blood transfusions.

## ENDOCRINE SYSTEM

Numerous hormonal changes take place during labor and immediately after birth which allow the infant to adjust to the change in the environment and the loss of the placental supply of nutrients and minerals. There is a rapid surge in thyroid hormones, thought to be a response to cold exposure. Cortisol and ACTH rise with labor and peak a few hours after delivery in response to stress. Intact pituitary, thyroid, parathyroid, adrenal and pancreatic functions are required to maintain glucose, calcium and electrolyte homeostasis. Babies with disorders of pituitary function may present with hypoglycemia or prolonged jaundice, and this may be associated with midline structural abnormalities of the brain (septo-optic dysplasia). Inborn errors of

adrenocortical steroid synthesis (congenital adrenal hyperplasia) can present with ambiguous genitalia and/or salt loss.

## THE IMMUNE RESPONSE AND INFECTION

Once delivered from the protected environment of the uterus, the baby is subjected to many potentially infectious agents. IgG transferred actively across the placenta in the last trimester of pregnancy will last for only a short time (up to 6 months). During this time the infant must develop his own antibodies. Although both B and T cells are potentially functional in utero the virginal experience (in relation to foreign antigen) in the uterus leads to a gap of cell-mediated immunity in the neonatal period. It is sensible for people overtly suffering with viral or bacterial infections not to be intimately involved with the management of newborn infants. Exposure to a pathogen leads to a response at a rate similar in the baby to that seen in older age groups. Absence of either B or T cell functions after birth leads to severe infections and if the diagnosis is not considered, the infant may die (Ch. 27).

## ROUTINE CARE OF THE FULL-TERM INFANT

### EXAMINATION OF THE NEONATE

It is standard practice in the UK and many other countries for all newborn babies to have a formal clinical examination in the first few days of life. This is often referred to as the routine newborn examination and it can be defined as the detailed professional examination in the first few days of life of a baby who, at the start of the examination, is thought to be well and without significant problems. Examination of a baby to whom attention has been drawn, for example because of cyanosis, feeding problems, apneic episodes or an obvious congenital anomaly, is not a routine newborn examination.<sup>29</sup> In the UK, where most births take place in maternity units rather than the mother's home, this examination usually takes place before the family returns home.

The aims of the routine newborn examination are as follows:

- To ascertain the family's concerns and to provide the chance to discuss them.
- To consider the baby in the light of the mother's medical history, the family's medical history and any relevant concerns raised during the course of the pregnancy and delivery.
- To note birth weight and a baseline measurement of head circumference.
- To verify that the baby is appropriately nourished, is feeding acceptably and has passed urine and meconium.
- To appreciate the presence of clinical signs (e.g. cyanosis, respiratory distress, or inappropriate drowsiness) which identify the occasional baby who is clearly unwell.
- To perform a systematic examination of the baby with the aim of detecting variations of normal which may only need explanation (e.g. 'stork marks'); or which may need investigation (e.g. jaundice); or which require referral for treatment (e.g. posterior palatal cleft).<sup>30</sup>
- To examine the baby for specific target conditions, in particular congenital cataracts, congenital heart disease, developmental dysplasia of the hip, and cryptorchidism.<sup>31</sup>
- To ensure that the findings of the examination, and any plans for follow-up or treatment, are appropriately recorded and effectively communicated to the parents and to those involved in providing future health care to the family.

The mother's handling of her baby while the history is taken and her behavior during the examination may alert the doctor to problems in the developing relationship between mother and baby.

## EFFECTIVENESS OF THE ROUTINE NEWBORN EXAMINATION

Many of the aims of the routine newborn examination fit within the definition of screening. The criteria for appraising screening programs were set out by Wilson & Jungner<sup>32</sup> and enlarged upon by Cochrane & Holland.<sup>33</sup>

Fig. 12.5 Variation in infant's blood volume with time of clamping of the umbilical cord. (From Smith and Nelson 1976<sup>28</sup> with permission.)

If applied to the routine newborn examination these would essentially demand that the examination detect significant malformations reliably and accurately; that these conditions would, if left undetected, result in a worse outcome for the baby; that they are treatable; and that the mode of examination is acceptable to the parents. These criteria have been further developed in the UK by the National Screening Committee.<sup>34</sup> This body defines screening as 'the systematic application of a test or inquiry, to identify individuals at sufficient risk of a specific disorder to warrant further investigation or direct preventive action, amongst persons who have not sought medical attention on account of symptoms of that disorder'.

In these days of increasing patient expectations it is important not to exaggerate the effectiveness of the routine newborn examination. When evaluated as a screening test for the four target conditions mentioned below, the routine newborn examination does not perform well. Some justification for including these conditions in the newborn examination and some idea of the performance of the examination in the detection of affected children can be found in the next few paragraphs.

### CONGENITAL CATARACT

Congenital cataract occurs in 2–3 babies per 10 000 births in the UK and is well recognized as a preventable cause of blindness.<sup>35</sup> All babies should have their eyes examined and the presence of a red reflex confirmed as part of the routine newborn examination. If no red reflex is seen then urgent referral for ophthalmological examination is justified. Early surgical removal of dense opacities together with refractive correction produces the best results in terms of visual acuity.<sup>36</sup> Most ophthalmologists would wish to remove cataracts well before 8 weeks because studies show that delay beyond this age results in a measurable reduction in the quality of vision when compared with earlier correction.<sup>37</sup> A recent UK study showed that only 35% of infant cataracts were detected at routine newborn examination.<sup>38</sup>

### CONGENITAL CARDIAC MALFORMATION

Unrecognized cardiac malformation carries a serious risk of avoidable mortality, morbidity and handicap<sup>39</sup> but detecting such malformations in the newborn period is difficult for a number of reasons.<sup>40</sup> The prevalence is low (~ 6 per 1000 births) and most babies show no signs or symptoms in the newborn period.<sup>41</sup> Murmurs can be heard in about 1–2% of babies undergoing routine newborn examination but less than half of these indicate cardiac malformation.<sup>42</sup> Conversely, less than half the babies with such malformations have a murmur in the newborn period.<sup>29</sup> Finally the most dangerous diagnoses (systemic ventricle outflow tract obstructions) have a combined prevalence of only 1:1500<sup>41</sup> and usually become symptomatic only after they are already established on a rapidly deteriorating course which can lead to death in a matter of hours.<sup>43</sup> It is thus perhaps not surprising that the routine newborn examination only detects about 45% of congenital cardiac malformations and that serious conditions are no more likely to be detected than less serious ones.<sup>29</sup>

### DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (DDH) resulting in dislocation at about 1 year of age could be expected to occur in about 1 per 1000 live births in the UK in the absence of screening.<sup>44</sup> Even though universal screening was introduced in this country in 1969,<sup>45</sup> a national review 30 years later suggests that the number of children receiving surgery for this condition has not been reduced.<sup>46</sup> Results from South Australia appear more successful, though this is exaggerated by their presumption that all positive neonatal findings represented true cases.<sup>47</sup>

However, screening for this condition aims to achieve good hip structure and function, not merely to avoid surgery. No study has yet looked at the quality of hips in surgically treated screened and unscreened cases. In the past, departments with a special interest in this condition have been estimated to detect a little over 60% of cases at a 'cost' of splinting 10 or more false positives for every true case.<sup>44</sup> The

number of cases unnecessarily treated may be able to be safely reduced if ultrasound examination is included in the assessment of possible cases. Primary screening with ultrasound is unlikely to be helpful.<sup>48</sup> Complications can result from nonsurgical treatment.<sup>49</sup> An extensive review of the literature and various detection strategies are outlined in a clinical practice guideline recently issued by the American Academy of Pediatrics and its technical report.<sup>50,51</sup>

### CRYPTORCHIDISM

About 2% of term male babies have one or both testes undescended but most of these will descend in the first few months of life, probably as a result of the postnatal testosterone surge.<sup>52</sup> Many of those that have not descended by the age of 4 months will probably not descend until puberty when human chorionic gonadotrophin and testosterone levels increase once again. Most surgeons regard boys as cryptorchid if one or both testes are not descended at 1 year of age. In the cohort studied by Scorer & Farrington in the 1950s this definition applied to 0.8%.<sup>52</sup>

While it is reasonably clear that cryptorchidism is associated with both reduced fertility<sup>53</sup> and an increased risk of testicular malignancy<sup>54</sup> it is less clear that either of these risks is reduced by orchidopexy.<sup>55</sup> However, histological changes occur in testes not brought down in the first 2 years of life which are not apparent in those brought down earlier.<sup>56</sup>

### WHO PERFORMS THE ROUTINE NEWBORN EXAMINATION

In the UK at the present time most routine newborn examinations are performed by junior medical staff attached to a pediatric department for a period lasting perhaps 6 months. Training to perform such examinations is not standardized and supervision is variable. Recent data have shown that when neonatal nurse practitioners are responsible for performing these examinations the results are possibly improved.<sup>57</sup> This may be due to two factors: first, nurse practitioners receive specific training before taking on this responsibility; second, nurse practitioners are likely to remain in post for considerably longer, and thus are likely to gather considerably more experience of the examination than the average pediatric senior house officer.

A detailed description of a suitable approach to neonatal history taking and examination is given in Chapter 8.

### LABOR WARD ROUTINES

#### AIRWAY

Around 95% of term infants establish spontaneous respiration by one minute of age and rapidly become vigorous and pink. Suctioning these infants after delivery is unnecessary and may provoke bradycardia and apnea. If there was meconium staining of the liquor, prophylactic suctioning of the airway of the emerging baby at the maternal perineum before the delivery of the shoulders is of no benefit.<sup>58</sup> Airway suctioning after delivery of vigorous infants also carries no advantage.<sup>59</sup> A significant proportion of the infants who end up needing extensive resuscitation after birth cannot be predicted in advance of delivery. Although the empirical risk of this is small, this is one of the reasons that justify a recommendation that all infants should be delivered in hospital. Although they are clinically pink and healthy, term infants without breathing difficulties still have oxygen saturations in the low 80s at the time of the 5 minute Apgar score.<sup>60</sup> There is no evidence that they benefit from oxygen supplementation.

#### THERMAL STABILITY

Newborn infants lose heat rapidly, particularly if they have low birth weight. They should be dried with a warm towel as soon as possible after birth. This only takes seconds and should not prevent close contact between the baby and the mother from being established promptly. The delivery room should

be kept warm and draught free. Routinely bathing infants in the delivery room is not beneficial and places them at risk of hypothermia.

### CORD CARE

The cord should be clamped with a disposable clamp or tied twice with a cord ligature to prevent accidental hemorrhage. The optimal timing of cord clamping and the preferred position of the infant in relation to the mother prior to cord clamping remain uncertain.<sup>61,62</sup> Delayed clamping of the cord in preterm infants increases blood volume and may be advantageous. In term infants the increased blood volume may decrease the risk of later anemia but this must be balanced against the risk of occasional polycythemia and volume overload.

### SUCKLING

With a minimum of delay, the infant should be given to the mother. Skin to skin contact between the baby and mother will help keep the baby warm and encourage early suckling, which promotes successful breast-feeding.

### APGAR SCORES

The condition of the infant should be continually assessed during the first minutes of life. A policy of assigning Apgar scores at 1 and 5 minutes of age helps to ensure that assessment takes place (p. 204).

### OTHER ISSUES

Mistaken identity must be prevented. Someone who was present at the birth should stay with the baby at all times until two identity labels have been securely fastened to the baby, particularly if the baby is removed from the birthing room for resuscitation. At some point, the baby should be weighed, vitamin K should be given (p. 295) and the baby should be inspected for congenital malformations, dysmorphic features and signs of illness.

### POSTNATAL WARD ROUTINES

Unless they are unwell, babies should generally remain with their mother rather than be admitted to a separate nursery. A further assessment of the general well-being and temperature of the infant should be made at the time of admission to the postnatal ward.

Long postnatal ward stays in healthy mothers and infants used to be the norm but discharge home soon after birth is now increasingly common. This means that an increasing proportion of the problems which occur during neonatal adaptation now develop after discharge and require re-admission to hospital.<sup>63</sup> High levels of support for mothers and infants in the community are required to prevent occasional serious morbidity. Hypernatremic dehydration due to inadequate milk intake in breast-fed infants is common<sup>64</sup> and kernicterus has reappeared.<sup>65</sup>

At some point in the newborn period the infant should be thoroughly examined by someone competent in neonatal hip examination, auscultation and ophthalmoscopy (p. 135). Once milk feeds are established, a capillary blood sample is collected onto filter paper (the Guthrie test). This is used for screening for hypothyroidism and phenylketonuria. A sample is also archived. A formidable array of tests is now possible on these samples and many new screening tests are proposed but not yet offered universally. Archived blood spots have also been used for population-based research and anonymous screening.

### VITAL FUNCTIONS

Most infants (95%) are observed to pass urine during the first 24 hours after birth. Those who do not probably did so at the time of delivery. By 48 hours 99% of infants have micturated and failure to do so should prompt further assessment. Meconium is also passed soon after birth by

most infants. Failure to do so by 24 hours may indicate an underlying cause such as Hirschsprung disease or meconium ileus and further investigation may be required if there is clinical suspicion. Infants should be kept under review until normal meconium passage has been documented.

After 2–3 days of milk feeding the dark green meconium (bile stained intestinal secretions, intestinal debris and cells) becomes mixed with milk stool and after a further 2–3 days yellow milk stools are present. Delay in the development of changed stools in a breast-fed infant should prompt assessment of the adequacy of the milk intake. There is wide variation between healthy infants in the frequency of passage of stool in the first weeks. Breast-fed infants tend to pass loose yellow stools that may be mistaken for diarrhea, many times per day. The stool frequency of formula-fed infants tends to be lower and the consistency more solid.

Most babies lose weight in the days after birth. A 10% weight loss in the first 4 days is common as excess extracellular fluid is excreted. Thereafter, provided that the milk intake is adequate, a steady pattern of weight gain of approximately 25 g/day is observed. The weight gain may be established more slowly in breast-fed infants and this can undermine maternal confidence in breast-feeding. A very small number of breast-fed infants do not establish an adequate milk intake, continue to lose weight and develop hypernatremic dehydration which can be life threatening.<sup>64</sup> They are often felt to have been feeding satisfactorily although clues to an inadequate intake may have been present such as delay in developing changed stool. One approach to preventing this problem is to weigh all breast-fed infants at the time of the Guthrie test with the aim of identifying excess weight loss before illness develops.

Vomiting is common in the healthy newborn but may be a sign of abnormality. Occasional mucus or milk vomits are acceptable. Bilious or blood-stained vomits require prompt investigation (p. 273). The commonest explanation for blood-stained vomits in the newborn period is maternal blood swallowed, either during delivery or when feeding from a cracked nipple.

The umbilical stump remains a potential portal for infection until it has healed. It is important to keep the area clean as the stump necroses and separates. Some advocate the regular application of surgical spirit, chlorhexidine powder or antiseptic dyes to the umbilical stump. Trials of these practices in resource rich countries do not demonstrate them to be advantageous.<sup>66</sup> Periumbilical erythema indicates infection and requires prompt medical review.

Mothers may require support and education in the basics of baby care, including feeding, feed preparation, bathing and temperature control. If the environmental temperature is warm enough for the mother to be clothed only in a nightdress then the baby should be warm enough in a babygrow under two blankets. Overheating is probably as common as hypothermia in term infants. Both may be dangerous. Epidemiological data demonstrate that the incidence of sudden infant death syndrome is lower when infants sleep supine rather than prone.

### GENITALIA

Routine circumcision is a nonmedical ritual that should not be imposed on infants of either sex.

### FEEDING THE FULL-TERM NEWBORN

Newborn infants make a rapid change from the parenterally nourished in utero environment to the outside world where their nutritional needs are normally met by enteral nutrition alone. A small minority of infants encounter problems when trying to make that change. This may be because of impaired metabolic adaptation shortly after birth or because they are unwell in some way, e.g. with sepsis. Some infants with structural gastrointestinal abnormalities may be unable to tolerate enteral feeds but for the vast majority of infants milk feeding is established soon after birth. Despite extensive research, there are few adequately conducted or controlled trials of feeding in full-term infants. What good evidence there is, however, continues to demonstrate major short and long term benefits for breast milk.

## BREAST MILK

Evolution has designed breast milk to satisfy the needs of newborn infants. Despite rising prolactin levels during pregnancy, lactogenesis is inhibited by the concomitant high levels of progesterone. A further rise in prolactin, and withdrawal of other circulating hormones (progesterone, estrogen and placental lactogen) leads to milk production. Early skin-to-skin contact involves placing the newborn infant on the mother's bare chest and helps to release maternal oxytocin.<sup>67</sup> Oxytocin causes uterine contraction (and so reduces the risk of maternal postpartum hemorrhage), raises maternal skin temperature and decreases maternal anxiety. Systematic review has shown a significant benefit of skin-to-skin on breast-feeding at 1–3 months post birth [odds ratio (OR) 2.15] and breast-feeding duration.<sup>67</sup>

Nipple stimulation helps release further prolactin, and oxytocin leads to contraction of the myoepithelial cells surrounding the lactiferous sinuses resulting in milk ejection (the 'let down' reflex). Initially small amounts of colostrum are produced – this is high in protein and immunoglobulins, and contains a variety of hormonal factors and cells. Transitional milk produced after the first few days also contains higher concentrations of fat and lactose. Towards the end of the second week, 'mature' milk is produced. This continues to contain a bewildering array of substances: enzymes, growth factors, cytokines and prostaglandins.

After the first 2–3 days, further suckling results in milk production and many mothers will experience full and possibly tender breasts. Regular feeding and emptying of the breast results in continued milk production. The composition of milk changes during a feed (hind milk is much higher in fat) so successful breast-feeding involves emptying one breast before moving to the other. Cesarean section (compared to normal vaginal delivery) results in lower volumes of milk production over the first few postnatal days. Maternal opioid analgesia also seems to impair breast-feeding initiation.

## SUPPORTING BREAST-FEEDING

Hospital routines and environments are not necessarily conducive to breast-feeding. Wards are often busy and noisy, and may not provide adequate privacy. Sleep and rest (for both mother and baby) may be compromised. Education is effective at increasing breast-feeding initiation rates.<sup>68</sup> Many mothers benefit from support from established breast-feeding support staff. UNICEF has developed 'The 10 steps to successful breastfeeding' – evidenced-based standards that maternity providers can use to examine their own practice.<sup>69</sup> These state that every facility providing maternity services and care for newborn infants should:

1. Have a written breast-feeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help mothers initiate breast-feeding within half an hour of birth.
5. Show mothers how to breast-feed, and how to maintain lactation even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in – that is, allow mothers and infants to remain together – 24 hours a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or pacifiers (also called dummies or soothers) to breast-feeding infants.
10. Foster the establishment of breast-feeding support groups and refer mothers to them on discharge from the hospital or clinic.

Units that can meet these standards can be accredited with the 'Baby Friendly Initiative' (BFI) award.<sup>70</sup> Recent surveys (2005) have shown improvements with breast-feeding initiation rates in the UK currently at 76%.<sup>71</sup> Unfortunately, a rapid fall off in breast-feeding prevalence still seems common with less than half of all babies being breast-fed at 4 weeks' postnatal age.

Over the first 1–2 postnatal days some babies will only feed 3–4 times a day but this rapidly increases and most will be feeding every 2–3 hours by the end of the first week. This often settles to 3–4 hourly in the second postnatal week. Antenatal and postnatal education needs to alert mothers to this so they are prepared. Frequent feeding by breast-fed infants may be misinterpreted. Mothers who cease breast-feeding often express the concern that their baby was 'not satisfied'.

Early growth differs little between those fed breast or formula milk. Observational studies suggested that weight gain later on in the first year of life may be less in those breast-fed, although whether this is due to unmeasured confounding or a biologic effect of formula feeding remains unclear.<sup>72</sup> Body composition also differs – breast-fed babies tend to have a lower fat mass.

Failure of breast-feeding still occurs in the first few days. Improved education and support in the antenatal and postnatal period will reduce this, but support following hospital discharge still seems to be lacking. Early discharge may exacerbate the problem. Affected babies have often lost >10–12% of their birth weight, and may be jaundiced and hypernatremic. Coexisting morbidity (e.g. infections) requires consideration. Most can be managed with enteral rehydration (with breast or formula milk). Intravenous rehydration is complicated and potentially more dangerous and should be reserved for those unable to tolerate enteral feeds and/or those with very high sodium levels.

## BREAST MILK SUBSTITUTES

Formula milks based on cows' milk have been used for decades in place of breast milk. The macronutrient composition is designed to mimic that of breast milk (~65 kcal/100 ml and 1.3–1.5 g protein/100 ml) and requires that the relatively high levels of protein, sodium and phosphate in cows' milk are reduced. Modification of the protein and albumin is necessary, fat blend is altered, and iron and a range of vitamins and other micronutrients are added or modified. There are no good data to support the addition of long chain polyunsaturated fatty acids<sup>73</sup> or other substances (such as nucleotides) in term formulas. Most of these are probably safe but few have been subject to adequate controlled study.

In resource rich countries the risks of preparation using contaminated water or inadequate washing or sterilization of bottles are small. In countries where clean water is not available and where perinatal education may be lacking, formula feeding is associated with higher rates of serious infections and death. Promotion of breast-feeding remains one of the most cost-effective health interventions available. However, there will always be a need to produce and prepare safe formula milk where breast-feeding is not possible or recommended (e.g. maternal HIV positivity in resource rich countries, rare metabolic problems such as galactosemia or maternal cytotoxic therapy). These babies' parents also deserve appropriate education and support. This should emphasize the importance of hygiene and sterile water (boiled water that has cooled) and the avoidance of adding extra scoops to promote more rapid weight gain. Formula-fed babies generally feed less often than breast-fed infants.

## BREAST VERSUS BOTTLE FEEDING

Level 1 evidence from prospective trials directly comparing breast and formula milk is generally lacking as such trials may be considered unethical, but studies in preterm infants have been undertaken and provide compelling evidence of advantage. Epidemiological studies suggest a decrease in the incidence of sudden unexpected death in infancy.<sup>74</sup> The Promotion of Breastfeeding Intervention Trial (PROBIT), conducted in Belarus in over 17 000 mother – infant pairs, compared infant outcomes between those born in UNICEF BFI modeled hospitals (intervention) or standard practice.<sup>75</sup> Significant increases in breast-feeding rates occurred in BFI hospitals and were paralleled by reduced risks of gastrointestinal infections and atopic eczema.

There is also increasing evidence of long term advantage for breast milk. Blood pressure in childhood and adolescence is typically 4–6 mmHg lower, plasma lipid profiles are more 'beneficial', and obesity is reduced

(typical OR ~0.75).<sup>76</sup> There seems to be significant cognitive advantage of breast milk with adjusted benefits of 2–3 IQ points for term infants and possibly 5–6 IQ points for preterm infants. Data on the risks for later development of diabetes, celiac disease, inflammatory bowel disease and neoplasia suggest breast milk benefit but remain uncertain.<sup>76</sup>

## THE HIGH RISK NEWBORN

### BIRTH TRAUMA

A birth injury is a potentially avoidable mechanical injury occurring during labor or delivery (thus excluding damage from amniocentesis or intrauterine transfusion). Asphyxia and injury may occur together as the identification of a fetus in suboptimal condition inevitably leads to a rushed delivery. Even competent obstetric intervention in this situation may lead to injury but it is often possible that more serious damage such as severe asphyxia or death may have been prevented. Improvements in antenatal care and obstetric practice have reduced the incidence of birth trauma but where obstetric provision is poor, injuries are both common and severe. In resource rich countries, possibly because of the low incidence, obstetric anxiety and guilt may be an inevitable sequel to each case. It is important that information is given to the parents immediately problems are identified in order to avoid misunderstandings and recrimination. Sensitive counseling is a most important aspect of management. Estimates of incidence are meaningless as the frequency varies with the quality of obstetric practice but the more difficult or prolonged the labor and delivery, the more likely it is that trauma will occur. Conditions predisposing to injury are listed in [Table 12.1](#).

### SOFT TISSUE INJURIES

*Abrasions* and *blisters* from forceps or vacuum deliveries, *punctures* from scalp electrodes or blood samples and *incisions* from hurried Cesarean sections lead to potential infection sites. *Bruises* from trauma may be severe in preterm deliveries and extensive into the buttocks following breech deliveries leading later to jaundice and anemia and occasionally disseminated intravascular coagulation. Vitamin K should be given and phototherapy considered early. The *sternomastoid tumor* is originally a hemorrhage. Do *not* call it a tumor in front of parents. It may require passive physiotherapy. *Petechiae* are common over the head and neck following shoulder dystocia, face presentation or a nuchal cord. *Subconjunctival hemorrhages* are common in spontaneous deliveries (the mother may be worried about the baby's vision – reassure). *Subcutaneous fat necrosis* may be from obvious pressure from forceps or mother's pelvis, the thickened rubbery skin sometimes softening with resolution. This necrosis may occur over the back of head, cheek, outside of upper arm or greater trochanter of the femur. No treatment is required. *Fractures* ([Table 12.2](#)), deformity or pseudoparalysis may be observed and crepitations or later callus may be palpable. Pain relief is important.

### INTRA-ABDOMINAL INJURIES

Hepatosplenomegaly (e.g. rhesus hemolytic disease), coagulation disorders and hypoxia, breech deliveries and cardiac massage all predispose to *subcapsular hematomas of the liver and spleen*. Anemia, pallor, tachycardia and tachypnea may be the presenting features or rupture may occur (immediately or days later) to give hypovolemic shock and death. *Adrenal hemorrhages* may follow severe infection, severe asphyxia

or coagulation disorder. Hypovolemic shock with a flank mass and overlying skin discoloration may be evident. Adrenal failure may require treatment (p. 487) and later calcification may occur. All hemorrhages predispose to jaundice. Ultrasound assists in diagnosis.

### EXTRACRANIAL INJURIES

The *caput succedaneum* (present at birth) is a serosanguineous subcutaneous effusion over the presenting part in a vaginal delivery. It crosses the suture lines and disappears rapidly. *Subaponeurotic hemorrhages* are rare. They may follow vacuum deliveries or less commonly other instrumental deliveries. The hemorrhage is between the scalp aponeurosis and the periosteum and if it is massive it may present with hypovolemic shock and be fatal. Vitamin K (1 mg) intramuscularly should be given to all vacuum deliveries. Once diagnosed, full clotting tests should be performed and 10 ml/kg of fresh frozen plasma should be given followed by cross-matched blood. Later there may be jaundice and anemia. The *chignon* is usual from a vacuum delivery and requires no treatment. A *cephalhematoma* may follow an instrumental or less commonly a spontaneous delivery. This subperiosteal hematoma is limited by each cranial bone and is probably always associated with a hairline fracture. There is no scalp discoloration and it appears *after* birth. Jaundice may develop and phototherapy may be required. The hematoma usually resolves over 2–8 weeks with hardening of the edge and at this stage may mimic a depressed fracture. Thickening of the diploë on skull X-ray may be apparent for years. The commonest site is parietal (sometimes bilateral) followed by frontal and then occipital. No treatment is required. Do *not* drain as this potentially allows infection into the hematoma.

### INTRACRANIAL INJURIES

Asphyxia and intracranial birth injury show similar clinical features and frequently coexist. Prenatal asphyxia or congenital abnormality may have initiated an instrumental delivery so it may be impossible to attribute abnormal features neonatally or later neurodevelopmental problems to one cause rather than the other. It is also possible that prenatal asphyxia may make a baby more vulnerable to birth injury by causing a high venous pressure, acidosis or disordered coagulation.

#### Intraventricular hemorrhage (p. 307)

This hemorrhage usually found in preterm infants is not now thought to be related to birth injury. In the asphyxiated full-term infant the choroid plexus may bleed into the ventricle.

### COMPRESSION HEAD INJURIES

Cephalopelvic disproportion and instrumental delivery will predispose to intracranial injury. In many cases there will be obvious extracranial injury. Hypoxic–ischemic encephalopathy and cerebral edema (p. 205) may contribute to the clinical signs. If intracranial hemorrhage is massive, resuscitation may prove impossible or when initially successful the infant may survive only a few hours with generalized hypotonia progressing later to rigidity with convulsions and deep gasping respirations. Supratentorial bleeds lead to a tense fontanelle but posterior fossa bleeds do not. Head retraction may be marked, retinal hemorrhages may occur rapidly and the infant may have a high-pitched cry or may moan continuously. If unconscious the infant may make no sound.

Less severe hemorrhage leads to apathetic periods interspersed with periods of extreme irritability. The hemisyndrome may be evident with eyes and head turned to one side and paucity of movement on the other. Up to 50% of such infants convulse and tonic fits have a worse prognosis.

#### Subarachnoid hemorrhage

This may occur in preterm and term infants following perinatal hypoxia. The baby may be pale and irritable with a high-pitched cry, neck retraction and sometimes a full fontanelle. Diagnosis is difficult by ultrasound but the presumptive diagnosis by lumbar puncture may be confirmed by CT or MRI scan.

**Table 12.1** Conditions predisposing to birth injury

Poor maternal health	Cephalopelvic disproportion
Maternal age (very young and old)	Hydrocephalus
Grand multiparity	Macrosomia
Twins (particularly the second)	Dystocia
Prematurity/low birth weight	Contracted pelvis
Malpresentation	Instrumental delivery

Table 12.2 Fractures

	Specific cause	Potential problem	Treatment	Comment
Skull				
Linear	1. Forceps pressure 2. Pubic pressure 3. Sacral pressure 4. Ischial spine pressure	Usually none, rarely subdural or extradural hemorrhage		
Depressed	Forceps	Underlying brain injury	1. If asymptomatic, none 2. If symptomatic, elevate	Prevent sustained cortical pressure
Occipital subluxation	Traction on spine in breech deliveries with head fixed in the pelvis	Rupture of underlying venous sinus		Usually fatal from subdural hemorrhage or tentorial tear
Clavicle (common)	1. Breech – extended arms 2. Difficult shoulder in vertex delivery	Associated brachial plexus injury	1. None – or if pain: treat pain 2. Bandage arm to chest with pad in axilla for 10 days	Prognosis excellent
Humerus	Breech – bringing down a displaced arm	Nerve damage	As for clavicle	Prognosis excellent
Femur	Extended breech	Sciatic nerve damage	1. Immobilize leg onto abdomen for 2–4 weeks (the in utero position) 2. Gallows traction	Position unimportant, molding will repair
Epiphyseal separation		Callus interferes with joint mobility and bone growth		1. On the upper femur, pain on external rotation 2. Outlook good
Nose	Dislocation of nasal cartilage	Difficulty feeding	1. Insert oral airway 2. Straighten surgically	Nares asymmetrical and nose flat

### Subdural hemorrhage (hematoma)

Tears of the tentorium cerebelli or less often the falx cerebri are rare nowadays. If the hemorrhage is not rapidly fatal and if it is supratentorial, localization leads to hematoma. Signs of cerebral irritation settle after 48–72 h but later in the first week the head circumference begins to increase fast and there is clinical deterioration. Vomiting is common. Diagnosis is by CT or MRI scan and treatment by subdural taps at the lateral edge of the anterior fontanelle. Ultrasound may show midline shift but it is frequently difficult to see the subdural region to visualize the hemorrhage itself.

### Management of intracranial injury

Any baby suspected of having an intracranial injury should be closely observed in an incubator with monitoring of PaO<sub>2</sub> and PaCO<sub>2</sub>. Temperature, blood pressure, fluid balance, and metabolic problems of blood sugar, calcium and coagulation should be corrected.

The use of anticonvulsants may be required for convulsions (p. 304). Careful fluid balance is needed and it is wise to restrict intake initially to intravenous 10% dextrose at 50 ml/kg/24 h (to reduce edema secondary to inappropriate vasopressin secretion). Manual expression of the bladder may be needed. Treatment may be required for cerebral edema (p. 206).

### PERIPHERAL NERVE INJURIES

*Sixth nerve palsy* seen for a few days after birth is probably associated with cerebral edema and trapping of the nerve on the tentorium. *Facial nerve damage (VII)* is usually peripheral from forceps pressure or from pressure on the maternal pelvis (spontaneous deliveries). No facial movement or forehead movement is seen when the infant cries. The corner of the mouth droops with dribbling at feeds and the eye fails to close (this requires protection). Recovery usually occurs over weeks but if after months there has been no recovery surgical neuroplasty should be considered. Rarely a central nuclear agenesis leads, if one sided, to paralysis of the lower half of the face.

Neck retraction in breech deliveries or shoulder dystocia damages the upper brachial plexus roots to give *Erb palsy (C5, C6)* or *phrenic palsy (C3, C4, C5)*. The arm is limp with forearm pronated and wrist flexed (waiter's tip position) from paralysis of deltoid, biceps, brachioradialis and long wrist extensors. Finger movements and therefore grasp reflex are normal. The biceps and Moro reflexes are absent on the affected side. Initial splinting of the arm to the side of the head probably makes little difference to the rate of recovery which is usually within 3 weeks (if severe it may take up to 2 years). If severe, and little recovery is detected after 3 weeks, a neurological service should be involved in management. Phrenic involvement presents as acute cyanosis and irregular labored breathing. There are reduced breath sounds and an absent abdominal bulge on inspiration because of paradoxical diaphragmatic movement. Diagnosis is by ultrasound or fluoroscopy. Treatment is with oxygen and intravenous fluids and then the gradual introduction of enteral feeds. If there is no improvement in 2 months (on ultrasound), diaphragmatic plication is indicated to prevent recurrent infection and bronchiectasis. *Klumpke palsy (C8, T1)* may occur with a breech delivery when the arms are extended up beside the head and the lower roots are stretched. The hand and forearm are paralyzed and there may be an ipsilateral Horner syndrome. Edema and hemorrhage cause temporary problems but avulsion may lead to permanent disability so a neurological service should be involved soon after birth. Traditional treatment, strapping the upper limb to the trunk, probably makes little difference to the rate of recovery. *Radial nerve* damage is temporary and leads to wrist drop. It may be due to fat necrosis involving the nerve but frequently no predisposing factor can be found. Treat with a cock up splint.

In general peripheral nerve injuries need gentle passive exercise of the limb several times a day with splinting to avoid contractures. If paralysis continues for more than 3 months, recovery is unlikely. Neuroplasty and tendon transplant have usually been considered at 3–4 years of age but there has been a recent move in brachial plexus injuries to explore and attempt repair much earlier if there has been no improvement by a few months of age.

## SPINAL CORD INJURIES

The lower cervical or upper thoracic cord may be bruised or rarely transected by forceful longitudinal or lateral traction on the spine. Subluxation or fractures of the vertebrae may occur with breech deliveries where the head is hyperextended or in a vertex delivery with shoulder dystocia. Coincident brachial plexus injury is common. The infant may be normal at birth or shocked but paralysis with flaccidity below the lesion quickly occurs with accompanying constipation and urinary retention. Intercostal paralysis leads to respiratory recession (Fig. 12.6). Spinal reflex activity returns after a short time. The initial flaccidity and immobility are replaced after several weeks by rigid flexion at hip, knee and ankle with increased tone and spasms. Absent sensation and automatic bladder function necessitate treatment similar to that of the baby with a meningomyelocele (p. 832). Diagnosis may be confined by MRI or myelography. There is no reparative treatment but multidisciplinary involvement inclusive of physiotherapy may prevent or reduce contractural difficulties in the future.

## PERINATAL ASPHYXIA

When related to pathophysiological processes, asphyxia is the combination of both a lack of oxygen (hypoxia) and perfusion (ischemia) to an organ. In current clinical usage there remains variability in both the meaning and interpretation of the term 'birth asphyxia'. Hence when determining the incidence, etiology and outcome of birth asphyxia there is wide variation. Many have suggested that this term should no longer be used.<sup>77</sup> Undoubtedly hypoxia–ischemia (HI) can lead to severe brain injury but a major concern regarding the term is in those children who develop long term neurodisability such as cerebral palsy. In these children there is often a false assumption that they were 'injured' during the events of labor and delivery with the result that obstetricians and midwives are targeted as the person responsible for those neurologic injuries.<sup>78</sup> In resource rich countries two of every 1000 liveborn children develop cerebral palsy (CP). Evidence suggests that 70–80% of these CP cases are due to prenatal factors and that birth asphyxia plays a relatively minor role (<10%).<sup>79</sup>

However, of the approximately 130 million births worldwide each year, four million infants will suffer from birth asphyxia; of these, one million will die and a similar number will develop serious long term neurological sequelae. Ninety-eight percent of these neonatal deaths take place in resource limited countries. This leads to a neonatal mortality rate of about 4–5 per 1000 in resource rich countries and nearly 10 times this in resource limited countries.<sup>80,81</sup> Although restricted antenatal and peripartum care are important contributors to the high rates in resource limited countries, birth asphyxia remains a problem in resource rich countries with little reported improvement over the last two decades, and factors such as hospital shift work and night time working arrangements appear to contribute to higher risk periods for the occurrence of birth asphyxia in resource limited countries.<sup>82</sup>

The World Health Organization definition of birth asphyxia in the International Classification of Diseases (ICD-10) is based on the Apgar scoring system (see Table 12.3). Apgar scores are a method of describing the condition of an infant at birth, originally described by Virginia Apgar.<sup>83</sup> Using these markers of heart rate, respiratory effort, tone, reflex activity and color, a score is established at 1 min then at 5 min intervals as necessary (maximum score 10). The ICD-10 definition of asphyxia is dependent on the Apgar score at 1 min of age. An Apgar score at 1 min of 0–3 defines severe birth asphyxia and an Apgar score of 4–7 defines moderate asphyxia. There is much debate as to whether this definition is of clinical use. Specifically, regarding prognosis, Apgar scores in individual cases do not appear to correlate well with outcome and hence are frequently interpreted incorrectly from a view of long term prognosis.<sup>84</sup> Despite the controversy, this definition of severe birth asphyxia (Apgar < 3) appears useful in identifying a high risk group requiring further observation of their neurological condition<sup>85,86</sup> with an understanding that it overestimates eight-fold the scale of the problem. Table 12.4 summarizes the proportion of infants that either die or develop cerebral palsy with different Apgars at different time points immediately after birth.<sup>87</sup>

Newer terms include 'birth depression', which is a descriptive term to indicate a newborn with poor Apgars but without passing judgment on etiology. The use of the word 'perinatal' rather than 'birth' supports the pathological processes that may begin many hours before birth and

Fig. 12.6 Thoracic indrawing in newborn infant with broken neck.

Table 12.3 The Apgar score

Sign	0	1	2
Heart rate	Absent	< 100/min	> 100/min
Respiratory effort	Absent	Weak cry	Strong cry
Muscle tone	Limp	Some flexion	Good flexion
Reflex irritability on suctioning pharynx	No response	Some movement	Cry
Color	Pale	Centrally pink, peripherally blue	Pink all over

**Table 12.4** Risk of death or cerebral palsy (CP) in infants >2500 g with Apgar scores of 0–3 at varying times from birth (data from Nelson & Ellenberg<sup>87</sup>)

continue for many hours afterwards. There are numerous causes, and the clinical manifestations vary. Infants who experience mild asphyxia may show no neurological injury. However, severe asphyxia may be fatal in utero, or immediately after birth, with survivors showing extensive neurological sequelae, with or without cognitive deficits.

### ETIOLOGY OF PERINATAL ASPHYXIA

The fetoplacental unit seems well prepared to deal with transient episodes of hypoxia–ischemia. During contractions of the uterus, placental gas exchange is commonly interrupted and there are mechanisms that protect the fetus during these episodes. These mechanisms include increased extraction of oxygen from the blood,<sup>88</sup> redistribution of the fetal blood supply to the brain and heart at the expense of the gastrointestinal tract, kidneys and muscle, etc. The neonatal brain also appears to be able to utilize other substrates instead of glucose (such as lactate and ketones).<sup>89</sup> On top of this usual process other stresses may occur and these stresses may be acute or chronic or acute on chronic. Examples of these stresses include altered placental gas exchange such as may occur in placental insufficiency or abruption, interruption to the umbilical circulation (cord prolapse or cord compression), reduced maternal placental perfusion (such as may occur with maternal hypo/hypertension), impaired maternal oxygenation, or in the newborn infant the failure to establish adequate circulation after birth.

### ASSESSMENT OF FETAL WELL-BEING (see Ch. 12)

Many different assessments attempt to predict fetal well-being. These include observing for the passage of meconium, electronic fetal heart rate monitoring via a cardiotocograph (CTG) and the assessment of fetal acid–base balance. Umbilical cord blood gas and pH values should always be obtained in the high risk delivery and whenever newborn depression occurs. The most useful umbilical cord blood parameter is arterial pH. It is more representative of the fetal metabolic condition because arterial acidemia may occur with a normal venous pH. In general, the lower range for normal arterial pH extends down to 7.10 and that for venous pH to 7.20. It is the gold standard assessment of uteroplacental function and fetal oxygenation/acid–base status at birth.<sup>90</sup> The CTG parameters associated with asphyxia include abnormal fetal heart rate variability, repeated late decelerations, repeated variable decelerations, occasional late or variable decelerations and also a lack of accelerations.<sup>91</sup> However, these associations are not helpful in individual cases as they have poor correlation with longer term outcome in newborn infants. Nonreassuring fetal heart rate patterns, prolonged labor, meconium-stained fluid, a low 1 min Apgar score, and mild to moderate acidemia have no predictive value for long term neurological injury without signs of encephalopathy and seizures.<sup>92</sup> It is therefore essential that the entire pregnancy, labor, delivery and the period well beyond birth are examined to understand fully the pathophysiological mechanisms that are responsible for any particular infant's brain injuries, and their long term impact on the child.<sup>78</sup> It is extremely important when faced with a newborn infant with low Apgars to immediately provide proper resuscitation and ongoing support whilst allowing time for further evaluation.<sup>92</sup>

### EXTENT OF INJURY FOLLOWING PERINATAL ASPHYXIA

After a severe hypoxic–ischemic insult, multiorgan system failure is common including neurological, hepatic, cardiac, pulmonary and renal

systems.<sup>93,94</sup> However, apart from brain injury there appears to be no relationship between individual or combinations of organs involved and long term outcomes.<sup>95</sup> Ultimately, if the HI insult is overwhelming then death may occur.

### HYPOXIC–ISCHEMIC ENCEPHALOPATHY (HIE)

When the brain is affected by an HI insult there may be both short and long term sequelae. Infants show a sequence of often transient encephalopathic behavior, often lasting for many days, and this is dependent on the severity and duration of the asphyxial event. In the acute setting, the clinical features that result from an HI insult in the term newborn brain reflect an evolving process characterized by an initial primary injury followed by a secondary phase of brain damage lasting several hours or even days after the insult.<sup>96</sup> Experimental studies have shown that a severe HI insult results in an evolving process of adverse biochemical events that include increased levels of neurotransmitters, excessive production of free radicals, increased intracellular calcium and stimulation of inflammatory mediators that initiate apoptotic cell death.<sup>97,98</sup> HIE is the clinical marker of cerebral tissue that has suffered severe damage and may result in perinatal mortality or permanent neurodevelopmental disability. Between 2 and 6 infants per 1000 live births develop HIE<sup>99</sup> which cannot be reliably diagnosed in premature babies. Grading systems define the degree of encephalopathy in term babies<sup>100,101</sup> (Table 12.5). Mild HIE usually recovers completely within 48–72 h and moderate HIE often continues to show significant acute neurological signs for 7–10 days. However, babies with severe HIE may remain persistently neurologically abnormal although the signs of acute encephalopathy often improve prior to discharge home. In the longer term approximately 25% of infants with moderate HIE will develop cerebral palsy, whilst historically the majority of infants with severe encephalopathy either die or survive with multiple disabilities.<sup>102</sup> It is important to note that asphyxia is not the only cause of neonatal encephalopathy<sup>103</sup> and as well as looking for supportive evidence of perinatal HI, such as signs of fetal distress, acidosis and poor Apgars, the alternative causes listed in Table 12.6 should be considered.<sup>104</sup>

### MANAGING PERINATAL ASPHYXIA

In the antenatal period the reliability of continuous heart rate monitoring of the fetus during labor as well as validity of certain heart rate changes for the detection of developing hypoxia is a matter of ongoing dispute. In the presence of clearly pathological heart rate patterns hypoxic damage may already have occurred. Suspicious or 'nonreassuring' heart rate alterations are frequent and only in a small percentage is there a real threat to the fetus in the form of severe hypoxia. Up until now there is no proof that a combination of continuous fetal heart rate monitoring with additional tests can prevent hypoxic damage to the fetus. However, despite the high false positive rate, continuous intrapartum electronic fetal monitoring is recommended for pregnancies where there is an increased risk of perinatal death, cerebral palsy or neonatal encephalopathy. Fetal scalp blood sampling is recommended in association with electronic fetal monitoring patterns that are uninterpretable or nonreassuring, such as sustained minimal or absent variability, uncorrectable

**Table 12.5** The major clinical features for grading the severity of hypoxic–ischemic encephalopathy

Mild	Moderate	Severe
Irritability	Lethargy	Coma
Hyper-alert	Seizures	Prolonged seizures
Normal tone	Differential tone (legs > arms) (neck extensors > flexors)	Severe hypotonia
Weak suck	Poor suck, requires tube feeds	No sucking reflex
Sympathetic dominance	Parasympathetic dominance	Coma, requires respiratory support

Table 12.6 Differential diagnosis for hypoxic–ischemic encephalopathy

Infective	Meningitis (bacterial or viral) Encephalitis (herpes simplex)
Traumatic brain lesion	e.g. Subdural hemorrhage
Vascular	Neonatal stroke Shock secondary to acute blood loss (antepartum/intrapartum)
Metabolic	Hypoglycemia Hypo/hyponatremia Bilirubin encephalopathy
Inborn error of metabolism	Urea cycle defects Pyridoxine dependency Lactate acidemias Amino acidemias (e.g. NKH) Organic acidemias
Congenital brain malformation	e.g. Neuronal migration disorder
Neuromuscular disorder	e.g. Spinal muscular atrophy
Maternal drug exposure	Acute or chronic

late decelerations, increasing fetal tachycardia and abnormal fetal heart rate characteristics on auscultation. Recent advances such as fetal pulse oximetry, ST waveform analysis and near infrared spectroscopy as adjuncts to electronic fetal medicine are not recommended as standard care at present.<sup>105</sup>

In the perinatal period, staff training improves outcome. The introduction of obstetric emergencies training courses has been shown to lead to a significant reduction in both low 5 min Apgar scores and the incidence of hypoxic–ischemic encephalopathy,<sup>106</sup> and a significant improvement in neonatal Apgar scores has also been shown with neonatal resuscitation training.<sup>107</sup>

In the postnatal period, the current treatment approach to a term (or near term) infant at risk of progression to neonatal encephalopathy after intrapartum hypoxia–ischemia is fourfold: resuscitation, identification, supportive and neuroprotective strategies. Effective resuscitation is the main priority in the infant born with poor Apgars. Recent evidence regarding the resuscitation of infants with poor Apgars (1 min Apgar < 4) in either ambient air versus pure oxygen suggests that although mortality rates are similar, those infants resuscitated in air recover faster than those resuscitated in oxygen.<sup>108</sup> Once the infant has been resuscitated then early identification of the infant at highest risk for evolving brain injury is necessary. This identification is based on the criteria of a sentinel event during labor, prolonged depression at birth with the need for resuscitation, evidence of severe fetal acidemia based on a cord umbilical arterial pH less than 7 and/or a base deficit more than  $-16 < \text{mmol/L}$ . The entry requirement to the majority of large randomized studies of neuroprotective strategies is stepwise through criteria A to C as summarized in Table 12.7.

The assessment of amplitude integrated EEG (aEEG) using a cerebral function monitor (CFM) in the identification of at risk infants is based on studies of infants between 3 and 6 h of age after HI and has been shown to be highly sensitive and specific in determining which of these children are most at risk of death or disability.<sup>109–111</sup> Infants meeting criteria A, B and C have a 70% chance of mortality or long term severe neurodisability. Based on animal experiments, the therapeutic window for neonates with signs of perinatal hypoxia–ischaemia is probably less than 6 h, and early selection of patients is of utmost importance. At present, neurophysiological methods such as (amplitude integrated) EEG and evoked potentials have the best predictive value.<sup>112</sup>

It is important that supportive therapy is instituted to maintain adequate ventilation; in particular severe hyperoxemia and severe hypocapnia are associated with adverse outcome in infants with post-asphyxial HIE. During the first hours of life, oxygen supplementation and ventilation should be rigorously controlled.<sup>113</sup> Mean arterial blood pressure should be kept within the normal range so as to avoid fluctuations in cerebral perfusion. Glucose should be kept in the normal range to avoid hypoglycemia, and seizures should be treated. Animal studies have also suggested that preventing spontaneous hyperthermia after HI in the newborn is neuroprotective.<sup>114</sup>

Table 12.7 Identification of infants at highest risk of evolving brain injury

<b>Criteria A – One of the following must be present</b>
Apgar score of $\leq 5$ at 10 min of age
Continued need for resuscitation (including mask ventilation) at 10 min after birth
Acidosis within 60 min of birth [defined as any pH < 7 in umbilical cord or infant blood (arterial or capillary)]
Base deficit $\geq 16$ mmol/L in umbilical cord or any sample (arterial, venous or capillary) within 60 min of birth
<b>Criteria B – Abnormal neurological status</b>
<i>Infants that meet criteria A should then be assessed to determine whether they are affected neurologically</i>
Altered state of consciousness (reduced or absent response to stimulation) and
Abnormal tone (hypotonia or flaccidity) and
Abnormal primitive reflexes (weak or absent suck/Moro)
Or seizures in isolation
<b>Criteria C – Neurophysiological abnormality</b>
Abnormal EEG or amplitude integrated EEG

There is insufficient evidence from randomized controlled trials to determine whether the infusion of sodium bicarbonate reduces mortality and morbidity<sup>115</sup> or that fluid restriction is beneficial<sup>116</sup> or that prophylactic use of anticonvulsants confers benefit other than in the treatment of prolonged or frequent clinical seizures.<sup>117</sup>

Until recently there has been no neuroprotective treatment available for infants with HIE. Induced systemic hypothermia is currently the only strategy that has been evaluated in large, multicenter randomized studies. The results of studies in human infants suggest that not only is cooling safe (when used in a tightly controlled fashion within a clinical trial) but that it also appears to confer a beneficial effect. One large study used a cooling cap device to induce selective head cooling whilst lowering rectal temperature to  $34.5^\circ\text{C}$ ; another large study induced total body hypothermia using a cooling blanket system reducing core temperature to  $33.5^\circ\text{C}$ . The majority of clinical cooling studies in infants induced hypothermia for a period of 72 h. No significant side-effects were noted with this degree of cooling. The combined data from these studies indicate that hypothermia is associated with a reduction in the incidence of death and/or severe disability at 18 months follow-up, with the most significant effect observed in infants who at the start of therapy presented with moderate encephalopathy and/or did not exhibit seizures.<sup>118–120</sup> However, there remain many unanswered questions about this type of treatment (such as the long term effects of hypothermia) and the fact that only a subgroup of babies seems to benefit. There are also no data on optimal duration, degree of cooling, best method, or whether the methods and degree of cooling should be adapted to the type or timing of brain injury. Therefore many people still feel that further data are needed before health care policies can be changed to make cooling the standard of care for all babies with suspected birth asphyxia.

For clinicians practicing in the UK the results of a large multicenter study of total body cooling to  $33.5^\circ\text{C}$  are still awaited.<sup>121</sup> Until the results of this study become available, clinicians involved in the study have permission to induce hypothermia in infants with HIE (using both the study protocol and eligibility criteria from the trial – see Table 12.7). Data from patients cooled in this way are collected as part of a national register. A similar system has been used in the USA for clinicians pending longer term safety data.

## PROGNOSIS AFTER HIE

Early indicators of prognosis are invaluable in the clinical setting and especially when discussing issues with parents. As previously mentioned, aEEG in the first 3–6 h can be used to predict future outcome. Early EEG is an excellent prognostic indicator for a favorable outcome if normal within the first 8 h of life and for a poor outcome if the background activity continues to be low or grossly abnormal beyond 8–12 h of life. However, an inactive or very depressed EEG within the first 8 h of life can be associated with good outcome if the EEG activity recovers within 12 h.<sup>122,123</sup> The highest recorded

lactate level in the first hour of life and serial measurements of lactate (to determine how quickly the levels fall) are important predictors of moderate to severe HIE.<sup>124</sup> Plasma nonprotein bound iron is also a good early predictive marker of neurodevelopmental outcome, with 100% sensitivity and 100% specificity for good neurodevelopmental outcome at 0–1.16 micromol/L, and for poor neurodevelopmental outcome at values > 15.2 micromol/L.<sup>125</sup> At 24 h of age neurological assessment using a Sarnat assessment score as well as ultrasound Doppler assessment of resistance index of blood flow in the anterior cerebral artery also add valuable information about prognosis in the individual patient.<sup>100,126</sup> Imaging of the brain with an MRI scan in the first week of life also provides further information to determine prognosis. Abnormal signal intensity in the posterior limb of the internal capsule (PLIC) is an accurate predictor of neurodevelopmental outcome in term infants suffering HIE.<sup>127</sup> The apparent diffusion coefficient (ADC) value in the PLIC is also an indicator of ischemic injury.<sup>128</sup> It is of interest that the distribution of injury appears to be different in those infants that have undergone hypothermia. The hypothermia group appear to have had less cortical gray matter signal abnormality on MRI which may indicate differing regional benefit from systemic hypothermia.<sup>129</sup>

### THE IMPORTANCE OF AUTOPSY

It is a sad fact that many infants die of overwhelming HI injury. In those cases it is essential that a postmortem is offered to the parents. HIE is a symptom rather than a final clinical diagnosis. A full autopsy is required to fully explore the reasons for fatal neonatal HIE and it may also provide information that is important medicolegally. One study reported that significant new information was added to the clinical diagnoses in over 60% of cases after autopsy.<sup>130</sup> Detailed autopsy examination should include the search for infection. The placenta should be examined for the presence of thrombosis and infarction. Careful autopsy of the neck and paravertebral tissues, spinal cord, brainstem and nerve roots is important where trauma is suspected. Metabolic disease, including peroxisomal disorders, nonketotic hyperglycinemia, lipid and glycogen storage disorders and mitochondrial diseases may cause profound hypotonia and respiratory failure at birth or shortly afterwards.<sup>131</sup>

### RESUSCITATION IN THE NEWBORN

In Western countries relatively few mature newborn infants require active resuscitation at birth. In Sweden, just 1% of babies weighing over 2.5 kg required artificial ventilation, but significantly 20% of these were unexpected in babies with no obvious risk factors.<sup>132</sup> In the UK, a comparison between two large obstetric units found that there was a five-fold variation in the proportion of newborn infants who required intubation; 2% versus 10%. In resource limited countries it is estimated that 1 million babies a year die of asphyxia and that lack of simple airway interventions is a significant factor in many of these deaths. The more preterm the delivery, the more likely it will be that the baby needs active resuscitation.

The physiology of fetal hypoxia leading to the need for resuscitation at birth is well understood and has been known for many years. In recent years, a number of national and multidisciplinary groups have described optimal practice for neonatal resuscitation based on the best available scientific evidence.<sup>133–135</sup> Although there are some differences in detail between these recommendations, these are relatively minor. Current British recommendations are outlined in this section.

### THE PHYSIOLOGICAL RESPONSE TO HYPOXIA

Our understanding of the newborn's response to hypoxia is based on neonatal animal experiments published in the 1960s<sup>136,137</sup> and is summarized in Figure 12.7. At the onset of hypoxia there is a period of small-volume but rapid breaths lasting for several minutes followed by a period of primary apnea. Prior to primary apnea the heart rate and blood pressure are maintained. Once apnea occurs the heart rate falls, but with increasing stroke volume a good cardiac output is maintained with continued perfusion of the vital organs. At this stage the baby looks cyanosed.

Fig. 12.7 The effects of asphyxia on a newborn animal showing primary and secondary apnea. (Redrawn from Dawes 1968<sup>137</sup> with permission of Blackwell Scientific Publications.)

If hypoxia continues then after a period of primary apnea lasting up to 5 minutes, spontaneous gasping occurs (10–15 per minute) and this lasts for a further period of 5–6 minutes before a second period of apnea develops. This is referred to as terminal apnea and if nothing is done to resuscitate the animal at this time death will occur within another 10 minutes. During the period of primary apnea and subsequent gasping, blood pressure and heart rate are maintained, but with increasing metabolic acidemia. Cardiovascular deterioration commences with the onset of terminal apnea.

These timings are based on rhesus monkey studies but are likely to reflect the human situation although the timing of the sequence of events may be a little shorter than in monkeys.

### THE PRINCIPLES OF NEONATAL RESUSCITATION

All babies must be born in an environment where they have rapid access to expert resuscitation skills. In home births there must be two attendants, one of which will be responsible for resuscitating the baby (if necessary) and who has appropriate training and knowledge of the equipment, which should be in full working order. Most babies will require no active resuscitation other than gentle stimulation, but others are slow to adapt to their extrauterine environment and some active steps will need to be taken by caregivers. The vigor of the response will depend on the stage of the baby's reaction to the hypoxic event. The baby who is not breathing may start to breathe spontaneously if in the stage of primary apnea but will not if in secondary apnea. Whether the baby is in primary or secondary apnea may be difficult to determine clinically. Consequently, the attendant must undertake a measured response and be prepared to escalate resuscitative measures if the initial response is inadequate.

**Table 12.8** Indications for calling a pediatrician to be present at a delivery

Prematurity
Gestation <36 weeks
Fetal distress
Thick meconium staining
Severely abnormal CTG
Fetal scalp acidosis (pH <7.2)
Operative delivery
Any delivery under general anesthesia
Mid-cavity or rotational forceps
Multiple pregnancy
Significant antepartum hemorrhage
Fetal disease
Known major congenital abnormality
Rhesus disease

CTG, Cardiotocograph.

Many, but by no means all, infants who are born in a depressed state can be anticipated. [Table 12.8](#) lists the indications for calling a pediatrician or other person competent to resuscitate the newborn infant.

### PREPARATION PRIOR TO DELIVERY

The pediatrician called for a high risk delivery should spend some time prior to delivery acquainting himself with the mother's medical and antenatal history. It is important to check all the equipment that may be required prior to delivery and not rely on the fact that this should have been done by others.

### Resuscitation trolley

A stop clock permanently fixed to the trolley is started at delivery, giving the operator a reference point for the duration of resuscitation. An integral overhead heater should be of fixed height above the infant with a dial to give variable temperature settings.

### Medical gases

It is most important that both air and oxygen are readily available, together with appropriate reduction valves so that a variable and measurable flow of gas can be given to the infant. As well as controlling the flow of gas, a blow-off valve must be fitted so that the baby's lungs are not overdistended by unacceptably high pressures.

### Suction

The presence of suction apparatus on the resuscitation trolley is essential. This must also be fitted with an accurate valve device with a display of negative pressure as too high a suction pressure may damage the infant's respiratory tract. Mouth suction must not be used. A number of suction catheters of different sizes (FG 4, 6 and 8) must also be at hand with appropriate connectors to attach to the suction device.

### Bag and mask

Bag and mask resuscitation equipment is essential in every hospital where babies are delivered or cared for and all staff must be familiar with their effective use. The method for appropriate bag and mask ventilation is described below. A number of different bags exist, the best being the Laerdal type. These are fitted with a blow-off valve which can be adjusted to give a maximum inflation pressure. Tubing can be fitted to these devices so that the baby can be ventilated with additional oxygen. As well as the bag, a tight-fitting deformable silastic Laerdal face mask is essential. These should be of variable sizes to fit the faces of the smallest and the biggest babies likely to be encountered. The technique is described below.

### Intubation equipment

Two laryngoscopes should be available with fresh batteries and these should be checked prior to delivery of the baby. A selection of endotracheal tubes should be present varying in size from 2.5 to 4.0 mm. The correct connector must also be available together with a malleable metal introducer. Reliable means of securing the tube to the baby's face should also be available and the assisting nurse must be skilled in the fixation of the tube. A stethoscope should be worn by the resuscitator prior to delivery of the baby.

### A SCHEME FOR RESUSCITATION

All staff responsible for neonatal resuscitation must have received appropriate training and regular retraining to maintain appropriate skills. In Britain the Resuscitation Council (UK) has developed the Newborn Life Support course, which is now widely available. The following are currently recommended by this course<sup>133</sup> and summarized in [Figure 12.8](#).

The need for resuscitation must be carefully assessed and an incremental approach is required depending on the condition of the baby and the response to initial measures. The six steps in this approach are as follows:

1. Conserve heat: dry and cover the baby.
2. Assess the need for resuscitation.
3. Airway: check and stabilize.
4. Breathing: bag and mask inflation.
5. Circulation: start chest compressions.
6. Drugs if required.

### Assess

Whilst drying the baby observe its responses. Watch the baby's color, respiratory efforts, heart rate and tone. Most babies will rapidly adapt to birth with improving color, increasing heart rate with the development of spontaneous breathing or crying activity. If the baby has a heart rate >100 bpm and has reasonable tone, it is reasonable to wait for up to 3 minutes for the baby to breathe spontaneously. If this is the case then nothing more needs to be done once the baby is breathing and pink; it can then be given to the mother. In premature babies great care must be taken to avoid hypothermia (see below).

### Airway

The airway must be clear for breathing to occur. The commonest cause of an impaired airway is positional: the baby lies with his head flexed causing the tongue to fall back and obstruct the pharynx. The baby's head must be put into the neutral position with the jaw drawn forward (jaw thrust maneuver – [Fig. 12.9](#)). Do not overextend the neck.

Sometimes the airway must be cleared, particularly if meconium is present (see below). This is best done by visualizing the oropharynx with a laryngoscope and giving gentle suction. Do not blindly use a suction catheter to suck out the mouth as stimulation of the posterior pharynx and larynx may induce vagal stimulation with apnea and bradycardia.

Rarely the baby may have an anatomical abnormality of the face, jaw or palate and an oropharyngeal airway (Guedel) of the appropriate size should be available to insert into the baby's mouth with its tip beyond the back of the tongue.

### Inflation breaths

If the baby fails to breathe 30–60 s after an airway has been established then the lungs must be inflated with gas. This is done by giving 5 long inflation breaths each lasting 2–3 s with an opening pressure of 30 cmH<sub>2</sub>O in term babies (less in preterm infants). This is performed with an appropriately sized soft, tight-fitting face mask which makes a good seal around the baby's mouth and nose. The lungs are expanded by a self-inflating bag ([Fig. 12.10](#)). An alternative is a T-piece attached to the mask and pressurized gas directed into the baby's lungs by occluding the T-piece with a finger for the requisite period of 2–3 s. The pressurized gas must blow off at a predetermined level (usually 30 cmH<sub>2</sub>O), often by an underwater seal.

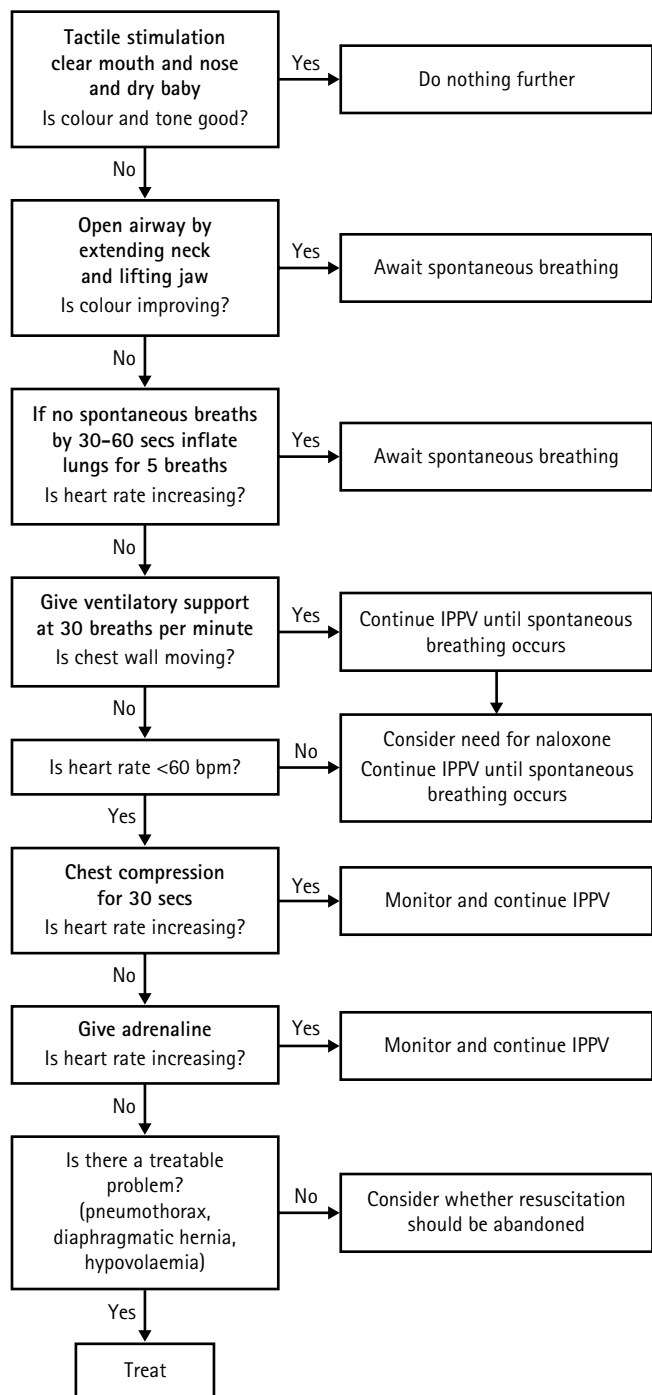

Fig. 12.8 Summary of approach to neonatal resuscitation.

Fig. 12.9 Slight head extension with chin support to open airway.

Fig. 12.10 Cardiorespiratory resuscitation. One operator inflates the baby's lungs with the bag and mask. The head is slightly extended and the chin pulled forward. The other operator gives external cardiac massage with hands encircling the chest. (From Levene et al 1987 with permission of Blackwell Scientific Publications.)

After 5 breaths observe its effect. There should be an increase in heart rate; if there is not, the lungs are not being appropriately inflated. Immediately check that the chest is moving with inflation breaths. If it does not, then the airway is probably not clear. Readjust the baby's position and check the seal of the mask on the baby's face. Repeat 5 breaths and if there is still no chest movement consider the following:

- Does the baby need more jaw thrust?
- Does he need longer inflation breaths?
- Is there an obstruction in the oropharynx (consider laryngoscopy and suction)?
- Does the baby need a Guedel airway?

Once the lungs are inflated, continue shorter breaths at 30 per min until the baby establishes spontaneous respiration. In most babies bag and mask ventilation is all that is required. Intubation may be necessary if bag and mask resuscitation fails, during prolonged resuscitation, where copious tracheal suction is required or if surfactant administration is anticipated. A recent study has suggested that use of a laryngeal mask airway is as effective and rapid as intubation in achieving a secure airway.<sup>138</sup>

### Circulation

With appropriate inflation breaths the baby's heart rate should improve and the baby will become pink. If the chest is inflating well and the heart rate remains slow (< 60 bpm) circulatory support is required. This requires two people: one to maintain ventilation and the other to give chest compressions. With the fingers over the baby's spine, the resuscitator's thumbs are placed on the sternum just below the inter nipple line and the lower third of the sternum is compressed by one third of the depth of the chest (Fig. 12.10). The ratio of compressions to breaths is 3:1 to achieve 90 compressions and 30 breaths per min.

### Drugs

In most cases the baby recovers rapidly with appropriate ventilation and chest compression, but sometimes further resuscitation with drugs is required. It is essential to first establish an effective route by which the drugs can be given. The most rapid way is to insert a sterile catheter into the umbilical vein into the inferior vena cava. A rough guide to achieve this is to insert the radio-opaque cannula the distance from the umbilicus to the inter nipple line. The sequence of drug administration depends on the baby's response and is hierarchical as follows:

- Sodium bicarbonate, 2–4 ml/kg of 4.2% solution. It is not necessary to correct a metabolic acidosis but merely to improve the intracardiac pH. Although sodium bicarbonate is widely used, a recent randomized controlled trial showed no benefit in terms of survival or neurological complications in a group of asphyxiated newborn infants still requiring intubation 5 min after birth.<sup>139</sup>

- Adrenaline (epinephrine) 0.1 ml/kg of 1:10 000 dilution. Do not use more concentrated solutions. This should only be given after sodium bicarbonate as cardiac receptors are less sensitive in the presence of severe acidosis. Up to three repeated doses may be given if there is no response. An alternative route of administration is via the endotracheal tube but other drugs must not be given through the tube and it is preferred to give all the drugs via the umbilical venous catheter.
- 10% Dextrose at 2.5 ml/kg.
- Volume infusion with 0.9% saline 10 ml/kg.
- Naloxone is only indicated when the baby appears to have respiratory depression as a result of maternal opiate administration within 3 h prior to delivery. Small doses of naloxone (40 mcg ampoule of 'neonatal' Narcan) provide only transient antagonism of respiratory depression and a full dose (200 mcg) intramuscularly should be given if naloxone is indicated. Intramuscular use is preferred to intravenous except if the baby is shocked with poor tissue perfusion. Never use naloxone without suspicion of neonatal opiate depression. Do not give naloxone to the baby of an opiate dependent mother as this may cause acute and severe withdrawal symptoms in the baby.

There is no evidence that calcium infusion is of any benefit in cardiac resuscitation.

## CONTROVERSIES IN NEONATAL RESUSCITATION

### Volume expansion

Administration of 10 ml/kg 0.9% saline in babies with circulatory failure is recommended. Care should be taken if large volume administration is given (>40 ml/kg) as this may exacerbate metabolic acidosis due to hyperchloremia.<sup>140</sup> Hypovolemia at delivery may arise as a result of prenatal bleeding, premature clamping of the cord, when the baby is held above the mother prior to cord clamping or with a nuchal cord and failure of adequate blood flow to the fetus from the placenta. If the baby is shocked at birth and is thought to have recently sustained a significant hemorrhage then he should be given an infusion of group O rhesus negative blood immediately.

There remains considerable controversy about the role of albumin in treating hypovolemia. There is no evidence that giving human albumin improves survival when compared to giving saline.<sup>141</sup> An isotonic crystalloid solution such as normal saline is recommended in both the British and American Neonatal Resuscitation guidelines.

### Resuscitation in room air or 100% oxygen

In 1999 the International Liaison Committee on Resuscitation recommended that resuscitation of the newborn should be performed with 100% oxygen,<sup>142</sup> but there has been concern about the potential adverse effects of high oxygen concentrations and in particular increasing the work of breathing in newborn infants and the generation of excess free radicals with adverse effect to the eyes, lungs and brain. High concentrations of oxygen have also been shown to reduce cerebral blood flow. A recent Cochrane review<sup>143</sup> identified five studies where babies were randomized at resuscitation to receive either 100% oxygen or room air. Those babies given air had significantly better Apgar scores<sup>144,145</sup> and time to first breath was longer in the 100% oxygen group.<sup>145,146</sup> It is suggested that the effects of 100% oxygen may be more adverse in preterm infants than at term.<sup>147</sup> Pooled analysis of four trials where mortality was reported showed a significant reduction in mortality rate in the room air compared with the 100% oxygen resuscitated group. In one trial where follow-up data on survivors at 18–24 months was described there were no significant differences in the rates of adverse neurodevelopmental outcome. The conclusion of this Cochrane review was that there were insufficient data to support the routine policy of resuscitation with room air. Until this controversy has been fully resolved the most appropriate recommendation is to use a blender on the resuscitation trolley so that 30–40% oxygen is used initially and modified according to the baby's oxygen saturation.<sup>148</sup>

### Meconium stained liquor

In the presence of severe prenatal hypoxia, fetal gasping may cause aspiration of meconium deep into the bronchial tree. Approximately 15% of babies are born with meconium staining of the liquor and in approximately 5% meconium aspiration syndrome (MAS) occurs. In the US 25–60% of infants with MAS require mechanical ventilation.<sup>149,150</sup> Strategies to reduce the risk of MAS such as amnioinfusion (injection of fluid into the amniotic cavity intended to dilute the meconium prior to delivery) have been evaluated in a Cochrane review.<sup>151</sup> This showed that amnioinfusion significantly reduced the incidence of meconium aspirate. More recently a large international multicenter study<sup>152</sup> enrolling almost 2000 women showed no reduction in the rate of moderate or severe meconium aspiration syndrome and the authors concluded that meconium staining of the amniotic fluid is not an indication for amnioinfusion for women in labor.

Suctioning of the oro- and nasopharynx after birth of the head and before delivery of the baby's trunk has also been suggested to be effective,<sup>153</sup> but others have not shown a similar beneficial effect (see Wiswell 2001<sup>154</sup> for review) and this technique remains of unproven benefit. A further strategy is endotracheal intubation at birth for babies born through thick meconium stained liquor so that effective suctioning of the airways can be undertaken. This has been evaluated within the context of a Cochrane review.<sup>155</sup> Four randomized controlled trials of intubation at birth in vigorous term infants born through meconium stained liquor were identified. There was no evidence that routine intubation with lavage in vigorous term meconium stained babies reduced the incidence of significant lung disease. Chest compression immediately after birth to avoid aspiration of meconium is dangerous and should not be performed.

The US recommendations for resuscitation of a baby born through meconium stained liquor are initially thorough suctioning of the mouth, nose and pharynx with either a bulb syringe or 12–14F suction catheter as soon as the head is delivered and before the body emerges. After delivery, if the baby is in a *depressed* state (slow to establish regular breathing, reduced tone, or heart rate < 100 bpm) then immediate direct laryngoscopy should be performed with intubation/suctioning of any residual meconium from the trachea under direct vision. Saline lavage is not recommended. Delay gastric suctioning of meconium until initial resuscitation is complete. If the baby is vigorous, intratracheal suctioning is not recommended. This technique has not been subject to meta-analysis.

### Hypothermia

There is accumulating evidence that controlled hypothermia to 35°C for 72 hours may significantly reduce the adverse outcome (death and disability) in term babies born with severe birth asphyxia. Wyatt JS, Gluckman PD, Lin PY, et al. Determinants of outcomes after head cooling for neonatae encephalopathy. *Pediatrics* 2007;119:912–21. This is the subject of ongoing research (TOBY TRIAL). It is, however, not appropriate to inadvertently allow a baby to become cold during resuscitation and it is particularly disadvantageous in preterm infants, in whom it has been shown to increase mortality. Conversely, inadvertent hyperthermia must be avoided during resuscitation and this may occur as a result of an overhead warmer. This may cause an exacerbation of cerebral injury.

Various methods have been evaluated to maintain body temperature in prematurely born infants whilst in the delivery room. One method uses a barrier to prevent heat loss: four studies have evaluated either wrapping the baby from the neck down in a plastic sheet or placing the baby in a warmed plastic bag secured at the baby's neck. A Cochrane systematic review of these randomized controlled trials showed that this method significantly reduced heat loss in premature babies below 32 weeks<sup>156</sup> and was particularly effective in babies below 28 weeks of gestation. These studies did not show that there was a significant reduction in duration of hospital admission, major brain injury or duration of oxygen therapy. Another study of reducing heat loss by a tightly fitting hat showed that this method of reducing heat loss was ineffective.

### Early versus delayed umbilical cord clamping

Controversy exists concerning the timing of clamping of the umbilical cord following birth. Delayed clamping allows blood to be transferred from

the placenta to the baby until pulsation of the cord ceases. It has been suggested that this may result in a lower incidence of respiratory distress and the need for fewer blood transfusions. Early clamping will allow the baby to be more rapidly resuscitated and in theory prevent hypothermia, polycythemia and hyperbilirubinemia in premature infants. Seven randomized controlled trials have been conducted to compare early clamping (less than 30s) with delayed cord clamping (30–120s) and these studies have been evaluated in a Cochrane review.<sup>157</sup> Delayed clamping was associated with a reduced number of blood transfusions, less hypotension and fewer intraventricular hemorrhages compared with a group who had early clamping. The current evidence supports the recommendation that delayed clamping is of benefit in prematurely born infants.

### WHEN TO STOP RESUSCITATION

All babies should be considered for active resuscitation unless they are macerated or show an obvious lethal congenital malformation. The prognosis for very immature babies of 23 weeks' gestation and below is extremely poor<sup>158,159</sup> and it is important to discuss with the parents prior to the delivery in light of the poor prognosis whether it is appropriate to offer vigorous resuscitation. The parents should be encouraged to consider whether they wish their baby to receive resuscitation at birth and their views should be respected. If the baby is vigorous at birth it may be appropriate to resuscitate fully and transfer the baby to the neonatal unit where with time a more considered decision can be made about the continuation of intensive care.

In mature infants failure to achieve a spontaneous cardiac output after 10 min of vigorous resuscitation indicates a very poor prognosis and resuscitation should be abandoned. A more difficult situation is when the baby has a reasonable cardiac output but fails to breathe. Other causes of respiratory failure must first be considered such as maternal drug effect and neuromuscular disorders. If the baby is not breathing by 40 min and particularly if he remains extremely depressed with severe hypotonia, then further active resuscitation should be considered to be inappropriate. The most senior doctor available should make this decision. If there is any doubt it is best to take the baby to the neonatal intensive care unit until such time as a full assessment can be made. It is much easier for the parents to mourn the loss of their baby if they are convinced that full resuscitation

was attempted and they will come to terms with it better if they have time to understand the severe problems that are present. Parents should be encouraged to hold their baby when resuscitative efforts are abandoned.

### THE SMALL FOR GESTATIONAL AGE INFANT (Fig. 12.11)

The World Health Organization in 1950 defined a baby as small for gestational age (SGA) when it was below the 10th weight centile for gestation. At that time perinatal mortality of this group even in the Western world was very high. Obstetric deaths due to placental failure in utero and acute intrapartum asphyxia were relatively common. Neonatal problems such as pulmonary hemorrhage and hypoglycemia were inadequately treated and the mortality and morbidity from congenital rubella was more common (immunization schedules were not introduced until 1966 in the UK). Times have now changed but the definition has not. With modern antenatal and intrapartum care it is unusual for the pediatrician to be confronted by an unexpectedly small baby. Intrauterine and peripartum asphyxia and death are rarities. Rubella embryopathy is much less common and ultrasound policies for infants early diagnosed as small may allow termination of pregnancy for a lethal congenital abnormality. Better feeding policies postnatally have made all but the smallest of light for dates babies (SGA) manageable with care on the postnatal wards. It is unlikely that the baby more than 1800 g birth weight will need to be transferred to the neonatal unit if delivery care and care on the postnatal wards are appropriate.

### ETIOLOGY

#### Maternal causes

These consist of in utero starvation and placental insufficiency [essential hypertension, pregnancy associated hypertension (PET), chronic renal disease, long-standing diabetes, heart disease in pregnancy, multiple pregnancy, poor socioeconomic circumstances with severe malnutrition, excess smoking, excess alcohol, living at high altitude]. Classically, placental insufficiency leads to asymmetric growth retardation, the weight being more affected than the length or particularly the

Fig. 12.11 Size with gestation. The baby on the left at 1.7 kg and 39 weeks is small for gestational age. The baby on the right is 1.9 kg and 34 weeks' gestation and is both appropriate for gestation and preterm. The center baby at 4.4 kg and 39 weeks' gestation is large for gestational age.

head circumference. The obstetrician may identify this problem in utero, ultrasound showing a small abdominal and thoracic circumference and a relatively spared head circumference. Small mothers and elderly primigravidae tend to have smaller than average babies.

### Fetal causes

These include congenital abnormality (chromosomal and many syndromes, e.g. Potter) and congenital infection (rubella, toxoplasmosis, cytomegalovirus, herpes simplex and syphilis) as well as early fetal toxins such as alcohol, phenytoin and warfarin. Such infants usually display symmetrical growth retardation, the head size being as retarded as the weight and length.

## PROBLEMS OF THE SGA BABY

### Hypoglycemia

A large proportion of SGA babies develop hypoglycemia, which may be present before birth. The etiology after birth is complex.

1. Reduced glycogen deposits (in liver, muscle and heart).
2. The brain and heart (but not the liver, spleen, thymus and adrenals) are large in proportion to the rest of the body and have high energy substrate demands.
3. A reduced catecholamine response to a falling blood sugar suggests that the adrenal medulla is failing with consequent reduced glycogenolysis.
4. Rapid glucose disappearance may in some cases be due to high insulin levels. However many infants show a reduced insulin response to a glucose load which suggests either a defect in peripheral glucose utilization or reduced insulin sensitivity.
5. Defective lipolysis is suggested by reduced levels of beta-hydroxybutyrate and lack of the normal inverse relationship between free fatty acids and blood sugar.
6. Elevated gluconeogenesis is reduced. Frequently there are elevated levels of alanine, lactate and pyruvate and an alanine load does not provoke an appropriate increase in blood sugar. There may be a delay in the postnatal development of hepatic gluconeogenic enzymes.

Hypoglycemia may lead to neuroglycopenia. Clinical signs of apnea and convulsions do not occur until a blood sugar of less than 1 mmol/L has been present for several hours, probably because alternative substrates are available (glycerol, lactate, beta-hydroxybutyrate, acetoacetate). Nevertheless, Koh et al<sup>160</sup> have shown that auditory evoked potentials are compromised at much higher blood sugar levels so it is important to be obsessive in blood sugar management in these small infants.

Practically, in all except the very small for gestational age (less than 3rd centile), management can and should be on the postnatal ward.

Breast-feeding mothers are encouraged to breast-feed 3-hourly, and prefeed dextrostix or BM stix are done after 6 h for 48 h. If hypoglycemia less than 2.6 mmol/L is detected, 8 ml/kg of formula are given after each breast-feed on day 1 and 12 ml/kg after each feed on day 2, if necessary by nasogastric tube. After 48 h, if there has been no hypoglycemia the bottle feeds after the breast can be withdrawn gradually as the mother's milk comes in.

Bottle-fed babies should be given 90, 120, 150 ml/kg/day respectively on each of the first 3 days of life. Prefeed dextrostix or BM stix should be done at 6, 9, 12, 18, 24, 30, 36 and 48 h. If the blood sugar is low, <2.6 mmol/L, or the baby is asymptomatic add 2 ml/kg/feed of 50% dextrose. If the dextrostix is still low or the baby is vomiting or the hypoglycemia is symptomatic a drip of at least 90 ml/kg/24 h of 10% dextrose is required.

Hypoglycemia is unlikely to be problematic after 48 h of age if it has not been so beforehand.

A baby both small for gestational age and less than 1800 g should probably be admitted to the neonatal unit for observation and treatment.

Infants with transient diabetes mellitus are usually small for gestational age.

### Hypothermia

SGA infants may be born with a temperature above mother's as the inefficient placenta will not exchange heat. The scraggy baby with large surface area:body weight ratio may cool fast after delivery if appropriate steps are not taken to prevent this (p. 221).

### Polycythemia

The high altitude effect associated with poor placental oxygen transfer leads to increased packed cell volume, red cell mass and high erythropoietin levels. This may lead to viscosity problems. Sheer stresses may reduce the platelet count and on rare occasions liberated platelet thromboplastins may set off disseminated intravascular coagulation (DIC). It is appropriate if the baby looks plethoric to do a venous packed cell volume (PCV) and also platelet count and clotting tests. Treatment with partial exchange transfusion may be required on occasions and vitamin K should be given (p. 295).

### Neutropenia and thrombocytopenia

Severely SGA infants, particularly those less than 1000 g birth weight, may show neutropenia and thrombocytopenia.<sup>161</sup> Platelets may be reduced in number partly by the mechanisms mentioned above but it may be that the marrow in utero is more committed to manufacture of red cell series (high normoblasts) because of hypoxia and there is a temporary reduction in the ability to produce other cells after birth.

### Hypocalcemia

This is less commonly seen now that babies are delivered in good condition by the obstetric team. It was probably related to perinatal asphyxia but the pathophysiology is not clear.

### Infection

With modern management it is rare for SGA infants to develop a postnatal infection unless they are in addition very preterm.

### Congenital abnormality

Three to six percent of SGA babies have congenital abnormalities; these are usually obvious and lethal such as the chromosome abnormalities, Potter syndrome and the baby with disseminated congenital infection.

### Meconium aspiration

This is rare with modern obstetric management.

### Pulmonary hemorrhage

This was probably related to intrapartum asphyxia and polycythemia. Modern obstetric and pediatric practice should identify and rectify these problems before hemorrhage results.

### Other humoral and metabolic abnormalities

High ammonia, urea and uric acid levels after birth may reflect the reduced calorie reserve of these infants or a protein catabolic state. High circulating cortisol, corticosterone and growth hormone levels have also been demonstrated at birth.

## CLINICAL FEATURES OF SGA BABIES

A minority of infants will have obvious congenital abnormalities, chromosome defects or intrauterine infection. Most infants will be scraggy individuals with wasting, particularly of the thighs. The fingernails are mature and long and cracks and desquamation of the skin begin rapidly after birth. The infant is usually active and vigorous and apparently anxious lest his starved state in utero may continue after birth. Sucking is usually strong and the weight loss after birth is less than for an appropriately sized baby.

## MANAGEMENT

Early obstetric diagnosis should be followed by a planned delivery in the presence of pediatric staff capable of skilled resuscitation. Labor and birth are asphyxial stresses so labor should be carefully monitored. The baby may be hypoglycemic at birth so a dextrostix should be performed immediately. If there are no signs of anomaly or infection the major pediatric concerns are to prevent hypothermia and hypoglycemia – hopefully on the normal postnatal ward.

## OUTCOME

Babies with asymmetric growth retardation usually catch up to within the normal centiles after birth whereas many symmetrically growth retarded infants do not. Unless they suffer symptomatic hypoglycemia, they will in all probability develop with a normal DQ and later IQ. Babies that are SGA because of syndromes, chromosome abnormalities and intrauterine infections will have a high neonatal mortality and later morbidity.

## THE LARGE FOR GESTATIONAL AGE INFANT (Fig. 12.11)

By definition heavier than the 90th weight centile for gestation.

### ETIOLOGY

1. Constitutionally large baby from heavy large mother.
2. Maternal diabetes or prediabetes – the infant of the diabetic mother (IDM) or the infant of the gestational diabetic mother (IGDM).
3. Severe erythroblastosis.
4. Other causes of hydrops fetalis and ascites.
5. Transposition of the great arteries (sometimes).
6. Syndromes:
  - a. Beckwith–Wiedemann (BW) syndrome (p. 337)
  - b. Sotos syndrome
  - c. Marshall syndrome
  - d. Weaver syndrome.

## PROBLEMS OF LARGE FOR GESTATIONAL AGE (LGA) BABIES

### Birth asphyxia and trauma

Shoulder dystocia may delay delivery leading to low Apgars, acidosis, meconium aspiration and hypoxic–ischemic encephalopathy and the consequent interventions may lead to fractured clavicle or long bones, brachial plexus injury (Erb or phrenic palsy), subdural or cephalhematoma and skin bruising (later resulting in jaundice).

### Hypoglycemia

The IDM, IGDM, baby with erythroblastosis and BW syndrome baby all have hyperinsulinism leading to reactive hypoglycemia after birth.

### Polycythemia

Unusual.

### Apparent large postnatal weight loss

A 5 kg baby may naturally lose more than 0.5 kg in weight over a few days (10% body weight being 500 g) even if supplied with adequate milk.

## CARE OF THE PRETERM INFANT

### DEVELOPMENTAL CARE

#### INTRODUCTION

Changes in neonatal care over the last 25 years have had a significant impact on infant mortality and morbidity. The increasing survival of low birth weight infants and especially those born at the limits of viability has created new challenges; in particular how best to reduce the increasing incidence of developmental delay, neurosensory impairment and cerebral palsy that accompanies extreme prematurity.<sup>162,163</sup> These infants, with their rapidly developing and extremely vulnerable brains, spend many weeks in an environment that is in stark contrast to that of the protective uterus. Whilst it is accepted that fetal development and experience might not be an appropriate model for determining newborn care, animal studies provide evidence that positive and negative early experiences can alter the structure and function of the developing brain.<sup>164</sup>

The theoretical framework underpinning the ‘developmentally supportive’ model of care is that the neonatal intensive care unit (NICU) environment and activities associated with medical and nursing interventions are developmentally unexpected and therefore are likely to be stressful for both infant and parent. Decreasing this stress enables greater physiological and behavioral stability, better attainment of developmental skills and more positive engagement with the caregiver.<sup>165</sup> The provision of developmental care interventions is based on recognizing stress and stability cues in the infant (and parent), using them to positively modify environmental stimuli, care activities, and human interactions.

### FETAL SENSORY RESPONSES

From conception to birth, fetal development and maturation is continuously influenced by the varied sensory experiences within the uterus. The neurosensory system develops in an orderly and predictive manner so that by 28 weeks’ gestation the neural pathways for tactile, vestibular and chemosensory perception are well established and functional: contralateral movement to touch,<sup>166</sup> sucking,<sup>167</sup> altered swallow pattern to changes in amniotic fluid composition,<sup>166</sup> tachycardia and excessive movement with vibroacoustic stimulation<sup>168,169</sup> are seen. At this gestation the auditory and visual pathways are still establishing but the fetus responds physiologically and behaviorally to stimulation and is able to recognize the maternal voice.<sup>170–172</sup>

### NICU ENVIRONMENT

In the mid 1970s Cornell and Gottfried<sup>173</sup> summarized the literature on sensory stimulation of premature infants and concluded that the NICU environment was not lacking in stimulation but rather it was inconsistent and inappropriate to the needs of the newborn. Neonatal units are frequently places of extreme stimulation because they present experiences which are not the norm for the developing infant:

- Cutaneous stimulation commonly takes the form of medical/nursing procedures with little opportunity for gentle and comforting care.
- Movement is often prohibited and restricted by the use of equipment and/or bedding.
- Alcohol or other antiseptic solutions are frequently presented to infants and positive taste experiences are seldom reinforced unless the infant is receiving oral feeds.
- Sound is created by staff/parent activities and conversation, use of routine equipment and alarm mechanisms; the reported range of sound within the NICU is between 53 and 90 dB with bursts of excessive loudness over 90 dB with no attenuation of higher frequencies.
- Lighting levels depend upon postmenstrual age (reflecting maturity), illness acuity, number and location of exposed windows, incubator/cot position within the unit and seasonal changes. Exposure can be between 24 and 150 foot-candles; this might be continuous lighting, intermittent for procedures and/or treatment (phototherapy = 300–400 foot-candles) or natural daylight (1000 foot-candles).

Stimulation from the NICU environment has a physiological and functional impact on the infant. Whilst some changes in state are considered to be normal arousal responses others are considered to be stress signals.

### Caregiving activities

Prematurely born infants respond to touch differently than term infants; they show an increased sensitivity in both flexion withdrawal and general body movements.<sup>174</sup> This increased sensitization may account for the stress responses seen in relation to routine caregiving<sup>175–177</sup> and oral feeding.<sup>167</sup> Whilst individually these disruptions may be short lasting, they may endure throughout the first year of life and can lead to complications in adulthood.<sup>178–180</sup>

Minimal handling and clustering of care procedures has become the norm so that the infant has prolonged rest periods between disturbances. However these practices appear to stress the infant<sup>181</sup> and increase the infant’s sensitivity to painful interventions.<sup>182,183</sup> The available literature suggests it would be prudent to reduce the frequency of handling

episodes and perhaps more importantly to reconsider the number of interventions clustered together at any one time.

When a procedure or investigation has been completed, the infant is positioned to promote physiological stability and secure fixation of equipment. Traditional positioning strategies, for example the use of flat unyielding surfaces and prolonged lying in either supine or prone position, may have long-lasting effects on the infant and child. Whilst quality of movement and subsequent performance is strongly correlated with degrees of neurological abnormality,<sup>184</sup> preterm infants who have little or no cerebral abnormality on ultrasound scanning exhibit dysfunction in movement and postural control as they grow older.<sup>185</sup> It is suggested these abnormalities stem from early experiences of being less mobile with less opportunity to 'learn' from the different positions.<sup>186</sup> 'Supportive positioning' attempts to override these limitations by incorporating techniques and aids that promote physiological stability whilst encouraging a balance between flexion and extension and facilitating self-regulatory behavior.<sup>187</sup> Use of these strategies results in significantly fewer stress responses as denoted by a lower heart rate, improved oxygenation, less crying and fewer sleep state changes.<sup>188,189</sup> Other handling techniques that seem to have benefit are comforting touch and massage and skin-to-skin care.<sup>190</sup> In the systematic review by Vickers<sup>191</sup> gentle still touch showed no negative effects on infants but did reduce motor activity and behavioral distress. Studies on massage showed that the intervention brought about physiological stability in more mature infants but induced hypoxia and tachypnea in the immature infant. Studies on skin-to-skin care (as reported by Harrison<sup>190</sup>) indicate that there are physiological and behavioral advantages for the infant if held in the 'kangaroo position'. The systematic review by Conde-Agudelo<sup>192</sup> concludes that although kangaroo mother care appears to reduce severe infant morbidity without any serious deleterious effect reported, there is still insufficient evidence to recommend its routine use in LBW infants.

This work highlights the fragility of premature infants to non-noxious stimuli and should remind the caregiver to consider frequency and timing of interventions.<sup>176</sup>

## Environmental effects

Two features of the environment that have been examined extensively are sound and light. In the NICU the infant is exposed to chaotic and variable levels of sound originating from a multitude of sources. In terms of perceived loudness, for each increase of 6 dB, the perceived loudness doubles. Even when the unit is thought to be quiet (35 dB), the level perceived by the infant might exceed 60 dB.<sup>193</sup> Morris et al<sup>194</sup> reviewed the literature about the effects of sound on the newborn. The authors describe physiological and behavioral responses of infants to mild to high range (55–100 dB) stimuli. When presented with sound stimuli, infants increase their heart rates whilst respiration effects are more variable and associated with maturity, age and previous exposure. Low frequency stimulation is also noted to increase blood pressure and produce fluctuations in intracranial pressure and oxygenation. Unlike the term infant, the premature infant does not readily habituate to the stimulus but is continuously aroused by it. Whilst respiratory pattern appears to be more related to sleep wake state than acoustic stimulation, acoustic stimulation can affect sleep state and thus adversely influence respiratory pattern and oxygenation.<sup>195</sup> The literature to date focuses on immediate and medium term deleterious effects of sound in the infant but little is known about the optimal sound level for stability.<sup>194,196</sup> Slevin<sup>197</sup> showed that introducing a quiet period altered ambient noise levels and staff behavior considerably but these changes had little effect on the infant's heart and respiratory rate and oxygenation. Rather the impact was seen by an increase in restfulness. Supplemental sound interventions appear promising for the stable infant greater than 28 weeks' postmenstrual age. In a meta-analysis on music therapy for premature infants, Standley<sup>198</sup> concludes that 'Music alone or combined with the human voice would seem to be a valuable resource for enhancing developmental goals in the NICU, functioning to reduce stress, to provide developmental stimulation during a critical period of

growth, to promote bonding with parents, or to facilitate neurological, communication, and social development'.<sup>198</sup>

Concern has also been raised as to whether, in the absence of impairment of functional hearing, there is some alteration in the recognition and integration of sound. The high levels of continuous sound or 'white noise' and lack of rhythm mask the infant's ability to make associations between source and sound; it has been postulated that this may account for the difficulties which preterm infants experience with concept learning and recognition.<sup>199</sup> Apart from these physiological and behavioral responses, prematurely born infants also show more hearing related disorders than term infants (approximately 13% of premature infants experience significant hearing loss compared to 2% of term infants). However there is little to suggest a cause and effect response between the NICU sound environment and the impairment.

At term the visual system is functionally relatively immature. Given this and the typical lighting of the NICU, concern has been expressed about the impact that light levels and lighting pattern might have on the visual system of the developing infant.<sup>200</sup> In the healthy preterm infant visual maturation proceeds in the expected fashion irrespective of the exposure of the infant to light. However, between 1% and 3% of the preterm population have visual impairments which are associated with birth weight, cerebral hypoxia/hyperoxia, intraventricular hemorrhage and lung function.<sup>201</sup> Studies have generally focused on light exposure and the effect of illumination on the incidence of retinopathy, physiological stability and the development of circadian rhythm.

There is no evidence to suggest that continuous bright or variable lighting affects the incidence of retinopathy.<sup>202</sup> It does however affect physiological stability and circadian rhythm development. High lighting level is implicated in disturbing sleep and producing stress-like responses in the infant: variable heart rate pattern, increased respiratory rate and activity and a reduction in oxygenation.<sup>203–205</sup> Cycled levels of lighting appear to have the greatest impact on infant well-being. When compared to continuous high or dim lighting, cycled lighting promotes physiological stability, improved growth, increased sleep time and earlier entrainment of circadian rhythms.<sup>200,204–207</sup>

Newborn infants have acute chemosensory perception. When presented with various olfactory stimuli preterm infants respond with facial movements and changes in heart and respiratory rate and cerebral oxygenation.<sup>208–211</sup> These alterations equate with stress signals and are seen more often in infants presented with noxious compared to pleasant or control odors. Schaal<sup>208</sup> describes several studies where the maternal odor or that of breast milk elicits a calming effect on full-term infants and higher non-nutritive sucking episodes when compared with formula milk or neutral odors in preterm infants.

A recent systematic review of non-nutritive sucking found that the activity was associated with decreased length of stay for infants on the NICU and was beneficial in promoting the transition of infants from gastric to oral feeding.<sup>212</sup> Furthermore it is found to be effective in decreasing the effect of a painful intervention (eye examination). The magnitude of the effect was greater when non-nutritive sucking was combined with the administration of sucrose.<sup>213</sup> Although odors and non-nutritive sucking can help relieve stress, Schaal<sup>208</sup> cautions that care should be taken not to produce negative conditioning which might interfere with the infant's developing social relationship.

## CONCLUSION

This review has considered the effects of single interventions on the reduction of infant stress and promotion of infant stability. Multimodal stimulation, specific developmental care assessment programs and parent support have not been taken into account. When proposing interventions to reduce stress and promote stability, it should be noted that it is unlikely that any one intervention has a single mode of action. For example, modifying the environment to promote auditory recognition may positively impact on the development of visual and motor systems and collectively or individually these may affect the developing parent – infant relationship.

## SPECIAL CARE – FLUID BALANCE

During fetal life, the placenta maintains biochemical homeostasis even in the absence of fetal renal function. Immediately following birth, however, the kidney becomes essential for chemical and fluid balance. The preterm infant is particularly vulnerable, and dehydration and hyponatremia are the commonest problems.<sup>214</sup>

### BODY WATER CONTENT AND DISTRIBUTION

#### Changes in body fluid related to delivery

Plasma sodium concentration in the newborn correlates closely with maternal plasma sodium concentration at delivery.<sup>215</sup> Crystalloid fluids administered to laboring mothers equilibrate across the placenta and increase fetal extracellular fluid (ECF) volume. Subsequently, at delivery, stress hormones, including glucocorticoids, aldosterone, anti-diuretic hormone and angiotensin<sup>216</sup> are elevated in the newborn and may contribute to salt and/or water retention.

#### Postnatal changes

The ratio of ECF to intracellular fluid (ICF) decreases in the immediate postnatal period owing to water loss from the ECF space. A postnatal weight loss of 5–8% of birth weight is common in term infants, the nadir occurring around the fifth day with birth weight usually regained by the tenth day. An even greater percentage weight loss of 12–21% may occur in premature infants.<sup>217</sup> Whilst some of this weight loss is meconium, vernix and the umbilical stump, most is water derived from the ECF space.

ECF comprises interstitial fluid and circulating blood and most of the early postnatal weight loss is due to a reduction in interstitial fluid volume since plasma volume is well maintained over the first week of postnatal life. The interstitial fluid lost from the body as urine is virtually isotonic,<sup>218</sup> and the negative sodium and water balance and weight loss which result from this appear to be obligatory as these are not prevented by administration of water, sodium or both.<sup>219</sup>

### WATER BALANCE

To maintain a stable water balance:

- Water intake
- = water for growth
- + insensible losses (respiratory losses + transepidermal losses)
- + sensible losses (sweat + urine + fecal losses).

Pre-existing deficits or overload must also be corrected to achieve fluid balance.

#### Water for growth

Approximately 75% of increase in weight in utero is water. If the intra-uterine growth velocity of approximately 16 g/kg/24 h<sup>220</sup> is to be sustained in infants born preterm, 12 ml/kg/24 h of water intake will be diverted towards growth, mostly into the ICF space. However, if the infant is not being fed enterally or parenterally, this consideration of water for growth is irrelevant as intravenous crystalloid solutions contain no nitrogen for anabolism.

### Respiratory water losses

Inspired air is humidified and warmed by the respiratory tract so that expired air leaves the nose and mouth almost fully saturated at a temperature of 35–36 °C. The amount of water lost from the respiratory tract is inversely proportional to the humidity of the inspired air – highest when the inspired air is dry and non-existent when it is fully saturated. Such water loss will also depend on the minute volume, the product of tidal volume and respiratory rate – around 7 ml/kg/24 h at an ambient humidity of 50% in term infants<sup>221</sup> and similar in preterm infants in the absence of respiratory disease. The management of the fluid balance of the very immature infant is, therefore, simplified if a high humidity (> 90%) is provided within the incubator or ventilator circuit.

### Transepidermal water loss

Transepidermal water loss (TEWL) is the passive diffusion of water through the epidermis and is dependent on the ambient humidity and temperature. TEWL is lower in the full-term newborn (6–10 ml/kg/24 h) than in the child or adult. Values are much higher in preterm infants in the days after birth, especially before 30 weeks' gestation, as a result of their poorly developed keratinized layer of epidermis. As the stratum corneum rapidly matures in the first 2 weeks of life, TEWL falls towards term values.<sup>222</sup> The relationship between TEWL and ambient relative humidity is such that TEWL is much higher if the surrounding air is dry and is abolished when it is fully saturated. TEWL is also increased by phototherapy and radiant heat. As infants nursed naked on radiant heaters can lose 200–300 ml/kg/day as TEWL, the management of the fluid balance of very immature infants is simplified if a high ambient humidity is routinely provided within the incubator for infants less than 30 weeks' gestation or less than 1000 g in the first week (Grade D, Level 5).<sup>223</sup> Humidification close to 100% can be achieved if incubator ports are kept closed, reducing TEWL by 50% in infants 24–27 weeks' gestation.

Respiratory and transepidermal water loss together make up insensible water loss. This, measured as insensible weight loss, is around 15 ml/kg/24 h for a term infant. Values in preterm infants are higher (especially in the very immature infant in the early neonatal period, because TEWL is so high), ranging from 15 to 120 ml/kg/24 h, and depend on gestational age, postnatal age and ambient conditions.<sup>224</sup> Insensible water loss is best derived by adding 7 ml/kg/24 h (respiratory water loss) to the values of TEWL shown in Table 12.9.<sup>222</sup>

### Sweating

The ability to sweat is impaired in the term newborn compared with children or adults. If heat stress is sufficient to raise the body temperature above 37.5 °C, evaporative water loss increases by a factor of two to four – an increase from 15 to 30–60 ml/kg/24 h. Before 30 weeks' gestation, sweating is absent in the first 2 weeks and can be ignored in fluid balance consideration. From 30 weeks to 36 weeks' gestation, sweating does not appear until a few days after birth and is limited compared with that of a term infant.

### Fecal water loss

Fecal water losses are usually around 5–10 ml/kg/24 h. However, such losses can be excessive and may lead to profound fluid imbalance in infants with diarrhea or an enterostomy. As infants with high

**Table 12.9** Average values of transepidermal water loss (in ml/kg/24 h) at an ambient relative humidity of 50%. There is wide individual variation in the higher values. Data from Hammarlund et al<sup>222</sup>

Gestation (weeks)	Postnatal age (days)						
	1	3	5	7	14	21	28
25–27	110	71	51	43	32	28	24
28–30	39	32	27	24	18	15	15
31–36	11	12	12	12	9	8	7
37–41	6	6	6	6	6	6	7

fecal losses increase renal reabsorption of water and sodium, tracking of renal sodium excretion can be useful as a low urinary sodium may precede other signs of dehydration.

### Urinary losses

During early postnatal life, the kidney of even a full-term infant has a limited capacity to produce concentrated urine and fractional sodium excretion is usually high. In the immediate period after birth, urine production falls and the urine becomes more concentrated. Failure to pass urine postnatally is not clinically significant until 24 h have elapsed (7% of neonates do not void in the first 24 h),<sup>225</sup> unless there are other pointers to a urogenital abnormality. This oliguric period may be due to the high levels of antidiuretic hormone in the newborn following birth as there is no evidence of a fall in glomerular filtration rate (GFR). Indeed, over the first week of postnatal life, both GFR<sup>226</sup> and blood pressure increase in term and premature infants and the initial period of oliguria and relatively concentrated urine is followed by a diuresis of isotonic, or even hypotonic, urine<sup>227</sup> and contraction of the ECF volume. Overall, in the VLBW infant, GFR varies from 0.4 to 1.0 ml/min/kg with a mean of 0.7 ml/min/kg at 26 weeks' gestation and 0.84 ml/min/kg at 33 weeks.<sup>226</sup> Given the reported maximum concentrating capacity of 800 mOsm/kg of urine (Table 12.10), compared to 1200 mOsm/kg of urine for an adult, and average renal solute load, fluid intake should be such as to maintain a minimum urine output of 1 ml/kg/h.

### WATER REQUIREMENTS

The aims of fluid management are to maintain satisfactory volumes of total body water (TBW), ICF and ECF, normal tissue perfusion, a normal blood pressure and a normal plasma sodium concentration. Changes in plasma sodium during the first week of life are usually due to changes in water balance rather than sodium balance.<sup>219</sup> In the first week of pre-term life, hyponatremia is commonly secondary to inadequate fluid replacement in the face of excessive insensible losses and hyponatremia is usually due to excessive intravenous fluids.

Four randomized controlled trials were included in a Cochrane review of liberal water intake (the standard or control group) versus a restricted water intake<sup>227</sup> (Grade A level 1a). In the von Stockhausen study<sup>228</sup> (n = 56, 'most of whom were premature' – published in German), the prescribed water intake was given only during the first 3 days of life; in the Lorenz study<sup>229</sup> (n = 88, 750–1500 g), only during the first 5 days; in the Tammela study<sup>230</sup> (n = 100, <1751 g), between 24 h and 28 days; in the Bell study<sup>231</sup> (n = 170, 751–2000 g), before 72 h up to 30 days (Table 12.11).<sup>228–231</sup>

A significantly greater postnatal weight loss occurred in the restricted water intake groups. There was no difference in intracranial hemorrhage, and the trend towards less bronchopulmonary dysplasia in the restricted water intake groups was not statistically significant. The risks of persistent ductus arteriosus, necrotizing enterocolitis and death (Table 12.12) were statistically significantly lower with restricted water intake in the overall analysis.

The interpretation of the overall analysis was heavily influenced by the Bell study since this contained most participants. This study also continued the restriction for the longest duration. Moreover, all the infants were enrolled at least a decade ago and only limited numbers of ELBW infants were included and there would be few units in the UK now using fluid regimens in early postnatal life as liberal as those in these trials. These studies did not control for sodium intake and it is not clear

Table 12.10 Normal renal function in newborn infants in the first week of life

Glomerular filtration rate	0.35–0.85 ml/kg/min
Urine flow rate	1.0–3.0 ml/kg/h
Urine osmolality	45–800 mOsm/kg

Table 12.11 Fluid regimens

	Restricted water intake (ml/kg/day)	Liberal water intake (ml/kg/day)
Von Stockhausen <sup>228</sup>	60	150
Lorenz <sup>229</sup>		
Day 1	65–70	80
Increasing gradually to day 5	80	140
Tammela <sup>230</sup>		
Day 1	50	80
Day 2	60	100
Day 3	70	120
Day 4	80	150
Day 5	90	150
Day 6	100	150
Day 7	120	150
Thereafter	150	200
Bell <sup>231</sup>	Mean 122 ml/kg/day throughout study period	Mean 169 ml/kg/day throughout study period

how many infants were exposed to antenatal steroids or postnatal surfactant. Furthermore, the analysis included five infants in the Tammela study who died on the first day of life. It could be argued these were too early to be influenced by the fluid regimen. If these five, who were all in the liberal fluid group, were excluded from analysis, restriction of water intake would no longer significantly affect the risk of death. This Cochrane review<sup>227</sup> does not include the study by Kavvadia et al<sup>225</sup> (n = 168, 486–1500 g), described below, which may ultimately influence the overall analysis of the systematic review. Future work required in this regard is outlined in Table 12.13.

### GESTATIONAL AGE AND POSTNATAL AGE

Fluid requirements depend on gestational age. The premature infant has a greater surface area to volume ratio, a thinner epidermis and more limited renal water conservation than a term infant. The premature infant is also more likely to require ventilation and phototherapy, and be nursed under a radiant heater. Fluid requirements also vary with postnatal age, increasing during the first week of life to cope with the transition from oliguria to diuresis and reaching a plateau as water balance is restored and birth weight is regained. Fluid requirements do not fall again until after the first 6 months of life.

If the infant is fed enterally, all or part of the water requirement is delivered in breast or formula milk. If the infant is not fed, all the water must be administered intravenously. This may be incorporated into a total parenteral nutrition regimen (providing other essentials such as nitrogen) or as 10% dextrose solution on the first day and 10% dextrose/0.18% saline thereafter (see section on sodium balance).

Water requirements for well infants may be given according to Table 12.14 and, provided there is no water retention due to inappropriate secretion of antidiuretic hormone (ADH) or excessive water loss due to transepidermal evaporation, plasma sodium concentration generally remains within the normal range as urinary losses are initially isotonic. However, greater caution is advisable in sick and ELBW infants for whom more cautious daily increments should be guided by changes in daily body weight, hyper- or hyponatremia and calculated and insensible losses. Thus, fluid administration must be adjusted in light of continuing assessment of fluid balance and the presence of the conditions in Table 12.15.

### CRYSTALLOID VERSUS COLLOID

Colloid is not routinely given to newborn infants as part of their fluid balance management. Historically, colloid was used in an attempt to

**Table 12.12** Risks of persistent ductus arteriosus, necrotizing enterocolitis (NEC) and death on low compared to high fluid intake regimen

	Typical RR (95% CI)	Typical RD (95% CI)	Number needed to treat to prevent one case (95% CI)
Persistent ductus arteriosus	0.40 (0.26, 0.63)	-0.19 (-0.27, -0.11)	5.3 (3.7, 9.1)
NEC	0.30 (0.13, 0.71)	-0.08 (-0.14, -0.03)	11.9 (7.2, 33.3)
Death	0.52 (0.28, 0.96)	-0.06 (-0.12, -0.01)	15.9 (8.4, 167)

**Table 12.13** Future work required

- ELBW infants
- Critical period over which water intake must be controlled
- A larger study to determine whether mortality really is reduced
- New trials with the previous 'restricted' regimens as the control arm and even greater restriction during the early postnatal period as the intervention arm, provided infants are nursed in incubators rather than under radiant warmers

ELBW, extremely low birth weight.

**Table 12.14** Daily fluid requirements for well infants (ml/kg/24 h)

	Day 1	Day 2	Day 3	Day 4	Day 5
Premature infants	60	90	120	120–150	120–150
Term infants	40	60	80	110	120–150

**Table 12.15** Fluid intake alterations

Conditions in which fluid restriction should be considered  
 ELBW infants nursed in 100% humidification with humidified respiratory gases

- Persistent ductus arteriosus, especially if indometacin given
- Hypoxic-ischemic encephalopathy
- Severe respiratory distress
- Oliguric renal failure
- Inappropriate release of ADH

Conditions in which fluid requirements are increased

- Excessive insensible water loss
- Use of a radiant warmer
- Phototherapy
- Vomiting
- Diarrhea
- Polyuria (e.g. due to glycosuria or following relief of obstructive uropathy)

ADH, antidiuretic hormone; ELBW, extremely low birth weight.

treat reduced tissue perfusion and hypotension but these are better managed with dopamine (Grade A, Level 1a).<sup>232</sup> Whether colloid administration may actually increase mortality in resuscitation and intensive care settings<sup>233</sup> is controversial and caution is necessary in interpreting studies involving heterogeneous indications and patient groups. The possible role of colloid in the genesis of chronic lung disease (CLD) is discussed below.

## ASSESSMENT OF WATER BALANCE

Water and sodium constitute the major solvent and solute of the ECF and water balance cannot be assessed independently of that of sodium. Most clinical and laboratory observations give information about the ECF volume rather than ICF volume.

## Clinical examination

Heart rate, systemic arterial blood pressure, central venous pressure and skin-core temperature gradient are all variables which are related to intravascular volume and cardiac output. However, these signs are crude monitors of fluid balance, and tachycardia, hypotension and poor perfusion are features of decompensation following significant hypovolemia. Moreover, many factors other than fluid balance modulate cardiovascular responses.

Classic signs of decreased interstitial fluid volume are sunken eyes, a depressed fontanelle and reduced skin turgor but only semiquantitative interpretation is possible and this is much more difficult in premature infants in whom these skin changes may be less apparent. Furthermore, edema is not a reliable sign of fluid overload in the premature infant.<sup>234</sup>

## Fluid balance charts

If obsessively maintained, these are a helpful guide to monitoring fluid balance. Obviously, interpretation of the cumulative arithmetic balance must include possible insensible losses and may be very misleading if these are overlooked. The omission of volumes administered to flush vascular cannulae and as drug vehicles, as well as the omission of the blood volumes sampled (injurious sampling may cause significant cumulative losses leading to anemia<sup>235</sup> and even hypovolemia), are important sources of error in calculated fluid balance.

## Body weight

This is the best cot-side guide to TBW. Where fluid balance is important, the infant should be weighed daily, on the same scales and at the same time, particularly in relation to feeds. Serial body weights are of great value in distinguishing hyponatremia due to water overload from that due to sodium depletion. However, a stable or increasing body weight must be interpreted alongside the infant's evolving clinical condition as it may be falsely reassuring under circumstances in which TBW and intravascular volume do not move in parallel, e.g. concealed losses from the intravascular compartment into the so-called 'third space' in peritonitis and ileus, in hydrops and in congestive cardiac failure.

## Urine flow rates

Estimation of urinary fluid loss is helpful in the fluid management of the preterm infant as are urine chemistry (see below), urine pH, glucose testing, specific gravity and osmolality (Fig. 12.12).<sup>236</sup> A urine specific gravity of between 1.005 and 1.012 is desirable as the newborn kidney is not then at the limits of its concentrating or diluting capacity. Specific gravity and osmolality are unreliable in the presence of glycosuria or significant proteinuria. The normal range for urine flow rates is given in Table 12.10. Although catheterization is best avoided wherever possible, urine output must be assessed in all infants when fluid balance is considered critical, particularly if there is evidence of renal disease. Bag collections may be reliable in male infants but the adhesive used may damage the skin of a very immature infant. Alternatively, the infant may be nursed on a plastic sheet and the urine collected with a syringe. Nursing infants on cotton wool or absorbent, plastic coated nappies which are weighed before and after micturition also have roles but may overestimate fluid loss in high incubator humidity.

## Urine and plasma biochemistry

Plasma creatinine concentration is of limited value as an index of glomerular filtration in the newborn because:

Fig. 12.12 Comparison of urinary specific gravity and urinary osmolality in 1000 urine samples. Third order regression line is shown:  $r = 0.97$ . (From Jones et al 1976<sup>236</sup> with permission.)

1. Initially the neonatal concentration mirrors the maternal concentration before birth.
2. Non-creatinine chromogens may interfere with measurement.
3. The reference range is wide.<sup>226,237</sup>

Similarly, the interpretation of urinary electrolytes is also difficult as the ranges encountered are so wide (Table 12.16).<sup>238–240</sup> Interpretation should always be made in the light of simultaneous plasma electrolytes and a clinical assessment. As fractional sodium excretion declines with increasing gestation and increasing postnatal age, fluid intake is best adjusted to maintain a normal plasma sodium concentration rather than relying on urinary measurements. Moreover, a high fractional sodium excretion may reflect excessive sodium supplements once these have been initiated.

Despite these caveats, urinary chemistry may be of value in distinguishing oliguria due to hypovolemia (guiding an increase in fluid administration) from established renal failure, when fluid intake should be restricted. As another cause of oliguria is inappropriate ADH secretion, urinary electrolytes and osmolality are necessary for the definitive diagnosis before initiating fluid restriction. Although in VLBW infants, random urine creatinine concentration is related to instantaneous urine flow rate by the formula: urine flow rate (ml/kg/24 h) = 90/urine creatinine concentration ( $\mu\text{mol/L}$ ), the 95% confidence limits are wide.<sup>237</sup>

### Plasma albumin and colloid osmotic pressure

Albumin concentration accounts for 70% of colloid osmotic pressures (COP). The two measurements are closely correlated in the premature newborn and both increase postnatally, in a similar fashion to the increase in fetal albumin concentration in utero. However, low albumin concentrations

Table 12.16 Normal reference values for urinary excretion

Term infants	Mean	SD
Sodium*	1.63	(0.78) mmol/kg/24 h
Potassium*	0.68	(0.31) mmol/kg/24 h
Creatinine†	0.45	(0.23) mmol/24 h
Preterm infants	Median	Range
Sodium‡	2.23	(0.18–4.12) mmol/kg/24 h
Potassium‡	0.75	(0.06–3.50) mmol/kg/24 h
Creatinine	0.06	(0.03–0.36) mmol/kg/24 h

\* Full term, appropriate weight, breast-fed babies during the first and second weeks of life.<sup>238</sup>

† Normal full term infants during the first month of life.<sup>239</sup>

‡ Male infants, 24–36 weeks' gestation, during the first week of life (Stephenson Et Broughton Pipkin, unpublished observations.)

correlate poorly with clinical edema<sup>234</sup> and, although high albumin concentrations may reflect reduction in plasma volume ('hemoconcentration'), this relationship has not been demonstrated directly.

### Packed cell volume

Packed cell volume (PCV) falls with decreasing gestation and increasing postnatal age, but with great variability between individuals, so that single measurements are a poor guide to fluid balance. However, if serial measurements of PCV (a simple and reproducible task) show a rising trend in a sick infant, in whom erythropoiesis is usually depressed, then fluid intake is probably insufficient. Falling levels of PCV may be due to blood loss, red cell destruction or hemodilution and are, therefore, difficult to interpret.

### POSSIBLE CLINICAL CONSEQUENCES OF WATER OVERLOAD AND DEFICIENCY

Poor control of water balance leads to both volume and osmolar changes within body fluid compartments. Overload of water and sodium, which if it is isotonic expands only the ECF, has been implicated in the pathogenesis of a number of neonatal disorders. The consequences of pure water overload and deficiency are discussed under the headings hyponatremia and hypernatremia.

### Respiratory distress syndrome (RDS) and chronic lung disease (CLD)

In infants with RDS, the oliguric phase following birth persists for longer and there is correlation between the degree of oliguria and the minimum  $\text{PaO}_2$ .<sup>241</sup> There is also correlation between the duration of oliguria, the duration of oxygen therapy and the risk of bronchopulmonary dysplasia (BPD). Pharmacological muscle relaxation, at least with pancuronium, exacerbates this fluid retention with peripheral edema and weight gain<sup>242</sup> and special attention should be paid to fluid balance and brevity of the period of muscle relaxation. Colloid administration appears to adversely affect short term measures of lung function in the perinatal period.<sup>243</sup>

The orthodox view is that the onset of the diuretic phase precedes improvement in respiratory function but this has been questioned.<sup>244,245</sup> High levels of ADH<sup>241</sup> and angiotensin II have been reported in RDS, which would contribute to salt and water retention, and increased levels of atrial natriuretic peptide (ANP)<sup>246</sup> which would antagonize these hormones have been reported during the diuretic phase of RDS.<sup>247</sup> The use of diuretics in the treatment of acute RDS and CLD has given differing results (see also Energy, fluid and electrolyte requirements, Chronic lung disease).

The role of fluid intake between the first and seventh postnatal days (Table 12.17) in CLD has been studied in a trial in which 168 VLBW

Table 12.17 Prescribed fluid regimens

	Documented mean restricted fluid intake (crystalloid + colloid) (ml/kg/day)	Documented mean standard fluid intake (crystalloid + colloid) (ml/kg/day)
Day 1	66	86
Day 2	79	93
Day 3	84	114
Day 4	103	124
Day 5	121	142
Day 6	136	148
Day 7	146	159

ventilated infants, at high risk of CLD and routinely exposed to antenatal steroids and postnatal surfactant,<sup>225</sup> were randomized to liberal or restricted water intakes. Actual intakes initially exceeded the recommended regimen by up to 26 ml/kg/day, although variances from the trial protocol became smaller after the first 48 h of life.

There were no significant differences in the two primary outcome measures, the proportions developing chronic lung disease or surviving without chronic lung disease. There were no differences in the secondary outcomes of persistent ductus arteriosus, intracranial hemorrhage, NEC and death. Significantly fewer infants who received the restricted regimen received postnatal steroids after the first week (19% versus 43%), prescribed for infants fully ventilator dependent beyond 7 days or in 40% O<sub>2</sub> after 3 weeks, although it is unclear whether this was enforced by trial protocol or left to the clinicians' discretion. However, since the duration of ventilation (median 7 days in both) and O<sub>2</sub> dependency (median 40 days in the restricted group and 38 in the standard group) was similar, it is difficult to explain the difference in steroid therapy except to note that the trial was not blinded. In a post hoc analysis, volume of colloid infused was associated with duration of oxygen dependency. However, this was not a randomized intervention and colloid may well have been administered to sicker infants.

### Persistent ductus arteriosus (PDA)

PDA is extremely common in premature infants and this has been associated with high fluid intake.<sup>231</sup> The persistence of the duct may be partly due to failure of the usual postnatal contraction in ECF and this, in turn, may be responsible for the elevated levels of ANP found with persistent ductus arteriosus.<sup>248,249</sup> Moreover, prostaglandin E<sub>2</sub>, which is the most potent dilator of the duct,<sup>250</sup> is also involved in regulation of sodium balance, causing natriuresis. Elevated levels of PGE<sub>2</sub> may, therefore, be provoked by salt and water retention.

There has been no systematic trial of the place of fluid restriction in the treatment (as opposed to prevention) of PDA and, as in cardiac failure, given the importance of adequate calorific intake it may be more rational to restrict sodium and maintain fluid intake, using diuretics to reduce fluid overload if necessary. Diuretics can also be used with indometacin in the treatment of PDA since PGE<sub>2</sub> synthesis is inhibited by indometacin and fluid retention may result (see p. 267) although caution is important in the face of fluid depletion.<sup>251</sup>

In a number of other conditions, such as cardiac failure, renal failure or ascites, salt and water overload occurs as a *consequence* of organ dysfunction rather than as an etiologic factor.

## SPECIAL CARE – SODIUM AND POTASSIUM

### BODY SODIUM CONTENT AND DISTRIBUTION

Sodium is the major extracellular cation. As the percentage of body weight which is ECF falls during fetal life, so the sodium content in the fetus falls from 94 mmol/kg at 25 weeks' gestation to 74 mmol/kg at term. However, with the continued increase in absolute fetal weight, there is a daily accretion of sodium in utero of about 1 mmol/kg/24 h.

Following birth, as there is isotonic contraction of the ECF, there is an inevitable loss of sodium during the first week which averages 14 (range 6–22) mmol/kg. This loss cannot be prevented but may be excessive if sodium intake is inadequate.<sup>252</sup> Negative sodium balance is maximal on day 4 and becomes positive by day 6 or 7,<sup>253</sup> provided sodium intake is maintained at 6–8 mmol/kg/24 h.

### REGULATION OF SODIUM HOMEOSTASIS

The control of sodium and water balance is regulated by a number of homeostatic mechanisms to maintain a normal plasma sodium concentration (132–142 mmol/L) and normal circulating volume. Moreover, conservation of sodium throughout childhood is essential for growth. The regulating mechanisms are:

1. sodium and water intake under the influence of thirst;
2. glomerular filtration rate which determines the amount of sodium and water delivered to the renal tubules;
3. reabsorption of sodium and water by the renal tubules and collecting ducts.

The healthy term infant can respond to thirst by demand feeding but infants of less than 34 weeks' gestation have little control over intake (as solutes are delivered not sought). Moreover, as the rise in GFR over the first week outstrips the more gradual improvement in renal tubular sodium reabsorption, transient glomerulotubular imbalance develops and a high fractional sodium excretion results. Sodium sensors in the macula densa are stimulated by this high delivery of sodium to the distal tubule, as shown by correlation between urinary sodium and plasma renin even in very premature infants.<sup>254</sup> However, the immature nephron appears to be unresponsive to the high circulating concentrations of angiotensin II and aldosterone generated by this system. ANP levels are high in the immediate newborn period<sup>255</sup> and ANP inhibits the sodium-retaining actions of both angiotensin and aldosterone.<sup>256</sup>

This initial sodium-losing state continues until the end of the first week following which positive sodium balance ensues to ensure growth. Maturation of the aldosterone-dependent distal tubular reabsorption, which is gestation dependent but accelerated by birth, appears to be responsible for the transition to net sodium gain, since proximal tubular reabsorption is unchanged.

During the initial period of glomerulotubular imbalance, urine flow rates do not increase significantly<sup>257</sup> although GFR is increasing. This suggests that the collecting ducts are sensitive to ADH, the levels of which are high in the immediate newborn period.<sup>253</sup> The feedback control of ADH secretion is operative from 26 weeks' gestation (although inappropriate secretion of ADH also occurs commonly in this group<sup>253</sup>) and, as a result, plasma osmolality is normally maintained within a narrow range of 282–298 mOsm/kg despite variable water intake.

### SODIUM BALANCE

To maintain a stable plasma sodium concentration and allow growth:

$$\begin{aligned} &\text{Required sodium intake} \\ &= \text{sodium for growth (mostly increase in ECF)} \\ &+ \text{sodium lost [in urine + in sweat (after 36 weeks' gestation) + in feces].} \end{aligned}$$

Sodium for growth is roughly 1–2 mmol per week over the first year of life and fecal sodium losses are trivial (0.23 mmol/kg/24 h) in the absence of diarrhea. In a healthy term infant, urinary sodium losses (1–2 mmol/kg/24 h) far exceed other losses and in VLBW infants urinary sodium losses up to 20 mmol/kg/24 h occur.<sup>258</sup>

As urinary sodium losses account for the greatest sodium losses in the newborn period, but there is initial oliguria after birth, no sodium intake is required for the first 24 h of postnatal life. During the succeeding week, 4–8 mmol/kg/24 h is usually adequate. Thereafter, term infants may require as little as 1 mmol/kg/24 h, whereas immature infants may require 8–12 mmol/kg/24 h if 'late' hyponatremia is to be avoided (see below). The needs of a term infant are ideally supplied by human breast milk which, with a nominal intake of 150 ml/kg/24 h, provides 4 mmol/kg/24 h on day 3 but only 1.2 mmol/kg/24 h after a month, the sodium

concentration of breast milk naturally falling with time. Preterm human milk alone can rarely keep pace with the obligate renal losses in preterm infants of < 2 kg. The addition of breast milk fortifiers or preterm formula milk (if human breast milk cannot be provided) provides a sodium content 14–26 mmol/L. Nevertheless, additional sodium supplements may also be required if the plasma sodium concentration is to be maintained. When enteral fluids are contraindicated and parenteral fluids are given, sodium homeostasis can be achieved by supplying sodium alongside nitrogen-containing parenteral nutrition or by giving 10% dextrose on day 1 and 10% dextrose and 0.18% saline (30 mmol/L NaCl). Thereafter the rates for well infants in Table 12.14 deliver 4.5 mmol/kg/24 h of sodium by day 5 if 150 ml/kg/24 h 10% dextrose/0.18% saline is administered.

Changes in plasma sodium concentration during the first week of life are more often due to changes in water balance than sodium balance<sup>253</sup> so the volumes of water may need to be adjusted on the basis of frequent plasma sodium estimations.

## HYPONATREMIA

The causes of hyponatremia (plasma sodium < 130 mmol/L) are listed in Table 12.18. Water overload is the major cause during the first week of life but, thereafter, sodium depletion becomes more important. Under conditions of sodium depletion, initially the kidney loses water to maintain a normal plasma osmolality but eventually the need to conserve plasma volume becomes the overriding stimulus, there is appropriate release of ADH and hyponatremia occurs.

The clinical features of hyponatremia have three origins:

1. Hypotonia, lethargy and convulsions due to the hyponatremia, irrespective of the cause. These symptoms are not usually seen until plasma sodium falls below 125 mmol/L and are partly related to the acuteness of the fall.
2. Inappropriate weight gain with iatrogenic water overload in early postnatal life or weight loss with sodium depletion in later postnatal life.
3. Features associated with the underlying disease.

The underlying cause should be treated but, in the interim, symptomatic treatment may be necessary to achieve a safe plasma sodium concentration. It is critical that a definitive diagnosis is made as the appropriate treatment may be either fluid restriction or sodium supplementation.

**Table 12.18** Causes of hyponatremia in the newborn

A. Water overload
1. Maternal water overload prior to birth
2. Iatrogenic water overload following birth
3. Decreased free water clearance in a sick preterm infant
4. Inappropriate release of antidiuretic hormone
Cerebral disease (birth asphyxia, meningitis)
Respiratory disease (pneumonia, pneumothorax)
B. Sodium depletion
This is usually accompanied by a lesser degree of water depletion
1. Excessive gastrointestinal losses (vomiting, diarrhea, nasogastric aspirate, enterostomy loss)
2. Excessive removal (repeated drainage of ascites, pleural fluid or CSF)
3. Excessive renal losses
a. Primary renal tubular problems
(i) 'late' hyponatremia of prematurity
(ii) following relief of obstructive uropathy
(iii) Fanconi syndrome
(iv) Bartter syndrome
b. Hypoadrenalism
(i) congenital adrenal hyperplasia
(ii) congenital adrenal hypoplasia
(iii) hypoadosteronism
(iv) pseudohypoadosteronism

If there is water overload, renal failure or hyponatremia following indometacin treatment, fluids should be restricted rather than more sodium given.

If there is a sodium deficit, the number of millimoles required is given by the formula:

$$(135 - \text{plasma sodium concentration}) \times \text{body weight (kg)} \times 2/3$$

This should be replaced slowly over 24 h by giving sodium intravenously [adding appropriate amounts of 30% NaCl (5 mmol/ml) to intravenous fluids].

In a symptomatic infant (irritable, apneic or convulsing), or in an infant with a genuine plasma sodium < 120 mmol/L, resuscitation should be initiated with a slow bolus of 15 ml/kg 0.9% saline (150 mmol/L).

In premature infants, a high incidence of 'late' hyponatremia is well recognized and, in contrast to the first postnatal week, this is frequently due to total body sodium depletion (accompanied to a lesser extent by water depletion) with poor weight gain or even weight loss. The sodium depletion is due to prolongation of the period of obligate renal sodium loss, possibly due to a delay in endocrine maturation, so that plasma sodium concentration is dependent on sodium intake which must be increased accordingly. This may be provided within parenteral nutrition or supplementation of enteral feeds using 30% NaCl (5 mmol/ml).

## HYPERNATREMIA

Hypernatremia is almost invariably the result of water depletion (Table 12.19) and is associated with weight loss, failure to thrive or irritability. Hypertonicity and convulsions may occur when plasma sodium exceeds 150 mmol/L. A 'doughy' quality of the skin and a paradoxically full fontanelle may also suggest hypernatremic dehydration. The osmotic gradient favors maintenance of the ECF at the expense of the ICF and the diagnosis may be delayed as signs of hypovolemia and decreased skin turgor occur late. As hypernatremia may occur where restrictive fluid administration regimens in ELBW infants underestimate their excess fluid losses, daily body weights and twice daily plasma sodium measurements are a helpful guide to fluid management.

Treatment is difficult as persistence of hypernatremia is associated with cerebral hemorrhage and renal vein thrombosis in the newborn but overaggressive correction may cause cerebral edema as water enters cells down the osmotic gradient. A solution of 0.9% saline should be used initially and the deficit should be corrected slowly over 48 h.

## BODY POTASSIUM CONTENT AND DISTRIBUTION

Potassium is the major intracellular cation. Although fetal growth is accompanied by a more than commensurate increase in total body potassium (as the ICF fraction of TBW increases), the potassium concentration in blood throughout life is virtually unchanged from 15 weeks' gestation.<sup>259</sup> Plasma potassium concentration is a major determinant of the cell membrane potential and if significant changes do occur, they must be corrected. As the vast majority of body potassium is intracellular, significant body depletion of potassium may occur for only a modest reduction in measured extracellular

**Table 12.19** Causes of hypernatremia in the newborn

A. Water depletion
1. Inadequate intake
2. Excessive transepidermal water loss
3. Excessive renal losses
a. Glycosuria
b. Diabetes insipidus
B. Sodium overload
Isolated sodium overload is rare as water is usually retained with sodium. It is caused by the administration of hypertonic solutions, such as sodium bicarbonate

potassium concentrations below a laboratory reference range. Similarly, as only 2% of total body potassium is found in ECF, large changes may occur in total body potassium without significantly altering plasma potassium concentration. In ventilated premature infants, a negative potassium balance of 10% of total body potassium occurs over the first 4 postnatal days, but hypokalemia (measured as ECF potassium concentration) is a rare problem. Subsequently, provided potassium-containing fluids are provided, positive potassium balance is restored and net potassium accumulation then continues at an average of 1 mmol/24 h over the first year of life (approximately 0.3 mmol/kg/24 h initially and 0.05 mmol/kg/24 h at 1 year).

## POTASSIUM BALANCE

Required potassium intake = potassium for growth  
+ potassium lost (in urine + from GI tract).

As with sodium balance, urinary losses far exceed other losses, particularly during early newborn life. As the newborn's prostaglandin E<sub>2</sub> levels decline, the distal tubule becomes more aldosterone responsive (leading to reabsorption of sodium from the tubular lumen in exchange for excretion of potassium) so that the urinary potassium to sodium ratio increases with postconceptional age. Urinary potassium excretion in VLBW infants is 1–5 mmol/kg/24 h.<sup>258,260</sup> Gastrointestinal losses are normally less than 0.5 mmol/kg/24 h but very significant cumulative losses of potassium can occur if gastric contents are aspirated and not replaced, in fluid lost from enterostomies and in ileus.

For most infants in the newborn period, daily potassium intake of 3 mmol/kg/24 h is usually adequate. Human breast milk provides 2.25 mmol/kg/24 h (assuming 150 ml/kg/24 h intake). The sodium:potassium ratio in mature human breast milk is about one, the same as the ratio in the urine of healthy term infants.<sup>258</sup>

## HYPOKALEMIA

Symptoms of hypokalemia rarely occur until the plasma potassium concentration is more than 0.5 mmol/L below the lower limit of the normal range (3.0–6.6 mmol/L up to 1 month of age) with a concomitant increase in plasma bicarbonate being common. As the clinical features of weakness, hypotonia, hyporeflexia and lethargy are extremely difficult to recognize in the newborn, plasma potassium should be measured frequently in sick infants. Such infants should receive continuous cardiac monitoring (ECG features of hypokalemia are small T waves, depression of the ST sequence, and the appearance of U waves) because cardiac arrhythmias may occur. Loop diuretics and aminophylline<sup>261</sup> predispose to hypokalemia in the newborn and hypokalemia sensitizes the heart to digoxin.

Causes of hypokalemia are listed in Table 12.20. Treatment is by oral or intravenous (5 ml of 20% solution contains 1 g or 13 mmol) potassium chloride administration, depending on the infant's condition and the severity of the hypokalemia, and by reversal of the underlying cause if possible. Intravenous potassium supplements should not exceed a con-

centration of 40 mmol/L. ECG monitoring is mandatory, infusion through a central venous catheter is preferable (provided the tip is not in the right atrium), and potassium added to fluid in plastic containers must be well mixed to prevent adherence. Potassium should not be added to blood products as it may cause red cell lysis. Oral potassium supplements should be avoided in gastrointestinal disorders because they may cause vomiting, ulceration and stricture. Diuretics should be stopped if possible or the potassium-sparing aldosterone antagonist, spironolactone, added.

## HYPERKALEMIA

The causes of hyperkalemia are listed in Table 12.21. Plasma potassium concentrations above the 'normal' range occur in 3.5% of infants under 1500 g, particularly sicker infants less than 28 weeks.<sup>258,262</sup> Acute rises in plasma potassium can occur with intravenous administration but, apart from this, hyperkalemia due to excessive intake is rare because the kidney has a large reserve for potassium excretion. Hyperkalemia is more commonly due to a failure of excretion by the distal tubule, and this is supported by the finding of impaired renal function in 50% of cases of hyperkalemia in VLBW infants.<sup>262</sup> Altered Na<sup>+</sup>, K<sup>+</sup>-ATPase cation pump function may contribute to this non-oliguric hyperkalemia of the preterm neonate.<sup>263</sup> Preterm infants have lower erythrocyte intracellular sodium concentrations and higher intracellular potassium concentrations suggesting Na<sup>+</sup>, K<sup>+</sup>-ATPase enzyme activity is increased.<sup>264</sup>

As with hypokalemia, there may be apathy, weakness, hypotonia and hyporeflexia and also ileus. The ECG shows tall peaked T waves and arrhythmias occur in 60% of premature infants with serum potassium above 7.5 mmol/L, the commonest being supraventricular tachycardia.<sup>262</sup> Hyperkalemia > 7.5 mmol/L (or 6.5–7.5 mmol/L if there are associated ECG abnormalities) requires urgent treatment to redistribute potassium into cells as measures to improve renal excretion are too slow. Although Grade A evidence is lacking in the newborn, salbutamol has been shown to be an effective short term measure for the emergency management of hyperkalemia in older children<sup>265</sup> and adults and has the potential to have fewer short term side-effects than insulin/dextrose.<sup>266</sup> The myocardium is stabilized by intravenous calcium whilst the other measures in Table 12.22 take effect.

## SPECIAL CARE – THERMOREGULATION

Soranus of Ephesus (98–131AD), in his treatise *On Diseases of Women*, clearly understood the importance of keeping newborn infants warm. In late 19th century Paris, Tarnier and Budin reduced by half the mortality of infants under 2000 g birth weight by nursing them in a warming chamber they designed from an incubator used for rearing poultry.<sup>267</sup> In a series of randomized controlled trials in the 1950s, William Silverman showed that keeping babies warm resulted in a 25% absolute reduction in mortality in all birth weight groups, including those under 1000 g.<sup>268–270</sup> Despite these studies, recent data show that newborn babies still get cold and hypothermia, especially in the preterm infant, remains associated with increased mortality.<sup>271–274</sup>

Table 12.20 Causes of hypokalemia in the newborn

<i>Gastrointestinal losses</i>
Vomiting or excessive nasogastric aspirate
Diarrhea
Enterostomy losses
Ileus
<i>Renal losses</i>
Bartter syndrome
Fanconi syndrome
Following relief of obstructive uropathy
Diuretic therapy
Alkalosis from any cause
<i>Inadequate intake</i>
Inadequate enteral or intravenous supplements

Table 12.21 Causes of hyperkalemia in the newborn

<i>Erroneous</i>
Sample hemolysis
Sample contamination with EDTA
<i>Excessive intake/production</i>
Iatrogenic supplementation of i.v. fluids or parenteral nutrition
Excessive hemolysis (e.g. accompanying intraventricular hemorrhage in VLBW infant)
<i>Inadequate excretion</i>
Acute renal failure
Hypoadrenalism (especially congenital adrenal hyperplasia and hypoplasia)
Hypoadosteronism

**Table 12.22** Management of hyperkalemia in the newborn

1. Discontinue all potassium administration, potassium-conserving diuretics and potentially nephrotoxic drugs. Correct prerenal failure due to hypovolemia, treat sepsis (avoiding potassium-containing penicillin salts) and optimize nutrition to minimize catabolism. Monitor ECG continuously
2. Intravenous salbutamol 4 mcg/kg over 5 min – can repeat if necessary
3. Intravenous 10% calcium gluconate 0.5 ml/kg over 5 min
4. Intravenous 4.2% sodium bicarbonate 4 ml/kg over 5 min  
This should be given via a different vein or after flush to prevent precipitation
5. A glucose + insulin infusion (less safe than salbutamol)  
Give 1 g/kg glucose + insulin 0.1 unit/kg infusion over 2 h, mixed in the same syringe, measuring venous blood sugar and plasma potassium concentrations hourly. Consider dialysis
6. Calcium resonium enema 0.5 g/kg, retained for at least 30 min. This can be repeated 8-hourly

Children and adults maintain a constant deep body temperature over a wide range of ambient thermal conditions (they are homeothermic). This is achieved by physiological and behavioral responses that control the rate at which heat is produced or lost. The newborn infant is also homeothermic but control of body temperature can only be achieved over a narrower range of ambient conditions. The preterm infant has even greater difficulty and the most immature infants behave at times as if they are poikilothermic – their body temperature tending to drift up or down with the ambient temperature. The aim in neonatal care is to provide a thermal environment which keeps body temperature in the normal range and which does not stress the infant to produce or lose large amounts of heat.

## HEAT BALANCE

### Heat production

Heat is produced as a by-product of cell metabolism. The basal metabolic rate is the lowest obligatory rate of heat production which occurs when an individual is starved, quiet and resting. In the newborn this is usually taken as the minimal rate of oxygen consumption in an infant who is lying still and asleep, at least 1 h after a feed in a neutral thermal environment. Values depend on gestation and postnatal age.

### Heat loss

#### Convection

Heat is lost from the skin surface to the surrounding air by convection. Loss is high if there is rapid movement of cold air over the exposed skin. A naked baby in a cold drafty room has a high convective heat loss.

#### Radiation

Heat is lost from the skin to the nearest surface facing the baby. Radiative heat loss varies with the temperature of that surface and its distance from the skin, but is independent of the temperature of the intervening air. A naked infant can radiate large amounts of heat to the cool walls of an incubator even if the air is warm. An overhead warmer provides heat by radiation.

#### Evaporation

Heat is lost as water evaporates from the surface of the skin (560 cal/ml of water). A newly born infant wet with amniotic fluid loses heat as the skin dries. Evaporative heat loss is low in mature infants unless they are sweating in response to heat stress. Losses are high in preterm infants who have a high transepidermal water loss (TEWL) due to passive diffusion of water through the thin, poorly keratinized immature epidermis. TEWL is related to both gestational and postnatal age.<sup>275–277</sup>

## Conduction

Newborn infants are not usually in direct contact with a structure of high thermal capacity, so conductive losses are small. Heat can be gained by conduction if the baby is lying on a heated gel- or water-filled mattress.

Heat production must be balanced by that lost from convection, radiation, evaporation and conduction. The more immature the infant, the greater the difficulty in temperature control. Heat loss is related to surface area which is relatively high in the smaller babies. There is poor insulation due to lack of subcutaneous tissue, and the poorly developed stratum corneum results in high TEWL and evaporative heat loss. The ability to conserve heat by vasoconstriction is limited and heat production, which is related to mass, is low. This poor response to relatively high heat losses means that hypothermia is a common problem in the immature baby.

## RESPONSE TO THERMAL STRESS

The thermoneutral environment is a range of environmental temperature over which an infant has a minimum rate of heat production and is not sweating. Within this range, small adjustments to thermal control can be made by alterations in posture, activity and skin blood flow with deep body temperature remaining constant.<sup>278</sup> The thermoneutral range is wide if the infant is mature and well insulated by clothes and bedding, but narrow in the small and naked baby. As environmental temperature falls below the lower end of the thermoneutral range, metabolic heat production increases. This is mainly the result of oxidation of brown adipose tissue which is distributed in the neck, between the scapulae and along the aorta. The metabolism of brown fat to produce heat is controlled by catecholamine release (nonshivering thermogenesis). A term newborn infant can double his resting heat production in this way without any increase in activity.<sup>279</sup> As environmental temperature continues to decline, heat production reaches a maximum and below this point the body temperature falls. If environmental temperature rises above the upper end of the thermoneutral range, sweating occurs until a point is reached when the heat lost by sweating is insufficient and body temperature starts to rise.

In all infants heat production is delayed during adaptation to extra-uterine life, especially if there is asphyxia, hypoxia or maternal sedative administration. Heat production per unit area is lower in preterm infants, particularly below 28 weeks' gestation, and the immature infant has a more prolonged impairment of nonshivering thermogenesis.

Sweating occurs from birth in infants above 36 weeks' gestation but is delayed by 2–3 weeks in the most immature infants.<sup>280</sup> This is a result of neurological rather than glandular immaturity. Sweating is a relatively poor defense against overheating in the newborn because the production of sweat per unit area of skin is low compared with a child or adult. The term newborn can alter skin blood flow effectively, and hence the amount of heat lost by convection and radiation, but this is impaired in the very immature infant. Change of posture to increase or decrease the surface area available for heat loss by convection and radiation is important in thermoregulation. It occurs in the healthy term infant and to some extent in the preterm infant but not in the presence of illness.

## BODY TEMPERATURE AND ITS MEASUREMENT

Measurement of body temperature is the only practical way of assessing the thermal environment in day-to-day care. It is crude because it tells us nothing about the amount of energy the baby may be using to maintain its body temperature. An infant can be exposed to very significant thermal stress and still maintain a normal deep body temperature. The corollary of this is that just because a baby has a normal deep body temperature does not necessarily mean that it is in a neutral thermal environment.

Deep body temperature varies depending on the metabolic rate of the tissue, with the brain having the highest temperature. Esophageal temperature, measuring the temperature of the blood in the great veins close to the heart, is often used to represent deep body temperature but this is not used in routine care. Tympanic temperature closely correlates with brain temperature but is impractical in the newborn. In clinical

practice we need an easily measured temperature that is at least close to, and follows changes in, deep body temperature.

Rectal temperature should no longer be used in infants and children as there is a significant risk of damage to the mucosa. Temperature in the rectum is an unreliable measure as it is affected by the depth of insertion of the thermometer, whether the baby has just passed a stool and by the temperature of the blood returning from the lower limbs. It is very difficult to retain rectal probes in the same position to allow continuous monitoring of temperature.

Axillary temperature is a reasonable guide to deep body temperature. The bulb of the thermometer should be held in the roof of the axilla with the infant's arm pressed against the side of the chest until a stable reading is obtained, usually by 3 min. The normal range is 36.3–37.0°C.

Skin temperature reflects tissue insulation and environmental conditions as well as deep body temperature. In the preterm baby, the temperature of the skin over the liver can be used to monitor trends in deep body temperature. If the infant lies on a temperature probe which is insulated on the outside, the skin under the probe cannot lose heat and so equilibrates with the deep body temperature. This is the zero heat flux temperature and is a practical method for continuous monitoring of a central temperature.<sup>281</sup>

A single temperature, measured intermittently, gives limited information on the thermal state of the baby. Particularly in the sick or unstable baby, more information can be obtained from the continuous measurement and display of a central (abdominal, axillary or zero heat flux) and a peripheral (foot) temperature. Changes in peripheral temperature can detect cold stress before the central temperature falls. The preterm baby who appears to be comfortable in its environment will have a central temperature, measured from a skin probe, of 36.8–37.3°C and a central–peripheral temperature difference of 0.5–1°C. An increasing central–peripheral temperature difference, particularly above 2°C, is commonly due to cold stress and occurs before any fall in central temperature. Hypovolemic babies will vasoconstrict their peripheral circulation in an attempt to maintain blood pressure. This results in a rise in central–peripheral temperature difference but, in such cases, there are other signs of hypovolemia such as a rising heart rate and falling blood pressure.<sup>282</sup> A high central temperature, particularly if unstable, along with a wide central–peripheral gap is seen in septic babies.<sup>283</sup>

## MANAGEMENT OF THE THERMAL ENVIRONMENT

### At delivery

The newborn baby loses heat by convection and radiation, but evaporation of amniotic fluid from the skin is the greatest source of heat loss. Delivery rooms should be warm, with a minimum temperature of 25°C. The term newborn infant should be dried at delivery, wrapped in a warm dry blanket and given to the mother. Skin to skin contact with the mother is an effective way of maintaining body warmth but it is important to cover the baby to prevent heat loss from exposed skin on the back. Exposure for weighing, cord care and fixing of name bands should be minimized and bathing avoided.

In the preterm infant low temperature on admission to the neonatal unit has been associated with increased mortality and morbidity. Evaporation, the major source of heat loss, can be significantly reduced using occlusive dressings.<sup>284</sup> Clean plastic bags are easier to use and

prevent hypothermia immediately after delivery.<sup>285,286</sup> The baby can be slid into the bag, up to the neck, whilst still wet. The head is covered with a hat. No blankets are used, allowing radiant heat to warm the infant through the bag. Clinical inspection and auscultation during resuscitation can be done through the bag and if vascular access is needed a small hole can be cut in the plastic over the vessel to be cannulated. The infant can be transported while still in the bag, which is only removed once the baby is in a humidified environment.

### Nursing

The healthy term newborn will maintain a normal temperature if nursed fully dressed in a cot in a warm room. Most healthy preterm babies can be managed in the same way, although comparative data between open cot and incubator care are limited.<sup>287</sup> Some very small infants may need to be nursed clothed in an incubator to provide a sufficiently warm ambient temperature.

- Over 2 kg: nurse clothed, with bedding in a cot, in a room temperature of about 24°C.
- 1.5–2 kg: nurse clothed with a hat and bedding in a cot, in a room temperature of about 26°C.
- Below 1.5 kg: nurse clothed with a hat, in an incubator temperature of 30–32°C.

### Heated cot

A water-filled mattress, heated to a set temperature between 35 and 38°C, can be used to provide conductive heat to a preterm infant nursed in a cot. This can be as effective as an incubator for keeping small babies warm, resulting in similar rates of resting metabolism and growth.<sup>288,289</sup>

It is cheap, simple and does not depend on a constant unbroken supply of electricity (because of its stored heat), so that it is particularly useful in resource limited countries. It is only of use if the infants are healthy and do not need to be nursed naked for observation and access. It has been effectively used as a method of rewarming cold preterm infants.<sup>290</sup> Gel-filled heated mattresses are also available but are more expensive.

### Incubator

The incubator provides a warm environment suitable for nursing small or sick infants, particularly if they need to be naked for observation and access. Air within the canopy is warmed by a heater and circulated by a fan. The heater output can be controlled in two ways. In air mode the incubator air temperature is set to a point between 30 and 37°C and the heater is thermostatically controlled to reach and maintain this temperature. In servo mode a thermister probe is taped to the infant's abdominal skin and the desired skin temperature is set – the heater output varies to provide an air temperature which maintains the set skin temperature. In practice, air mode control is simpler to use, safer and results in a very constant ambient air temperature regardless of the condition of the infant and the amount of care being received. Servo control results in wide fluctuations in air temperature, particularly during handling, and in the preterm baby this has been associated with an increase in apnea and possibly a poorer outcome.<sup>291,292</sup> The probe can become detached or wet, and the infant's own attempts at thermoregulation are overridden so that a fever may be disguised.

Suggested air temperature (Table 12.23)<sup>278,293</sup> and skin temperature settings (Table 12.24)<sup>294</sup> for the two modes of control are shown.

Table 12.23 Average incubator air temperatures needed to provide a suitable environment for naked, healthy infants (from Rutter<sup>294</sup>)

Birth weight (kg)	Environmental temperature					
	37°C	36°C	35°C	34°C	33°C	32°C
Less than 1.0	For 1 day	After 1 day	After 2 weeks	After 3 weeks	After 4 weeks	After 6 weeks
1.0–1.49			For 10 days	After 10 days	After 3 weeks	After 5 weeks
1.5–1.99				For 10 days	After 10 days	After 4 weeks
2.0–2.5				For 2 days	After 2 days	After 3 weeks
More than 2.5					For 2 days	After 2 days

**Table 12.24** Suggested abdominal skin temperature settings for infants nursed in servo mode incubators or under radiant warmers (from Rutter<sup>294</sup>)

Weight (kg)	Abdominal skin temperature (°C)
Less than 1.0	36.9
1.0–1.49	36.7
1.5–1.99	36.5
2.0–2.5	36.3
More than 2.5	36.0

These are a guide only and there will be variation in individual requirements. In particular, dressed babies will need lower incubator temperatures. Monitoring of body temperature is essential to allow appropriate changes in environmental settings.

The naked infant will lose heat by radiation to the cooler walls of the incubator. This can be reduced by raising the temperature of the nursery, and therefore of the incubator wall, raising the incubator air temperature, using a radiant heat shield within the incubator which warms to the air temperature and shields the infant from the canopy, or by using a double-walled incubator.

In infants below 30 weeks' gestation, especially if weighing less than 1 kg, evaporative water and heat loss is high during the first days of life and may exceed the infant's own heat production. Raising the humidity of the air around the body will reduce evaporative losses so that a normal body temperature can be achieved and fluid losses minimized. Beyond 1 week of age the immature infant's skin has matured to such an extent that evaporative water and heat losses are less important and added humidity is rarely required.<sup>295</sup> Incubators using a sealed system do not need to be run dry for part of the day and there does not appear to be any increased risk of infection when humidity is used. Evaporative heat losses can also be reduced by covering the baby with a plastic sheet. This reduces visibility and when removed to handle the baby there are high evaporative losses. The use of semipermeable non-adhesive skin dressings lowers TEWL and reduces the number of bacteria in the covered skin. Emollients have also been used to cover the skin and reduce fluid loss. They are safe and reduce excessive drying, skin cracking and fissuring. However the effect of these products wears off after about 3 h, necessitating repeated application.

There are few data available to help in deciding the optimum time to make the transition from incubator to cot.<sup>296</sup> Traditionally this is usually based on weight, with most babies able to maintain their temperature in a cot, and continue to gain weight, when they are between 1700 and 1800 g.

### Radiant warmer

The infant lies naked on a platform with a radiant heat source above. The output of the heater is controlled by a temperature sensor in contact with the infant's skin, set to the desired temperature. The sensor should be taped to the abdomen or chest rather than a limb and must be shielded from the heat source. The normal range of abdominal skin temperature under neutral thermal conditions for infants of different size is shown in [Table 12.24](#).

Heat losses by convection and radiation are high when radiant warmers are used. Evaporative water loss is also very high, a mean of about 23 ml/kg/day,<sup>297</sup> due to the low relative humidity in the surrounding air. These losses are all balanced by a large radiant heat gain from the heater. Wide fluctuations in heater output occur, producing a very uneven, asymmetrical thermal environment compared with an incubator. In the more immature infants, evaporative water loss may lead to hypernatremia and dehydration. The wide fluctuations in thermal environment and high evaporative water losses can be reduced by placing a small clear plastic canopy over the infant – radiant heat can still reach the infant but heat losses by convection, radiation and evaporation are greatly reduced.

Overheating can occur and regular measurement of the infant's body temperature by an independent method is essential. It is important to be sure that the skin temperature probe is securely attached to the baby. If the heater is switched off, moved to one side or if something

is interposed between the infant and the heat source, the infant's heat losses are very great and rapid cooling occurs. The advantage of radiant warmers is that they allow access to the infant for practical procedures whilst keeping the infant warm.

Babies nursed with similar skin temperatures have a higher basal metabolic rate when managed under radiant heaters compared with incubators. However, no study has shown any significant difference in outcome for babies nursed using either device.<sup>297</sup>

### Transport

The newborn, and in particular the preterm infant, is at high risk of cold stress during transport. High radiant heat losses, especially in cold weather, can be reduced by covering the incubator and using blankets around the baby. Evaporative heat loss can be reduced by putting the baby in a plastic bag. If ventilator gases are not heated and humidified there will be high evaporative heat losses from the respiratory tract. Heated gel mattresses that can be used during transport are available, with the baby gaining heat by conduction. All units transporting babies should collect data on temperature control during transfer and use this to audit the efficacy of the transport process.

### Surgery

There is a major risk of cold stress during surgery. The baby is starved and anesthetized, reducing the normal metabolic response to cold. The operating theater is often cool and the baby may have had to travel some distance from the nursery. Exposure of the skin and moist organs increases heat loss significantly. Heat losses can be minimized by increasing the environmental temperature to 28–30 °C, exposing only the minimum area during surgery and adding a supplementary heat source such as an electric heating pad or radiant heater.

## DISORDERS OF BODY TEMPERATURE IN THE NEWBORN

### A low body temperature (below 36 °C)

Mild hypothermia (central temperature 34–36 °C) is not uncommon. In hospital it is most often seen following resuscitation or when infants are exposed to a cool delivery room or theater. This is easily preventable by paying careful attention to keeping infants warm after delivery. Moderate (30–34 °C) or severe (below 30 °C) hypothermia due to cold exposure occurs most often when infants are born outside hospital, either unexpectedly or after a concealed delivery – if the infant is small, born into a toilet, abandoned, or inadvertently exposed to cold, severe hypothermia may result.

Accidental hypothermia also occurs later in the newborn period or early infancy because of inadvertent cold exposure due to inadequate clothing or cold thermal environments. Infants with bacterial sepsis or with respiratory syncytial virus (RSV) infection are prone to mild hypothermia – so too are infants in severe heart failure or with marked cyanosis. Malnutrition predisposes to hypothermia because of poor tissue insulation and an impaired metabolic response to cold. Hypothyroidism also results in an impaired metabolic response to cold. Drugs given to the mother which cross the placenta have a similar effect on the newborn infant, particularly the long-acting sedatives such as diazepam. Intentional hypothermia is used as an adjunct to cardiopulmonary bypass, the body temperature being lowered to about 28 °C by surface cooling with ice to reduce the metabolic demands of the brain. The infants tolerate this brief, acute severe hypothermia well. Whole body or local head cooling appears to be effective in reducing brain damage in asphyxiated animals and trials have shown potential benefit in newborn infants following birth asphyxia.<sup>298,299</sup>

Hypothermic infants develop symptoms when their deep body temperature falls below 34 °C. They become lethargic, feed poorly and have a weak cry and reduced movements. If exposure to cold has been persistent there may be peripheral edema, sclerema and marked facial erythema in the presence of a strikingly cold skin – these are the features of neonatal cold injury. In very severe hypothermia there is profound bradycardia with slow, shallow respiration and the infant may appear to be dead.

There are anecdotal reports of such infants being left for dead yet eventually making a full recovery. The diagnosis of hypothermia is made by recording a low rectal temperature – it is important that a low reading thermometer is used, not the standard clinical thermometer with a minimum reading of 35°C.

The treatment of accidental hypothermia is rewarming. If there is an underlying cause, this obviously also needs to be treated. There is limited information about the correct rate for rewarming cold infants but in cases of mild hypothermia this can take place rapidly. In moderate or severe cases there is concern that rapid rewarming of the infant's surface causes peripheral vasodilation, diversion of blood from the core and therefore hypotension. There is no evidence for the routine use of plasma expanders in these cases. Following acute accidental hypothermia it appears to be safe to restore deep body temperature to normal over a few hours. This can be achieved using a radiant warmer, an incubator or a heated cot.<sup>290</sup>

Hypoglycemia may occur during rewarming and should be anticipated and prevented with an intravenous infusion of 10% dextrose. Care should be taken in interpreting blood gas results – a metabolic acidosis at 37°C is less severe at 30°C and should not be overenthusiastically treated. Abdominal distention is common as a result of ileus and feeding should not be started until a normal body temperature is achieved. NEC and hemorrhagic pulmonary edema have been described. The reported mortality rate in severe hypothermia is 25–50% but this includes infants with overwhelming sepsis or congenital abnormalities that predisposed them to cold. Most survivors develop normally.

### A high body temperature (above 38°C)

An infant with a high body temperature may be either febrile or overheated. A febrile infant has a high set point temperature and behaves as if cold. He makes physiological and behavioral responses which reduce heat loss, increase heat production and therefore raise body temperature. Although he has a raised central temperature, his central–peripheral temperature difference will be high (above 2°C). An overheated infant makes physiological and behavioral responses in an effort to increase heat loss and therefore lower body temperature. In this case the central temperature will be high but the central–peripheral temperature gap will be small (below 1°C). Overheated infants simply need a cooler environment, not a series of painful investigations to find an infective cause for the 'fever'. In a large study of term infants with a high body temperature, 90% were found to be overheated and only 10% had infection.

The newborn infant may develop a raised body temperature in the presence of infection but this is usually not marked. It is not known why serious infection in a newborn seems to elicit such a mild febrile response when mild infection in a toddler is often associated with a very high body temperature. Infection is not the only cause of a raised set point temperature in the newborn; it is also caused by a severe cerebral abnormality, either congenital (holoprosencephaly, hydranencephaly, encephalocoele) or acquired (birth asphyxia). Such infants have hypothalamic dysfunction leading to poor temperature control.

Overheating is less common than accidental hypothermia in the newborn. Mild degrees occur when active, large infants are overwrapped and left in a warm room, or when small infants are overheated by an incubator or radiant warmer. Severe overheating occurs when there is electrical or mechanical failure of a warming device, or when an incubator is exposed to direct sunlight (this turns it into a greenhouse). It can also occur if infants are left in closed cars exposed to direct sunlight.

Mild overheating has been suggested as a predisposing factor in apnea of prematurity but otherwise seems not to be dangerous. Severe overheating leading to hyperpyrexia (rectal temperature above 41°C) has caused sudden death in the newborn without prior symptoms.

## SPECIAL CARE – ENTERAL NUTRITION

Preterm babies have very little stored energy and urgently need adequate nutrition in order to survive beyond a few days. Subsequently, good nutrition is essential to promote the rapid growth which characterizes this period of life, and is important for long term outcome.<sup>300</sup> Nutrients

can be provided parenterally or enterally but the aim in all infants is to use full enteral feeding as soon as it is safe. This section reviews the balance of benefits and risks of enteral feeding and recommends suitable intakes, aimed at promoting growth and avoiding deficiencies.

### DEVELOPMENT OF GUT FUNCTION

The motility, digestive and absorptive functions of the gut develop in utero. Gut development continues postnatally and enteral feeding influences this. An understanding of gut development is essential to the discussion of benefits and risks of enteral feeding.

Sucking, swallowing, gastric emptying and small gut peristalsis are inefficient in the preterm baby.<sup>301</sup> The fetus begins to swallow at 16 weeks but in babies born before 34 weeks' gestation feeding behavior is characterized by short bursts of sucking, a small intake of milk, uncoordinated swallowing, and nonpropagative, disorganized esophageal motor activity.<sup>302</sup> Lower esophageal sphincter pressure is low,<sup>303</sup> predisposing to gastroesophageal reflux. Gastric emptying time is prolonged to about twice that of the term infant, and is even longer in the presence of illness or when feeds are of high energy density, fat or carbohydrate content.<sup>301</sup> In the fetus small intestinal transit is seen from 30 weeks, but the normal pattern of migrating motor complexes and peristalsis is not observed until a few weeks later. The coincidence of nutritive sucking, swallowing and gut motor activity at about 34 weeks is a good example of developmental coordination.

Gastric acid production is present by 24 weeks' gestation. Pepsin production is low, but this does not appear to inhibit utilization of dietary protein and may enhance the passage of intact IgG and IgA into the small bowel. Pancreatic enzyme secretion is reduced in the term infant, and in the preterm infant levels of trypsin, lipase, amylase and bicarbonate secretion are further reduced.<sup>304</sup> In the preterm baby, studies using test meals have demonstrated inadequate intraluminal digestion of fat, protein and carbohydrate, but clinical malabsorption is rare. Fat absorption, for example, limited by low pancreatic lipase and low intraluminal bile salt concentration, may be improved by the high contribution of lingual and gastric lipase and bile salt dependent lipase in breast milk. Alpha-glucosidase (sucrase, maltase and isomaltase) activities are about 70–80% of normal at 32 weeks' gestation.<sup>305</sup> Lactase is at 25% of adult levels at 26 weeks and increases markedly towards term.<sup>306</sup>

Intestinal permeability is increased in the preterm baby and results in increased macromolecular transport across the epithelium.<sup>307</sup> This may be relevant to the development of NEC by allowing bacteria and their antigens to penetrate the gut wall.

### INTRODUCTION OF ENTERAL FEEDS

Healthy preterm babies should be fed within 1 or 2 h of birth, in order to prevent hypoglycemia and to maintain hydration. Deciding when to feed enterally in intensive care is a more contentious matter and practice varies widely.<sup>308</sup> Most would not attempt enteral feeding in ill preterm infants, unstable on intensive care. In the preterm infant who is stable on intensive care and receiving ventilatory assistance, should milk feeds be given? The main arguments for not feeding are the fear of milk aspiration, respiratory embarrassment through gastric distention, and NEC (see Complications of feeding). With a cautious approach, however, many neonatal units successfully milk feed babies on ventilators. Milk feeds should be stopped for a period following extubation, to allow recovery of laryngeal protective reflexes.

The growth-restricted infant also merits particular care. In intra-uterine growth restriction (IUGR) with abnormal fetal Doppler studies, fetal gut perfusion is reduced, predisposing the infant to NEC.<sup>309</sup> A large European study of women whose pregnancies were complicated by hypertension or IUGR showed no significant increase in NEC in infants with a history of abnormal fetal Doppler studies, however IUGR was present in less than 50% of the cases.<sup>310</sup> A meta-analysis of 14 studies

compared the incidence of NEC in infants who had exhibited absent or reversed end-diastolic flow on fetal Doppler, compared to those with normal flow. Affected babies showed a significant increase in NEC with OR 2.13 (95% CI 1.49–3.03).<sup>311</sup> In infants with IUGR, notably those with the triad of IUGR, abnormal fetal Doppler studies and fetal echogenic gut, difficulty with enteral feeds is common.<sup>312</sup> It is common practice to delay introduction of milk feeds in these infants<sup>313</sup> although there is no clear evidence that this is of benefit. Parenteral nutrition accompanied by a period of trophic feeding (see below) and a gradual increase in enteral feed volumes seems a pragmatic approach while awaiting further research evidence.

## TROPHIC FEEDING (TF)

TF is also known as minimal enteral feeding, hypocaloric feeding and gut priming. It is an important advance in the use of enteral feeding, entailing the administration of small, nutritionally inconsequential amounts of milk in order to confer the benefit of milk feeds on the infant receiving parenteral nutrition.<sup>314</sup>

### Physiology

Absence of enteral feeding is associated with reduced gastrointestinal growth and maturation. Gastric, intestinal and pancreatic weight and DNA content is reduced if milk is withheld, changes that occur in the first days of enteral starvation.<sup>315,316</sup> Bile flow is reduced and this may underlie the high incidence of conjugated hyperbilirubinemia in infants on parenteral nutrition.

The administration of TF has major advantages in inducing maturation of gastrointestinal motor function,<sup>317</sup> an effect which is not seen if water is given. This translates to more rapid whole gut transit time in infants receiving TF.<sup>318,319</sup> Milk tolerance is improved with a reduction of 4 days in time to reach full feeds.<sup>314,320</sup> Gastric emptying is not altered in infants who have received TF (Fig. 12.13).<sup>318</sup>

TF induces surges in gut hormones<sup>321</sup> including motilin and enteroglucagon which are known to be trophic and promote normal motility. In animals, enteral feeds enhance digestive capacity, with increase in gastric lipase, intestinal lactase activity, and pancreatic responsiveness to glucose. TF has also been shown to induce lactase activity measured in duodenal aspirate,<sup>322</sup> which was subsequently

Fig. 12.13 Individual whole gut transit time at 3 and 6 weeks of postnatal age. Broad horizontal bars represent median; narrow horizontal bars interquartile ranges:  $p < 0.05$  at 3 and 6 weeks.

found to relate to improved milk tolerance.<sup>323</sup> Chymotrypsin activity is not altered by TF.<sup>322</sup>

## Clinical trials

A Cochrane review of TF compared to no feeds, including 617 infants in nine trials, showed a mean reduction in days to full feeding of 2.6 days (95% CI -4.12, -0.99), and showed no difference in NEC (RR 1.16, 95% CI 0.75, 1.79).<sup>324</sup> Comparison of TF with advancing feeds in 141 infants resulted in longer time to achieve full feeds, with a mean weighted difference of 13.4 days, but a lower incidence of NEC (RR 0.14, 95% CI 0.02, 1.07). The feeding regimen used was not typical of UK practice.

TF appears to confer a reduction in time to full enteral feeds, improved milk tolerance, shorter hospital stay, more rapid full nipple feeding and accelerated growth in the first 6 weeks.<sup>314</sup> Avoidance of cholestatic jaundice has not been explored by studies with sufficient power. One trial showed a large reduction in culture positive sepsis with parallel decrease in days with elevated C-reactive protein in the infants who received TF.<sup>320</sup> An associated reduction in upper gut colonization with coagulase negative staphylococci may, in part, explain this observation.

None of the 10 randomized controlled trials examining TF has demonstrated any adverse effects.<sup>314</sup> There is no evidence to suggest an increase in respiratory problems.

## NUTRITIONAL REQUIREMENTS OF THE PRETERM INFANT

Table 12.25 compares body composition of infants of 26 weeks' gestation and term. Fetal and infant metabolic demands differ, and nutrient requirements based on prenatal growth may not be appropriate for the preterm baby. Current consensus, however, is that the fetal growth curve seems a reasonable 'gold standard', and a growth rate falling far below it should be regarded as a risk factor for poor long term outcome.<sup>325,326</sup> Composition of growth varies during late fetal life. For example, in the term infant, during the first weeks after birth over 40% of weight gain is fat and about 12% protein, whereas in late fetal life only 15–20% of the weight gain is fat, and protein accretion rates are higher. It is also extremely hard in the preterm infant to achieve fetal accretion rates of calcium (3 mmol/kg/day) and phosphate (2 mmol/kg/day).

The nutritional requirements of the preterm baby for the major nutrients, electrolytes, minerals, vitamins and trace elements remain uncertain. European consensus was reached by ESPGAN in 1987<sup>327</sup> and a trans-Atlantic agreement reached in 1993.<sup>325</sup> The latter has recently been revised and gives the most up-to-date evidence base for intake of individual nutrients as well as different fortifiers and formulae.<sup>328</sup> Aiming for a growth rate of 15–18 g/kg/day, the requirements of the preterm baby for the major nutrients (Table 12.26) and electrolytes, minerals, vitamins and trace elements (Table 12.27) are shown.

## THE CHOICE OF MILK FOR THE PRETERM INFANT

The chosen milk should meet nutritional requirements, be well tolerated, digested and absorbed and minimize risk of adverse effects.

Table 12.25 Some aspects of body size and composition at 26 weeks gestation and at term

	26 weeks	40 weeks
Weight	850 g	3500 g
Length	34 cm	51 cm
Brain weight	260 g	490 g
Body water	730 ml	2400 ml
Body sodium	70 mmol	280 mmol
Total nitrogen	10 g	60 g
Fat	6 g	540 g
Calcium	6 g	35 g
Phosphate	3 g	18 g

**Table 12.26** Requirements of the preterm baby for the major nutrients

Calories	130 kcal/kg/day
Water	150–180 ml/kg/day
Carbohydrate	16 g/kg/day
Fat	7 g/kg/day
Protein	3.5 g/kg/day

**Table 12.27** Requirements of the preterm baby for electrolytes, minerals, trace elements and major vitamins

Sodium	2.5–5 mmol/kg/day
Potassium	2.5–3.5 mmol/kg/day
Chloride	2.5–3.5 mmol/kg/day
Calcium	2–3 mmol/kg/day
Phosphate	2–3 mmol/kg/day
Magnesium	0.5 mmol/kg/day
Iron	2 mg/kg/day
Copper	120 µg/kg/day
Zinc	1000 µg/kg/day
Vitamin A	1000 IU/day
Vitamin D	400 IU/day
Vitamin C	30 mg/day
Vitamin E	8 mg/day
Vitamin B <sub>12</sub>	0.3 µg/day
Folic acid	50 µg/day

notably NEC. The choice of milk also has effects upon neurodevelopmental outcome and intelligence, with breast milk conferring significant advantage.<sup>329</sup> All mothers of preterm infants should thus be encouraged to express their milk, which is the feed of choice. As will be described below, human milk fulfills all requirements listed above, apart from meeting nutritional requirements, and for some nutrients supplements will be required.<sup>330</sup>

## Human milk

In the preterm infant human milk is better tolerated and full enteral feeding is achieved more rapidly than with formula,<sup>331</sup> gastric emptying is quicker<sup>332</sup> and stool frequency greater.

The advantages of human milk are now well established: considerable reduction in risk of NEC,<sup>333</sup> protection against gastrointestinal and respiratory tract infection in the first years of life;<sup>334</sup> reduction in atopic symptoms in infants with a family history of atopy;<sup>335</sup> and, most importantly, its association with optimal neurodevelopmental and intellectual outcome.<sup>300,329</sup> The semi-essential long chain polyunsaturated fatty acids contained in breast milk are structurally important in the central nervous system and may underlie this advantage of breast milk.<sup>336</sup> Breast milk may also protect against adult disease such as diabetes mellitus and Crohn's disease and confer protection against cardiovascular disease through nutritional programming, whereby early nutritional experience exerts a later effect upon health, independent of other influential factors during life.<sup>337–339</sup> Human milk also contains growth factors, IgA and immunoprotective factors.

There are two main problems with human milk: it is not always available, and its energy, protein, calcium, phosphate and sodium content do not meet theoretical nutrient requirements despite optimal absorption of breast milk.

Breast milk varies in composition and is particularly affected by gestation, postnatal age and method of collection. The mothers of term and preterm infants produce milk which is different in important respects during the first 2–3 weeks after birth. Preterm milk has about a three times higher concentration of sodium, protein and IgA, and a lower water content producing a general increase in the concentration of most constituents, but not calcium or phosphate. Method of collection is important, and drip milk is of lower energy content than expressed milk (Table 12.28). Banked donor milk from term mothers produces less good weight gain than either expressed preterm milk or preterm formula. Breast milk can be given in larger volumes than formula milk at around 180–200 ml/kg/day.

If donated milk is used, great care must be taken to prevent transmission of HIV<sup>340</sup> and hepatitis B and C, through screening of donors and pasteurization. Records are kept on all donors and recipients. This disincentive to the use of donor milk led to a reduction of milk banking, but several banks still exist and their role is currently being evaluated.<sup>341</sup>

## Breast milk fortification

Fortification of breast milk is now used in most neonatal units in the UK.<sup>308</sup> Breast milk fortifiers are powders added to breast milk to increase energy, protein, carbohydrate, sodium, calcium and phosphate contents of the milk (Table 12.29). Most studies have found acceptable

**Table 12.28** Composition of milks

Per 100 ml	Colostrum	Mature breast milk	Drip breast milk (foremilk)	Unmodified cows' milk	*Whey based	Casein based
Energy (kcal)	67	70	45	65	67	67
Protein (g)	2.3	1.34	1.0	3.2	1.5	1.6
Fat (g)	2.95	4.2	2.2	3.8	3.6	3.6
Carbohydrate (g)	5.7	7.1	6.5	4.7	7.2	7.0
Sodium (mg)	50	19		77	23	22
Calcium (mg)	48	27		137	66	56
Phosphorus (mg)	16	14		91	42	44
Iron (µg)	100	50		45	700	800
Vitamin A (µg)	161	60		23	60	75
Vitamin C (µg)	7.2	5.2		1.1	8.0	9.0
Vitamin D (µg)	0.04	0.1		0.02	1.0	1.1
Vitamin E (mg)	1.5	0.24		0.06	0.6	0.74
Vitamin B <sub>6</sub> (mg)	–	0.018		0.05	0.04	0.06

**Table 12.29** Nutrient change in 100 ml breast milk after fortification

Nutrient	Energy (kcal)	Protein (g)	Carbohydrate (g)	Fat (g)	Sodium (mmol)	Calcium (mmol)	Phosphorus (mmol)
Increase	10–14	0.6–1.0	2.0–2.4	Small	0.3–0.9	1.0–2.2	0.7–1.2

tolerance of feeds and gastric emptying during introduction of fortified milk feeds.<sup>342,343</sup> Two studies however have shown less good feed tolerance and one a trend towards increased risk of NEC.<sup>344</sup>

Growth and mineral accretion is improved with fortification<sup>345</sup> although the impact on long term outcome is not clear. At 18 months, infants given fortifier show no neurodevelopmental advantage over those whose milk was not fortified.<sup>344</sup> A recent trial exploring protein content of fortifier has shown improved growth and increase in head circumference with a higher protein content.<sup>346</sup>

The optimal use of breast milk fortifier and its ideal composition is not fully established. In most centers fortifier is only used after full feeding with breast milk is achieved, and either growth failure is observed, or protein indices such as blood urea/nitrogen or serum albumin levels are low. This strategy avoids fortification during the introduction of feeds when the infant's mother is producing milk with a naturally high nutrient content.

### Preterm formula milks

Preterm formulae are based upon human milk. The principal differences are: more protein (approx. 1.8–2.5 g/100 ml); more energy (approx. 75–90 kcal/100 ml); higher sodium, calcium and phosphorus content; and the addition of iron and vitamins, especially D, E and the B complex. Some lactose is replaced with glucose or its polymers, and a small proportion of fat may be given as medium chain triglyceride to improve fat absorption. The addition of long chain polyunsaturates (see above), similar to those found in breast milk, has been shown to produce more rapid maturation of the visual pathway and may confer neurodevelopmental advantage.<sup>336</sup> Purified sources of these fats are now added to formula milk. Preterm formulae work well, growth rates are good, nutritional deficiencies are rare, and medium term growth and development outcome almost matches that seen with breast milk.<sup>300</sup>

### Other milks

Term formula is not adequate for the preterm infant.<sup>347</sup> Preterm formula is given until an infant weighs 2.0–2.5 kg. Most, who are not breast-fed, then go on to a whey-dominant term formula. Many preterm infants remain underweight at term, and better weight gain may be seen after discharge home if a formula of composition between preterm and term formula is given.<sup>328,348</sup> Infants may compensate by taking a larger volume of formula, but male infants have increased linear growth and head circumference if fed a nutrient enriched formula for 6 months post term.<sup>349</sup> A number of preterm post-discharge formulae are now available. At no time during the first year of life is unprocessed cows' milk a suitable food for the preterm baby.

Special milks are occasionally required to treat cows' milk protein or lactose intolerance and inborn errors of metabolism. This should be done in collaboration with a pediatric dietitian. Soya milks are not designed to meet the needs of preterm infants, are potentially allergenic and have levels of phytoestrogens which may be harmful. They are not recommended for infants under one year (Department of Health January 2004).

## FEEDING IN PRACTICE

No-one is in a better position to make individual decisions about feeding than the experienced neonatal nurse caring for an infant. Feeding policy and each infant's nutrition should be managed jointly by nursing and medical staff, while empowering the neonatal nurse to make feeding management decisions when necessary.

Enteral feeding should be introduced gradually and increased with care. Tolerance should be assessed and, whenever possible, infants should be weighed and measured regularly. It is reasonable to begin with 0.5–1 ml/kg/h in a baby of less than 30 weeks' gestation, increasing by 0.5–1 ml/kg every 6–12 h. In more mature babies, larger starting volumes and a faster rate of progress may be indicated. In a healthy baby, enteral feeds may be given at 75 ml/kg on day 1, 90 ml/kg on day

2, 120 ml/kg on day 3, 135 ml/kg on day 4 and 150 ml/kg on day 5, with subsequent increases up to a maximum of 180 ml/kg/day according to tolerance and growth rate. Preterm formula is usually given at 160 ml/kg/day and fortified breast milk at 160–180 ml/kg/day.

Full nipple feeding from breast or bottle depends upon maturity and health. In most it is achieved at a postmenstrual age of 34–37 weeks.

### Avoidance of NEC

Trials of strategies aimed at preventing NEC are inherently difficult. The condition is unpredictable with variation in incidence that demands very large studies to obtain adequate power. There is some evidence for the following in order to avoid NEC during enteral feeding:

Use of breast milk was protective in a large multicenter trial of 926 infants randomized to donor breast milk or formula as sole diet or supplement to mother's own milk with an odds ratio of 10.6.<sup>333</sup> Avoidance of hyperosmolar feeds<sup>350</sup> and rapid, incautious increase in feed volume<sup>351</sup> has also shown some benefit. Delaying introduction of milk in infants with IUGR is common practice and is currently being evaluated in the 'ADEPT' trial, comparing introduction of a graded feeding schedule on either day 2 or day 6 after birth in IUGR infants with abnormal fetal Doppler blood flow.<sup>352</sup>

Control of infection in epidemic NEC has been evaluated in a number of trials. A systematic review in the Cochrane Library demonstrated a statistically significant reduction in NEC with use of prophylactic oral antibiotics, but also an increase in colonization with resistant bacteria and concluded there was insufficient evidence to recommend this practice.<sup>353</sup> Manipulation of enteric organisms by inclusion of either prebiotics (oligosaccharides which promote colonization with benign bifidobacteria), or probiotics (actual organisms of the genera lactobacilli and bifidobacilli) in preterm infants' diets shows some promise as a method by which healthy gut colonization may be achieved and risk of NEC may be reduced.<sup>354,355</sup> Continuous or intermittent feeds have also been considered. A systematic review included six trials and showed a trend towards improved tolerance with bolus feeds, but faster weight gain in infants under 1000 g with continuous feeds. There was no difference in NEC and insufficient evidence to make clear recommendations.<sup>356</sup>

### Feeding tube placement

Meta-analyses of trials of tube placement have shown a 15% (95% CI 5–23) increase in mortality in association with transpyloric feeding compared with gastric feeding.<sup>357</sup> Transpyloric feeding can no longer be recommended.

The choice between nasal and oral tube passage is more a matter of esthetics than of clinical importance. Nasal tubes are easier to fix but may increase resistance to air flow through the nose and increase the work of breathing. Most commonly fine bore nasogastric tubes are used.

Non-nutritive sucking (use of a dummy during gastric tube feeds) has no effect upon gastric emptying or nutrient absorption, but meta-analysis shows a mean reduction of hospital stay of 6 days (95% CI 2–10).<sup>357</sup>

Weaning from tube to breast or bottle feeds is usually a gradual process and most experienced neonatal nurses say that if rushed, it will take longer. There may be parental pressure to accomplish the task as soon as possible as the time for discharge approaches. Special soft teats are available for preterm babies and do seem to have some advantages over conventional teats.

## NUTRITIONAL SUPPLEMENTS

### Protein and energy

There is no need to routinely supplement fortified breast milk or preterm formula. Occasionally an energy supplement (glucose polymers or a mixture of glucose polymers and fat) is needed when larger feed volumes are not possible (e.g. heart failure). These supplements are usually well tolerated when added to milk at a rate up to 5 g/100 ml. Energy:protein ratio should not exceed 100 kcal/2 g of protein. Special high energy formulae are also available.

## Vitamins

Preterm infants are denied some of the placental transfer of fat soluble vitamins which occurs in the third trimester and although breast milk will provide adequate amounts of most vitamins, it contains little vitamin D or vitamin K. Infants born below 34 weeks and more mature infants with perinatal complications should have supplements for the first 1–2 years of life. Preterm formulae and breast milk fortifiers contain additional vitamins. All preterm infants should receive vitamin K (phytonadione 0.4 mg/kg) at birth for prevention of hemorrhagic disease of the newborn and in most this is given parenterally (p. 295). Extra vitamin K should be given i.m. if the preterm baby needs to undergo surgery or has clinical liver disease or severe diarrheal illness during the first 4 months of life. A daily intake of vitamin D of 400 IU (10 mcg) will prevent deficiency.

Multivitamin preparations used for breast- and term formula-fed infants usually contain vitamins A, C, and D, B<sub>1</sub>, B<sub>2</sub>, nicotinamide and pyridoxine.<sup>358</sup>

## Sodium

The preterm infant requires 2.5–5 mmol/kg/day of sodium, usually as chloride. When intake is poor, urinary excretion may well exceed intake, leading to poor growth and hyponatremia. Routine supplementation of fortified breast milk or preterm formula is not necessary. Initially after birth, preterm milk may contain 20 mmol/L of sodium but this falls over 2–3 weeks to levels seen in mature human milk, at about 7 mmol/L. This is one reason, as suggested above, to fortify breast milk only when lactation is established. If feeding with unfortified breast milk, a sodium supplement should be considered. Certainly, if a preterm baby is not growing well, it is always worth checking the serum and urinary sodium concentrations, as the response to an additional 2–4 mmol/kg/day of sodium (as chloride) can be dramatic. Serum concentrations should be monitored during therapy.

## Calcium and phosphorus

Metabolic bone disease of prematurity (previously, osteopenia of prematurity or neonatal rickets) is largely due to substrate deficiency which is the almost inevitable consequence of preterm delivery. In fetal life, active transport across the placenta during the final trimester results in fetal accretion rates which cannot be matched by enteral or parenteral supplementation after birth because when sufficient calcium and phosphate is added to feeds, precipitation of insoluble salts occurs. It is, however, known that addition of calcium and phosphate to enteral feeds will result in improved bone mineral density and lower levels of alkaline phosphatase.<sup>357,359</sup>

Addition of calcium and phosphate to preterm formulae or fortified breast milk is usually unnecessary. If unsupplemented breast milk is used, a supplement of phosphorus (as buffered sodium phosphate 1–2 mmol/kg/day) is recommended. Serum chemistry and alkaline phosphatase should be monitored. Adequate provision of substrate should prevent fractures although special care should be taken in infants exposed to systemic steroids or long term diuretics.

## Iron

Iron absorption from human milk is very efficient, but its iron content is low. The iron accretion rates of the third trimester cannot be achieved in human milk fed preterm infants. Fortification and preterm formulae provide additional iron but this may be inadequate and most preterm infants are supplemented with 2 mg/kg/day of iron from 6–8 weeks of age until about 6 months corrected age.

## COMPLICATIONS OF FEEDING

### Milk aspiration

Regurgitation of milk into the esophagus, as shown by esophageal pH monitoring, is common among preterm babies<sup>360</sup> but significant aspiration is uncommon in infants receiving milk feeds during intensive care. The extent to which milk aspiration contributes to chronic lung disease

or recurrent apneic attacks remains uncertain, but in the infant who has atypical disease with unexplained deterioration or failure to respond to standard therapy, gastroesophageal reflux and aspiration should be considered. Prone positioning, thickening agents and smaller, more frequent feeds may help. Xanthines may be withdrawn. A number of trials have investigated the role of low dose oral erythromycin as a prokinetic agent, either prophylactic or as rescue treatment. While some report success, a systematic review found too many differences in trial design to perform a meta-analysis and concluded this treatment could not yet be widely recommended.<sup>361</sup>

### Respiratory embarrassment resulting from gastric distention

When the lungs are normal, tube feeding has little or no effect on lung function, but when the lungs are abnormal a tube feed of only 5 ml of milk has been shown to produce a small reduction in arterial PO<sub>2</sub> for about 30 min. During suckling, a fall in arterial PO<sub>2</sub> and a small rise in arterial PCO<sub>2</sub> has been shown in preterm infants. It is important to be aware of this effect in babies recovering from respiratory distress syndrome (RDS) and those with bronchopulmonary dysplasia.

### Food intolerance

Intolerance of cows' milk protein seems uncommon among preterm babies, perhaps reflecting the relative unresponsiveness of their immune system. It may present as colitis with fresh bleeding per rectum. Lactose intolerance is more common, especially after NEC or gut surgery. Treatment by exclusion diet is appropriate as long as the substitute food is carefully chosen with the nutritional needs of the preterm baby in mind. The advice of the pediatric dietitian is most helpful.

## NUTRITIONAL ASSESSMENT

The final validation of any nutritional regimen is satisfactory growth and prevention of deficiency states. Careful and frequent assessments of the growth of the preterm baby should be made. Weight, length and occipitofrontal circumference are measured at least weekly and related to centile charts. In addition to the routine measurements, reference data are available for skinfold thickness, mid-upper arm circumference (MUAC) and MUAC:head circumference ratio which can be used as indicators of fat deposition and lean body mass.

Hematological and biochemical assessments should be undertaken regularly to look for signs of nutritional deficiency such as: anemia due to iron deficiency; raised alkaline phosphatase and low serum phosphate related to metabolic bone disease; hypoalbuminemia suggesting absolute or relative protein deficiency; hyponatremia; hypocalcemia; metabolic acidosis due to excessive protein intake, etc.

Finally, growth monitoring and dietary advice are an important part of follow-up for the VLBW infant after discharge, and throughout the first year.

## INTENSIVE CARE OF THE NEWBORN

### ORGANIZATION OF NEONATAL INTENSIVE CARE SERVICES

It is now accepted that 1.0–1.9 neonatal intensive care cots are required per 1000 deliveries.<sup>362</sup> Each unit providing for anything other than anticipated normal deliveries should have special care back-up facilities. Providing neonatal intensive care requires highly trained medical and nursing staff and complex equipment. Continuous back-up maintenance and service support is required. Without such expertise and support outcomes are likely to be compromised and consequently such care should only be carried out in recognized centers.<sup>362</sup> There is evidence that outcomes are improved when intensive care is centralized but this has not been observed universally.<sup>363</sup> Neonatal patient outcomes are worse when nursing care

is not delivered by specially qualified neonatal nurses<sup>364</sup> and when unit workloads are close to maximum capacity according to available nurse staffing.<sup>365</sup>

## HIERARCHY OF CARE

Every hospital concerned with the delivery of babies should *at all times* provide expertise for the resuscitation of the newborn (basic neonatal life support) – this can be by trained medical or nursing staff and it is the training of these staff that is critical rather than their job title. In addition, all district hospital maternity services should have a neonatal unit that can provide special care. This care can be given by midwives under the supervision of staff trained in neonatal care but the skill mix must be adequate. There should be staff capable of providing advanced neonatal life support and ongoing medical input on site at all times. These can be doctors or advanced neonatal nurse practitioners (ANNP).<sup>366</sup> The British Association of Perinatal Medicine has published a guidance document to assist those planning new neonatal units.<sup>367</sup>

The special care unit (level 1 care – USA) must be capable of providing safe temperature control, oxygen therapy, intravenous access and therapy, and treatment for hypoglycemia, hypocalcemia, hyperbilirubinemia and infection. Though not intended to carry out ongoing intensive care, the special care unit must still provide expertise for the safe resuscitation and stabilization of the unexpected critically ill child prior to transport.

The subregional center (level 2 – USA) will usually be sited in a larger hospital and will be able to offer short term neonatal intensive care to its own deliveries. Infants likely to require long periods of intensive care (e.g. the ELBW infant or infant requiring surgical treatment) would reasonably be diverted to the perinatal intensive care unit (ICU) which when busy could itself refer back shorter term problems and high dependency cases.

Each region should have one or more perinatal ICUs (level 3 – USA) (Table 12.30) dealing with the very high risk mother and infant. These centers provide care for all the most difficult medical problems of the region but also are intimately concerned with the improvement of standards in the region by specialist education and research. Some of these centers will also provide neonatal surgical care. In the UK, extracorporeal membrane oxygenation (ECMO) is provided supraregionally at four centers (level 4).

## CATEGORIES OF NEONATAL CARE

The British Association of Perinatal Medicine revised the definitions of categories of care for babies in 2001<sup>362</sup> and recommended that babies categorized as intensive care should receive 1:1 care from a qualified neonatal nurse. High dependency care babies should have at least one nurse for every two babies, and special care babies at least one nurse for every four babies. The most dependent intensive care babies will require more than one nurse.

## TRANSPORT OF SICK OR HIGH RISK NEONATES

### Introduction

With different hospitals capable of providing different levels of care and the evolution of networks it is inevitable that a significant number of infants will require transfer to another center for care that is not available where the infant was originally destined to deliver. If the issue can be anticipated before delivery, e.g. in the case of antenatally diagnosed problems or planned surgical deliveries of pregnancies with complications arising before term, then transfer of the mother with the infant in utero is generally the preferred option. Even if this is optimized, a large number of postnatal transports will be required for acute care and to return convalescing infants to their referring unit. In Scotland there are around 50 000 total births per annum and this gives rise to approximately 1300 neonatal transfers per year, of which around 30% are emergencies.

**Table 12.30** The perinatal intensive care unit (ICU) (at least one in every health region)

Facilities
1. Obstetric ICU facilities/fetal medicine service
2. Neonatal ICU facilities
a. Minimum medical provision
Resident junior doctor or ANNP always on duty
Resident Specialist Registrar or highly experienced ANNP always on duty
Consultant Neonatologist always on call
b. Nursing provision
One qualified neonatal nurse per intensive care baby per shift*
c. 24 h back-up provisions
Radiology service to the unit
Biochemistry with blood gases and electrolytes
Hematology service for diagnosis and transfusion
Microbiological service
Medical physics and electronics
d. Specialist facilities: surgery, cardiology, audiology, ophthalmology, pharmacy and physiotherapy
Responsibilities
1. Provision of medical neonatal intensive care
2. Provision of surgical neonatal intensive care
3. Administrative liaison within the region
4. Neonatal education for the region
a. Ward rounds and seminars for nursing and medical visitors to the ICU
b. Medical and nursing outreach by staff to the district and subregional centers
5. Regional audit
6. Training base for medical and neonatal nursing staff
7. Research
Epidemiological, applied, basic

\* Although recommended and ideal, the provision of one neonatal intensive care trained nurse per intensive care baby per shift is not available anywhere in the UK at this stage. One is forced back to stipulating that there be adequate overall numbers of trained nurses and a reasonable skill mix of trainers to trainees. This in fact means that most units are unable to take all the sick infants that they are asked to because of insufficient nursing staff.

Neonatal transport is best delivered by a dedicated transport service and this is now generally organized on a regional or network basis. This enables the provision of trained staff with appropriate equipment whenever needed, without compromising the core staffing of any individual unit. Despatching a transport team and traveling to the referring unit takes time and this means that support cannot be immediate; referring units must be capable of providing whatever initial resuscitation and stabilization is required. Training in these matters may be required as part of the overall risk management of a network and transport service. Individual units need an agreed policy on which categories of infants should be transferred and to which units the babies would usually travel. It should be clearly defined who is responsible for identifying an appropriate cot and who is the senior clinician responsible for the infant before, during and after the transfer. Good communication between senior clinicians is essential. Transport may be by road, helicopter, fixed wing aircraft or a combination of these.

### Equipment

Transport equipment should enable the provision of full neonatal intensive care during the journey. Regulations cover the specification of the equipment to ensure that it is fit for purpose and is light enough to be moved by transport staff without compromising health and safety. A transport trolley incorporating portable incubator, ventilator, gas supply, monitor, infusion pumps and battery power is usually used. Systems have been designed to enable this to be fixed securely in the ambulance

Table 12.31 Indicators for antenatal (in utero) transfer

1. Obstetric assessment of the high risk fetus where urgent delivery is likely (e.g. IUGR, fetal cardiac rhythm disorder)
2. The severely ill mother (e.g. with pregnancy-associated hypertension) at an early stage of pregnancy with a potentially viable fetus
3. Early preterm labor where the referring hospital has inadequate facilities
4. Hemolytic disease with a severely affected fetus
5. Fetal malformation needing postnatal surgery
6. Prolonged and preterm rupture of the fetal membranes with resulting oligohydramnios
7. Any other situation where advanced neonatal resuscitation is anticipated

and inside dedicated transport aircraft. There is no longer a justification for attempting transport on an ad hoc basis without such equipment. The transport staff will also carry equipment bags with a full range of resuscitation and stabilization equipment, as well as any drugs that might be required. Presently available transport systems do not enable the provision of high frequency oscillatory ventilation and infants on this treatment need to be stabilized on conventional ventilation before transfer. The provision of a fully equipped and trained service means that the transport team can spend whatever time is necessary in the referring unit to secure the stability of the patient before transport so that the actual transport of the baby can be as unhurried as possible. This minimizes the need for the use of blue lights and hazardous driving.

### Antenatal (in utero) transfer (Table 12.31)

With few exceptions the best portable incubator for the high risk problem is the uterus, with delivery of the infant where support and expertise are readily available. Such transfers should be with agreement between district and central obstetric consultants and should also involve the neonatal staff of the ICU. Mothers in advanced stages of preterm labor may need delivery peripherally to avoid the danger of a delivery in the ambulance. The mother with severe pregnancy-associated hypertension or antepartum hemorrhage should be stable before transfer and an obstetric doctor should accompany her. Systems for transferring mothers are not yet as well developed as those for transporting infants.

## PRACTICAL PARENTERAL NUTRITION

All units providing neonatal intensive and high dependency care must be able to provide optimal parenteral nutrition for sick, full-term and preterm infants. All regimens should provide complete nutrition in terms of macronutrients (protein, carbohydrate and fat) and micronutrients, with minimal adverse nutritional or other consequences. Energy and nutrient stores are mainly laid down in the third trimester of pregnancy, so parenteral nutrition of the preterm infant must supply energy and nutrients not only to meet basic needs, but also to promote growth, which occurs at a rate of 15 g/kg/d or 1.5% of body weight at this stage.<sup>368</sup> About 15 years ago, it was stated that there was a dearth of well-designed studies of parenteral nutrition use in the newborn,<sup>369</sup> and despite the advent of evidence-based medicine and the Cochrane Collaboration, there remain few high quality systematic reviews with homogeneous studies, and low numbers of randomized controlled trials of parenteral nutrition of the newborn without major methodological flaws. This is exemplified by the joint ESPGHAN/ESPEN guidelines on pediatric parenteral nutrition,<sup>370</sup> which by necessity are based mainly on adult data and expert opinion due to the scarcity of good pediatric trials.

## INDICATIONS IN THE NEONATAL UNIT

Parenteral nutrition may provide all the nutritional requirements of the infant (total parenteral nutrition, TPN) or may more usually be

supplemented by some enteral nutrition (partial parenteral nutrition, PPN). Low volume or 'minimal' enteral feeding should be started in all sick newborn infants.<sup>371</sup>

There are three major indications for parenteral nutrition in the neonatal unit:

1. surgical lesions such as omphalocele or gastroschisis, or following extensive bowel resection (PPN if possible, or TPN);
2. the medical (and surgical) treatment of necrotizing enterocolitis (NEC) (usually TPN);
3. in immature and usually very premature infants where enteral feeds cannot be fully established, due to gastrointestinal immaturity (PPN).

## NUTRITIONAL REQUIREMENTS DURING PARENTERAL NUTRITION

### Fluid and sodium

After birth, loss of interstitial fluid causes contraction of the extracellular compartment, and the resulting loss of sodium and water accounts in part for the early postnatal weight loss seen in all babies.<sup>368</sup> After this, growth can only be supported by a positive sodium balance. Some preterm babies have renal salt wasting, and thus very high sodium needs. Fluid needs vary depending upon maturity, postnatal age and environment, and may be huge in very immature infants; cohort and case control studies have suggested that excessive fluid intake in early life is associated with worse outcome in preterm infants in terms of chronic lung disease and NEC.

### Energy

It has been suggested that a parenteral energy intake of 90 kcal/kg/d with adequate nitrogen intake will support weight gain in preterm infants equivalent to the intrauterine rate.<sup>369</sup> The energy needs of the very preterm or ventilator dependent baby are likely to be higher.<sup>372</sup> Chronic energy imbalance is common in very preterm babies, particularly those with chronic lung disease, and there is often a major problem in the shortfall between prescribed and actual energy intakes.<sup>373</sup> Multiple reasons contribute to this shortfall, such as the need for fluid restriction, intolerance of standard dextrose infusions, withholding parenteral lipid due to concerns about clinical status, delay in commencing and advancing enteral feeds, and technical problems such as delay in re-establishing venous access. Only determined efforts to monitor and negate this shortfall in energy intake will help prevent the growth problems that are very common at hospital discharge of very preterm infants.<sup>374</sup>

### Protein

Although milks provide between 2 and 4 g/kg/d of protein, most preterm infants receive only 2.5 g/kg/day of parenteral amino acids, and few randomized controlled studies have assessed higher intakes.<sup>374</sup> During evolution, the animal kingdom lost the enzyme capacity to synthesize nine amino acids and therefore were dependent upon supply from exogenous sources for these *essential* amino acids; the remainder were termed *non-essential*. A more accurate terminology has been created,<sup>375</sup> which now divides amino acids into *indispensable* (equivalent to essential), *conditionally indispensable* (whose rates of biosynthesis may be inadequate, particularly during certain pathophysiological or metabolic states), and *dispensable* (no dietary need for preformed amino acids, but do contribute to nonspecific nitrogen pool). The original parenteral amino acid solutions were protein hydrolysates, and were replaced by crystalline amino acid solutions, which were then specifically refined for use in children; problems such as hyperammonemia, metabolic acidosis and hyperphenylalaninemia were associated with the use of these in newborn infants. The latest amino acid preparations for neonatal TPN contain amino acids felt to be conditionally indispensable for the newborn. They have low phenylalanine contents, are carbohydrate and electrolyte free and are based upon the amino acid profile of either human breast milk or cord blood.<sup>376</sup>

## Fat

The absence of an intravenous lipid emulsion in early parenteral nutrition regimens led to a syndrome of essential fatty acid deficiency with inadequate growth and a scaly dermatitis. In the UK and Europe lipid solutions can be obtained as 10% or 20% concentrations; randomized controlled trials have demonstrated the superiority of use of 20% emulsions.<sup>377</sup> These solutions are usually based on soya oil, although olive oil based solutions and solutions containing medium chain triglycerides are available; few studies have compared different types of solutions. Preterm infants can tolerate incremental increases up to 3.5–4.0 g/kg/day of parenteral lipid without side-effects.<sup>374</sup> Concerns about under-nutrition in the sick preterm infant have led to the use of parenteral lipid solutions soon after the commencement of parenteral nutrition. A Cochrane review<sup>378</sup> of five RCTs containing 397 preterm infants found no statistically significant effects on either benefits or adverse outcomes of early introduction of lipids, defined as before day 6 of life.

## Carbohydrate

Term newborns have a significantly higher glucose requirement than older children, and preterm infants have the highest needs of all. It is

usual to start with a 10% dextrose solution at approximately 6 g/kg/d (4 mg/kg/min), and to increase this incrementally if there is no hyperglycemia. Continuous insulin infusions have been used as an effective treatment of hyperglycemia in preterm infants.<sup>374</sup>

## Vitamins and minerals

In the past the vitamin and mineral requirements of preterm infants have often been poorly met with parenteral feeding; a typical parenteral prescription that meets these needs is shown in Table 12.32 using the Scottish standard neonatal bag.

## Other additives

Heparin increases the clearance of lipid from the circulation; there is a belief, not backed up by any evidence, that addition of 1 IU/ml to parenteral nutrition solutions preserves i.v. line patency and promotes lipolysis. Preterm infants have low concentrations of carnitine, required for oxidation of long chain fatty acids; a Cochrane review evaluated the many studies of supplemental carnitine in parenterally fed newborns, and concluded that there was no evidence to support its use.<sup>379</sup>

**Table 12.32** A typical parenteral nutrition prescription using the standard Scottish neonatal bag for a 20-day-old infant of 1500g with necrotizing enterocolitis (150 ml/kg/d). Note further additions of electrolytes may be added to the bag. (Courtesy of David Hoole, Senior Pharmacist, Royal Hospital for Sick Children, Edinburgh.)

Aqueous bag		Lipid bag	
Vaminolact*	68 ml	Intralipid 20%*	26 ml (3.5 g/kg/d)
Glucose 20% w/v	96 ml	Vitlipid Infant*	6 ml (4 ml/kg/d)
Solvito*	1.5 ml (1 ml/kg/d)		
Potassium chloride 15%	0.95 ml		
Sodium glycerophosphate 21.6%	1.9 ml		
Magnesium sulfate 2 mmol/ml	0.13 ml		
Peditrace*	1.5 ml (1 ml/kg/d)		
Calcium gluconate 10% w/v	8.5 ml		
Water for injections	15 ml		
	<b>Total</b>		<b>32 ml</b>
The final solution has the following composition:			
Amino acids	4.8 g (3.2 g/kg/d)		
Retinol	414 µg (276 µg/kg/d)		
Nitrogen	0.64 g (0.43 g/kg/d)		
Ergocalciferol	6 µg (4 µg/kg/d)		
Carbohydrate	19.1 g (12.7 g/kg/d)		
Tocopherol	3.84 mg (2.56 mg/kg/d)		
Sodium	3.8 mmol (2.5 mmol/kg/d)		
Phytomenadione	120 µg (80 µg/kg/d)		
Potassium	1.9 mmol (1.3 mmol/kg/d)		
Lipid	5.2 g (3.5 g/kg/d)		
Calcium	1.9 mmol (1.3 mmol/kg/d)		
Phosphate	1.9 mmol (1.3 mmol/kg/d)		
Magnesium	0.26 mmol (0.17 mmol/kg/d)		
Vitamin B <sub>1</sub>	0.38 mg (0.25 mg/kg/d)		
Vitamin B <sub>2</sub>	0.54 mg (0.36 mg/kg/d)		
Nicotinamide	6.0 mg (4.0 mg/kg/d)		
Pantothenic acid	2.25 mg (1.5 mg/kg/d)		
Biotin	9.0 µg (6.0 µg/kg/d)		
Folic acid	60 µg (40 µg/kg/d)

Vitamin C	15 mg (10 mg/kg/d)		
Copper	0.47 µmol (0.31 µmol/kg/d)		
Zinc	5.7 µmol (3.8 µmol/kg/d)		
Manganese	0.027 µmol (0.018 µmol/kg/d)		
Selenium	0.038 µmol (0.025 µmol/kg/d)		
Fluoride	4.5 µmol (3.0 µmol/kg/d)		
Iodide	0.012 µmol (0.008 µmol/kg/d)		

\* Fresenius Kabi, UK.

Other additives have been given to parenteral nutrition in the newborn to try to either improve clinical outcome or prevent adverse outcomes. Cysteine, cystine or *N*-acetyl cysteine supplementation has been parenterally fed to neonates. L-cysteine is a conditionally indispensable amino acid for neonates, and is a precursor of the antioxidant glutathione. A Cochrane review of six RCTs of mainly preterm infants, of which five were short term studies, concluded that the available evidence does not support the routine use of these substances.<sup>380</sup> There has long been an interest in glutamine supplementation to prevent morbidity and mortality in preterm infants. In a Cochrane review<sup>381</sup> of glutamine supplementation in preterm infants, six RCTs were identified, of which two (involving 1468 infants) were of parenteral glutamine administration. There was no evidence that the routine use of glutamine supplementation altered mortality or other important clinical outcomes for very low birth weight infants. Arginine can act as a substrate for the production of nitric oxide in the tissues and arginine supplementation may help in preventing NEC – decreased concentration of nitric oxide is proposed as one of the possible cellular mechanisms for NEC. A Cochrane review<sup>382</sup> of arginine supplementation to parenteral nutrition to prevent NEC in preterm infants identified only one RCT, involving 152 infants, and concluded that this was insufficient evidence and that a large multicenter RCT was required.

## TECHNIQUE OF PREPARATION, ADMINISTRATION AND MONITORING

As for all nutritional support, involvement of a multidisciplinary nutrition support team (NST) will optimize parenteral feeding and reduce complications (Table 12.33).<sup>383</sup> Nutrition support teams have long been used in pediatric hospitals on the basis that they improve nutritional management of sick children. This includes screening for nutritional risk, identification of patients requiring nutritional support, and the provision of adequate nutritional management, education and training of hospital staff. This is provided by a multidisciplinary team with expertise in all aspects of clinical nutrition care.<sup>383</sup> The use of neonatal NSTs has been slow to develop, with many major neonatal units still not having a specialist dietitian with a neonatal interest, let alone a nutrition support nurse. A common practice in the United Kingdom is that parenteral nutrition is provided using a standard neonatal infusion bag (see Table 12.32). There are concerns that this does not meet the currently recommended nutrient guidelines,<sup>370</sup> so increasing risk of undernutrition with prolonged use.

Once it appears that an infant will require prolonged parenteral nutrition (beyond the corrected age of term), is having complications related to parenteral nutrition, or seems to have irreversible intestinal failure, it is transferred to a pediatric teaching hospital with a pediatric nutrition support team, a pediatric gastroenterology and nutrition department, a pediatric surgical department, and a defined pediatric pharmacy, all with appropriate expertise. In Table 12.34, a typical parenteral prescription that meets the currently recommended nutrient guidelines<sup>370</sup> is shown for the same infant as Table 12.32, in this case using the Royal Hospital for Sick Children, Edinburgh, standard

0–2-year-old infant infusion bag. This standard bag has met the needs of more than 95% of all 0–2-year-olds, including neonates with prolonged intestinal failure, in the last 2 years. The exceptions have been severely ill infants in intensive care with major fluid restriction and multiple infusions of medications.

Prescription of TPN is often aided by the use of computer programs, although nutritional regimens may be individualized depending on the degree of prematurity, postnatal age, concurrent illness, enteral feed tolerance, and presence of undernutrition requiring catch-up growth.<sup>368</sup> Whether the final solution is infused by central or by peripheral vein, it should be made up by pharmacy under laminar flow conditions to prevent contamination. It should be run through from the bag to the giving set delivery point so that all that is required on the neonatal unit is the linking of the sterile connection of the set to the intravenous line on the baby. The lipid should join the main set by a Y-connector just prior to this connection. Covering the bags with colored polyethylene will reduce the photodegradation of vitamins. In many units, it is practice to use in-line filters for intravenous solutions. A Cochrane review of three randomized controlled trials of 262 infants found insufficient data to determine any benefit to their use.<sup>384</sup>

Since Wilmore & Dudrick's original description in 1968,<sup>385</sup> central lines have frequently been used to give parenteral nutrition. This is because access to the circulation can be very difficult in infants, particularly if prolonged parenteral nutrition is required. Peripheral venous cannulae have a limited life span and are associated with infiltration of the infusate and skin sloughs.<sup>369</sup> Frequent occlusion will result in increased handling of the baby and interruption of nutrient supply. Central access is usually provided by noncuffed silicone catheters that are inserted percutaneously and threaded to a central position. Due to concerns about pericardial effusions, these are usually placed close to, but not in, the right atrium. In most units, parenteral nutrition is given initially by peripheral cannulas, with a change to percutaneous central venous catheters if it appears that the child will need more than a few days of nutrition. In a Cochrane review of three randomized controlled trials of 262 infants, there was a suggestion that use of percutaneously replaced central venous catheters improved nutrient intake, with no evidence of increased adverse events.<sup>386</sup> If longer term parenteral nutrition is required, at some stage a surgically placed central venous catheter with a tunneled subcutaneous portion (such as a Hickman catheter) will be needed. It is important to liaise with both a pediatric surgeon interested and experienced in vascular access and a pediatric gastroenterology and nutrition team if a preterm infant is thought to require prolonged parenteral nutrition but is not yet well enough to be transferred to a pediatric unit. Many infants run into problems out of hours with vascular access, and end up having lines placed in external jugular veins or femoral veins. For children with prolonged intestinal failure, emergency line placement in these sites may be associated with thrombosis and loss of central venous access, potentially in all four major central venous quadrants (upper right, upper left, lower right and lower left), a situation which either requires novel methods of vascular access or will push a child towards an assessment for small intestinal transplantation.

Monitoring of growth and biochemical and metabolic tolerance of parenteral nutrition is mandatory. A few infants, for example those with intestinal failure due to short gut syndrome (see later), will require prolonged parenteral feeding in hospital or at home, and early liaison with pediatric gastroenterologists is advised.

## BLOOD GASES AND RESPIRATORY SUPPORT

Optimal respiratory support requires meticulous attention to blood gases, equipment settings, blood pressure and infant behavior. Maintenance of appropriate gas exchange with minimal complications requires knowledge of:

1. lung mechanics;
2. mechanisms of lung injury;
3. the principles of gas exchange;
4. appropriate blood gas values;
5. measurement of blood gases.

**Table 12.33** Complications of parenteral nutrition

1. Catheter related
  - a. Sepsis – bacterial or fungal
  - b. Thrombosis/obstruction
  - c. Hemorrhage
  - d. Extravasation of fluid from peripheral lines
  - e. Catheter displacement, breakage or removal
2. Metabolic related
  - a. Cholestasis – often reversible, and reduced by minimal enteral feeding
  - b. Fat embolism, lipid overload – rare
  - c. Hyperglycemia and glycosuria
  - d. Hyperammonemia and acidosis – rare

**Table 12.34** A typical parenteral nutrition prescription using the standard RHSC Edinburgh (0–2 years) TPN bag for a 20-day-old infant of 1500 g with necrotizing enterocolitis (max nutrition supplied on 135 ml/kg/d). Note further additions of electrolytes may be added to the bag. (Courtesy of David Hoole, Senior Pharmacist, Royal Hospital for Sick Children, Edinburgh.)

Aqueous bag		Lipid bag	
Vaminolact*	90 ml	Intralipid 20%*	26 ml (3.5 g/kg/d)

## LUNG MECHANICS

To inflate the lungs, work must be done against their elastic recoil and resistance. Even with adequate surfactant most of this recoil is attributable to surface tension. Lung compliance is the change in lung volume per unit change in pressure. This is proportional to the number of recruited alveoli and is therefore determined by the size of the lungs but is reduced by atelectasis or consolidation and improves as these improve. Resistance reflects airway caliber and increases with airway narrowing.

### The pressure–volume curve of the lungs

When lungs are inflated from complete atelectasis, large pressure changes are required to begin opening the alveoli. Once opened, they inflate easily and smaller changes in pressure achieve large changes in volume. As the alveoli become overdistended, further pressure changes add little volume. During deflation the alveoli do not collapse completely. Surfactant enables lung volume to remain higher per unit pressure than during inflation. Around 30 ml/kg body weight of gas remains in the lungs at end-expiration. This functional residual capacity (FRC)

enables gas exchange to continue during expiration. Surfactant deficiency impairs deflation stability causing alveolar collapse, reduced FRC and impaired gas exchange. Once the alveoli collapse, high pressures are required to re-recruit them.

The time required to inflate or deflate the lungs depends on the tidal volume, the pressure applied and the resistance to flow. If resistance is high, as in chronic lung disease or endotracheal tube obstruction, the same volume takes longer to exchange. Where compliance is low, as in RDS, the recoil pressure is high and the lungs empty rapidly.

## MECHANISMS OF LUNG INJURY

The same mechanisms of lung injury operate in all age groups.<sup>387,388</sup> High volume injury (volutrauma) occurs when the airspaces are inflated to excess end-inspiratory volume. Low volume injury (atelectrauma) occurs when the lungs are allowed recurrently to collapse at end-expiration and are re-inflated with each breath. Both mechanisms cause epithelial disruption and alveolar capillary leak. This causes accumulation

within the airspaces of proteinaceous material which inhibits surfactant function and adds further to the cycle. Injury may begin within minutes and is accompanied by inflammation, the persistence of which has been implicated in the pathogenesis of chronic lung disease.<sup>389</sup>

Respiratory support techniques should aim to maintain optimal alveolar recruitment and limit excess tidal volume. This is associated with lower mortality and more rapid resolution of pulmonary inflammation in adults.<sup>390,391</sup> There are no published trials examining this approach in neonates. A healthy, term infant breathes with a tidal volume of around 7–9 ml/kg.<sup>392</sup> In the presence of lung disease there may be less fully functional alveoli than normal. Ventilator tidal volumes of around 4–7 ml/kg may be more appropriate if focal overinflation is to be minimized.

Oxygen in high concentration generates free radicals. The pre-term infant has poorly developed antioxidant lung defenses and may be at greater risk of oxygen toxicity. Failure to maintain adequate end-expiratory lung volume causes hypoxia and results in greater exposure to supplemental oxygen.

## PRINCIPLES OF GAS EXCHANGE

If ventilation and perfusion are well matched, gas tensions in the blood equilibrate with those in the airspaces. Mechanisms of ventilation/perfusion mismatching and impaired gas exchange are illustrated in Figure 12.14.

### Oxygenation

When alveoli collapse or are filled with blood, edema or exudate, blood perfusing them traverses the lungs without exchanging gas (right to left shunt). If the pulmonary vascular resistance is elevated, extrapulmonary right to left shunt can take place through the foramen ovale and ductus arteriosus. This occurs in association with acidosis, hypoxia, hypercarbia, lung disease or persistent pulmonary hypertension of the newborn and is worsened by low systemic blood pressure. High ventilator pressures may also compromise pulmonary blood flow. If cardiac output is low, the blood perfusing the alveoli has lower oxygen tension and higher carbon dioxide tension than normal and equilibration with alveolar gas may be incomplete. If blood volume is low the increased rate of recirculation may reduce the time available for equilibration. Inadequate alveolar ventilation results in lower alveolar oxygen tension and hypoxia.

Mild degrees of shunt can be compensated for by increasing the inspired oxygen concentration. If the shunt is more substantial, increased inspired oxygen is ineffective. The vast majority of the oxygen carried in blood is bound to hemoglobin. Relatively little can dissolve in the plasma. Once hemoglobin is fully saturated, further large increases in oxygen tension ( $PO_2$ ) generate small increases in total blood oxygen content as they only reflect increased dissolved oxygen in plasma. When fully saturated blood from alveoli with good ventilation/perfusion matching is mixed with large amounts of desaturated shunt blood, the mixture cannot be fully saturated. Severely compromised oxygenation can only be improved by decreasing the degree of shunt. This requires recruitment of unventilated alveoli or improvement of pulmonary perfusion. By improving pulmonary perfusion, correction of hypotension may improve gas exchange without alteration of the ventilator settings.

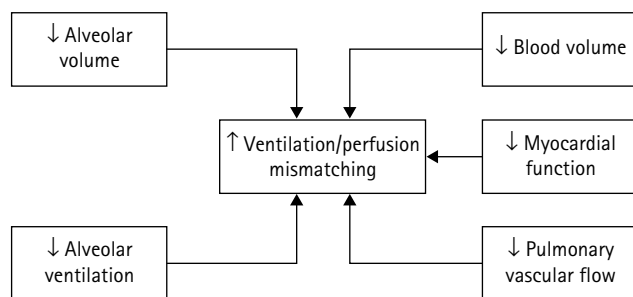

Fig. 12.14 Mechanisms leading to ventilation/perfusion mismatching.

## Carbon dioxide elimination

Carbon dioxide is more soluble in plasma than oxygen and its pulmonary diffusion capacity is greater. The relationship between blood carbon dioxide content and arterial carbon dioxide tension ( $PaCO_2$ ) is linear. Carbon dioxide elimination is proportional to total alveolar ventilation. This can be expressed as minute ventilation (tidal volume times respiratory rate). In respiratory failure or where there is right to left shunting, the carbon dioxide tension of blood returning from alveoli with good ventilation/perfusion matching can be lowered by increased alveolar ventilation. This can compensate for the elevated carbon dioxide of shunt blood and normalize  $PaCO_2$ . Minute ventilation may be inadequate with poor respiratory drive, airway obstruction, widespread atelectasis or increased respiratory dead space.

## MEASUREMENT OF BLOOD GASES

All neonatal units should have immediate 24h access to a blood gas analyzer. Blood samples are usually obtained from an umbilical arterial catheter, or by indwelling catheter or needle puncture from the radial or posterior tibial arteries after assessing the collateral circulation. Use of end arteries (temporal, brachial or femoral) is less desirable because of the risk of irreversible ischemia.

Measurements of  $PO_2$  in capillary or venous blood underestimate arterial oxygen tension ( $PaO_2$ ) and cannot be relied on. Capillary blood obtained by heel prick provides an acceptable estimate of arterial  $PCO_2$ , pH and base excess, but warming the heel to 40 °C does not significantly improve accuracy of  $PO_2$ .<sup>393</sup>

Continuous monitoring of blood gas tensions or oxygen saturation is an important supplement to, but not a substitute for, intermittent sampling. Continuous measurements can be made by an indwelling device in the umbilical artery.<sup>394</sup> Transcutaneous monitors generate local hyperemia by gently heating the skin. Diffusion of gases through the skin then permits measurement of gas tensions and both  $PO_2$  and  $PCO_2$  can be measured. This technique is unreliable when the skin is poorly perfused or compressed and becomes less reliable as the skin thickens with age. In very immature infants, repeated reattachment of the electrode can damage the skin. Pulse oximetry is easier and less invasive but gives less information. A probe transilluminates a body part and measures the light absorption characteristics of oxygenated hemoglobin. Pulse oximeters can be used at all gestations, require no calibration and are not affected by changes in skin thickness or perfusion. The technique is very prone to movement artefact, although new signal processing techniques can reduce this problem.<sup>395</sup> In the steep portion of the oxygen–hemoglobin dissociation curve, small changes in  $PO_2$  cause large changes in  $O_2$  saturation, so in this range the pulse oximeter reflects hypoxia and oxygen availability to tissues better than  $tPCO_2$  measurements. In the flat portion of the oxygen–hemoglobin dissociation curve large changes in  $PO_2$  cause small changes in  $O_2$  saturation, so hyperoxia cannot safely be excluded when  $tSaO_2$  is 95–100% and  $tPCO_2$  monitoring is more reliable.

## RECOMMENDED BLOOD GAS VALUES

Present recommendations are based on physiological reasoning and clinical observations. There is a need for prospective trials which compare the outcomes of infants with different target blood gas values as the interventions introduced to normalize blood gases may be harmful.

### Oxygenation ( $PaO_2$ , $tPCO_2$ and $tSaO_2$ )

Values for  $tPCO_2$  and  $tSaO_2$  in the first weeks of life from healthy term and preterm infants<sup>396,397</sup> are shown in Table 12.35. In preterm infants hyperoxia is associated with increased risk of chronic lung disease, retinopathy of prematurity<sup>398</sup> and periventricular leukomalacia.<sup>399</sup> Even modest variations in oxygen administration policy may be associated with significant changes in risk of adverse outcome.<sup>400</sup> There is considerable variation in policy between units.<sup>401</sup> Randomized controlled trials are under way in the USA, Australia and New Zealand and the United Kingdom comparing different target ranges for oxygen saturation. At all

**Table 12.35** Normal range of tcPO<sub>2</sub> and tcSaO<sub>2</sub> in healthy infants in air\* (adapted from Mok et al 1986,<sup>396</sup> 1988<sup>397</sup>)

	Awake	Quiet sleep	Active sleep
Term infants (n = 55)			
tcPO <sub>2</sub> (kPa <sup>†</sup> )			
Postnatal age			
< 1 week	8.5–13.0	7.8–12.1	6.7–12.8
6 weeks	9.1–12.2	7.1–12.3	7.1–12.4
tcSaO <sub>2</sub> (%)			
Postnatal age			
< 1 week	91.8–100	87.4–98.3	86.1–98.4
6 weeks	95.0–99.0	89.4–98.1	87.5–98.5
Preterm infants (n = 28)

tcSaO <sub>2</sub> (%)			
Postconceptional age			
29–34 weeks	86.6–96.3	86.0–96.1	86.6–96.5
35–38 weeks	86.8–96.8	87.6–97.9	88.6–96.8

\* No infant appeared cyanosed or had signs of respiratory distress during any of the studies.

<sup>†</sup>To convert oxygen tension in kPa to mmHg, multiply by 7.5.

gestations prolonged severe hypoxia causes organ damage. Until new data become available, a reasonable policy for preterm infants receiving respiratory support is to aim for PaO<sub>2</sub> or tcPO<sub>2</sub> between 6.7 and 10.7 kPa (50–80 mmHg) or tcSaO<sub>2</sub> between 86 and 94%.

### Carbon dioxide tension

Hypercapnia produces pulmonary vasoconstriction, but cerebral vasodilatation. In a prospective study of 200 very low birth weight infants, PaCO<sub>2</sub> > 7 kPa (52.5 mmHg) was associated with both periventricular hemorrhage and periventricular leukomalacia.<sup>402</sup> Severe hypocapnia causes a profound reduction in cerebral blood flow, and has been associated with periventricular leukomalacia, intracerebral hemorrhage and cerebral palsy.<sup>399,403–405</sup>

Broad consensus in current practice is to keep PaCO<sub>2</sub> between 4.7 and 8 kPa (35–60 mmHg).<sup>406</sup> However in severe respiratory failure some authors routinely keep PaCO<sub>2</sub> between 6.7 and 8 kPa (50–60 mmHg) or higher, provided arterial pH remains above 7.25. By allowing lower ventilator pressures to be used this, it is suggested, may increase the number of infants surviving without chronic lung disease.<sup>407–410</sup> Whether allowing higher values of PaCO<sub>2</sub> may also increase the risk of cerebral insult and handicap in preterm infants is uncertain. Data from prospective trials in newborn infants are limited and inconclusive at present.<sup>411</sup> In the meantime a reasonable compromise is to aim for PaCO<sub>2</sub> between 5.3 and 7.0 kPa (40–52.5 mmHg) in preterm infants below 33 weeks' gestation during the first 3 days of life. In term infants or older preterm infants, higher levels of PaCO<sub>2</sub> are probably acceptable in order to limit ventilator pressures, provided acidosis is avoided. Iatrogenic hypocapnia should be avoided.

### pH

Acidosis causes cerebral vasodilatation and alkalosis cerebral vasoconstriction. Acidosis may also promote pulmonary vasoconstriction and right to left shunting. In preterm infants, pH < 7.20 has been associated with periventricular hemorrhage<sup>412</sup> and pH < 7.1 with periventricular leukomalacia.<sup>402</sup> In very low birth weight infants pH < 7.20 has been associated with retinopathy of prematurity.<sup>398</sup> Acidosis may be due to tissue hypoxia, respiratory failure, excess acid load, renal dysfunction or inborn error of metabolism. It is unlikely that a pH value will have

the same implications whatever its origins. Simultaneous measurements of plasma lactate may give additional information. Interventions aimed at altering pH should reflect the likely underlying explanation. On present information, a reasonable policy for infants receiving respiratory support is to keep pH between 7.20 and 7.45.

## RESPIRATORY SUPPORT

### Reducing the need for respiratory support by antenatal steroids or methylxanthines

Treating mothers at risk of preterm delivery with antenatal steroids reduces infants' risks of RDS, death and brain damage by around 50%<sup>413</sup> and should be a standard of care. In women at less than 32 weeks' gestation who remain undelivered but still at risk of preterm birth 7 days after treatment, repeating the steroids weekly reduces the severity of neonatal lung disease but does not alter the risk of air leak, chronic lung disease, major cerebral ultrasound scan abnormality or death.<sup>414</sup> Long term follow-up data are required to determine the full balance of risks and benefits of this approach.

Trials demonstrate that methylxanthines such as caffeine and theophylline reduce the occurrence of apnea of prematurity and decrease the need for ventilation.<sup>415,416</sup> This is associated with lower risk of bronchopulmonary dysplasia.<sup>417</sup> Long term follow-up data are awaited to determine whether there are any other health benefits or risks.

### Continuous positive airway pressure

Continuous positive airway pressure (CPAP) helps to establish and maintain alveolar recruitment. This protects against low volume lung injury, improves gas exchange and reduces work of breathing. CPAP may also maintain the patency of the upper airways and reduce the frequency of apnea. Use of nasal CPAP in preterm infants after extubation is associated with a lower risk of extubation failure.<sup>418</sup> CPAP can be generated by placing the outlet tubing of a gas source under water (bubble CPAP), by a mechanical ventilator, or by a flow generated method (Infant flow<sup>TM</sup> driver or Benveniste valve). None is proven to be clearly superior in clinical trials. Epidemiological data suggest that chronic lung disease may be observed less frequently when CPAP is preferred to mechanical ventilation in preterm infants<sup>419</sup> but so far trials have not confirmed this.<sup>420,421</sup> Two current randomized controlled trials (the COIN trial and the SUPPORT trial) may help to answer this question.

When nasal CPAP is delivered using a mechanical ventilator, nasal intermittent positive pressure ventilation can be delivered and this can be synchronized to the infant's breathing pattern. This has been called 'non-invasive ventilation'. Similar support can be delivered using a device that can generate bi-level CPAP. Three small trials comparing synchronized nasal intermittent positive pressure ventilation (SNIPPV) with conventional CPAP in infants post extubation suggest that SNIPPV may reduce the risk of extubation failure.<sup>422</sup>

Nasal CPAP can be combined with surfactant administration to treat RDS.<sup>423,424</sup> Infants with worsening respiratory failure are sedated, intubated, surfactant is administered and the infants are extubated and returned to CPAP. This may reduce the number of infants that require ventilation but it has not been demonstrated to be superior to elective intubation soon after birth for prophylactic surfactant treatment.

### Indications for respiratory support by endotracheal tube

No consensus exists as to when to start intermittent positive pressure ventilation by endotracheal tube. Some start it electively at birth in the smallest infants, others use it as rescue therapy in infants failing on CPAP. Prolonged apnea, or progressive respiratory failure are the principal indications. Intubation can be hazardous. An endotracheal tube prevents laryngeal closure which removes the infant's capacity to maintain lung volume by grunting. Adequate positive end-expiratory pressure (PEEP) is required to prevent atelectasis. By narrowing the airway the resistive work of breathing is increased. The extra work is done by the ventilator except at low ventilator settings. Other complications include

blockage or malplacement of the tube, airway injury, impaired mucociliary clearance, infection and aspiration, which all may contribute to chronic lung disease.

## CONTROLLING GAS EXCHANGE BY MECHANICAL VENTILATION

Despite variations in the type and severity of neonatal respiratory disorders, alterations in ventilator settings often have predictable effects on oxygenation and PaCO<sub>2</sub>. These are summarized in Tables 12.36 and 12.37.

### Mean airway pressure and oxygenation

Herman & Reynolds<sup>425</sup> showed in infants with severe hyaline membrane disease a linear relationship between mean airway pressure and oxygenation, expressed as A-aDO<sub>2</sub> (Fig. 12.15). Improved oxygenation was mainly attributed to improved alveolar inflation with reduced intrapulmonary right to left shunt. Increases in (1) peak pressure, (2) inspiratory:expiratory ratio and (3) positive end expiratory pressure were thought to (a) expand collapsed lung units, (b) hold them open longer and (c) prevent their collapse during expiration. With stiff lungs in severe disease, high mean airway pressures had no effect on cardiac output or arterial blood pressure. Stewart et al<sup>426</sup> achieved greater increases in oxygenation per

**Table 12.36** Ventilator settings and gas exchange: methods of increasing oxygenation

Maneuver	Probable underlying mechanisms
1. ↑ FiO <sub>2</sub>	a. ↑ Saturation of alveolar capillary blood b. Relieving hypoxia can decrease pulmonary vascular resistance, reducing extrapulmonary right to left shunt through fetal channels
2. Adding CPAP	Maintains lung volume in spontaneously breathing infants with reduced lung compliance
3. ↑ PIP	These three maneuvers increase MAP, hence lung volume and oxygenation
4. ↑ PEEP	
5. ↑ I:E ratio	
6. Achieving synchronous ventilation	a. Maximizes efficiency of baby's contribution to gas exchange b. ? Minimizes compression of pulmonary circulation during ventilator inflation and consequently reduces right to left shunting
7. Correcting hypovolemia and hypotension	If there is evidence of hypovolemia hypotension (systemic hypotension ± peripheral vasoconstriction), correcting it with an infusion of blood, plasma or an inotrope may reduce extrapulmonary right to left shunt, improving pulmonary perfusion and oxygenation without a change in ventilator settings
8. Exogenous surfactant	Increases alveolar recruitment and improves deflation stability by decreasing surface tension

CPAP, Continuous Positive Airway Pressure; I:E Ratio, Inspiratory:Expiratory Ratio; Mean Airway Pressure, MAP; PEEP, Positive end-Expiratory Pressure; PIP, Peak Inspiratory Pressure.

**Table 12.37** Ventilator settings and gas exchange: methods of decreasing PaCO<sub>2</sub>

Maneuver	Probable underlying mechanisms
1. Reduce excess CPAP	In a spontaneously breathing baby, excess CPAP a. Decreases compliance and tidal volume b. Obstructs the pulmonary circulation c. Increases the work of breathing
2. ↑ Ventilator rate	Increases minute volume
3. ↑ PIP	
4. ↓ PEEP	
<i>In severe disease, with stiff lungs:</i>	
5. ↑ Inspiratory time	If expansion of the chest wall is poor and PaCO <sub>2</sub> is elevated, increasing the inspiratory time may improve alveolar ventilation and decrease PaCO <sub>2</sub> . <i>Increasing the expiratory time may have the opposite effect</i>
<i>In mild or improving disease, with compliant lungs:</i>	
6. ↑ Expiratory time	Compliant lungs need longer to deflate. If expiratory time is too short, inadvertent PEEP is produced and alveolar ventilation is decreased. Inadvertent PEEP can be reduced by increasing expiratory time

CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure.

unit increase in mean airway pressure by raising positive end expiratory pressure (PEEP) than by adjusting inspiratory:expiratory ratio or peak inspiratory pressure (PIP). With earlier intervention and less severe lung disease shorter inspiratory times and faster rates were associated with improved outcomes.<sup>427,428</sup> High airway pressures are now seldom required. In mild disease, excess airway pressures may cause lung injury and impair gas exchange by compromising the pulmonary and systemic circulation. If oxygenation is good with low FiO<sub>2</sub>, high PEEP and long inspiratory times are inappropriate. However, extremely short inspiratory times may compromise lung inflation. Field et al<sup>429</sup> found a significant fall in tidal volume at inspiration times under 0.3 s.

### Minute ventilation, carbon dioxide exchange and inadvertent PEEP

Herman and Reynolds<sup>425</sup> showed that PaCO<sub>2</sub> (a) falls with increasing ventilator rate (increased minute volume), and (b) rises with increases

**Fig. 12.15** Inverse relationship between mean airway pressure (MAP) and A-aDO<sub>2</sub> in severe hyaline membrane disease, indicating that MAP is directly proportional to oxygenation. (From Herman & Reynolds 1973<sup>425</sup> with permission.)

in PEEP (i.e. decreased minute volume). Bartholomew et al<sup>430</sup> showed that the average effect on tidal volume of a 1 cmH<sub>2</sub>O change in PEEP was comparable to that of a 2 cmH<sub>2</sub>O change in PIP in infants with hyaline membrane disease. This probably reflects the sigmoid shape of the pressure–volume curve.

Inadvertent PEEP occurs when the expiration time is too short to allow adequate deflation before the next inflation is imposed.<sup>431</sup> The gas trapped in the lungs increases the respiratory dead space and may compress the pulmonary circulation, impairing gas exchange. The intrapulmonary pressure does not fall as far as the PEEP set on the ventilator. Inadvertent PEEP may be dangerous<sup>432</sup> and is most likely when compliance is improving and airway resistance is elevated, as in chronic lung disease. Reducing the ventilator rate by lengthening expiration time may improve gas exchange under these circumstances by allowing more complete expiration.

## HUMIDIFICATION

Bypassing the upper airway with an endotracheal tube makes the baby dependent on external humidification. Inadequate humidity slows mucociliary clearance causing viscid secretions and may predispose to pneumothorax and chronic lung disease.<sup>433</sup> The presence of condensate in the ventilator tubing indicates that relative humidity is close to 100% but unless the gas temperature is above 30.5 °C the absolute humidity will be inadequate. Inspired gas temperature or humidity may vary considerably<sup>434,435</sup> and should be measured continuously, close to the patient's airway. Excess humidification may cause fluid overload, increased respiratory system resistance and surfactant dysfunction.

## ENDOTRACHEAL LAVAGE, SUCTION AND PHYSIOTHERAPY

Clearance of secretions by intermittent endotracheal tube lavage and suction reduces respiratory system resistance<sup>436</sup> and may prevent tube blockage. However, endotracheal suction is associated with hypoxia, bradycardia, increased blood pressure<sup>437</sup> and altered cerebral hemodynamics<sup>438</sup> and should be used in a measured way, particularly in the first 48 h of life when secretions are scant.

## ADDITIONAL TECHNIQUES

The latest neonatal ventilators offer a wide range of new ventilation modes. These utilize the capacity to monitor the interaction between the baby and the ventilator and to measure flow and volume at the airway. The situation is made confusing by the lack of a standard terminology.

### Synchronous ventilation modes

If the ventilator rate is set slightly faster than the spontaneous respiratory rate, many babies begin to breathe synchronously with the ventilator and show improved gas exchange.<sup>439</sup> Breath-sensing technology now eliminates the need for this entrainment. Modern ventilators can detect the onset of spontaneous inspiration quickly enough for a ventilator breath to be delivered in synchrony. To prevent the inflation continuing after the onset of spontaneous expiration, short inspiratory times are required. Inspiratory efforts can be measured directly at the patient airway or sensed by changes in the ventilator circuit pressure or flow, thoracic impedance, or pressure changes in a Graseby capsule attached to the abdomen. Increased trigger sensitivity allows smaller respiratory efforts to be sensed but also promotes accidental triggering (autocycling) by other signals such as air leak around the endotracheal tube or water in the ventilator circuit. Autocycling is common<sup>440</sup> and may cause hypocapnia in triggered modes where the ventilator rate is unrestricted.

Synchronized intermittent mandatory ventilation mode (SIMV) leaves the clinician in control of ventilator rate, inspiratory time and pressures. The ventilator divides the minute into equal blocks of time determined by the set rate. In the first part of each time block (trigger window) the ventilator can sense an inspiratory effort and deliver a trig-

gered breath. If no breath is sensed, a mandatory breath is delivered. There is then a brief refractory phase. Weaning is accomplished as the clinician chooses. The need for a preset inspiratory time and a refractory period in each time block limits effective SIMV to slower respiratory rates because the trigger window is narrow at higher rates.

In patient triggered ventilation mode (PTV), all inspiratory efforts made by the infant of greater than trigger threshold are rewarded by a ventilator breath. The infant determines the ventilator rate and the clinician the inspiratory time and pressures. A mandatory back-up rate is delivered in the event of apnea or failure to trigger. Weaning is accomplished by decreasing the pressures. Assist control is another term for PTV.

In comparison with unsynchronized ventilation, tidal volume and gas exchange were superior on SIMV.<sup>441,442</sup> A meta-analysis of trials of both PTV and SIMV in comparison with conventional IMV suggests that synchronized modes may be associated with more rapid weaning from ventilation but not with altered clinical outcomes.<sup>428</sup>

Pressure support ventilation is a further adaptation of PTV where changes in flow at the airway are used to initiate and terminate inspiration, leaving the infant in control of everything except pressure. Further adaptations now permit delivered volume to be adjusted breath by breath in relation to measurements of tidal volume. This volume controlled approach can be applied in association with the other modes of ventilation. The value of these newer modes is presently unclear. Volume guarantee ventilation has been associated with less hypocarbia<sup>443</sup> and less lung inflammation<sup>444</sup> but so far trials powered to examine clinical outcomes have not been performed.

## Paralysis

Greenough et al<sup>445</sup> demonstrated in randomized trials that ventilated infants breathing asynchronously sustain fewer pneumothoraces if paralyzed with pancuronium. Shaw et al<sup>446</sup> found that routine paralysis of all ventilated infants was not more effective than selective treatment of those breathing asynchronously. Prolonged neuromuscular blockade is associated with decreased lung compliance<sup>447</sup> and edema. When pancuronium is administered rapid hypoxia can develop if ventilation is inadequate. With milder lung disease and gentle ventilation, paralysis is seldom required.

## High frequency ventilation

High frequency ventilation describes any technique using ventilator rates of 60/min or more. It can be divided into three major types: high frequency positive pressure ventilation (HFPPV 60–150/min – see ref 427 and previous discussion on synchronous ventilation); high frequency oscillatory ventilation (HFOV 180–3000/min); and high frequency jet ventilation (HFJV 200–600/min).

### High frequency oscillatory ventilation

HFOV eliminates the large changes in lung volume generated with conventional ventilation. A continuous distending pressure is applied to establish and maintain alveolar recruitment. As with conventional ventilation, oxygenation is determined by the mean airway pressure. The FiO<sub>2</sub> becomes low once alveolar recruitment is established.<sup>448</sup> In addition, the ventilator produces oscillations in pressure, above and below the mean airway pressure, at around 10 Hz (3–50 Hz). These oscillations have little effect on the mean airway pressure but cause small volumes of gas to move in and out of the lungs. The tidal volume (typically around 2 ml/kg) is determined by the amplitude of the oscillations and is much lower than with conventional ventilation. Carbon dioxide elimination on HFOV is proportional to tidal volume squared.<sup>449</sup> Because of the high frequency employed, there is only time for around 10% of the pressure oscillation in the ventilator circuit to reach the airspaces. Increasing the frequency reduces the tidal volume.<sup>450</sup> Carbon dioxide elimination is optimal at around 10 Hz.<sup>451</sup> By maintaining alveolar recruitment and avoiding overinflation, both low volume (atelectrauma) and high volume (volutrauma) lung injury may be avoided.

The indications for HFOV are unclear. Some infants with severe lung disease appear to be easier to stabilize on HFOV than conventional ventila-

tion. A meta-analysis of trials of elective early HFOV versus conventional ventilation shows no advantage to routine early HFOV.<sup>452</sup> In an uncontrolled prospective study, 21 out of 46 term or near term infants with severe respiratory failure who were referred for extracorporeal membrane oxygenation (ECMO) were successfully managed with HFOV without an increase in mortality or morbidity.<sup>453</sup> No clear advantage was demonstrated in a small randomized controlled trial<sup>454</sup> although some infants failing on conventional ventilation could be successfully managed with HFOV. In a randomized controlled trial of rescue HFOV in preterm infants with severe respiratory distress syndrome, HFOV was associated with reduced risk of new air leak but increased risk of intraventricular hemorrhage and no effect on mortality or chronic lung disease.<sup>455</sup>

### High frequency jet ventilation

The principles of ventilation strategy with HFJV are similar to those with HFOV.<sup>456</sup> With this technique high frequency positive pressure pulses of gas are introduced into the endotracheal tube through a cannula within its lumen. These pulses entrain additional gas through the endotracheal tube. Expiration is passive and is promoted by the use of low I:E ratios. Rate, peak pressure and inspiratory time are controlled and tidal volume and mean airway pressure are dependent on them. The optimum frequency for carbon dioxide elimination tends to be lower than with HFOV. HFJV has been associated with improved gas exchange in RDS.<sup>457</sup> A meta-analysis of three small trials of elective high frequency jet ventilation for RDS suggests that HFJV may be associated with a decreased risk of chronic lung disease at 36 weeks' gestation but too few infants have been studied to recommend this for routine practice.<sup>458</sup>

### Extracorporeal membranous oxygenation

This technique uses an artificial membrane oxygenator to achieve gas exchange outside the body. It is used where there is severe reversible respiratory failure such as in persistent pulmonary hypertension of the newborn, severe lung disease or diaphragmatic hernia. The rarity of such sick infants and the complexity of the treatment mean that it is only available in a few centers and infants must be transferred for treatment. Among 190 infants in severe respiratory failure, the risk of death or disability at 1 year was reduced by 50% among those randomly allocated to be transferred to an ECMO facility versus those who remained in their local center.<sup>459</sup> Exactly which infants should be referred for ECMO is unclear because nitric oxide, HFOV and surfactant treatment for term respiratory failure reduce the need for ECMO but were not in widespread use when the UK ECMO study began. It is essential not to allow infants to die of potentially reversible respiratory failure without reaching an ECMO center. Sick infants should be discussed with an ECMO specialist early in their illness.

### Pulmonary vasodilators

Pulmonary vasodilators may improve oxygenation where there is right to left shunt secondary to increased pulmonary vascular resistance. They have not been shown to reduce mortality. The most promising agent is nitric oxide. Others include sildenafil, prostacyclin (PGI<sub>2</sub>), glyceryl trinitrate, nitroprusside, magnesium and tolazoline. Systemically administered vasodilators may cause hypotension.

### Nitric oxide

Vascular smooth muscle relaxation is induced by nitric oxide.<sup>460</sup> Inhaled nitric oxide is inactivated by combining with hemoglobin to form methemoglobin, which largely confines its effects to the lungs. Nitric oxide reacts with oxygen to form nitrogen dioxide, nitric and nitrous acid, raising issues of toxicity. US safety regulations recommend that nitrogen dioxide exposure should not exceed 5 ppm in an 8 h period. Miller et al<sup>461</sup> found that in an infant ventilator circuit, nitric oxide concentrations greater than 80 ppm resulted in nitrogen dioxide levels greater than 5 ppm in the presence of 90% oxygen. Nitric oxide concentrations of less than 70 ppm did not result in excess nitrogen dioxide. A meta-analysis of randomized trials of nitric oxide in term or near term infants with respiratory failure suggests that around 50% of infants show improved oxygenation and this is associated with a significant reduction

in the number of infants who require ECMO.<sup>462</sup> A reasonable starting dose is 20 ppm. Trials in preterm infants with respiratory failure have not demonstrated benefit from nitric oxide.<sup>463</sup> When nitric oxide is discontinued, a rebound worsening of oxygenation is frequently observed whether or not the infant responded to treatment.<sup>464</sup> This is minimized if the nitric oxide is weaned down to 1 ppm before it is discontinued. Methemoglobin levels and NO<sub>2</sub> levels should be monitored. Because nitric oxide may inhibit platelet adhesion, caution is warranted in the presence of hemorrhage or thrombocytopenia.

### Hyperventilation

Hyperventilation to unphysiological levels of pH > 7.6 can reverse extrapulmonary right to left shunt in severe pulmonary hypertension.<sup>408,465</sup> A similar effect is achieved through infusion of alkali to high pH.<sup>466</sup> However, since both maneuvers may cause cerebral ischemia their use is not recommended. They should not be preferred to nitric oxide treatment or transfer to an ECMO center.

## NEURODEVELOPMENTAL OUTCOME

Survival with good health into childhood and beyond is the true measure of success of perinatal care. Severe neurodevelopmental disability remains the worst adverse long term outcome associated with prematurity. The types of neurological disability seen amongst preterm survivors include spastic diplegia, spastic hemiplegia and quadriplegia with and without intellectual impairment. Other problems include blindness, deafness and severe epilepsy. Minor motor problems, specific learning disorders and attention deficits are commonly recognized amongst school-age survivors.

The median prevalence of cerebral palsy in a meta-analysis of 111 studies reporting outcome of VLBW survivors was 7.7%.<sup>467</sup> The median prevalence of any disability in VLBW survivors was high at 25% with a positive correlation between the reported incidence of disability and length of follow-up. Time trends showed that the prevalence of cerebral palsy increased in the VLBW population in the 1980s but data from cerebral palsy registries have shown a recent welcome decline in the prevalence, with severe motor disability being found in around 12 per 1000 VLBW survivors.<sup>468</sup> The risk of cerebral palsy was strongly related to gestational age in this Oxford study, with a 40-fold higher incidence amongst babies born at less than 28 weeks of gestation when compared to those at term (Fig. 12.16). Whilst increasing survival means that there has been a net gain of normal survivors amongst the VLBW group over time, there is still no room for complacency.

## EVALUATING THE OUTCOME STUDIES

The vast literature reporting the outcome of preterm babies can be a minefield for the unwary reader. The results of outcome studies show a huge variation and there has been little improvement in methodology over time. A recent evaluation confirmed that there can be considerable selection bias.<sup>469</sup> Recently a collaboration between cerebral palsy registers has been set up in Europe and work has begun on harmonization of definitions; in future the very large population base of this collaboration should lead to extremely valuable information on trends in the subtypes of cerebral palsy.<sup>470</sup>

### Population

Most reports of preterm morbidity are hospital based making it difficult to compare results as referral practices vary widely between units. Birth weight cut-offs are extensively used, perhaps the most frequent being the reporting of the outcome for babies less than 1500 g. Small for dates infants of around 30 weeks' gestation are over-represented in these reports. The ideal study would report results from an entire geographical region and contain information about the outcome of all pregnancies ending between 22 and 32 weeks' gestation. The EPICURE study comes closest to this, and has provided data on the outcome of all pregnancies ending between 20 and 25 weeks of gestation in the UK in 1995; EPICURE

Fig. 12.16 Cerebral palsy rate per 1000 live births by completed week of gestation. (Adapted from Surman et al 2003<sup>468</sup> with permission.)

It is currently recruiting cases and the 10-year outcome of EPICure I will soon be available.<sup>471</sup> Recent reports remind us that babies of 32–36 weeks' gestation are also at increased risk of death and disability, and the population is larger than that of babies born at 23–25 weeks.<sup>472,473</sup>

### Treatment of multiples

As many as a quarter of most preterm cohorts are one of a multiple delivery, and this trend seems set to continue. Some outcome studies exclude multiples, and many do not differentiate between singleton and multiple deliveries making specific counseling difficult. Although some researchers say that the outlook is not different for preterm twins compared to singletons there is considerable evidence that twinning is associated with an increased risk of cerebral palsy, and that the proportion of cerebral palsy accounted for by multiple births has increased.<sup>468</sup> This is particularly important when there is intrauterine death of a co-twin, where the risk of significant handicap may be as great as 1 in 10.<sup>474</sup>

### Reason for prematurity

As more data accrue, it becomes possible to analyze outcome by etiology of prematurity. There are differences between the outcomes of babies born because of maternal pre-eclampsia (about 12% of preterm deliveries), prolonged rupture of membranes (22%), placental abruption (4%), IUGR (4%), idiopathic preterm labor (40%) or multiple pregnancy (20%). Chorioamnionitis carries a particularly high risk of subsequent periventricular leukomalacia and spastic diplegia.<sup>475</sup> The obstetric team's perception of the chance of survival has also been shown to influence outcome.

### Missing cases

Tracing the movements of babies is never easy. Frequent changes of surname and address are common and some leave the country of their birth altogether. Work from the Northern region of the UK continues to show that the last few babies remaining to be found in a follow-up study contain a disproportionate number of handicapped infants.<sup>476</sup> The reasons for the discrepancy include the fact that the parents of the handicapped infants are already busy with hospital attendances or that they do not wish to confront the adverse outcome. Studies reporting less than 95% follow-up are likely to be underestimating handicap and an ideal study would have 100% ascertainment.

### Duration and timing of follow-up

The diagnosis of cerebral palsy cannot be made with any degree of confidence before 2 years, and may not be stable until 5 years or more. Late deaths will alter the denominator if the handicap rates are to be reported for survivors rather than for live births, another potential source of difficulty when trying to compare studies. Some report neo-

natal survival, some survival to discharge, and some survival to the time of late follow-up. There is a tendency to use cranial ultrasound results as a proxy for the more expensive and time-consuming neurodevelopmental assessments; this will underestimate the number of cases and is becoming less accurate as the incidence of large hemorrhages and 'periventricular leukomalacia' continues to reduce because periventricular leukomalacia is not reliably detected with ultrasound.

### Definition of disability

This is perhaps the most variable of the many problems with the outcome studies. The WHO international classification of impairment, disabilities and handicap contains useful definitions which are listed in Table 12.38. Usually major handicap includes cerebral palsy, severe developmental delay (more than two or three standard deviations below the mean on the particular test used), blindness and deafness. There are differences of opinion regarding inclusion of conditions such as epilepsy and shunted hydrocephalus. The latter can cause impairment without disability, as can a mild hemiplegia. Types of cerebral palsy include spastic, ataxic, dyskinetic (athetoid and dystonic) and hypotonic and can involve a single limb through to quadriplegia. Few groups have enough subjects to allow analysis of outcome according to type of cerebral palsy: there are probably different associated antecedent variables for spastic diplegia, hemiplegia, athetosis and quadriplegia. Important associations may be missed by 'lumping' adverse outcome in small studies.

Table 12.38 WHO definitions of impairment, disability and handicap

#### Impairment

Any loss or abnormality of psychological, physiological or anatomical structure or function: in principle impairments represent disturbances at organ level

#### Disability

Any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being. A disability thus reflects the consequence of an impairment in terms of functional performance and activity by an individual

#### Handicap

A disadvantage for a given individual resulting from an impairment or disability that limits or prevents the fulfillment of a role that is normal (depending on age, sex and social and cultural factors). Handicap thus reflects interaction with the surroundings and is a difficult outcome to use for comparison as it depends on attitudes within the family and society to disability

Minor disability, clumsiness, language disorder, school failure and behavior disorder are even more difficult to define and the wide range in the reported incidence between studies reflects this.

### Diagnosis of disability

The tests used to diagnose disability should be reproducible and have been previously evaluated in an appropriate population in order to minimize problems such as intraobserver variability. At present there is a large number of tests applied at different ages by people of varying levels of experience and this can severely bias results. Well validated in this respect are the Bayley and Griffiths scales of infant development, and the Amiel-Tison method of neurological examination.

### Control groups

In a cohort descriptive follow-up study of all children below a certain weight there can be no control group. Consideration needs to be given to the inclusion of control subjects such as term infants, particularly in view of the known effects of socioeconomic deprivation on the incidence of prematurity. As studies of preterm outcome begin to report school performance, variables such as birth order and social class will become relatively more important factors than they are in the current descriptions of the prevalence of major handicap.

## OUTCOME RELATED TO BIRTH WEIGHT, SEX, GESTATIONAL AGE AND OTHER FACTORS

That the incidence of handicap increases with decreasing birth weight and gestational age was shown as early as 1956. Most large regional studies reporting the outcome of VLBW babies born during the last 50 years record serious disability in less than 10% of the survivors, increasing to 13–25% of affected children when moderate disability is included. The interaction of birth weight and gestational age on survival and disability can be studied by those who have access to large datasets. One approach is to calculate the birth weight ratio, which is the actual birth weight divided by the mean birth weight for the same gestational age.<sup>477</sup> A birth weight ratio of 0.8 corresponds to the 10th centile. This is a statistically useful tool because the number generated is a normally distributed continuous variable. Morley and her colleagues<sup>477</sup> were unable to show any association between birth weight ratio and neurodevelopmental outcome at 18 months, but others have reported a higher mortality and morbidity for very preterm growth retarded infants.<sup>478,479</sup> In the longer term, most follow-up studies describe worse cognitive outcome for preterm SGA infants when compared with appropriate for gestational age controls.<sup>480</sup>

Male sex has been associated with a doubling of the risk of death and/or handicap in almost every study which has included sex as a factor in logistic regression analysis. Some studies suggest an increased chance of survival amongst black preterm babies, whereas others show the opposite.<sup>481</sup>

### Outcome related to gestational age

Survival at 22 weeks' gestation remains very rare, but at 23 weeks the chance of survival has improved considerably over the last decade, providing the fetus is well grown and weighs more than 500 g. For the small number of babies born preterm and with birth weight less than 500 g the outcome remains dismal, probably reflecting the combined effects of prematurity and severe intrauterine growth failure. For appropriately grown babies of 23 weeks' gestation many centers around the world are now reporting 50% survival, improving to 70% at 24 weeks and 80% at 25 weeks.<sup>482</sup> These data are in contrast to the more gloomy outlook revealed in the 1995 EPICURE study, which considered the population of the UK rather than single center outcomes,<sup>471</sup> and a wide range of outcome at 23, 24 and 25 weeks was reported in a careful review of outcome studies reporting births in the 1990s.<sup>483</sup> A comparison between EPICURE, data from UCLH, and that from Minneapolis<sup>482</sup> is shown in Figure 12.17. After 28 weeks' gestation survival is now regularly reported as above 90%.

Fig. 12.17 Survival rates (percentage) for each week of gestation between 22 and 26 weeks. Data adapted from EPICURE, UCLH, and Minneapolis.<sup>471,482</sup>

The major neonatal complications which influence later development remain preterm brain injury (intraventricular hemorrhage or periventricular leukomalacia), chronic lung disease, necrotizing enterocolitis and sepsis. Chronic lung disease continues to occur in a significant proportion of VLBW infants and is associated with long hospital stays, poor weight gain and episodes of infection; all of these probably affect neurodevelopment. NEC that requires surgery doubles the risk of an adverse neurodevelopmental outcome.<sup>484</sup>

The rates of disability, and cerebral palsy in particular, increase with decreasing gestational age (Fig. 12.16). Precise estimates of neurodevelopmental outcome at 23–26 weeks are still hard to find and vary widely, but 34% of the Minneapolis cohort born at 23 weeks had severe disability at follow-up, with 52% normal at a mean age of about 4 years, and this fits fairly well with many of the studies summarized by Hack & Fanaroff.<sup>482,483</sup> Four years is too young to assess school performance or attention deficit hyperactivity disorder (see below). At 24–26 weeks the percentage of children who survive with severe neurodisability is around 20%, with a similar percentage affected by minor disability. Many disabled ex-preterm children continue to have multiple impairments, and Maureen Hack pointed out that her meta-analysis gave strikingly similar results to that performed by Rennie in 1996.<sup>485</sup>

## SENSORY HANDICAP

In addition to the high cerebral palsy rate in VLBW infant survivors there are a significant number of visually impaired children, often as a consequence of retinopathy of prematurity. About 3% are blind, and many more have severe myopia: about a quarter of the children in most cohorts need prescription glasses. Deafness afflicts slightly fewer children but is still a problem in about 1–2%. Early diagnosis by screening can help limit the handicap resulting from this latter disability. Long term follow-up studies in the state of Victoria have been in place since the early 1980s, and the most recent cohort had far fewer blind children (1%) than earlier cohorts.<sup>486</sup>

## MINOR HANDICAPS AND SCHOOL FAILURE

Follow-up to school age and beyond has been reported for several cohorts of ex-preterm children. More of the children are left-handed, which has been suggested as a possible risk factor for a later risk of schizophrenia. More are hyperactive with a short attention span and require special help at school.<sup>487</sup> The meta-analysis of Aylward showed a mean reduction of six points in IQ when disabled survivors were excluded<sup>488</sup> and more recent studies continue to show a downwards shift of similar magnitude.<sup>489</sup> There is a considerable overlap between behavioral disorders, neurodevelopmental abnormalities and school problems – ‘clumsiness’ may be a marker for this type of dysfunction, which remains very common.<sup>490</sup> More (14%) Finnish LBW children born in 1966 than controls

(6%) were educationally subnormal at the age of 14, but when the disabled survivors were excluded similar numbers succeeded in higher education.<sup>491</sup> The Bavarian follow-up study showed that ex-preterm children had significant problems with sequential and simultaneous information processing and language.<sup>492</sup> These problems are not limited to those with obvious white matter disease of prematurity, and MRI cohort studies are revealing abnormalities in brain volume, gyral folding and subtle white matter damage which may be important (see below). 'Executive function' is a term used to describe the end result of a series of processes involving goal setting, planning, problem solving, attention and concentration on tasks; this ability is often impaired in ex-preterm children.<sup>493</sup> Nevertheless, many young adults who were born very preterm rate their own quality of life as high.<sup>494</sup>

## OUTCOME RELATED TO NEUROIMAGING APPEARANCES

Cohort screening of asymptomatic VLBW infants with cranial ultrasound continues to show a high incidence of lesions involving the periventricular zone. Damage to premyelin cells abundant in this region provides a convenient explanation for the high prevalence of cerebral palsy. Cysts in the parenchyma and cerebral atrophy indicate loss of white matter and are the strongest predictors yet found for cerebral palsy. Delayed myelination has been confirmed with later MRI studies, suggesting that the cysts are markers of even more diffuse injury to oligodendroglia. Ultrasound is a poor predictor of periventricular leukomalacia diagnosed later with MRI, detecting only about 30% of cases. Most studies are in remarkable agreement about the outcome of cystic change, showing a five-fold increase in the risk of cerebral palsy following ultrasound diagnosis of any parenchymal lesion, and a 15-fold increase in the presence of bilateral occipital periventricular leukomalacia. Accumulated experience is still relatively meager, however, and the predictions have wide confidence intervals due to the small numbers of cases. Visual handicap can be accurately predicted from ultrasound abnormalities. A normal scan is not therefore a guarantee of a normal outcome, although the chances are about 90%.<sup>495</sup> The risk may be higher in the group weighing less than 1 kg.<sup>496</sup>

### Germinal matrix hemorrhage, subependymal hemorrhage

There is consistent agreement that the appearance of increased echodensity in the region of the germinal matrix capillary bed carries no increased risk of adverse outcome. This is probably also true for intraventricular hemorrhage which is not associated with ventricular enlargement. Again, more recent studies suggest that for the highest risk subgroup of extremely low birth weight infants, even this lowest grade of intracranial hemorrhage does carry an increased risk of adverse outcome.<sup>497</sup> The mechanism of this effect remains to be elucidated; isolated intraventricular hemorrhage is not associated with impaired myelination in MRI studies,<sup>498</sup> but bleeding into the germinal matrix may damage the subplate neurons with a consequent reduction in the population of the cortex.<sup>499</sup>

### Ventricular dilation and progressive hydrocephalus

The natural history of ventriculomegaly secondary to the presence of blood in the ventricular cavity in VLBW infants is that about 50% will progress to require a ventriculoperitoneal (VP) shunt insertion and the remainder will arrest or regress. Attempts at preventing the progression by early cerebrospinal fluid (CSF) drainage have proved unsuccessful. Many of these infants have associated parenchymal lesions of the brain making the assessment of risk due to persistent dilation alone very difficult. Nevertheless, the prognosis of shunted hydrocephalus in the preterm infant with post-hemorrhagic hydrocephalus remains concerning, with 75% of those enrolled in the ventriculomegaly trial ending up with cerebral palsy.<sup>500</sup> More recent studies claim better results, and some are of the view that the criteria for treatment in the ventriculomegaly trial were set too high.<sup>501</sup> Even nonprogressive ventriculomegaly probably reflects significant white matter damage, and carries a substantial risk of cognitive delay.

### Noncavitating transient parenchymal echodensity, and the MRI finding of DEHSI

The incidence with which a 'flare' or 'blush' is seen in the parenchyma surrounding the ventricle varies widely with the observer and the frequency of ultrasound scanning, and the importance of transient 'flare' seen with ultrasound remains uncertain. Now that several centers have imaged cohorts of preterm babies with MRI, it has become obvious that subtle white matter deficits are common. Diffuse excessive high signal intensity (DEHSI) is found in up to 70% of VLBWI imaged with MRI at term.<sup>502</sup> Increasing severity of periventricular white matter signal intensity at term is associated with poorer performance on the Bayley scales, as well as with an increased risk of cognitive and motor impairment.

### Persistent parenchymal echodensities and porencephalic cysts

A single large echodense area in the parenchyma of the brain may be the end result of one or several pathological events including venous infarction, secondary hemorrhage into an ischemic area or a primary hemorrhagic event due to transmission of a hypertensive peak or release of vasoactive substances.

Large parenchymal lesions often cavitate to form porencephalic cysts: these are associated with a risk of hemiplegia rather than spastic diplegia; the risk is high and further information can be obtained by imaging the posterior limb of the internal capsule with MRI.

### Periventricular leukomalacia

There is no doubt that cystic periventricular leukomalacia is the most powerful predictor of cerebral palsy amongst the neonatal cranial ultrasound lesions so far described.<sup>503</sup> In many cohort follow-up studies almost all the cases of cerebral palsy had bilateral occipital leukomalacia in the neonatal period. Single cysts and cysts confined to the frontal region have a better outcome than multiple bilateral occipital cysts, where the outlook is universally dismal.

## NEONATAL DEATH

Although neonatal deaths have become uncommon, they are still frequent enough both on the labor ward and on the neonatal unit for consideration of best management to be important. Neonatal intensive care units have developed to rescue preterm and sick infants but there is still a steady trickle of deaths in a neonatal unit from congenital abnormality and the problems of extreme prematurity. With all formal nursing and medical training geared to rescue, the death of the patient is often regarded as failure. As an occasional occurrence, a neonatal death may be rapidly 'set aside', but in a referral unit the frequency and regularity of such events cannot be easily avoided. The emotional load of guilt and depression that arises with frequent deaths almost certainly plays a part in the high turnover of nursing staff and the incidence of 'burnout' in physicians. In the arena of neonatal intensive care, perinatal mortality meetings and more universally perinatal mortality statistics highlight the unsatisfactory nature of death, yet many will be inevitable.

### PARENTAL GRIEF

The grief of the parents after a neonatal death seems independent of the size of the offspring. Such grief is present even when the infant is nonviable or lives for only a very short time and there is an identical reaction after a stillbirth. The failure of a mother to come to terms with a perinatal death can lead to emotional problems. Over 30% of mothers in a study by Cullberg<sup>504</sup> had overt psychiatric problems in the 2 years after such an event. It was the recognition that psychiatric sequelae could be considerably reduced by parents touching their infants before and after death that led to an acknowledgment that the management of death is as important as the rescue of life. This has recently been questioned.

## THE DEATH

The death of a baby in the neonatal unit is an undignified event for the baby and the family, especially when 'rescue therapy' is given until the last moment. It is difficult for the parents to express their true emotions in the intensive care unit where staff are busy with other critically ill patients. It is difficult for staff to cope on the one hand with the rescue care for some patients and still provide sensitivity for grieving parents in the same nursery. It is particularly difficult for parents of other babies in a unit with an open visiting policy. The emphasis in neonatal death must be changed from a medical failure, which must be rapidly forgotten, to an event, tragic indeed, but in which the parents are if at all possible closely involved. Deaths in a neonatal unit should occur, if possible, with the parents present and life support can often be withdrawn with the baby in the mother's or father's arms. Thus in many instances the time of death is itself organized for the benefit of the parents. Death then becomes a reality and with this involvement parents may feel, in retrospect, that they have done their best for their infants by allowing death to occur in a dignified way in the presence of love and company. In an attempt to dissociate death from the urgency of the intensive care unit it is helpful to set aside a room for the parents in the unit which can be used for terminal care. This room may be less clinical than the main nurseries with wallpaper, curtains, a rug and easy chairs. Full supportive care can still be given but in this setting the parents will be more able to provide hospice type care for their infant's last hours or sometimes days and will more easily be able to come to terms with the impending death. The availability of a special room allows extended families to be involved in culturally important ritual. During the terminal period a senior member of the nursing and medical staff should be available to provide continuity and it must be made clear to the parents that someone will always be present unless they wish otherwise. The cultural and religious background of the families must be acknowledged so that a flexible and individual approach can be developed. Discussions early on with the parents should elaborate their religious beliefs and standpoints and outside support from a priest, mullah, rabbi, etc., should be encouraged if appropriate. The introduction of this support at an early stage in a critically ill infant is important as it allows more constructive relationships to develop than when the meeting is for the baptism of a terminally ill infant. In Christian families hospital chaplains and social workers can be actively involved with the family from an early stage. The presence of young siblings can enrich the feeling of family togetherness at this time of grief and is unlikely to damage the siblings.<sup>505</sup> Ritual is important. If an emergency baptism is required this should be memorable with a proper silver christening bowl to facilitate baptism with meaning and dignity. It is important to suggest to parents that they might like to hold or groom their dead infant. This may be met with agitation and a certain degree of horror, particularly by European parents, but after a short time many mothers will request such involvement. In some instances parents have left the hospital to obtain their own baby clothes in which to dress their infant in the laying out process. Photographs of the infant will usually have been taken during life but if the life span has been short it is suggested that pictures of the dead infant are taken, often in the parents' arms. Frequently the baby can be specially clothed to enable a better photograph for remembrance to be taken than the ones in life, which have had evidence of intensive care support. The neonatal unit can provide the parents with a bereavement folder which combines advice and information (to help them at this time) with mementos of their baby (lock of hair, name band, hand and foot prints, etc.).

## THE IMMEDIATE AFTERMATH OF DEATH<sup>506</sup>

Their baby's death is an intensely private and personal experience for all parents. Many will wish to follow the customs of their own culture or the rites of their own particular religion and these wishes should be respected. It is important that no assumptions are made. It may be helpful to ask parents as sensitively and gently as possible to explain their needs. If language problems make this or any other discussion with parents difficult every effort should be made to find an appropriate and

skilled interpreter. Parents who have a specific religious commitment may want to make contact with their minister, priest or other religious leader and he or she will advise them about their baby's funeral as well as provide support and help. Some parents who do not hold any particular religious belief will still find comfort with a simple ceremony in the hospital, perhaps in the hospital chapel with their families and the nursing and medical staff involved in the care of their infant taking part. This may be suggested, bearing in mind that it is not appropriate for all parents. Parents will inevitably be bewildered by a neonatal death. It may be their first experience of losing a close relative and sensitivity is required by staff at all stages.

## AUTOPSY IN THE UK

The parents themselves may request an autopsy. If they make such a request it should always be fulfilled. The autopsy may be necessary because the cause of death is unclear. In this case a coroner (or in Scotland, a procurator fiscal) will be involved because the medical practitioner is unable to issue a death certificate of the medical cause of death. In this event it is not open to the parents to withhold their consent but parents can withhold their authorization if the medical practitioner is prepared to put a cause of death on the death certificate. I believe that all babies should have an autopsy independent of whether the cause of death is apparently known. I believe this because:

1. Even today and with modern imaging techniques, in a significant proportion of autopsies further information is discovered which has a direct bearing on the counseling of the parents for the future.<sup>507</sup>
2. It is important for the medical staff to know that their diagnosis has been accurate and that their management has not caused pathology. It is only in this way that medical science can progress.
3. At some stage in the future it is not uncommon that parents will have anxieties that something went undiscovered in their baby and that this led to the death. The autopsy is often a more objective measure of cause of death.
4. Retained tissue as organ blocks may be helpful at a future date to make a specific genetic diagnosis.

Where the parents' authorization is necessary, it is highly desirable that they can give this freely. An honest and unhurried approach to parents by consultant or senior resident (not a junior staff member), explaining the reasons for an autopsy and what it involves, will help them to reach a decision. Parents will also feel more comfortable if the request is made as a normal rather than an exceptional procedure. Although the consent of only one parent is required by law, it is advisable that whenever possible parents should be asked to sign the consent form together. It will help parents to make their decision if they are given clear information about the following:

1. Why it is thought an autopsy is necessary and why their authorization is being sought. Although many parents wish to be given the reason for their baby's death, many also find the thought of an autopsy distressing. It is important that they can feel their baby is still theirs and is not becoming a hospital specimen.
2. The possible outcome of the examination. While it should be explained that an autopsy can provide a definite cause of death, parents should also be warned that an indecisive result is possible.
3. Where, when and by whom the autopsy will be performed. Parents are also likely to want information and reassurance about the whereabouts of and their access to their baby and, if the autopsy is to be performed at another hospital, the body should not be removed to that hospital until the day of the autopsy and should be returned as quickly as possible after the examination.
4. When, to whom and how the results of the autopsy will be made available. If you are not prepared to give the full information to the parents you should not be doing an autopsy.

Most parents feel anxious about authorizing an autopsy and need reassurance. A particular fear is the damage which will be done to their baby. With good practice by the pathologist (who can be introduced to the parents), it is possible for the baby to be restored and carefully dressed

so as to be acceptable for the parents to see again before the funeral. If the parents are to hold their infant following the autopsy, they should be warned that he or she will be lightweight as in most cases the brain will be removed for later processing. It may also be suggested that the parents might like to provide clothes including a bonnet for the baby to be dressed in after the autopsy or the parents may prefer a funeral director to prepare the baby for them.

The results of an autopsy are anxiously awaited by most parents and there should be a minimum of delay in providing parents not only with the results but also with the opportunity to discuss them fully. The full autopsy report should be sent to the parents with an appointment shortly after so that they can bring it and discuss it fully with the pediatrician involved. In this way they have both written information and the access to a pediatrician to discuss all the implications. If necessary the results can be discussed also with an obstetrician. If an autopsy shows the baby's death to be the result of a genetic disorder, parents should be offered the opportunity for later genetic counseling.

### CERTIFICATION AND REGISTRATION PROCEDURES IN THE UK

When a baby is born alive and subsequently dies, irrespective of the gestation or the duration of life, the medical practitioner who attended the baby is required by law to issue a medical certificate giving the cause of death. This certificate is required to enable the death to be registered. If the cause of death is not immediately apparent the medical practitioner may have to report the death to the coroner (or in Scotland, a procurator fiscal). The law requires that all births and deaths be notified to the registrar of births and deaths. It is best if parents can deal with the registration themselves and *both together* and this is necessary where the couple are unmarried and wish both parents' names entered on the certificate. The medical practitioner who attended the baby during his or her last illness will issue a medical certificate giving the cause of death. This certificate must be produced to the registrar of births and deaths within 5 days of the baby's death (8 days in Scotland). The registrar will issue a green certificate after registration (the certificate for disposal) to permit burial or cremation. This certificate is required before the funeral can take place. It is free of charge. The registrar will also issue, on request, a copy of a certified entry (a death certificate) for a small fee. It is helpful if parents are told in advance that this certificate is available since to many parents it is a valuable memento of their baby. Parents should be told in advance when registering a baby's death that the registrar can enter the baby's forename as well as the surname if they so wish. This may be particularly important for those parents whose baby died soon after birth, as they can then give some thought to the naming of the child before registering the death.

'Death grants' have now been abolished in the UK, but parents can apply to the Department of Social Security for a grant or loan to cover the funeral expenses. In Scotland, the health board will meet the funeral costs for stillborn babies and terminations.

### THE FUNERAL IN THE UK

Ceremonies can take many different forms and may be religious or non-religious. The certificate of disposal (Form 14) issued after registration is needed by the undertaker before a cremation can take place but is not needed for a burial. It should be handed to the funeral director or, if the parents have asked the hospital to take responsibility for the funeral, to the hospital. The funeral director involved will complete all necessary documentation according to the kind of funeral requested. It is also the parents' choice whether their baby is buried or cremated. The cremation of a baby leaves no remains whatsoever (ashes) and the parents should be aware of this. A baby cannot be cremated without the parents' formal consent. If the funeral is privately arranged the funeral director will organize all steps in conjunction with the parents. If on the other hand the parents wish for a hospital contract funeral, they must be aware that there may be some emotional risks in accepting this option. If there is any

anxiety about this the parents can always contact the British Institute of Funeral Directors or the Stillbirth and Neonatal Death Society (SANDS).

### GRAVES, MEMORIALS AND REMEMBRANCE

Depending on the funeral that the parents opt for, the baby may be buried with other babies in a common grave though this practice is becoming less common. Many parents find it comforting to know that their baby is buried with other babies but for others this is distressing and sometimes it takes a while before the grave is full (usually no more than 10 babies should be buried in one grave). Most parents accept a multiple grave so long as they are told about it in advance and do not find out about it when it is too late to consider alternatives. The common grave should be located in a special children's area of a cemetery with a general memorial stone. Parents should be warned that unless they purchase exclusive right to burial, they do not have the right to erect any kind of memorial of their own. If the parents buy exclusive right of burial they can mark their baby's grave with a memorial provided that it complies with local regulations. All crematoria and some cemeteries have a book of remembrance for individual entries. Many specialist neonatal units also have a book of remembrance for infants dying in their units. This book may be located on the neonatal unit or in the hospital chapel. A full page can be allocated to each baby with a personal inscription designed by the parents. This can be made in copperplate writing. The parents can then see the book at any time by arrangement with the hospital chaplain or neonatal unit staff.

### LATE BEREAVEMENT COUNSELING AND SUPPORT

It is now accepted that the aftercare of the parents and siblings is important for subsequent emotional well-being. The parents should be seen several times after the death of their infant. On the first occasion, usually on the day of death, sympathy is shown for the parents' situation. Explanation about the cause of death is often inappropriate at this stage and intrudes into the grief. Over the next few days, necessary formalities have to be completed and this can be a bewildering time. The parents need to be seen on the day after the death to explain what has to be done. If the mother is mobile (that is, not just postoperative after a Cesarean section) it is appropriate to encourage both parents to complete the formalities together rather than the man take on an organizational role. A social worker or member of the clergy may help in shepherding them through these routines. It is also at this second interview that permission is asked by a senior pediatrician for the autopsy. The final task on this second visit is to guide the parents through a few of the reactions and emotions that they will suffer in the ensuing period. At between 1 and 2 weeks after the death the parents are seen a third time. They will have received a copy of the morbid anatomy findings of the autopsy and this interview will explain the findings (the histology will return later and necessitate a further visit). If possible, the senior nurse who has been involved in the terminal events will also be present. It is important not to see the parents in the neonatal unit or in the middle of the busy outpatient session where other babies and infants intrude too easily into their consciousness. The distress and anxieties of the ensuing weeks are again raised and suggestions are made as to how best to deal with them. A final optional appointment is given for about 3 months at which outstanding questions may be clarified and at which pathological grief, if present, should be evident. At all stages hospital social workers and chaplains should be informed (not necessarily to be active) of what is proceeding and the GP should have a full letter with regard to each interview. Genetic counseling should be arranged for the future if this is appropriate from the results of the autopsy.

### VOLUNTARY SUPPORT ORGANIZATIONS

The Stillbirth and Neonatal Death Society (SANDS), 28 Portland Place, London W1B 1LY. SANDS national helpline: 020 7436 5881. The British Institute of Funeral Directors, 41 Bridge Street, Tranent, East Lothian, EH33 1AH.

## BOOKLETS

*Support For You When Your Baby Dies.* Outlines the support offered by SANDS to bereaved parents and those caring for them.

*Saying Goodbye to Your Baby* (1999) by Priscilla Alderson. Available from SANDS and the National Childbirth Trust, 9 Queensborough Terrace, London W2 3TB.

*Miscarriage, Stillbirth and Neonatal Death: Guidelines for Professionals.* Available from SANDS.

## STAFF SUPPORT

With the realization that the support and understanding of health professionals can play a vital role in the eventual recovery of the parents, there has also come the realization that this involvement can itself cause emotional stress and tension in the staff. After a death it is important not only to analyze in detail traditional physiological and pathological events but also to consider the stress aspects for the parents and the nursing and medical staff. Some units may feel it is important to involve formal psychiatric help in this process but regular discussion on a less formal basis (and at particular times of need) can be more important (our regular involvement of chaplaincy staff with parents in a neonatal unit pays dividends for the staff themselves at 'crisis times'). In this way we hope that the people involved in a neonatal death and who will inevitably be under considerable stress will not reach the point of physical and emotional exhaustion.

## PROBLEMS OF THE NEWBORN

### PULMONARY DISORDERS AND APNEA

#### LUNG EMBRYOLOGY

Viability of the preterm baby is limited by lung development. The airways begin as an outpouching from the primitive gut at 24 days. By 26 days two primary branches, which will form the major bronchi, can be discerned. This is called the *embryonic phase* and it ends about the 6th week. The *pseudoglandular phase*, from the 7th to 16th week, consists of branching of the endodermal tube into surrounding mesenchyme. By 10 weeks cartilage is deposited in the bronchi and by 16 weeks formation of new bronchi is almost complete. The *canalicular phase*, from 16 to 26 weeks, comprises canalization of the airways, increased capillary growth and differentiation of type I pneumocytes (needed for gas exchange) from type II pneumocytes which produce surfactant. The terminal *saccular phase* begins from 24 to 26 weeks and continues until term. Terminal air sacs or alveoli appear as outpouchings of the bronchioles after 26 weeks and increase in number to form multiple pouches of a common chamber called the alveolar duct. From 26 weeks the capillary network, which arises at about 20 weeks from vascular structures in the mesenchyme, proliferates close to the developing airway to constitute the *alveolar phase* which continues postnatally for about 2 years. There is a continuum between antenatal and postnatal lung development. Normal alveolarization proceeds rapidly to achieve alveolar numbers that are between 20 and 50% of the adult number of  $300 \times 10^6$  by 40 weeks' gestation. Normal lung development can be disrupted by antenatal events which lead to preterm birth. Before 24–26 weeks gas exchange must take place across terminal bronchioles into the developing capillary network.

#### Lung growth

Growth factors have a major role in lung growth and development. Mechanical and humoral factors also influence growth of the fetal lung. Lung growth requires distention of the fluid-filled lung, with tracheal fluid acting as an internal template or splint. Absence of lung fluid at appropriate pressure leads to pulmonary hypoplasia. Lung hypoplasia may be caused by oligohydramnios from renal agenesis, bladder neck obstruction or rupture of the membranes before 20 weeks. These lungs are structurally immature with persistent cuboidal epithelium and lack

of elastic tissue. They are also biochemically immature, containing low levels of phospholipids. Lung growth is also regulated by external forces, which include the phasic negative pressure of fetal breathing and the tonic negative pressure of diaphragmatic tone. Hypoplastic lungs may also result from absence of fetal breathing movements in babies with central nervous system anomalies, congenital muscle disorders or absent diaphragm. These lungs, although small, appear to be appropriately developed and have normal content of phospholipids. Pulmonary hypoplasia may also be caused by thoracic space-occupying lesions such as diaphragmatic hernia, lung cysts, or pleural effusions which may be associated with severe fetal hydrops.

#### Lung maturation

After birth alveolar stability is dependent upon release of pulmonary surfactant. Synthesis and release of surfactant rely mainly on humoral control mechanisms. Alveolar type II cells, which synthesize surfactant, have microvilli on the luminal surface and contain lamellar bodies. They constitute 16% of alveolar cells but only 7% of the alveolar surface area and can differentiate to form the larger, thinner type I cell which covers the remaining 93% of the alveolar surface. The lamellar bodies (storage sites for surfactant) are first recognized at about 22 weeks. They contain about 80% phosphatidylcholine, mostly dipalmitoylphosphatidylcholine (DPPC) but also unsaturated phosphatidylglycerol (PG). PG is used as a marker of lung maturity and levels rise as phosphatidylinositol levels decrease towards term. Lamellar bodies also contain surfactant proteins A, B and C (SP-A, B, C). A fourth surfactant apoprotein, SP-D, is not stored in the lamellar bodies and is secreted separately. SP-A and SP-D have major roles in host defense of the lung whereas SP-B and SP-C have surface active properties, helping to spread and recycle surfactant. Mature SP-B increases in amniotic fluid in late gestation and SP-A is the last surfactant protein to appear in amniotic fluid.

#### *Mechanisms controlling lung maturation*

**Glucocorticoids.** These induce both structural and biochemical changes in alveolar type II and type I cells. They act on lung fibroblasts to produce fibroblast pneumocyte factor (FPF) which in turn stimulates surfactant synthesis by alveolar type II cells. Glucocorticoids also increase the numbers of lamellar bodies, the rate of choline incorporation into phosphatidylcholine, the amount of DPPC in tracheal fluid and the lung content of SP-A. Induction of FPF is relatively slow, which may account for the delayed clinical effect of maternal glucocorticoid (betamethasone) treatment.

**Thyroid hormones.** Thyroid hormones increase synthesis of surfactant lipids in type II cells, probably by making the cells more responsive to FPF. They act earlier in the phospholipid biosynthetic pathway and are synergistic when used with glucocorticoids in animal studies. Synthetic analogues of  $T_3$  and thyrotropin releasing hormone (TRH) cross the placenta but clinical trials have shown poorer outcomes when mothers have been given combination treatment of TRH plus glucocorticoid.<sup>508,509</sup>

**Insulin.** Hyperinsulinemia is associated with reduced surfactant production. In pregnancies complicated by inadequately controlled maternal diabetes, fetal hyperinsulinemia is associated with an increased risk of neonatal RDS.

**Catecholamines.** Epinephrine, but not norepinephrine, decreases tracheal fluid secretion and increases surfactant release. The concentration of beta-adrenergic receptors in lung increases at term and in response to glucocorticoids. Beta-adrenergic agents delay preterm labor; if used in association with betamethasone, they have a synergistic effect in preventing RDS.

**Other hormones and agents.** Prolactin levels are lower in babies with RDS. Estrogen, testosterone, epidermal growth factor, prostaglandins, cholinergic agonists and leukotrienes have all been postulated as having roles in fetal lung development.

#### Role of surfactant and fetal lung fluid

Fetal lungs are filled with liquid secreted by the epithelium of potential airspaces. Before birth absorption across the epithelium is initiated by

increased circulating catecholamines associated with labor contractions. Air-filled lungs after birth retain a thin fluid layer in the alveoli. Pulmonary surfactant forms an insoluble film at the alveolar air–liquid interface, lowering surface tension and improving alveolar stability during expiration. Surfactant allows very low transpulmonary pressures to be used during normal respiration and also has a role in host defense mechanisms of the lung mainly through the actions of SP-A and SP-D.

Surfactant secretion is stimulated by lung inflation. When surfactant is released the contents of lamellar bodies are extruded into the alveoli as tubular myelin, which is formed into the surfactant monolayer by actions of surfactant proteins SP-B and SP-C. SP-B also regulates surfactant protein metabolism and enhances uptake of phospholipids by type II cells in vitro. SP-A and SP-D have a role in the feedback control of surfactant secretion. The surface film needs to be constantly replenished from freshly secreted surfactant and recycling occurs within type II cells. As much as 85–90% of surfactant is recycled. Clearance of surfactant is rapid and may be increased in the newborn period or after hyperventilation. Specific proteins may regulate clearance of surfactant back to type II cells and small amounts are also phagocytosed by alveolar macrophages and cleared up the airways.

## RESPIRATORY DISTRESS SYNDROME (HYALINE MEMBRANE DISEASE)

RDS is a condition of pulmonary insufficiency commencing at, or shortly after birth and increasing in severity over the first 2 days of life. If RDS is left untreated death can occur from progressive hypoxia and respiratory failure. In survivors resolution begins between 2 and 4 days. It is due to a lack of alveolar surfactant along with structural immaturity of the lung and is mainly confined to preterm babies, with incidence increasing as gestation decreases.<sup>510</sup> RDS is also known as hyaline membrane disease because of histological features at autopsy. Incidence is 2–3% of all births but it is important as it is responsible for the deaths of many preterm infants throughout the world each year. There is evidence that increased use of prenatal glucocorticoid treatment and perhaps prophylactic surfactant therapy have led to a reduction in both the incidence and severity of RDS (Table 12.39).<sup>511</sup> Apart from prematurity, other factors are known to affect the incidence of RDS (Table 12.40).

**Table 12.39** Risk of RDS by gestational age groups

Gestation (weeks)	Risk of RDS (%)
<27	41.5
27–28	54.0
29–30	44.6
31–32	37.2
33–34	12.0
35–36	2.0
37–42	0.1

Girls	Boys

## Pathogenesis and natural course of RDS

Deficiency of surfactant leads to alveolar collapse, reduced lung volume, decreased lung compliance and ventilation–perfusion abnormalities. Right to left shunting of up to 70% or more occurs through collapsed lung (intrapulmonary) or across the ductus arteriosus and the foramen ovale (extrapulmonary) if pulmonary hypertension is severe. Persistent hypoxemia (<4 kPa) causes metabolic acidosis and respiratory acidosis will also be present because of alveolar hypoventilation. This further reduces surfactant production and affects pulmonary vascular resistance, myocardial contractility, cardiac output and arterial blood pressure. Perfusion of the kidneys, gastrointestinal tract, muscles and skin is reduced leading to edema and electrolyte disorders.

Surfactant deficiency in RDS is primary and due to immaturity; the normal pool size of 100 mg of phospholipids/kg at term is reduced to <5 mg/kg in babies with severe RDS. In some babies there is sufficient surfactant at birth to sustain normal respiration but this is gradually used up so that a milder form of RDS can present some hours after birth. Surfactant may also be inactivated by plasma proteins leaking into the alveoli and this form of ARDS may be seen in infants born to mothers with severe pregnancy-induced hypertension. Usually after 2–3 days endogenous surfactant production begins and is followed by clinical recovery. Surfactant replacement will hasten recovery and does not delay the onset of endogenous surfactant production.

## Pathology

Macroscopically the lungs appear collapsed and liver-like and sink in water. Microscopic examination shows generalized collapse of alveoli with eosinophilic membranes in infants surviving more than a few hours. The membranes begin to break up by the third day and are removed by macrophages. Sometimes there is frank pulmonary hemorrhage and interstitial emphysema. The muscle layer of the walls of pulmonary arterioles is thickened and pulmonary lymphatics are dilated. Surfactant treatment may modify the pathological features of RDS reducing epithelial necrosis, interstitial emphysema and pulmonary interstitial hemorrhage.

## Clinical features

The disease has a wide spectrum of severity from mild respiratory distress lasting 2 or 3 days to a rapidly fatal illness causing death within a few hours. The early clinical signs are shown in Table 12.41. Each of these clinical signs may be explained by disturbed lung function. Increased respiratory rate is caused by the demand of increased alveolar ventilation and is related to blood gas changes of hypercarbia and hypoxemia. Later slow or decreasing respiratory rate which may progress to apnea

**Table 12.41** Early clinical signs of RDS

Tachypnea (>60/min)
Expiratory grunting
Sternal and intercostal recession
Cyanosis in room air
Delayed onset of respiration in very immature babies

may be related to diaphragmatic muscle fatigue. The sternal and intercostal recession or retractions are due to reduced lung compliance as a result of surfactant deficiency. Expiratory grunting results from expiration against a partially closed glottis in an attempt to prevent alveolar collapse but may be absent in the very immature or seriously ill baby. Cyanosis is due to decreased arterial oxygen tension caused by right to left interatrial and ductus shunts and to increasing intrapulmonary shunting after the first 12 h of life due to perfusion of collapsed or poorly ventilated parts of the lungs.

In severe disease, immature babies or those with asphyxia, positive pressure ventilation may be needed from birth. In more mature babies grunting and retractions are prominent and cyanosis may be apparent from soon after birth. Oxygen concentrations of greater than 60% are often needed to abolish cyanosis, and respiratory failure with hypercarbia and acidosis frequently supervenes, so that mechanical ventilation becomes necessary. Clinical signs outside the respiratory system also occur (Table 12.42).

The classic signs of RDS have become outdated for two reasons. First, most of the babies cared for in neonatal units are very immature and they often present with apnea at birth; second, prophylactic surfactant treatment is widely practiced for these babies and significantly modifies the clinical course and chest radiographic appearances.

## Investigations

These are needed to confirm the diagnosis and exclude disorders in the list of differential diagnoses (Table 12.43). The chest radiograph is the best way to confirm the diagnosis but there are two caveats: first, congenital pneumonia can have a similar picture often coexisting with RDS and, second, surfactant treatment rapidly improves the chest radiographic appearances and with prophylactic therapy this often happens before radiographs are taken.

Classic radiographic signs are a diffuse reticulogranular pattern of mottling of the lung fields, described as a 'ground glass' appearance with superimposed 'air bronchograms' due to air in the major bronchi being highlighted against the opacified lung (Fig. 12.18). With increasing severity the opacification increases and becomes confluent so that the heart borders are obscured. The radiological appearances may be atypical with asymmetry when changes are more pronounced on the right side or are confined to the lower lobes. Uneven distribution of

Fig. 12.18 Radiograph of severe RDS with widespread reticulogranular mottling and air bronchograms amounting to grade IV disease.

reticulogranularity on chest radiograph may be due to underlying pneumonia or maldistribution following surfactant treatment.

Other investigations may be biochemical, hematological or microbiological. Serial analyses of pH and arterial blood gases are essential for clinical management. Continuous measurements of oxygen and carbon dioxide tensions may be made transcutaneously, and oxygen saturation can be assessed non-invasively by pulse oximetry but this has a major disadvantage of failing to exclude hyperoxia. These measurements are necessary to follow the clinical course of a baby with RDS and to detect early signs of deteriorating respiratory function allowing effective interventions such as surfactant therapy, CPAP or assisted ventilation. Hematological and microbiological investigations are needed to exclude underlying infection especially that due to group B streptococcus (GBS).

## Natural history

The clinical course of classic RDS is that of increasing severity during the first 24–48 h, followed by a period of stability lasting another 48 h before improvement occurs. Severity of the disease may be expressed in terms of oxygen requirements and need for assisted ventilation. In the 24 h prior to recovery a diuresis usually occurs. The widespread introduction of prophylactic surfactant therapy has meant that this natural history is unfamiliar to today's resident pediatricians although the occasional more mature infant with RDS may be encountered.

## Prevention

Antenatal glucocorticoid administration reduces the incidence and severity of RDS provided 48 h of treatment is possible. Improved survival and reduced risk of complications such as pneumothorax, intraventricular hemorrhage (IVH) and persistent ductus arteriosus (PDA) but not bronchopulmonary dysplasia (BPD) have also been demonstrated.<sup>512</sup> RDS may also be prevented or at least ameliorated if care is taken to prevent hypoxemia, acidosis and hypothermia in preterm babies. Gentle resuscitation at birth with early expansion of the alveoli or terminal airways in the very preterm baby, especially those of less than 30 weeks' gestation, is very important. This may be facilitated by giving prophylactic surfactant or early use of CPAP.

Later surfactant replacement will also modify the course of RDS and in general the earlier it is given the greater the benefit.<sup>513</sup> Babies who might benefit most from prophylactic treatment at birth are those of less than 30 weeks' gestation, those needing endotracheal intubation for resuscitation or those who were not treated with prenatal corticosteroids.

## Treatment

The objectives of treatment are to maintain normal blood gases, pH, biochemistry and physiology (blood pressure, temperature and renal

Table 12.42 Nonrespiratory clinical signs in severe RDS

function) and in addition to avoid complications of both the disease and the treatments. Surfactant replacement therapy is an effective way of accomplishing these objectives. There are two basic types of surfactant, synthetic and natural, and both have been shown to improve survival by about 40% and reduce the risk of pneumothorax by 30–70% in babies with RDS.<sup>514–516</sup> Natural surfactants containing the proteins SP-B and SP-C are more effective than the protein-free synthetic surfactants<sup>517</sup> with improved survival and a reduced risk of pneumothorax. There are many natural surfactant preparations, prepared from animal lungs – Surfactant™ (bovine), Alveofact™ and Infasurf™ (calf) and Curosurf™ (porcine)—and there may be subtle differences between them in terms of efficacy.<sup>518</sup> The optimal dose of surfactant is from 100 mg/kg to 200 mg/kg and repeated doses may be needed for babies who show relapse.<sup>519</sup> Natural surfactants may be given to babies with moderate to severe RDS as soon after birth as possible or used prophylactically for very immature infants. Newer synthetic surfactants with SP-B analogues will soon be available but to date there are insufficient data on safety and efficacy to recommend them in place of natural surfactants.

### Maintenance of temperature

Occlusive wrapping in a polythene bag at birth helps to maintain temperature during resuscitation.<sup>520</sup> Preterm infants should be nursed in incubators or under radiant warmers. In order to maintain adequate temperature in very preterm infants incubators need high humidity and double walls (see p. 2.23).

### Maintenance of normoxemia

The aim is to achieve satisfactory oxygenation. For more mature babies (> 30 weeks) with spontaneous respiration, humidified oxygen may be administered directly into the incubator. For very immature infants (< 30 weeks) or when respiratory failure supervenes, some form of assisted ventilation may be necessary (see below). Excessive handling should be avoided as this causes hypoxemia and leads to deterioration. Monitoring of oxygenation is essential as too little oxygen will cause hypoxemia and metabolic acidosis and too much oxygen has been associated with the development of retinopathy of prematurity and BPD. Studies are currently underway to determine optimal oxygen saturation targeting using pulse oximetry. An initial right radial artery blood sample is helpful. An arterial catheter should be inserted in babies needing greater than 40% oxygen after the first hour (or greater than 30% oxygen in babies of less than 1200 g birth weight). Continuous methods of assessing oxygenation such as intravascular electrodes, transcutaneous monitors and pulse oximeters do not remove the need for intermittent arterial blood sampling to check calibration and measure pH, arterial carbon dioxide tension and base deficit. Oxygen delivery is affected by arterial oxygen tension, oxygen-carrying capacity, oxygen affinity, peripheral blood flow, temperature and pH. Fetal Hb allows more oxygen to be carried in the blood at any oxygen tension (greater affinity) but less oxygen will be released to the tissues. Transfusions of adult blood may improve tissue oxygen delivery.

### Correction of acid–base abnormalities

Respiratory acidosis due to raised arterial carbon dioxide tension is common in severe RDS. Hypercarbia can only be treated adequately by improving ventilation. Metabolic acidosis may arise from hypoxemia, hypotension, infection, renal failure, PDA or IVH. Treatment of the underlying cause, for example by increasing oxygen concentrations, giving blood or treating the PDA, may be more appropriate than infusion of sodium bicarbonate. The aim should be to keep the pH above 7.25. If the base deficit becomes greater than 10 mmol/L then sodium bicarbonate should be considered. The dose may be calculated as follows:

$$\text{dose (mmol)} = \text{base deficit (mmol/L)} \times \text{weight(kg)} \times 0.3$$

Molar sodium bicarbonate 8.4% (1 mmol/mL) is the most frequently used alkali in clinical practice but it is hyperosmolar and rapid infusions have been associated with the development of IVH. Severe tissue injury

may result from extravasation. It also has a high sodium content and will raise PaCO<sub>2</sub> unless ventilation is adequate. Sodium bicarbonate should be diluted and given slowly (not faster than 1 mmol/min) by peripheral venous infusion. Serum sodium levels should be monitored regularly.

### Energy, fluid and electrolyte requirements

The preterm baby with RDS has reduced stores of carbohydrate (as glycogen), fat and protein (as skeletal muscle), and also has increased metabolic requirements from extra work of breathing. Providing adequate exogenous sources of energy as parenteral nutrition for these sick babies is technically difficult. Most babies should be started on intravenous fluids of 70–80 ml/kg/d<sup>521</sup> while kept in > 80% humidity in an incubator. Indeed, 60 ml/kg/d may be better than 80 ml/kg/d in babies > 32 weeks' gestation. Sodium intake should be restricted over the first few days of life and initiated after onset of diuresis with careful monitoring of fluid balance and electrolyte levels. Fluid requirements may be monitored by looking at plasma sodium, urine output and specific gravity, osmolality and by regular weighing. Excessive fluid intake is associated with increased risk of PDA, NEC and BPD.

Oliguria in severe RDS is common for the first 48 h due to effects of asphyxia, hypotension and possibly inappropriate ADH secretion. Care must be taken to avoid fluid and electrolyte overload. Subsequently, when diuresis occurs, the large urinary losses mean that extra fluid, sodium and potassium intake will be necessary to prevent hyponatremia or hypokalemia (see p. 2.20).

There should be early introduction of protein, calories and lipids in parenteral nutrition (PN).<sup>522</sup> Early use of PN improves survival by 40% in infants of 28–30 weeks with RDS.<sup>523</sup> Once the baby shows signs of recovery, extra energy should be provided in the form of enteral milk feeds started very gradually to reduce the risk of NEC.<sup>524</sup>

### Assisted ventilation

**CPAP.** Continuous positive airways pressure (CPAP) is a distending pressure which prevents alveolar collapse during expiration and thus improves oxygenation. CPAP is often used as a substitute for mechanical ventilation to provide respiratory support for babies with RDS.<sup>525</sup> The indications for using CPAP in RDS are not absolute and may depend upon maturity of the baby (Table 12.44). Babies with mild RDS can often be managed on CPAP without needing surfactant treatment. In babies who do require surfactant, mechanical ventilation can also be avoided by the 'INSURE' technique (INtubate – SURfactant – EXtubate to CPAP).<sup>526</sup> There are various methods of applying CPAP, but today nasal prongs using a ventilator circuit or a flow driver are generally used. There is no evidence to date of any differences in long term outcomes among various devices used to provide nasal CPAP, however studies have shown that short binasal prongs are better than a single prong at reducing the need for re-intubation.<sup>527</sup> Recently devices such as the infant flow driver have been developed with the technology to provide a background of synchronized nasal ventilation (NIPPV). This can reduce extubation failure rates but it is not yet clear if there are any long term advantages.<sup>528</sup>

**Mechanical ventilation.** Mechanical ventilation (MV) is used to treat respiratory failure or intractable apnea (Table 12.45). For babies less than 30 weeks' gestation, PaCO<sub>2</sub> of > 8 kPa is usually accepted as an indication for MV. The aim of MV is to provide acceptable blood gases whilst minimizing lung injury, hemodynamic impairment or other adverse events. The strategy for minimizing lung injury is to optimize

**Table 12.44** Indications for CPAP in RDS

1. Early treatment of infants < 30 weeks if good spontaneous respiratory effort
2. After surfactant treatment in infants > 27 weeks
3. For infants > 30 weeks and oxygen need > 30% to keep PaO<sub>2</sub> > 8 kPa (60 mmHg)
4. Recurrent apneic attacks
5. Weaning from IPPV and after extubation

Table 12.45 Indications for IPPV in RDS

1. Failure to establish respiration at birth
2. To administer surfactant at birth in infants <27 weeks
3. To administer surfactant in infants >27 weeks and <32 weeks when they need >30% oxygen
4. In infants >32 weeks when respiratory failure develops
  - pH <7.20
  - PaCO<sub>2</sub> >9 kPa (68 mmHg)
  - PaO<sub>2</sub> <7 kPa (53 mmHg) in 60% oxygen
5. Intractable apneic attacks not responding to other measures

lung volume with avoidance of excessive tidal volumes and atelectasis.<sup>529</sup> MV can be provided as intermittent positive pressure ventilation (IPPV) or high frequency oscillatory ventilation (HFOV).<sup>530</sup> HFOV may result in less lung injury thereby reducing BPD,<sup>531</sup> however the quality of the intensive care team may determine outcome to a greater degree than the type of ventilator used, and with the introduction of low tidal volume MV the benefits of HFOV over IPPV in lowering incidence of BPD have probably diminished.

A neonatal version of time-cycled, pressure-limited ventilation is provided by many manufacturers in several modalities such as: IPPV, intermittent mandatory ventilation (IMV), synchronized intermittent mandatory ventilation (SIMV), assist control (AC) or synchronized IPPV (SIPPV), pressure support ventilation (PSV) or volume guarantee (VG). VG combines the advantages of pressure-limited, time-cycled, continuous-flow ventilation with those of volume-controlled ventilation by autoregulating peak pressures within preset limits to achieve tidal volumes set by the user.

IPPV is performed through an endotracheal tube inserted through either the nose or mouth into the trachea. The initial ventilator settings employed will depend upon the maturity of the baby and the severity of the lung disease. For the baby <30 weeks' gestation with severe lung disease, the aim of IPPV should be to expand the lungs as early as possible with the lowest peak airway pressure possible. Peak airway pressures of 15–25 cmH<sub>2</sub>O are often needed initially, with PEEP (positive end-expiratory pressure) of 3–5 cmH<sub>2</sub>O and ventilator rate of 40–60/min with a relatively short inspiratory time of 0.3–0.4 s.<sup>532</sup> Mechanical ventilation of the more mature baby with severe RDS may need higher peak airway pressures and lower rates. Sometimes muscle relaxants and sedation with morphine or fentanyl are needed to prevent these babies 'fighting' the ventilator which will increase the risk of pneumothorax.

If gas exchange remains impaired in a ventilated infant after surfactant treatment, oxygenation may be improved by increased mean airway pressure (MAP) or use of HFOV. Muscle relaxation with pancuronium (0.03 mg/kg) or vecuronium (0.05 mg/kg/h by infusion after a loading dose of 0.1 mg/kg) may be required. A further dose of surfactant may be required. Inhaled nitric oxide does not benefit preterm babies with acute RDS.<sup>533</sup> As the baby's condition improves the ventilator settings can be reduced. Peak inspiratory pressure should be lowered first, along with inspired oxygen concentration. Later, ventilator rates can be lowered keeping inspiratory time constant at about 0.4 s. Following surfactant treatment ventilator settings can usually be reduced quite rapidly. Patient triggered ventilation (PTV) can shorten the duration of mechanical ventilation during the weaning process in preterm babies, however there is no evidence of any long term benefit in terms of survival or reduction in BPD.<sup>534</sup> Methylxanthines such as caffeine are used as respiratory stimulants to promote successful weaning.<sup>535</sup> Extubation may be successful from MAP of 6–7 cmH<sub>2</sub>O on conventional ventilation and from 8–9 cmH<sub>2</sub>O on HFOV, even in very preterm babies. After extubation nasal CPAP reduces the need for re-intubation.<sup>536</sup>

## Complications of RDS (Table 12.46)

### Persistent ductus arteriosus (PDA)

The ductus arteriosus is likely to remain open in babies with severe RDS for a number of reasons: prematurity with poorly developed ductus musculature, reduced arterial oxygen tensions and inadequate metabolism of prosta-

4. Complications of mechanical ventilation (see above)
5. Long term neurological sequelae

glandins in the lungs.<sup>537</sup> Fluid overload and surfactant replacement may also increase the risk of PDA. The management is discussed on page 267.

### Intraventricular hemorrhage (IVH) (p. 307)

IVH can cause acute deterioration in infants with RDS and may be predisposed to by other causes of collapse such as pneumothorax.<sup>538</sup> Maintenance of physiological stability and prevention of air leak by manipulation of ventilator settings or surfactant replacement has reduced the incidence of IVH in recent years.<sup>539</sup>

### Pulmonary air leaks (p. 253)

The incidence of these depends upon the severity of RDS and the need for assisted ventilation. For babies with RDS not needing assisted ventilation the incidence is 5–10%. In the decades of the 1970s and 1980s, if CPAP was needed the incidence was about 10–15% and with IPPV 10–30%.<sup>540</sup> Since that time surfactant replacement,<sup>513–515</sup> together with better ventilators,<sup>541</sup> have reduced the incidence of pneumothorax to less than 5%, which means that many residents have not had much experience in insertion of chest drains.

### Bronchopulmonary dysplasia (p. 259)

This condition was not described until after the introduction of mechanical ventilation to treat RDS.<sup>542</sup> Positive pressure mechanical ventilation along with oxygen toxicity and chorioamnionitis have a significant role in pathogenesis. About 20% of babies needing MV for RDS will develop this complication<sup>543</sup> but infants with mild or no RDS can also develop BPD, particularly in the presence of chorioamnionitis.<sup>544</sup>

### Pneumonia (p. 250)

Pneumonia may coexist with RDS or be secondary associated with the presence of an endotracheal tube. Cultures of tracheal aspirates are of limited use in diagnosis of secondary infection but may guide the choice of antibiotics should the infant deteriorate. The presence of both pus cells and organisms in tracheal aspirates, development of patchy opacity on chest radiograph and general deterioration with elevated serum inflammatory markers along with positive blood cultures help to make the diagnosis.<sup>545</sup> Appropriate antibiotic treatment is then necessary. Aspiration pneumonia may also be common and may cause acute deterioration. In one study it occurred in up to 80% of mechanically ventilated neonates.<sup>546</sup> The chest radiograph may show areas of collapse and consolidation, especially in the right upper or right lower lobes. Antibiotic therapy and gentle chest physiotherapy may be helpful.

### Long term neurological sequelae (p. 239)

There is recent evidence that modern neonatal intensive care has not only reduced neonatal mortality very considerably, but has also improved the

quality of survival. A major contributing factor is the improved understanding of the pathogenesis of RDS as well as improved methods of prevention and treatment. For babies of > 30 weeks' gestation, ventilatory techniques are now well standardized and technical difficulties are minimal. Babies in whom RDS is the primary indication for mechanical ventilation are unlikely to develop permanent brain injury unless there is severe asphyxia or extensive IVH. The introduction of surfactant therapy after 1988 was largely responsible for the sharp reduction in the RDS-specific infant mortality rate from 2 per 1000 births in 1970 to 0.4 per 1000 in 1995.<sup>547</sup>

### TRANSIENT TACHYPNEA OF THE NEWBORN

First described in 1966,<sup>548</sup> transient tachypnea of the newborn occurs in both term and preterm babies, affecting about 1% of all births.<sup>511</sup> The risk is increased after Cesarean section to about 4% but the timing of elective Cesarean section is important, with the risk markedly decreasing between 37 and 40 weeks' gestation.<sup>549</sup>

#### Etiology and pathogenesis

Transient tachypnea of the newborn (TTN) has been attributed to delayed resorption of fetal lung fluid, and predisposing factors include elective Cesarean section, perinatal asphyxia, excessive maternal analgesia, maternal diabetes, hypothermia and male gender. Many of these factors are associated with increased production or decreased resorption of lung fluid.<sup>550</sup> Catecholamine levels after elective Cesarean section are lower than those following vaginal delivery with the result that fetal lung fluid production continues after birth. Mild left ventricular dysfunction is also found in echocardiographic studies of babies with TTN.<sup>551</sup> More severe TTN may present clinically as persistent pulmonary hypertension.<sup>552</sup>

#### Clinical presentation

Most affected babies are either term or near term infants; there is a male preponderance of 3:1. Tachypnea is apparent from about 1 h after birth, with respiratory rates of up to 120/min. Subcostal recession, grunting and cyanosis may be present but are not prominent features. Affected babies have barrel chests with increased anteroposterior diameter. Babies with a picture of persistent fetal circulation are uncommon, but present with marked cyanosis and often need mechanical ventilation.

#### Diagnosis

The chest radiograph shows hyperinflated lung fields, perihilar opacities, increased vascular markings, fluid in the transverse fissure and small pleural effusions (Fig. 12.19). Two important differential diag-

Fig. 12.19 Radiograph of TTN with overinflated lungs, fluid in the right costophrenic angle and horizontal fissure. The skinfold line seen at the right base may be mistaken for a pneumothorax.

noses should be considered in atypical infants. Early onset group B streptococcal (GBS) sepsis can mimic TTN initially but if unrecognized and untreated will be fatal. Blood culture, full blood picture and measurement of inflammatory markers will help to make this diagnosis. Some forms of congenital heart disease, for example anomalous pulmonary venous drainage, can also mimic TTN. Chest radiograph and echocardiography are helpful if a cardiac anomaly is suspected.

#### Management

Oxygen is often needed for 2 or 3 days but respiratory failure is uncommon unless a pulmonary air leak or pulmonary hypertension occurs. Pulse oximetry is used to monitor the oxygen needs. Only rarely are oxygen concentrations above 40% necessary. Penicillin should be given until GBS sepsis has been excluded. Diuretics do not alter the clinical course of TTN.<sup>553</sup>

#### Outcome

Most infants recover within 2–3 days. A few develop pneumothoraces and a few may need mechanical ventilation. The mortality rate should approach zero and survivors should have normal neurodevelopment. Recent studies have reported an association between TTN and the subsequent development of childhood asthma.<sup>554</sup>

### PNEUMONIA

Pneumonia is probably the most common serious infection of the newborn. It may be either congenital or acquired, although intrapartum infection can occur and may not fit easily into either category (Table 12.47).

#### Incidence

Preterm babies are more at risk for at least three reasons. First, chorioamnionitis is a common stimulus for preterm labor;<sup>555</sup> second, preterm babies have problems with host defense mechanisms; third, they are more likely to need intensive care and thus be exposed to risks of acquired infections. Early onset pneumonia has been estimated to occur in 1.79 per 1000 live births.<sup>556</sup> Pneumonia complicates endotracheal intubation for mechanical ventilation of very low birth weight babies in about 30% of cases.<sup>557</sup>

#### Pathogenesis

Pneumonia acquired congenitally or intrapartum usually presents within the first 4–6 h of life. Nosocomial infections are of later onset although colonization with organisms acquired during birth can lead to subsequent infection occurring after 7 days. This may occur in late onset GBS infections.

Transplacentally acquired pneumonia may be due to viruses (CMV, coxsackie, herpes simplex and rubella), bacteria (*Listeria monocytogenes*, coliforms, pneumococci and streptococci) or toxoplasmosis. The ascending route of infection is most important in early onset infection and organisms found in the maternal genital tract and in the baby's lungs are very similar. Prolonged rupture of the membranes, maternal GBS colonization and prematurity significantly increase risk of ascending infection with chorioamnionitis and pneumonia.<sup>558</sup> Ascending infection can also occur through intact membranes and cause illness or perinatal death.<sup>559</sup> Organisms involved in ascending infection are coliforms, streptococci, *Haemophilus influenzae*, pneumococci, staphylococci and herpes simplex virus.

Table 12.47 Pathogenesis of neonatal pneumonia

Congenital (transplacental acquisition)	
Intrapartum	
a. Ascending infection and chorioamnionitis	
b. Aspiration of infected secretions at delivery	
Acquired	
Nosocomial – often during mechanical ventilation or late infection after colonization at birth	

Intrapartum aspiration of infected secretions can cause infection with *L. monocytogenes*, streptococci, herpes simplex and varicella. Nosocomial or environmentally acquired infection can be transmitted by hospital staff, usually from poor handwashing. Organisms involved are usually staphylococci, streptococci and RSV. Sometimes infection is acquired from nursery equipment and the organisms involved are pseudomonas, serratia, klebsiella and listeria. Late onset infection may also be due to delayed invasion of organisms acquired at birth. This typically occurs with certain serotypes of streptococci and listeria and is probably not preventable by prophylactic antibiotic use.

### Early onset pneumonia

#### Clinical features

Intrapartum stillbirth may occur, although often the baby is born alive but appears septicemic and needs resuscitation. The onset of respiratory signs may be more gradual with a clinical picture very similar to that of RDS (Table 12.41). Helpful distinguishing features include temperature instability, hypotension, apneic spells and acidosis. Sometimes a skin rash or hepatosplenomegaly (listeriosis) will be present or the baby may be malodorous (coliforms or bacteroides). The severity of respiratory distress is variable and some babies may have profound shock and metabolic upsets with right to left shunting and a clinical course resembling severe persistent fetal circulation whereas others have respiratory signs such as tachypnea.

A chest radiograph is necessary to exclude other causes of respiratory distress. With transplacentally acquired infection there are diffuse, interstitial opacities giving a ground glass, reticular pattern which may be indistinguishable from RDS or there may be extensive consolidation (Fig. 12.20). With ascending infection there may be alveolar involvement which produces bilateral coarse opacities which are much less uniform (Fig. 12.21). Air bronchograms may also be seen, especially if the opacities become confluent.

Pneumonia acquired following aspiration is usually less evenly distributed on chest radiograph and may show as segmental or lobar collapse (Fig. 12.22).

#### Diagnosis

Clinical diagnosis is confirmed by culturing organisms from tracheal fluid or blood along with typical changes on chest radiograph. There is not time to wait for culture results before starting treatment, and hematological (white cell and platelet counts) and biochemical (C-reactive protein) tests are not sensitive enough to be relied upon if negative. If in doubt, it is best to start antibiotics after cultures have

Fig. 12.20 Radiograph of congenital listeriosis showing extensive consolidation in both midzones but more marked on the right. An arterial catheter is seen with its tip at T7 and T8.

Fig. 12.21 Radiograph of intrauterine pneumonia from ascending infection showing patchy bronchopneumonic consolidation.

Fig. 12.22 Chest radiograph showing aspiration pneumonia with collapse and consolidation in right upper lobe.

been taken. If tracheal aspirate can be obtained and examined within 8 h of birth there is a good correlation between organisms seen and those subsequently cultured.

#### Differential diagnosis

This includes RDS, TTN and meconium aspiration syndrome in addition to causes of severe asphyxia at birth including pulmonary hypoplasia. Often these conditions coexist and all babies with respiratory distress should be assumed to have GBS infection until proven otherwise. Severe pneumonia may also be difficult to distinguish from cyanotic heart disease and persistent fetal circulation.

#### Management

**Prevention.** Early onset GBS infection can be predicted from maternal risk factors such as prolonged rupture of the membranes, colonization of the genital tract, spontaneous preterm labor and maternal pyrexia in labor. In women with these risk factors who are colonized with GBS and who are treated with

intravenous penicillin in large doses during labor there is a significant reduction in neonatal infection.<sup>560</sup> Penicillin may also be effective in pregnancies complicated by infection with listeria, haemophilus and pneumococci but other Gram negative organisms and anaerobes will not usually be sensitive. A combination of ampicillin and metronidazole improves the spectrum of cover in these high risk cases. Maternal erythromycin improves neonatal outcome when there is preterm prelabor rupture of the membranes.<sup>561</sup>

**Treatment.** Babies born to mothers with the risk factors mentioned above should have cultures taken and be given antibiotic prophylaxis. There is no evidence that routine penicillin prophylaxis for all preterm babies is effective and this approach might increase risk of Gram negative infections. Routine monitoring of respiratory rate for 24 h on the postnatal ward is effective in shortening the time to diagnosis and treatment of the occasional late-presenting case.<sup>562</sup>

For symptomatic infants with respiratory distress, penicillin therapy should be started after appropriate cultures have been taken; the antibiotic can be stopped after 48 h if cultures are negative and the baby's condition improved or a clear diagnosis of non-infective illness has been made. If infection is strongly suspected, cultures become positive or the infant deteriorates, an aminoglycoside such as gentamicin should be added to the antibiotic regimen.

Treatment of the ill baby requires good resuscitation, stabilization and respiratory support, in addition to antibiotics given after cultures have been taken. Blood or plasma transfusion, inotropic drugs and correction of acidosis are all important. Penicillin or ampicillin and gentamicin or amikacin in combination provide the best cover for early onset pneumonia. Cefotaxime has also been advocated because of increased Gram negative cover and better penetration into lung tissue, although with cephalosporins there is an associated increased risk of fungal sepsis.<sup>563</sup>

Surfactant treatment may be helpful to treat respiratory failure from surfactant inactivation in streptococcal pneumonia but it is less effective than in infants with RDS.<sup>564</sup> The role of intravenous immunoglobulin therapy in neonatal pneumonia remains to be determined.<sup>565</sup>

### Late onset pneumonia

This may be associated with mechanical ventilation, aspiration or bacteremia or occur secondary to late invasion with an organism acquired during birth, e.g. GBS or *L. monocytogenes*. Occasionally unusual organisms such as chlamydia, candida, CMV, herpes simplex, RSV or mycoplasma are implicated although staphylococci and coliforms are much more commonly found.

### Clinical features

Late onset pneumonia occurs after 24 h and presents with signs of respiratory distress although preterm babies may develop apnea. There may be systemic signs with pyrexia in term and hypothermia in preterm babies. Bacteremia and meningitis may coexist.

A chest radiograph is necessary for diagnosis, and culture of blood, tracheal aspirate and CSF should be performed. The differential diagnosis includes PDA and heart failure, aspiration pneumonia, early chronic lung disease or an inborn error of metabolism.

### Management

General supportive measures, antibiotics and perhaps gentle chest physiotherapy form the basis of management. Antibiotic selection must cover staphylococci and Gram negative organisms and, if meningitis is suspected, be capable of penetrating the CSF. A combination of flucloxacillin and amikacin or one of the third generation cephalosporins, e.g. cefotaxime, is usually satisfactory. For pseudomonas infections cef-tazidime is used and some staphylococcal infections respond only to vancomycin or teicoplanin.

### Outcome

Early onset pneumonia has a high mortality of about 50%, especially when due to GBS which often affects very immature babies who have septicemia with pneumonia. Late onset pneumonia has a mortality rate of less than 15% despite its association with bacteremia and meningitis.

## MECONIUM ASPIRATION SYNDROME

This is a serious and potentially preventable condition occurring usually in term and post-term babies.

### Incidence

Meconium staining of the amniotic fluid is found in about 9% of deliveries at term, however in resource rich countries the incidence of meconium aspiration requiring intubation and mechanical ventilation is low (0.43 per 1000 births).<sup>566</sup> The incidence may be falling because of increased induction of labor in prolonged pregnancy beyond 41 weeks and better monitoring for signs of fetal distress in labor.<sup>567</sup>

### Etiology and pathogenesis

In the term or post-term infant asphyxia prior to birth stimulates intestinal peristalsis and relaxation of the anal sphincter. Meconium passage is most likely to occur in the post-term baby, the term baby after asphyxia or the baby with IUGR. It rarely happens in the preterm baby of < 34 weeks' gestation and if it does one should consider an alternative cause such as congenital infection, especially that due to listeriosis<sup>568</sup> or GBS. Once meconium reaches the major airways, respiration after birth ensures distal migration into the smaller airways. This may lead to obstruction with air trapping and atelectasis with pneumothorax occurring in 5–10% of cases.<sup>566</sup>

Other factors producing lung disease are chemical pneumonitis and secondary bacterial infection. Progression to persistent pulmonary hypertension occurs in about 20% of cases, particularly those with asphyxial insult or pneumothoraces.<sup>569</sup>

### Clinical features

Affected babies are usually post-term or growth retarded. There may be meconium staining of the skin, umbilical cord and nails. The baby may present with respiratory distress from birth but respiratory signs may gradually develop over 12 h with tachypnea, cyanosis, indrawing and a hyperinflated chest. There may be profound hypoxemia although hypercarbia is less common. Metabolic acidosis and hypoglycemia are common and postasphyxial signs may be found in the central nervous system, kidneys and heart.

### Diagnosis

Diagnosis is made on the basis of meconium-stained amniotic fluid, presence of meconium in the trachea and radiological changes. On chest radiograph there is overinflation of the lungs with widespread coarse, fluffy opacities (Fig. 12.23). Sometimes the appearances are confined to

Fig. 12.23 Radiograph of meconium aspiration syndrome with overinflated lungs, depressed diaphragm and coarse modular opacities alternating with areas of focal overinflation.

the right lung or right upper lobe. Pneumothorax, pneumomediastinum and cardiomegaly may be present. Radiological clearing is usually slow over 10 days but in some babies the meconium disappears within 2–3 days possibly by ciliary action, phagocytosis or enzymatic lysis.

## Management

This comprises prevention by intervention in pregnancy, labor or at birth and the treatment of established aspiration.

### Prevention

Meconium aspiration syndrome should be largely preventable by careful antenatal monitoring, rapid delivery for fetal distress and rapid resuscitation with tracheal suctioning at birth if indicated. A pediatrician skilled at neonatal resuscitation should attend all deliveries complicated by meconium staining of the amniotic fluid. Suctioning of the mouth and nose after delivery of the head but before delivery of the shoulders was previously advocated, however a large randomized trial showed that this technique had no impact on the incidence of meconium aspiration.<sup>570</sup> Meconium aspiration often occurs before birth. Intubation of all meconium-stained babies and careful tracheal toilet has been advocated to prevent aspiration, however randomized trials have shown no benefit of routine endotracheal intubation in babies who are vigorous at birth.<sup>571</sup> Intubation should be reserved for babies with signs of respiratory depression and asphyxia. Tracheal aspiration using a wide bore suction catheter or an endotracheal tube adapter should be repeated until the trachea is cleared. Saline washouts should be avoided as this may liquefy the meconium allowing it to pass distally. Positive pressure ventilation should be postponed if possible until tracheal aspiration has been completed.

### Treatment

All babies with meconium below the vocal cords should be admitted to the neonatal unit for observation and further management. All symptomatic babies should have a chest radiograph performed and oxygen supplementation as indicated by blood gas analyses and pulse oximetry. Babies with mild disease may need only humidified oxygen in a head-box. Gentle chest physiotherapy and postural drainage may be helpful. Broad spectrum antibiotics should be given to treat any coexistent pneumonia or congenital sepsis. There is no benefit from hydrocortisone and it may even delay recovery. Surfactant bolus treatment may hasten recovery but larger (150 mg/kg) and more frequent (6-hourly) doses are required,<sup>572</sup> presumably to overcome inactivation of surfactant by meconium. Dilute surfactant lavage may also help to remove particulate material from the airways<sup>573</sup> but this cannot be recommended as a routine treatment.

Severely asphyxiated babies with meconium aspiration often have multisystem involvement and require careful management. Mechanical ventilation may be indicated to treat respiratory failure and severe hypoxemia. Rapid ventilator rates with low PEEP are advised because of risk of pneumothorax and cardiovascular side-effects. Muscle relaxation or sedation with morphine or fentanyl is often necessary. If hypoxemia due to right to left shunting persists the PEEP may be increased up to 6 cmH<sub>2</sub>O or higher and use of inhaled nitric oxide might reduce ventilation–perfusion mismatching and obviate the need for ECMO.

### Outcome

Infants with mild disease who do not require assisted ventilation recover within a few days. Recent reports suggest mortality rates of about 2.5%.<sup>566</sup> Both mortality and long term neurodevelopmental sequelae are related to the severity of the underlying perinatal asphyxia. There is an increased risk of asthma among survivors of meconium aspiration syndrome compared with the general childhood population.<sup>574</sup>

## OTHER ASPIRATION PNEUMONIAS

Aspiration may occur before, during or after birth. Apart from meconium the substances aspirated may be amniotic fluid, blood, secretions or milk.

## Incidence

This is unknown but early contrast radiography studies showed that 10–15% of newborn babies aspirate fluid into their lungs during the first few days after birth. The incidence of milk aspiration in preterm babies probably has substantially decreased with introduction of more cautious feeding regimens for preterm babies. Ventilated preterm babies probably aspirate secretions quite frequently; one study suggested that this occurred in as many as 80% of such babies.<sup>546</sup>

## Etiology

Aspiration can occur before birth and amniotic debris including squamous cells has been found in lungs of stillborn babies. Aspiration of small amounts of fetal and maternal blood does not appear to cause major problems and they are rapidly removed from the lungs. If purulent secretions are aspirated during birth there is increased risk of subsequent bacterial pneumonia. Aspiration of milk may occur in the very preterm infant, those with swallowing disorders, and those with esophageal atresia and tracheoesophageal fistula. Before 34 weeks, sucking and swallowing are uncoordinated and most babies need gastric tube feeds. Aspiration of liquids may cause apnea as part of a protective laryngeal reflex.

## Clinical features

Aspiration before or during birth may cause signs of asphyxia and immediate respiratory distress in the same way as meconium aspiration syndrome. Aspiration after birth presents with apneic or cyanotic attacks and there may be choking or signs of airway obstruction. After such an episode there may be tachypnea and indrawing.

Apart from immaturity, babies at risk of aspiration are those who have suffered asphyxia or those with neuromuscular disorders such as congenital myotonic dystrophy. If there are recurrent episodes of aspiration, an underlying disorder such as H-type tracheoesophageal fistula or posterior laryngeal cleft should be excluded. In supine infants aspiration is most likely to occur into the right upper lobe and crepitations may be heard there. Occasionally there may be complete collapse of a lobe with mediastinal shift.

## Diagnosis

The chest radiograph may be clear or show localized or diffuse opacities and areas of atelectasis. These changes are most frequently seen in the right upper lobe (Fig. 12.22). Tracheal aspirate may show fat-laden macrophages in babies who have aspirated milk. If gastroesophageal reflux is suspected a contrast swallow may be necessary. Esophageal pH studies are of limited value in the newborn period.<sup>575</sup> Videofluoroscopy may demonstrate aspiration of secretions or milk even in the absence of reflux.<sup>576</sup>

## Management

Direct laryngoscopy and careful suction of the airways should be performed to resuscitate babies who have aspirated. Supportive care includes oxygen to correct hypoxemia, intravenous fluids and the treatment of acidosis. Broad spectrum antibiotics should be given if the aspiration is large or the secretions aspirated appear to be infected. Careful nursing is important; gastric emptying is most rapid with the baby lying either prone or on the right side.

## PULMONARY AIR LEAKS

These comprise pneumothorax, pulmonary interstitial emphysema, pneumomediastinum, pneumopericardium, pneumoperitoneum, subcutaneous emphysema and air embolism.

## Etiology and pathogenesis

Alveolar rupture occurs more commonly in the neonate than at any other time of life. It is more likely to occur in states of hyperinflation of the chest and risk is increased because of lack of pores of Kohn which are communications between alveoli.

Air leak occurs at the base of a group of alveoli and tracks into the perivascular sheath at the center of the pulmonary lobule. Air later tracks along the bronchovascular spaces to the hilum where it dissects into the mediastinum and pleural space. Air may also form subpleural blebs which can later rupture to cause a pneumothorax. Extension of air into subcutaneous tissues of the neck will cause surgical emphysema, and down along perivascular or periesophageal tissue sheaths to form a pneumoperitoneum. A pneumothorax may result from high transpulmonary pressures generated by the first breath but it more usually arises later because of some underlying lung pathology such as RDS, aspiration syndromes or pulmonary hypoplasia with associated need for positive pressure ventilation. Traumatic pneumothorax may occur from perforation of the lung by a suction catheter or a chest drain. Although the more mature lung ruptures at lower transpulmonary pressures than the immature lung, pneumothorax is more common in the preterm baby who is more likely to have respiratory distress.

### Pneumothorax

This is accumulation of air within the pleural cavity and usually occurs following a pneumomediastinum, although the latter may not be obvious clinically or radiologically.

#### Incidence

About 1% of term babies have an asymptomatic pneumothorax. Symptomatic pneumothorax is less common occurring in about 1 in 1000 live births. Prior to surfactant therapy mild RDS had an incidence of pneumothorax of about 5% increasing to 10–20% with continuous positive airway pressure and to 20–40% with positive pressure ventilation. However, since introduction of surfactant therapy the incidence of pneumothorax has fallen to about 5% overall. Up to 10% of babies with meconium aspiration syndrome develop pneumothoraces.<sup>566</sup>

#### Clinical presentation

Most babies with spontaneously occurring pneumothoraces who have no underlying lung pathology have minimal signs of respiratory distress and the pneumothorax is seen as an incidental finding on a chest radiograph taken for another reason. Most significant pneumothoraces occur in babies with underlying pulmonary disease and the diagnosis should be suspected in any such baby whose condition suddenly deteriorates. If the baby is breathing spontaneously, tachypnea, grunting and cyanosis are often the presenting signs. In a unilateral pneumothorax there may be shift of the mediastinum (apex beat) away from the side of the pneumothorax and breath sounds may be reduced on the affected side. The affected hemithorax or the abdomen may appear distended because of increased tension within the pleural space. There may be hyperresonance to percussion on the affected side and hypotension may occur because of venous compression and reduced cardiac output. With a small pneumothorax there may be an increase in cardiac output, heart rate and blood pressure so that continuous monitoring of blood pressure can help make the diagnosis.<sup>577</sup>

In about 10% of cases pneumothoraces will be bilateral and this causes a major hemodynamic upset which for the very preterm baby may prove fatal.<sup>578</sup> In survivors there is an increased likelihood of IVH and adverse neurodevelopmental outcome.<sup>579</sup>

#### Diagnosis

The chest radiograph confirms the diagnosis. Anteroposterior (AP) (Fig. 12.24) and lateral views should be taken.<sup>580</sup> The lateral will show air in the anterior mediastinum and the thymus may be lifted up, which may also be evident on the AP film (Fig. 12.25). If the pneumothorax is extensive there will be collapse of the lung and mediastinal shift away from the affected side (Fig. 12.24). For the baby who deteriorates suddenly, there may not be time to wait for a chest radiograph, and two alternative methods of confirming the diagnosis of pneumothorax can be used. For the baby in extremis diagnostic pleural aspiration using a needle, syringe and three-way tap can be performed without delay. The second or third intercostal space in the mid-clavicular line should be used for this procedure

Fig. 12.24 Radiograph of a right tension pneumothorax with depression of the diaphragm and shift of the mediastinum to the left. There is also mediastinal herniation.

Fig. 12.25 Radiograph showing bilateral pneumothoraces and a large pneumomediastinum with elevation of the lobes of the thymus clear of the cardiac shadow (the sail sign). The endotracheal tube is shown with its tip in the right mainstem bronchus.

which is both diagnostic and therapeutic. Transillumination of the chest with a fiberoptic bright light can be used to rapidly diagnose large pneumothoraces in less severely ill babies. This technique is less useful for diagnosing small pneumothoraces or those occurring in term babies.

#### Treatment

No treatment is necessary if the infant is asymptomatic. Increasing inspired oxygen levels has been shown to speed the resolution of pneumothoraces in animal studies,<sup>581</sup> but the benefits of this versus the risks of hyperoxia have not been evaluated in human newborns. The only satisfactory treatment of a tension pneumothorax is drainage, usually by insertion of a pleural catheter connected to a nonreturn valve such as an underwater seal drain. The catheter should be large bore and placed in the anterior mediastinal space with care to avoid perforation of the lung. Local anesthetic should be used before making a small skin incision and careful dissection of the intercostal muscle. Use of an artery forceps will prevent overpenetration of the trocar into the chest. Continuous suction of 10–20 cmH<sub>2</sub>O may occasionally be needed to prevent reaccumulation of the pneumothorax. Simple needle aspiration may be successful and avoid the need for insertion of a chest drain, especially when the pneumothorax is not under great tension.

Careful fluid balance should be observed as increased vasopressin secretion, leading to fluid retention, may occur after a pneumothorax although this is not common.<sup>582</sup> Fibrin glue pleurodesis has been used to treat persistent pneumothorax.<sup>583</sup>

### Prevention

Timely use of prophylactic and rescue natural surfactant results in dramatic reduction in the incidence of pneumothorax.<sup>513-517</sup> Air leaks may also be reduced by muscle relaxation for babies with asynchronous breathing on mechanical ventilation,<sup>584</sup> however there are concerns about using paralysis over prolonged periods.<sup>585</sup> Faster mechanical ventilator rates with short inspiratory time are protective.<sup>532</sup> Modern ventilation methods with targeted tidal volumes also reduce rates of pneumothoraces.<sup>541</sup>

### Prognosis

Pneumothorax is associated with increased morbidity and mortality depending upon the nature of the underlying lung disease and gestational age of the baby. Both mortality rate and IVH rate are approximately doubled following pneumothorax.

### Pulmonary interstitial emphysema

This is the presence of air in the interstitium or perivascular tissues of the lung and it is probably a prerequisite of all other forms of air leak.

### Incidence

The true incidence of pulmonary interstitial emphysema (PIE) is uncertain but it has been described in about 10% of neonatal autopsies. The incidence in control groups of the randomized surfactant trials varied from 25 to 50%. With introduction of surfactant therapy, widespread use of CPAP and more gentle forms of assisted ventilation the incidence of PIE is now much lower than this.

### Pathogenesis

After alveolar rupture, air escapes into the pulmonary interstitium to form regular air-filled cysts varying from 0.1 to 1.0 cm in diameter. These are localized to the interlobular septa and extend radially from the hila of each lung to form a diffuse or a localized pattern. Lung function is impaired by compression of normal lung tissue, decreased compliance and obstruction of pulmonary blood flow. PIE is associated with raised leukocyte elastase levels in tracheal aspirates suggesting that intrauterine infection or prior lung injury may predispose.<sup>586</sup>

### Clinical presentation

When PIE is localized it may be asymptomatic or the baby may gradually deteriorate. If it becomes diffuse there is progressive hypoxemia and ventilation-perfusion imbalance necessitating an increase in ventilator settings. There is usually decreased chest wall movement with hyperinflation of the chest and muffling of the heart sounds.

### Diagnosis

Chest radiograph may show areas of translucency and collapse scattered throughout the lung fields rather like a snowstorm, also described as 'lacy lungs' (Fig. 12.26). If the changes are localized to one lung there may be marked overinflation and shift of the mediastinum as in a tension pneumothorax. Pseudocysts may form within the pulmonary parenchyma beneath the visceral pleura or along fissure lines.

### Treatment

For diffuse PIE, fast rate mechanical ventilation using low pressures has been advocated. Permissive hypercapnia is used to minimize ventilator pressures, and maintaining pH levels above 7.20 is acceptable. More aggressive treatment has been used to manage severe unilateral forms of PIE and includes selective intubation of the normal lung to allow the emphysematous lung to collapse,<sup>587</sup> selective bronchial obstruction of the affected side, artificial creation of a pneumothorax by probing<sup>588</sup> or percutaneous drainage of large pneumatoceles.<sup>589</sup> HFOV has been advocated as a method of treating PIE<sup>590</sup> but there have been no randomized trials.

Fig. 12.26 Radiograph showing bilateral diffuse pulmonary interstitial emphysema with marked overinflation of the chest, lowered diaphragm and narrowed heart shadow.

### Prognosis

Severe diffuse PIE occurring soon after birth has a very high mortality rate. For babies weighing less than 1000 g, the mortality of 67% is more than twice that of babies without PIE.<sup>591</sup> Complications such as pneumothorax and IVH are common and affected babies need prolonged ventilator support with most survivors developing BPD.

### Pneumomediastinum

#### Incidence

Pneumomediastinum probably occurs prior to all cases of pneumothorax but it often goes unrecognized.

#### Clinical presentation

Pneumomediastinum may occur with other air leaks or in isolation, when it is asymptomatic in over 90% of cases, being noticed incidentally on a routine chest radiograph. If there are symptoms the baby may have tachypnea, cyanosis and an overinflated chest which is hyper-resonant to percussion. Occasionally a large pneumomediastinum causes severe symptoms by compressing the heart and lungs.

#### Diagnosis

This is confirmed by chest radiograph. The lateral view is most helpful to demonstrate air lying anteriorly. The thymus may be lifted off the mediastinum in the anteroposterior view giving rise to the 'sail sign' or 'spinnaker sign' (Fig. 12.25).

#### Treatment

In pneumomediastinum the air is loculated so that drainage is impracticable. The rate of absorption can be accelerated by breathing higher oxygen concentrations, but this should rarely be needed and only used in term babies.

### Pneumopericardium

This occurs in about 1.6% of babies with RDS.<sup>578</sup>

#### Clinical presentation

Pneumopericardium is occasionally asymptomatic but more usually presents with pallor, shock and hypotension due to cardiac tamponade. In most cases it is associated with other forms of air leak.

#### Diagnosis

Chest radiograph shows a complete ring of air around the heart. The transverse diameter of the heart is reduced if tamponade is present and

substernal transillumination may be used to make a rapid diagnosis in the baby who suddenly deteriorates during mechanical ventilation.

### Treatment

The only effective treatment for pneumopericardium with tamponade is immediate drainage of air from the pericardial sac using a needle and syringe directed anteriorly and superiorly from below the xiphisternum. Recurrence of tamponade is common and permanent drainage is often needed.

### Prognosis

The mortality is high despite early drainage with more than half of affected babies dying.

## Pneumoperitoneum

Air in the peritoneal cavity may result from a pulmonary air leak or a ruptured abdominal viscus.

### Incidence

Incidence of pneumoperitoneum as a complication of mechanical ventilation is about 2%.<sup>578</sup>

### Clinical presentation

Pneumoperitoneum may be asymptomatic or present as abdominal distention. There are usually other signs of air leak (Fig. 12.27).

### Treatment

Aspiration is only necessary if abdominal distention is severe enough to compromise ventilation.

## Subcutaneous emphysema

This is rare in the neonate and when it does occur it is usually associated with pneumomediastinum. Air from the superior mediastinum passes along the perivascular fascia to the subclavicular area before spreading subcutaneously. Apart from swelling and a typically crackling feel to the affected skin there are few other signs and the air usually absorbs in a few days.

Fig. 12.27 Radiograph showing a large pneumoperitoneum with the liver clearly outlined by the air in the peritoneal cavity. The lungs appear collapsed and airless.

## Air embolism (pneumatosis arterialis)

This is an uncommon and almost universally fatal condition which may present as air being withdrawn from an umbilical arterial catheter in an infant who has collapsed.<sup>592</sup> Air embolism results from rupture of pulmonary veins associated with raised intra-alveolar pressure during mechanical ventilation of very preterm babies. Affected babies have other forms of air leak and deteriorate acutely with pallor, bradycardia and hypotension. Chest and abdominal radiographs show gas shadows in the heart chambers and major arteries. There is no effective treatment and massive air embolism is usually fatal. The introduction of surfactant therapy and gentler forms of assisted ventilation has greatly reduced the risk of this serious condition.

## PULMONARY HEMORRHAGE

Sometimes called massive pulmonary hemorrhage, this poorly understood condition has a sudden onset and a high mortality.

### Incidence

Isolated pulmonary hemorrhage is a rare condition occurring in approximately 1/1000 live births. Between 2 and 5% of babies with RDS develop pulmonary hemorrhage.<sup>593</sup>

### Etiology and pathogenesis

Pulmonary hemorrhage can occur in SGA babies with no underlying lung disease but more usually there has been a history of severe perinatal asphyxia, hypothermia, rhesus isoimmunization, pneumonia, hypoglycemia, coagulation disorder or fluid overload, particularly when a PDA is present.<sup>594</sup> Pulmonary hemorrhage is probably a form of hemorrhagic pulmonary edema as the hemorrhagic fluid usually has a hematocrit of less than 10%. Pulmonary hemorrhage may be secondary to aspiration, hypoproteinemia and lung tissue damage from pneumonia, RDS, oxygen toxicity or mechanical ventilation. There is an association with surfactant treatment, especially in the very immature infant treated with synthetic surfactant.<sup>593,595</sup>

### Clinical presentation

The onset is frequently between the second and fourth day after birth when an infant with improving respiratory distress suddenly deteriorates with shock, cyanosis, bradycardia and apnea. Pink or red frothy fluid is aspirated from the mouth and lungs and urgent resuscitation is needed to prevent death. In ventilated babies, blood-stained fluid appears in the endotracheal tube during suctioning. Auscultation reveals widespread crepitations.

### Diagnosis

Chest radiograph shows large areas of consolidation with diffuse opacification. In massive pulmonary hemorrhage the lungs may appear completely white and there may be cardiomegaly. Sometimes the diagnosis is only confirmed at autopsy when widespread intra-alveolar and interstitial hemorrhage is found.<sup>596</sup>

### Treatment

Immediate resuscitation of the collapsed baby is important with endotracheal intubation for mechanical ventilation and cautious volume expansion with blood or plasma. High PEEP may help to reduce bleeding by tamponade, and a diuretic such as furosemide may reduce pulmonary edema. If the ductus arteriosus is widely patent indometacin or ibuprofen should be administered intravenously. Correction of acidosis and underlying coagulation disorder is beneficial and antibiotics should be given if infection is suspected. Repeated doses of surfactant may be beneficial.<sup>597</sup>

### Prognosis

Until recently massive pulmonary hemorrhage was invariably fatal but prompt use of mechanical ventilation with PEEP has improved the outlook. Pulmonary hemorrhage is associated with a four-fold increased

risk of CLD, seven-fold risk of death and three-fold risk of major IVH.<sup>598</sup> In survivors there is no apparent increase in long term morbidity at 2 year follow-up.

### Prevention

Prevention is most important because of the poor outlook once major pulmonary hemorrhage has occurred. Asphyxia, hypothermia, hypoglycemia and acidosis should be avoided in SGA babies. Coagulation defects should be corrected early and large PDAs should be treated with indometacin or ibuprofen.

## DEVELOPMENTAL ANOMALIES OF THE LUNG

### Pulmonary hypoplasia

In this condition, which is frequently bilateral, the lungs are smaller than normal. Unilateral hypoplasia may be primary but is more often associated with other congenital malformations such as diaphragmatic hernia.

### Incidence

Pulmonary hypoplasia is found in 15–20% of early neonatal deaths and is now the commonest single abnormality at autopsy.<sup>599</sup> Milder cases survive and are probably underdiagnosed.

### Etiology and pathogenesis

Pulmonary hypoplasia occurs as a primary lesion in about 10% of cases but is most often associated with other malformations that restrict lung growth (Table 12.48). Pulmonary hypoplasia, as a result of oligohydramnios, is caused by the combined effects of reduced lung fluid volume and impaired fetal breathing movements.

### Clinical presentation

Diagnosis may be suspected prenatally if there has been prolonged rupture of the membranes, especially if this occurs before 24 weeks or an ultrasound scan has demonstrated congenital diaphragmatic hernia or a chondrodystrophy. Babies with pulmonary hypoplasia may present at birth with signs of asphyxia and difficulties in resuscitation. Some have Potter syndrome and do not survive; pneumothoraces readily develop during resuscitation. With less severe degrees of hypoplasia the presentation is less acute with mild but prolonged respiratory distress and oxygen dependency. Congenital diaphragmatic hernia must be excluded by chest radiograph (Fig. 12.28). Such a hernia is usually left-sided, in 80% of cases occurring through the foramen of Bochdalek and there is displacement of the mediastinum to the right by stomach and bowel. About 25% of cases have associated congenital heart lesions which increase mortality.

### Diagnosis

In life it is difficult to confirm the diagnosis unless an associated abnormality such as Potter syndrome, diaphragmatic hernia, Jeune syndrome or prolonged oligohydramnios is present. Sometimes chest radiograph shows small lungs with a bell-shaped thorax. At autopsy lung: body weight ratio may be helpful and ratios of <0.012 for babies over 28 weeks' gestation and <0.015 for lower gestations are used to define pulmonary hypoplasia.<sup>600</sup> Strict confirmation of the diagnosis requires more sophisticated autopsy analysis such as radial alveolar counts or DNA estimation.<sup>601</sup>

Table 12.48 Pathogenesis of pulmonary hypoplasia

- |    |   |
|----|---|
| 1. | Oligohydramnios: renal agenesis, urinary tract obstruction, prolonged rupture of the membranes              |
| 2. | Lung compression: diaphragmatic hernia, lung cysts, pleural effusions, erythroblastosis, chondrodystrophies |
| 3. | Absent fetal breathing movements: anencephaly, neuromuscular disorders                                      |

Fig. 12.28 Radiograph of a large left-sided diaphragmatic hernia with mediastinal shift to the right. Air in the stomach and intestine is due to resuscitation with bag and mask.

### Management

Outlook depends upon severity of respiratory signs and the associated congenital anomalies. Severe pulmonary hypoplasia occurring with oligohydramnios is usually fatal but on occasions mechanical ventilation with high pressures has been successful in 'opening up' the lungs.<sup>602</sup> Surfactant replacement therapy is often used for associated RDS but it is not clear if it makes any difference.<sup>603</sup> Inhaled nitric oxide has been shown to improve oxygenation but more studies are needed.<sup>604</sup> Babies with diaphragmatic hernia need surgical correction, but even with this, severe unilateral pulmonary hypoplasia can be associated with marked pulmonary hypertension which does not respond to mechanical ventilation or vasodilators such as inhaled nitric oxide. ECMO is less effective in treating congenital diaphragmatic hernia than other causes of respiratory failure in term infants.<sup>605</sup> For babies who survive the neonatal period, lung growth occurs and their prognosis improves.

### Congenital lobar emphysema

In this uncommon condition overinflation of one or more lobes occurs secondary to bronchial obstruction or deficiency of bronchial cartilage. The left upper lobe and the right middle lobe are most commonly affected and babies present with signs of respiratory distress and occasionally wheezing. Boys are affected twice as commonly as girls. Chest radiograph may initially show lobar opacification due to fluid trapped beyond the obstruction but later the affected lobe becomes overdistended and there may be shift of the mediastinum (Fig. 12.29). Diagnosis can also be confirmed by CT scan and lung scintigraphy showing reduced perfusion in the affected lobe. If symptoms are slight, conservative management is preferred.<sup>606</sup> For babies with persistent respiratory failure, surgical excision of the affected lobe is necessary. In about 30% of affected babies there is an associated congenital heart defect.

### Cystic adenomatoid malformation

This is a rare form of congenital cystic disease of the lung which has three pathological types<sup>607</sup> (Table 12.49). The middle or upper lobes are usually affected and the condition is unilateral. At worst polyhydramnios and hydrops can occur in utero. About 25% of babies present with respiratory distress soon after birth, the remainder are asymptomatic.<sup>608</sup> Antenatal diagnosis by ultrasound is common and in some cases the lesion seems to regress before birth. Chest radiograph shows cystic overdistention of the affected lung in about 75% of asymptomatic cases.

(a)

(b)

Fig. 12.29 (a) Congenital lobar emphysema showing retained lung fluid on the right as a result of bronchial obstruction, and displacement of the heart shadow to the left. (b) After 24 h with clearance of the lung fluid the right lung shows gross overinflation and the mediastinal displacement is more clearly demonstrated.

Table 12.49 Types of cystic adenomatoid malformation (CAM)

Type	Frequency (%)	Features
I	70	Multiple large cysts which mimic type III lobar emphysema
II	20	Medium sized cysts (12 mm in diameter)
III	10	Small cysts evenly distributed in a bulky lung

However, when ultrasound findings return to normal and neonatal chest radiograph is normal many congenital pulmonary lesions are still demonstrable on CT scanning so careful follow-up is still indicated.<sup>609</sup> Early surgical excision is required for symptomatic cases and should also be considered for asymptomatic antenatally diagnosed lesions, because of risks of later infection and the possibility of malignant transformation, although this can be deferred for some time after birth.<sup>610</sup>

### Other lung cysts

Neurenteric cysts present as a mediastinal mass on chest radiograph in association with vertebral anomalies. Gastrogenic cysts, containing gastric mucosa, may ulcerate and cause hemoptysis. Duplication cysts of the duodenum may extend through the diaphragm and, if associated with a vertebral anomaly, can cause meningitis.

### Bronchogenic cysts

These may present as episodes of wheezing or stridor. They are found near the carina but may be radiolucent on chest radiograph. If bronchial obstruction occurs there may be retained lung fluid giving rise to confluent opacity of one lung or lobe on radiography. Antenatal diagnosis by ultrasound scan is possible.

### Sequestration of the lung

This is a mass of embryonic lung tissue that does not communicate with the bronchial tree and has a systemic rather than a pulmonary arterial supply. It may be intra- or extralobar; in the latter communication with foregut and other congenital anomalies including congenital heart disease are common. Males are more commonly affected and in about three quarters of cases the sequestration is left-sided. Ultrasound can be used to make the diagnosis prenatally and hydrops fetalis may occasionally occur. Extralobar lesions are more likely to be symptomatic but abnormality on chest radiograph is the commonest presentation. A triangular density at the left lung base extending to the mediastinum gives rise to the 'scimitar sign'. Bronchoscopy, radionuclide scanning or aortography may be needed to confirm the diagnosis. In 65% of cases there are associated anomalies.<sup>611</sup> Surgery for intralobar sequestrations prevents repeated respiratory infections and may also be needed for extralobar lesions that are symptomatic.<sup>612</sup>

### Chylothorax

This is a form of pleural effusion in which chyle or lymphatic fluid appears in the pleural cavity. It is typically unilateral with 60% being right-sided and may be congenital or acquired, both being more common in males. In congenital or spontaneous chylothorax there is usually an anomaly of lymphatic drainage and chylous ascites and lymphedema are associated. Acquired chylothorax may follow birth trauma or thoracotomy. About half of affected babies present with respiratory distress soon after birth and a further one quarter have symptoms by the end of the first week. Breath sounds are reduced on the affected side and there is mediastinal shift away from this side. Chest radiography shows diffuse opacity with depressed diaphragm and mediastinal shift. A pleural tap will show clear yellow fluid soon after birth and only after feeding does the effusion appear chylous. The fluid is sterile and contains large numbers of lymphocytes and fat globules. Treatment is initially by needle thoracocentesis, although if several taps are needed a chest drain is better.<sup>613</sup> Occasionally prolonged drainage is required but there is a risk of protein and lymphocyte depletion. If reaccumulation becomes a problem, use of a milk formula containing medium chain triglycerides reduces production of chyle. Occasionally it is necessary to discontinue oral feeds and use total parenteral nutrition. Recently somatostatin analogues have successfully treated persistent chylous effusions.<sup>614</sup>

Pleural effusion can also occur in cases of hydrops fetalis, Turner syndrome, pneumonia and congestive heart failure.

### Pulmonary lymphangiectasis

In this rare condition there is bilateral cystic dilation of pulmonary lymphatics with obstruction of lymph drainage. Three types have been described: a primary isolated developmental defect accounting for 70% of cases; a generalized type which presents with widespread edema, malabsorption, hemihypertrophy and other anomalies; and a type associated with congenital heart disease and obstruction of pulmonary venous return (total anomalous pulmonary venous drainage, closure of atrial septum in hypoplastic left heart syndrome or pulmonary vein atresia).

Babies with primary lymphangiectasis are often born at term and have progressive respiratory distress which until recently was uniformly fatal.<sup>615</sup> Clinical and radiological features mimic RDS so that there is underdiagnosis of this condition. Chest radiograph may show reticulo-granular mottling with hyperaeration, and dilated lymphatics may sometimes be seen. Confirmation of the diagnosis is by lung biopsy or at autopsy.

## Choanal atresia

Obstruction to the nasal airway may be unilateral or bilateral, membranous or bony. Incidence is about 0.3 per 1000 births with girls affected twice as commonly as boys. About two thirds of cases are unilateral and in about half there are associated anomalies such as coloboma, heart defects, micrognathia and tracheoesophageal fistula. If the obstruction is bilateral, babies often present with great distress at birth, although when crying they may remain pink. Babies with unilateral choanal atresia may be asymptomatic or present later with a purulent nasal discharge. Diagnosis may be confirmed by attempting to pass a fine feeding tube or suction catheter, instilling saline into the nostril, or nasal tympanometry.<sup>616</sup> The infant with bilateral choanal atresia needs an oral airway or oral endotracheal intubation followed by a surgical procedure. A transnasal or transpalatal approach may be used to open the posterior choanae and patency is maintained by inserting silastic tubes for up to 2 months. Operative correction of unilateral choanal atresia may be postponed until the child is several years old.

## Laryngomalacia

In this condition the larynx appears soft and flexible, associated with an elongated, floppy epiglottis and loose aryepiglottic folds which tend to be drawn over the glottis during inspiration. Also known as congenital laryngeal stridor, it needs to be distinguished from other causes of stridor such as vocal cord paralysis, vascular rings, laryngeal webs and cysts and papillomata. Onset of stridor is usually on the second day but delay of up to 4 months is possible. Usually the stridor persists for less than 1 year. Diagnosis is confirmed by direct laryngoscopy which excludes most other causes of stridor. No specific treatment is required apart from reassurance of the parents although occasionally long term feeding problems and speech difficulties occur.

## CHRONIC LUNG DISEASE

BPD remains the major pulmonary complication of preterm delivery. The term BPD was coined in 1967 to describe damage to lungs from high volume mechanical ventilation,<sup>542</sup> with the typical baby being more than 30 weeks' gestation and developing cystic X-ray changes and oxygen requirement beyond 28 days of life. With improved perinatal care the pattern of BPD has changed over the years, with 'new BPD' mainly affecting ELBW babies.<sup>617</sup> The latest definitions divide babies born < 32 weeks' gestation according to severity based on duration of oxygen therapy.<sup>618</sup> Those who require oxygen for < 28 days have no BPD, > 28 days but not beyond 36 weeks' corrected gestation mild BPD, < 30% oxygen at 36 weeks moderate BPD, and > 30% oxygen or on respiratory support severe BPD. This definition correlates well with longer term respiratory and neurological outcomes.<sup>618</sup> Severe BPD is independently predictive of death or neurosensory impairment in the first 18 months of life.<sup>619</sup>

## Incidence

Advances in perinatal and neonatal medicine have reduced mortality in ELBW babies resulting in greater numbers of survivors who are at risk of BPD.<sup>620</sup> Incidence increases with decreasing gestation; about 50% of babies < 1000 g and 85% < 700 g are affected.

## Etiology and pathogenesis

Rather than BPD being caused by 'ventilator-induced injury' it is now believed that chronic inflammation is important in its pathogenesis.<sup>621</sup> It is common in small preterm babies who, although ventilator dependent for long periods, have not needed high pressures or oxygen concentrations and may occur in infants who did not need assisted ventilation,<sup>622</sup> particularly if there has been chorioamnionitis.<sup>623</sup> Factors associated with development of BPD are listed in Table 12.50. Any of these, particularly in combination, leads to a process of pulmonary inflammation resulting in abnormal lung growth and alveolarization.<sup>621</sup>

Table 12.50 Factors associated with chronic lung disease

Chorioamnionitis
Low gestation
Congenital pneumonia
Mechanical ventilation
Oxygen therapy
Acquired pulmonary infection
Pulmonary interstitial emphysema
Persistent ductus arteriosus
Fluid overload

## Pathology

In BPD there is abnormal lung growth and modeling in combination with lung injury leading to scarring and fibrosis. Pathological changes are of arrested lung development with alveolar thickening and enlargement, hypoplasia of alveolar capillary development and decreased lung septation.<sup>617</sup> This pattern occurs in combination with areas of damage shown by septal fibrosis and evidence of hypertensive vascular changes leaving reduced surface area for gas exchange.

## Clinical presentation

The usual history is of a preterm baby treated with mechanical ventilation and surfactant for RDS whose condition improves and then deteriorates between 7 and 10 days with increasing oxygen requirements. Mild cases need increased inspired oxygen concentrations for a few weeks but in severe cases there may be progressive respiratory failure with ventilator dependence and later tachypnea, indrawing, wheezing and recurrent apnea with cyanotic spells. Cor pulmonale may develop secondary to pulmonary hypertension, and these babies show hepatomegaly, increased weight gain and edema. Chest radiographs initially show generalized haziness which later can progress to hyperinflation, coarse streaking or at worst cystic changes (Fig. 12.30).

## Management

The management priority is prevention by trying to limit pulmonary inflammation. This involves limiting mechanical ventilation and oxygen therapy to the shortest possible time. Management of infection, PDA and fluid balance are also important in trying to prevent BPD. Mechanical ventilation can often be avoided by early surfactant therapy and nasal CPAP,<sup>526</sup> and units with the lowest ventilation rates have the lowest incidence of BPD.<sup>624</sup> Weaning from ventilation may be helped by allowing PaCO<sub>2</sub> levels to rise to 7–9 kPa so that peak inspiratory pressures can be lowered. Reduced fluid intake, diuretic therapy and closure of the ductus arteriosus may all assist in weaning. Caffeine has also been shown to

Fig. 12.30 Radiograph of severe CLD (formerly called BPD) with basilar emphysema, coarse stranding and cystic changes.

improve lung function and shorten duration of ventilation with associated reduction in BPD.<sup>625</sup> Dexamethasone reduces BPD in the short term allowing rapid weaning from ventilation<sup>625-627</sup> but there are concerns about both short term complications (hyperglycemia, hypertension and gastrointestinal bleeding and perforation) and long term adverse effects on the central nervous system.<sup>628</sup> Dexamethasone use should be limited to babies who are ventilator-dependent and whose condition is deteriorating. The lowest possible dose should be used for the shortest duration.<sup>629,630</sup> Inhaled steroids may also facilitate extubation but are probably not as effective as dexamethasone in reducing death or later BPD.<sup>631</sup> Adequate supplemental oxygen needs to be given to preterm babies to maintain acceptable oxygen saturation levels of about 88–94%. It is not clear however whether or not to err on the side of higher or lower saturations within this range.<sup>632</sup> Oxygen toxicity contributes to development of BPD and retinopathy of prematurity but hypoxemia increases pulmonary vascular resistance and risk of cor pulmonale with poor growth and development. Intramuscular vitamin A, an antioxidant, has been shown to modestly reduce BPD.<sup>633</sup>

Established BPD is difficult to treat. Adequate nutrition is important and supplemental calories may be given in the form of long chain glucose polymers so that fluid restriction is possible without reducing energy intake. Drugs such as diuretics, inhaled bronchodilators and inhaled steroids may be used to reduce respiratory symptoms but their effects are marginal.<sup>634</sup> Chest infections should be promptly treated with antibiotics. In later infancy RSV infections may cause acute deterioration. Regular intramuscular anti-RSV monoclonal antibody such as palivizumab reduces hospital admission rates<sup>635</sup> although there is still debate over its cost effectiveness.<sup>636</sup>

## Prognosis

Many babies with BPD require prolonged oxygen therapy, usually given via nasal cannulae. Home oxygen therapy significantly shortens time in hospital. Mortality in babies with severe BPD is about 25–30%. Surviving babies have frequent lower respiratory tract infections and often require hospital admission with persistent tachypnea, intermittent wheezing and subcostal retractions. Growth and development depend upon severity of lung disease and adverse perinatal events. Growth retardation is present in about one third of survivors and major developmental defects in about 25%.

## CHRONIC PULMONARY INFECTION

This may account for a small proportion of cases of neonatal chronic lung disease. Infection with CMV may be congenital or acquired although pneumonitis is uncommon in congenitally infected babies. Interstitial pneumonitis can also occur with congenital toxoplasmosis, rubella, varicella and herpes simplex virus. Acquired infections with enteroviruses, adenovirus, RSV and rhinovirus can cause acute pneumonitis.

Chlamydia may cause a late pneumonitis with tachypnea, cough and chest radiograph showing disproportionately severe infiltrates and hyperinflation. Erythromycin treatment for 14 days is effective. Pneumocystis pneumonia has also been reported in preterm infants and is treated with co-trimoxazole.

## SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital or acquired. Acquired subglottic stenosis is due to prolonged endotracheal intubation and occurs in severe form in about 1% of ventilated babies. Use of endotracheal tubes that are too big, oral rather than nasal intubation and repeated intubations may increase the risk of subglottic stenosis. Presentation is with stridor and respiratory distress after extubation although there may be delayed onset of symptoms for several months with difficulty apparently precipitated by upper respiratory tract infections.

In mild cases treatment with high humidity and supplemental oxygen is sufficient, but use of dexamethasone or inhaled epinephrine has been advocated in more severe cases prior to a trial of extubation.

Sometimes tracheostomy is needed but minor surgery to split the cricoid cartilage anteriorly<sup>637</sup> has been successful as an alternative. Dilatation of the narrowed segment at intervals by an experienced ENT surgeon may be necessary.

## CONTROL OF BREATHING

Postnatal control of breathing is complex and involves chemical and nonchemical stimuli and respiratory reflexes. Inspiratory and expiratory centers in the brainstem are influenced by sensors (central and peripheral chemoreceptors) monitoring arterial blood and they maintain normal oxygen tensions and pH despite wide variations in oxygen demand and carbon dioxide production.

### Chemical stimuli

Hypoxemia and hypercarbia are the most important chemical stimuli for respiration. Hypoxemia depresses ventilation and blunts the ventilatory response to hypercarbia. For the first week after birth there are three phases of the respiratory response to hypoxemia:

1. initial stimulation of peripheral chemoreceptors causing transient hyperventilation for 1–2 minutes;
2. if hypoxia persists this is followed by central depression with decrease in ventilation;
3. central stimulation by severe hypoxemia causing gasps.

In the preterm baby these responses may persist for up to 6 weeks after birth. Breathing oxygen reduces ventilation by an effect on carotid body chemoreceptors but after several minutes hyperventilation occurs secondary to hypercarbia. This response, mediated by hydrogen ion receptors in the medulla, increases with gestational and also with postnatal age.<sup>638</sup>

### Respiratory reflexes

The Head and Hering–Breuer reflexes, arising from lung stretch receptors and mediated through the vagus nerve, are important in modulation of respiratory center output in the newborn. Head's paradoxical reflex, which is present for the first few days after birth, causes an extra inspiratory effort when the upper airways are distended. Its importance is in aeration of the lungs soon after birth. In the Hering–Breuer reflex sustained lung inflation inhibits respiration causing apnea in inspiration. This inflation reflex is stronger in preterm than term babies. The Hering–Breuer deflation reflex comprises an increase in respiratory rate in response to reduced lung volume and may also be important in the preterm baby. There are irritant receptors in the hypopharynx and larynx which, if stimulated by vigorous suctioning or cows' milk, cause apnea.<sup>638</sup>

### Apneic attacks

Apnea of prematurity is defined as cessation of breathing for more than 15 s, typically accompanied by desaturation and bradycardia. Periodic breathing is a series of respiratory pauses of about 10 s alternating with periods of hyperventilation of up to 15 s and occurring at least 3 times per min. It is not associated with cyanosis and bradycardia and may be a physiological response in the preterm baby.<sup>639</sup>

### Incidence

Apneic attacks occur in most infants < 30 weeks' gestation and in about half of babies of 30–32 weeks decreasing to less than 10% of babies at < 34 weeks. Periodic breathing is also common, occurring in nearly all LBW babies and about one third of term babies.

### Etiology and pathogenesis

Many clinical conditions are associated with apnea (Table 12.51). Only after exclusion of those listed from 1 to 6 can a confident diagnosis of apnea of prematurity be made. Immaturity of brainstem respiratory neurons is probably a major underlying factor and apnea may also occur if the medullary centers are immature or depressed by hypoxia. There is no evidence of a temporal relationship between gastroesophageal acid reflux and apneic episodes.<sup>640</sup>

**Table 12.51** Clinical conditions associated with apnea

1. Hypoxemia: respiratory distress syndrome, pneumonia, chronic lung disease, recurrent aspiration, airway obstruction
2. Infection: septicemia or bacteremia, meningitis, necrotizing enterocolitis
3. Metabolic disorder: hypoglycemia, hypocalcemia, hypomagnesemia, hypernatremia, hyponatremia, acidosis
4. Central nervous system disorder: seizures, intracranial hemorrhage, drugs and drug withdrawal, kernicterus, cerebral malformation
5. Circulatory disorder: hypotension, congestive heart failure, persistent ductus arteriosus, anemia, polycythemia
6. Temperature instability: hyperthermia, hypothermia
7. Apnea of prematurity: diagnosis by exclusion

### Pathophysiology

During a significant apneic attack the preterm baby has bradycardia, peripheral vasoconstriction and a variable alteration of blood pressure which may increase or decrease slightly. The interval between onset of apnea and bradycardia varies between 2 and 30 s. There are three types of apnea based upon polygraphic recordings (Table 12.52).<sup>641</sup> In preterm babies central apnea and mixed apnea occur with about equal frequencies. Use of apnea monitors which detect chest wall movement only will underestimate the incidence of apnea.

### Diagnosis

The infant should be examined carefully to look for signs of infection, airway obstruction, seizures or PDA. Laboratory investigations might include full blood picture, blood culture, C-reactive protein (CRP), blood glucose, electrolytes and calcium. Chest radiography, blood gas analysis and pH and examination of cerebrospinal fluid might also be indicated. Only after exclusion of infection, biochemical or drug causes of apnea can an infant be confidently labeled as having apnea of prematurity.

### Treatment (Table 12.53)

All preterm babies < 34 weeks' gestation should have continuous monitoring of heart and respiratory rate for several days until apnea has ceased to occur. Pulse oximetry or transcutaneous oxygen monitoring is also desirable in less mature babies. Monitors that respond to chest wall movement (the apnea mattress, pressure sensor pad or pressure-sensitive capsule) will fail to detect obstructive apnea as long as

**Table 12.52** Polygraphic classification of type of apnea

1. Central apnea: simultaneous cessation of respiratory effort and airflow at the end of expiration. Probably due to cessation of motor output from the respiratory center in the brainstem
2. Obstructive apnea: cessation of airflow while respiratory effort continues. Seen in babies with the Pierre Robin syndrome for example
3. Mixed apnea: cessation of airflow with continued respiratory effort on some occasions and not on others. Both central and obstructive apneas occur during the same episode

**Table 12.53** Management of apnea

1. Immediate resuscitation
2. Exclude underlying cause (Table 12.51)
3. Lower environmental temperature 0.5°C
4. Correct mild hypoxemia and anemia
5. Repeated stimulation
6. Intermittent bag and mask ventilation
7. Continuous positive airway pressure
8. Drug therapy – caffeine, aminophylline, theophylline, doxapram
9. Mechanical ventilation

respiratory movement continues. To detect obstructive or mixed types of apnea, the heart rate and oxygen saturation must also be monitored. Sometimes a simple adjustment of environmental temperature or feed frequency will prevent apneic attacks. During resuscitation, overzealous suctioning must be avoided as this stimulates irritant receptors in the pharynx and perpetuates the apnea and bradycardia. Many apneic attacks are self-resolving and provided bradycardia and hypoxemia do not occur these are probably not harmful.

**Repeated stimulation.** Stimulation by stroking, gentle rubbing or rocking often prevents or shortens apneic attacks by increasing input to the immature respiratory center by cutaneous, vestibular or proprioceptive pathways.

**Intermittent bag and mask ventilation.** When peripheral stimulation fails, bag and mask ventilation, using the same oxygen concentration as the baby is breathing, will stimulate spontaneous respiration without increasing the risk of retinopathy of prematurity.

**Continuous positive airway pressure (CPAP).** CPAP at 4–5 cmH<sub>2</sub>O reduces apnea by improving oxygenation and increasing functional residual capacity. It may also stabilize the chest wall and eliminate the Hering–Breuer deflation reflex. CPAP decreases incidence of both mixed and obstructive apneas but does not affect central apneas so it might work by helping to relieve upper airway obstruction. Gentle nasal ventilation via CPAP prongs is also helpful in avoiding the need for mechanical ventilation.<sup>528</sup>

**Drug therapy.** Methylxanthines such as aminophylline, theophylline and caffeine are useful in central as well as obstructive apnea and work by increasing the sensitivity of the respiratory center to hypercarbia, increasing minute ventilation, decreasing hypoxic depression and reducing periodic breathing. Other effects are stimulation of the diaphragm, positive inotropic and chronotropic effects, mild diuresis and increased heat production through utilization of brown fat. Unwelcome effects include decreased cerebral blood flow and some uncertainty about long term outcome.<sup>642</sup> Caffeine has a wider margin of safety than theophylline.<sup>643</sup> Concerns about potential long term adverse effects and the risk: benefit ratio will hopefully be resolved with completion of the CAP follow-up study.<sup>644</sup> Doxapram is a direct respiratory stimulant which has undergone limited study for treatment of neonatal apnea and has the side-effect of jitteriness and raised blood pressure. It appears to have similar efficacy to methylxanthines in the short term but its routine use should be limited because of lack of data on long term safety.<sup>645</sup> Antireflux medications do not reduce the frequency of apnea in preterm infants.<sup>646</sup>

**Mechanical ventilation.** This is reserved for babies whose apnea is resistant to other measures. Very immature infants and those with bacteremia often need mechanical ventilation and low inflating pressures should be used as lung compliance is usually normal.

### Prognosis

In most cases apnea of prematurity resolves at around 34 weeks' corrected gestation and caffeine therapy can be discontinued with continued monitoring for several days afterwards. Recurrent apnea does not appear to have deleterious effects on long term cognitive or neurodevelopmental outcome.<sup>647</sup> There appears to be no relationship between apneic spells in the neonatal period and subsequent sudden infant death syndrome (SIDS). Apnea can recur within 2 months of discharge from hospital if there is a respiratory infection or if general anesthesia is needed for surgery.<sup>648</sup>

## NEONATAL CARDIOVASCULAR DISEASE

This section considers normal perinatal cardiovascular changes (Fig. 12.4). Certain situations characteristically associated with the newborn period are then covered in detail. Congenital and acquired cardiac disease is described in detail in Chapter 21.

### PERINATAL CARDIOVASCULAR PHYSIOLOGY

Figure 12.3 illustrates fetal circulatory pathways. Labor and delivery trigger a number of cardiovascular events (Fig. 12.4), the occurrence or

failure of which have implications for the presentation and management of neonatal cardiovascular disease.

### Pulmonary vascular resistance

In healthy term babies the postnatal fall in pulmonary vascular resistance results in a rapid fall in right heart pressures over a few days with adult pulmonary:systemic pressure ratios being established by 2–3 weeks of age. Many factors can inhibit, delay or reverse pulmonary vasodilation in the newborn and these are listed with clinical examples in [Table 12.54](#). The fall in resistance may occur more slowly in certain congenital cardiac abnormalities such as atrioventricular septal defect (AVSD) and large ventricular septal defect (VSD). This delayed fall has implications for the time at which heart murmurs, clinical left to right shunting and heart failure develop. Thus, a small VSD is more likely to produce a murmur in the first few days after birth than a large one and a large VSD rarely causes heart failure in the first few weeks of life. In some congenital heart lesions, pulmonary vascular resistance never falls to normal and pulmonary vascular disease develops without clinical evidence of a large shunt ever having been present. This happens not infrequently in complete AVSD but can also happen with a large VSD, in both cases particularly if the child has Down syndrome. This process is accelerated in the presence of hypoxemia from cardiac or other causes.

### Ductus arteriosus

As gestation progresses, ductal smooth muscle becomes less sensitive to dilating circulating prostaglandins and more sensitive to the vasoconstrictor effects of oxygen. At term, increasing arterial oxygen tension causes functional closure of a normal ductus within 2–3 days of birth in virtually all babies. In preterm babies without respiratory distress the time of ductal closure is similar.<sup>649</sup> Babies with structural abnormalities of the cardiovascular system may maintain ductal patency longer than normal before spontaneous closure occurs. There are two groups of congenital heart lesions which are critically dependent on ductal patency for the baby to remain alive ([Table 12.55](#)). The first group, those with duct-dependent pulmonary circulation, show appearance of or worsening

of cyanosis on ductal closure. The second group consists of those conditions in which the systemic circulation is dependent on the ductus, and collapse with gross heart failure occurs when the ductus closes. An important part of resuscitation in both these groups of infants is the use of prostaglandin E<sub>1</sub> or E<sub>2</sub> to reopen and maintain ductal patency. In addition, babies with transposition without a large VSD will show a marked deterioration in oxygenation when the ductus closes. Persistent ductus arteriosus, either isolated or in association with other cardiac abnormalities, may also be a structural abnormality which will never close. If a normal ductus arteriosus is subject to abnormal conditions, its closure may be delayed. This situation is frequently seen in preterm babies with lung disease and may respond to prostaglandin synthetase inhibitor administration.

### Foramen ovale

Increased pulmonary venous return after birth results in closure of the flap-like foramen ovale as left atrial pressure rises. If intra-atrial pressures are abnormal, shunting can occur in either direction through the foramen ovale. Thus left to right shunting may occur in babies with an increase in left atrial pressure (due to left to right shunting through a ductus arteriosus or to obstruction to flow of blood through the left heart) and right to left shunting can occur in persistent pulmonary hypertension or mechanical obstruction to flow through the right heart giving desaturated blood access to the systemic arterial circulation.

### Ductus venosus

Blood flow through the ductus venosus falls dramatically when umbilical venous return ceases and functional closure occurs within a few days; however an umbilical venous catheter can sometimes be passed through it into the inferior vena cava and right atrium until at least a week after birth. The clinical relevance of patency of the ductus venosus relates to its usefulness as a route to the heart for central venous pressure monitoring or cardiac catheterization and also to the fact that when it closes, obstruction to pulmonary venous drainage becomes severe in total anomalous pulmonary venous return to the portal vein, causing marked deterioration in cyanosis and respiratory distress.

**Table 12.54** Situations associated with delay in or reversal of postnatal fall in pulmonary vascular resistance

Factor	Comment
Acidosis, hypoglycemia, hypoxemia, hypercapnia, polycythemia	Wide range of neonatal diseases
High altitude	Mediated via lower oxygen tension
Cardiac disease	See <a href="#">Table 12.64</a>
Respiratory disease	Any cause
Ductal closure in utero	Maternal prostaglandin synthetase inhibitor ingestion
Obstructed middle or upper airway	Any cause

**Table 12.55** Duct-dependent congenital heart lesions

Obstruction to flow through right heart
Pulmonary atresia with intact ventricular septum
Critical pulmonary stenosis
Severe tetralogy of Fallot
Pulmonary atresia with VSD and no aortopulmonary communicating arteries
Tricuspid atresia (unless with large VSD and without pulmonary stenosis)
Obstruction to flow through left heart
Aortic atresia
Critical aortic stenosis
Hypoplastic left heart syndrome
Interrupted aortic arch
Severe coarctation

## CARDIOVASCULAR EXAMINATION OF THE NEWBORN

The present history, perinatal and family histories may all give clues to a diagnosis. Routine examination of well babies should include an assessment of the presence or absence of central cyanosis, an evaluation for evidence of heart failure and observations about pulse rate, regularity and character with special reference to the nature of the femoral pulses when compared simultaneously to the right brachial pulse. If the femoral pulses cannot be satisfactorily palpated or are markedly different from right arm pulses, a more thorough cardiovascular assessment including blood pressure measurement in both arms and one leg, ECG and chest X-ray should be performed. Auscultation of the heart should be performed with an attempt to ensure that heart sounds are louder in the left chest than the right. Then attention should be given to whether the second sound is single or fixedly split and then to murmurs. The presence or absence of murmurs is only part of the neonatal cardiovascular examination. Some murmurs are innocent and many severe lesions have unimpressive murmurs or even none.

If cardiac disease is suspected, the precordium, suprasternal notch and subxiphoid region should be palpated for thrills or abnormal impulses, the skull auscultated for bruits, and a more detailed cardiac auscultation for added sounds and full murmur characterization carried out. Reliable blood pressure measurement in newborn infants requires a quiet and relaxed infant and a cuff of appropriate size (a cuff which covers two thirds of the length of the upper arm and in which the bladder either encompasses the entire circumference of the arm or is positioned in such a way as to have the center of the bladder over the brachial artery). Detection of pulse reappearance can be by palpation but a Doppler probe is more sensitive; auscultation is very difficult. Oscillometric devices need to be watched whilst recording to ensure that the infant remains peaceful and are second best to direct invasive

continuous monitoring of ill infants. The same cuff can be used on the calf with detection of posterior tibial or dorsalis pedis pulses for lower limb systolic pressures. Normal values for systolic pressures in term babies measured non-invasively are given in Table 12.56.<sup>650</sup> Acceptable values in ill preterm babies are different and less clearly defined (Table 12.57).<sup>651,652</sup> Non-invasive pressure up to 20 mmHg systolic higher in the arm than the leg can be normal; discrepancies between arm pressures may give clues as to the site of an aortic arch interruption. Significant coarctation may occasionally be associated with an aberrant right subclavian artery arising distal to the left subclavian, in which case upper to lower limb pulse discrepancy will not exist. Upper limb pressures may be raised in coarctation but in sick infants poor left ventricular function may prevent hypertension.

## CARDIOVASCULAR INVESTIGATION OF THE NEWBORN

### Chest X-ray

A systematic approach to the chest X-ray allows maximum information to be obtained; the particular points of relevance to cardiovascular diagnosis are listed in Table 12.58. Immediate management of a baby with a cardiac lesion may be greatly influenced by deciding whether lung blood flow is increased (plethoric lung fields, Fig. 12.31) or decreased (oligemic lung fields, Fig. 12.32). Pulmonary venous obstruction produces X-ray appearances often hard to distinguish from respiratory pathology. Clinical conditions associated with each of these abnormalities are given in Table 12.59.

### Electrocardiography

This can provide important diagnostic information when significant heart disease is suspected. A detailed consideration of the subject will be found in Chapter 21. It is important to recognize the normal evolution of the ECG in the newborn and to have access to reference information<sup>653</sup> (Table 12.60).

### Hyperoxia (nitrogen washout) test

If cyanosis is due to a cardiac cause, high concentrations of inspired oxygen rarely relieve it significantly, although there are exceptions, for example some common mixing conditions. If respiratory disease is the cause there is often relief from increasing inspired oxygen, although this will not be the case in severe respiratory disease and persistent pulmonary hypertension. This is the basis for the hyperoxia test. If a baby is put in 85% or more inspired oxygen for 15–20 min, a right radial arterial blood or right upper trunk transcutaneous oxygen tension should rise to well above 20 kPa. Failure to do so supports a cyanotic cardiac abnormality. Transcutaneous oxygen tension monitors placed on the right upper thorax can give similar information to right radial artery samples but pulse oximetry can be misleading in that elevation of saturation to normal, even to 100%, does not necessarily mean that arterial oxygen tension had risen above 20 kPa. Theoretical fears about precipitating ductal closure mean that the baby should be closely observed during the test; however, the risk of precipitating a problem is extremely small. Marked prematurity is a contraindication because of the possible consequence of retinopathy. Pulse oximetry may have a role in screening for cardiac disease (see below).

**Table 12.57** Systemic blood pressure in the neonatal period. Healthy LBW infants (no inotropes, no positive pressure ventilation). ### Echocardiography

Clinical evaluation should always precede echocardiography. Resuscitation and stabilization must always be achieved before transfer to another unit for evaluation. Ultrasound imaging and Doppler assessment allow a precise anatomical and functional diagnosis in the majority of symptomatic neonates with cardiac disease, so that surgery, be it palliative or definitive, is frequently not preceded by cardiac catheterization. The increasing expertise in echocardiography of neonatal pediatricians and the advent of telemedicine are altering transfer patterns of infants with actual or suspected heart lesions.

### Cardiac catheterization

Although echocardiography has made neonatal diagnostic cardiac catheterization uncommon, there has been an increase in the number and scope of interventional therapeutic catheterizations in neonates. Good neonatal care is required throughout the procedure. The heart can be approached via umbilical vessels, femoral vessels percutaneously or by cut-down, or rarely by axillary vessel cut-down. The procedure has mortality and morbidity, though these have been greatly reduced by good general neonatal care and by anatomical information obtained from prior echocardiography.

### Magnetic resonance imaging and computer assisted tomography

These modalities are increasingly used in specialist congenital cardiac centers.

## PATTERNS OF CARDIOVASCULAR DISEASE IN THE NEWBORN

Congenital disease accounts for most cardiac disease in the newborn but acquired disease can occur as a result of birth asphyxia, viral infections and other severe postnatal illnesses. Congenital heart disease presents in the newborn period in approximately 4 per 1000 live births. Congenital heart disease may be structural or functional, the latter group including conduction disturbances, dysrhythmias and heart muscle disease.

## PRESENTATION AND MANAGEMENT OF CARDIOVASCULAR DISEASE IN THE NEWBORN

### Fetal diagnosis<sup>654</sup>

Detailed fetal echocardiography may show cardiac abnormalities from 13 weeks' gestation onwards. Investigation is performed when a factor increasing the risk of heart disease is identified such as:

- increased nuchal translucency with normal karyotype;
- monochorionic twins;
- abnormal heart suspected at general anomaly scan;
- chromosomal or noncardiac abnormality detected in fetus;
- parental congenital heart disease;
- maternal diabetes;
- parental illness with fetal cardiac implications (e.g. autosomal dominant condition with cardiac aspects, maternal collagen vascular disease).

Detailed fetal echocardiography of all pregnancies is too resource consuming to be practiced in many places, especially as evidence for improved postnatal outcomes after prenatal cardiac diagnosis is conflicting.<sup>655-658</sup> When a baby is born in whom a fetal diagnosis has been made, this must be confirmed by postnatal echocardiography. A normal fetal cardiac scan should not prevent postnatal echocardiography being performed if clinical features point to the possibility of cardiac disease in the newborn.

### Cyanosis

Recognition of central cyanosis in a newborn infant is not always easy. Factors that complicate the assessment include a high hematocrit, traumatic petechiae on the face, racial pigmentation and acrocyanosis. A plethoric newborn infant may be normally saturated but still have enough deoxygenated Hb to look centrally cyanosed. Occasionally non-invasive monitoring or even blood gas sampling will be needed for confirmation. Some 'cyanotic' congenital heart disease may not produce recognizable cyanosis in a newborn baby (unobstructed total anomalous pulmonary venous drainage, double inlet and double outlet ventricles with high lung blood flow and good mixing, and tetralogy of Fallot in which right ventricular outflow obstruction progresses through infancy and is often only mild in the newborn period). Once central cyanosis is identified the immediate priority is to assess that airway and respiration are adequate, regardless of suspected cause. Detailed review of history and a complete physical examination are then important. Features of the different groups of causes and management pathways for a suspected cardiac cause are given in [Tables 12.61 and 12.62](#), respectively. In an ill infant with cyanosis from cardiac disease, the most important specific management issue is whether or not ductal patency needs to be secured with prostaglandin; if in doubt, a trial of the drug is appropriate. Prostaglandin E<sub>1</sub> or E<sub>2</sub> may be given intravenously; prostaglandin E<sub>2</sub> may be given orally or nasogastrically, hourly in the first instance. Doses are given in [Table 12.63](#).

Oxygenation is improved by prostaglandin in conditions with obstructed right heart flow (oligemic lungs on X-ray) and in many cases of transposition of the great arteries. Short term side-effects of prostaglandin include pyrexia, apnea, jitteriness, convulsions, flushing and diarrhea. These often improve with dosage reduction without loss of therapeutic effect. The drug should be stopped if no benefit is seen after 1–2 h. Persistent pulmonary hypertension in the newborn (PPHN, see below) can at times be difficult to distinguish from cardiac disease even with echocardiography and the two may coexist ([Table 12.64](#)).

**Table 12.61** Clinical features and investigations which help rapid differentiation of causes for central cyanosis

Causes of cyanosis	Clinical features	Investigations
Respiratory	Marked respiratory distress (unless PPHN in addition) Color improves in oxygen usually	Abnormal lung fields on X-ray Hypercapnia Hyperoxia test (pass)
Cardiac	May have other cardiac signs May have little or no respiratory distress	X-ray may help, lung pathology absent Normo- or hypocapnia Hyperoxia test (fail) ECG abnormal
Neurological (respiratory depression)	Slow respiration Color improves on stimulation and in oxygen. May have other neurological or syndrome features	X-ray normal Hypercapnia Hyperoxia test (pass)
Hematological (methemoglobinemia)	Black mucous membranes, not typical cyanosis, usually very well	Blood gas normal Hyperoxia test (pass)

In all groups history may provide valuable clues.  
PPHN, persistent pulmonary hypertension in the newborn.

**Table 12.62** Management approach to cyanosis due to a suspected cardiac cause

1. General measures	Temperature control, avoid hypoglycemia, ensure ventilation adequate
2. Arterial blood gas	Treat respiratory acidosis Treat metabolic acidosis Ventilate if necessary (hypoxemia alone not indication to ventilate) Consider value of hyperoxia test
3. Chest X-ray	Diagnostic clues may be present Management Oligemia – trial of prostaglandin Plethora – trial of prostaglandin if very hypoxemic or metabolic acidosis
4. ECG	May help with specific diagnosis
5. Drugs	Prostaglandin (see above) Alkali Diuretics if heart failure/pulmonary congestion Antibiotics if significant risk of serious infection
6. Echocardiography	Precise diagnosis often possible (transfer if necessary when stable)

### Heart failure

Features of heart failure include respiratory distress, sweating, hepatomegaly and in severe cases (particularly where failure has been present antenatally) ascites, generalized edema, pleural and pericardial effusions. Tachycardia, gallop rhythm and clinical features of the cause should also be looked for. Structural heart disease (particularly severe left ventricular outflow obstruction), rhythm disturbances, myocardial diseases (cardiomyopathy of any sort, myocarditis and myocardial ischemia or infarction) and noncardiac diseases may all cause heart failure.

Table 12.63 Drug dosage table

Drug	Route	Dose	Frequency
Prostaglandin			
E <sub>1</sub>	i.v.	0.005–0.1 µg/kg/min	–
E <sub>2</sub>	i.v.	0.005–0.05 µg/kg/min	–
E <sub>2</sub>	Nasogastric	25 µg/kg/h	Hourly initially
Indometacin	i.v.	0.2 mg/kg over 30 min	8- to 12-hourly ×3
Tolazoline	i.v.	0.5 mg/kg over 5 min then 0.5 mg/kg/h	–
Prostacyclin	i.v.	2–20 ng/kg/min	–
Dopamine	i.v.	2–20 µg/kg/min	–
Dobutamine	i.v.	2–20 µg/kg/min	–
Captopril	Oral/ nasogastric	0.1–0.5 mg/kg/dose	8-hourly
Start with lowest dose			

Table 12.64 Structural cardiac lesions which may be associated with persistent pulmonary hypertension in the newborn infant

Pulmonary venous hypertension	Pulmonary vein stenosis Obstructed total anomalous pulmonary venous drainage Absent left atrioventricular connection with restrictive foramen ovale Left ventricular dysfunction (any cause) Left ventricular outflow obstruction (any cause)
Left to right shunts independent of pulmonary vascular resistance	Atrioventricular septal defect Cerebral arteriovenous malformation Coronary arteriovenous fistula
Severe tricuspid regurgitation	Ebstein anomaly

Intracerebral and more rarely other arteriovenous malformations, generalized viral and bacterial infections, noncardiac hypoxemia, severe anemia, marked polycythemia and excessive fluid administration may all precipitate cardiac decompensation.

### Cyanosis and heart failure

Cyanosis is a feature only of very severe heart failure, and heart failure does not develop in many conditions which cause severe cyanosis. Thus, if both cyanosis and heart failure are present, this may be a useful diagnostic aid (Table 12.65).

### Collapse

This may be a feature of duct-dependent systemic circulation (Table 12.55). Such lesions are also characterized by respiratory distress, massive hepatomegaly, cardiomegaly with congested lung fields on X-ray, right ventricular dominance on ECG and metabolic acidosis. Differential diagnosis includes septicemia and metabolic disorders but if any doubt exists, resuscitation should include prostaglandin, which will almost invariably produce rapid improvement if the diagnosis is cardiac.

### Arrhythmia

Tachyarrhythmias may produce collapse, although supraventricular tachycardia (SVT) may produce either no symptoms or heart failure. Ventricular tachycardia may be life threatening or asymptomatic with a benign natural history and eventual spontaneous resolution. It is an indication for urgent cardiological referral. Complete heart block may be well tolerated, especially if the ventricular rate is above 55/min and rises on activity. Although Stokes–Adams attacks may

Cerebral arteriovenous malformation (vein of Galen aneurysm)	

PDA, persistent ductus arteriosus; TGA, transposition of the great arteries; VSD, ventricular septal defect.

occur, cardiac failure is the more usual problem in the neonate with complete heart block and both are indications for pacemaker insertion, as is a heart rate below 50/min even in the absence of symptoms. Chronotropic drugs rarely have much effect on ventricular rate. The association of rhythm disturbances with structural heart disease must be remembered and the majority of babies with complete heart block without structural heart disease have mothers with serological evidence with or without clinical features of lupus erythematosus or other collagen vascular diseases.<sup>659,660</sup> Supraventricular ectopics (SVEs) are common in normal fetuses and newborns; they are not always conducted to the ventricles (blocked SVEs) in which case they result in a slow and/or irregular pulse. In the absence of other cardiovascular signs or ECG abnormalities SVEs do not point to the presence of structural heart disease and resolve within 3 months of birth. There would appear to be an increased risk of SVT in infants with SVEs although clear information on the incidence is not available. Ventricular ectopics (VEs) are found in more than 30% of normal newborn infants and usually resolve rapidly. However if they are a sign of structural heart disease, heart muscle disease or a congenital long QT syndrome there is a risk of serious ventricular dysrhythmias. A variety of acute metabolic disturbances can precipitate rhythm disturbances but do not require detailed cardiac investigation if rhythm and ECG return to normal when plasma biochemistry is corrected.

### Cardiac murmur

Murmurs are often heard at routine examination of newborn infants. Other features of cardiac disease must be sought by thorough cardiovascular examination as the presence of a murmur is associated with cardiac disease in up to 50%.<sup>661</sup> Asymptomatic murmurs with no other abnormal features may be innocent and have been found in up to 2% of term infants in the first few days after birth.<sup>662</sup> Table 12.66 lists the characteristics of innocent neonatal murmurs. Trained staff are efficient at identifying murmurs indicative of important structural heart disease without investigation by ECG and chest X-ray.<sup>663,664</sup> It is possible that adding foot pulse oximetry or right arm and foot oximetry to clinical screening examination might further improve the pick up rate of heart (and respiratory) lesions if babies with a reading from the foot of less than 95% are reassessed.<sup>665</sup> However, the widespread use of this technique has yet to be evaluated.<sup>666</sup> Some cardiac abnormalities can be associated with asymptomatic murmurs without any other physical signs and with normal ECG and chest X-ray. Tricuspid regurgitation and VSD may produce similar pansystolic murmurs at the lower left sternal edge. Tricuspid regurgitation producing a murmur in an otherwise well baby is of no long term significance; a VSD heard in the early neonatal period may never cause symptoms and has a high chance of spontaneous resolution.<sup>667</sup> Aortic and pulmonary valve stenosis (including tetralogy

**Table 12.66** Features of innocent neonatal murmurs: in all groups the remainder of the examination is normal

Source/type	Features of murmur	Other points
Pulmonary arteries	Bilateral, base of heart, also over scapulae and lateral chest High pitched mid-systolic	Gone by 6 months
Ductus arteriosus	Pulmonary area rarely diastolic	Gone by 2–3 days
Tricuspid regurgitation	Same as VSD, heard day 1	May be perinatal asphyxia Goes in a few days–weeks
Still's innocent murmur	Vibratory Mid-systolic Between LLSE and apex	Rarely heard in newborn May last years

LLSE, lower left sternal edge.

of Fallot) will produce a murmur at birth; evaluation including ECG, chest X-ray and if possible echocardiography is necessary before allowing a baby home if significant outflow tract obstruction is suggested by a loud murmur at the base. The normal murmur from pulmonary artery branches in the newborn is not as loud or as harsh as that from semilunar valve stenosis and radiates laterally.

## Hypertension

Neonatal hypertension is usually only identified in infants with other cardiovascular signs or in those known to be at increased risk such as those with chronic lung disease or cocaine-using mothers. Treatment of neonatal hypertension is only occasionally necessary, but attention to the underlying cause is always appropriate (Table 12.67).

### Association with other abnormalities

Many syndromes include cardiac abnormalities;<sup>668</sup> in some the cardiac malformation may be a major determinant of length or quality of life. Any infant with a congenital abnormality should at very least have a full physical examination of the cardiovascular system so as to detect abnormalities which may influence management and allow comprehensive counseling of families.

**Table 12.67** Causes of hypertension in the newborn

Renal	Renal vein thrombosis Renal arterial emboli/thrombosis Dysplastic renal disease Polycystic renal disease Urinary tract obstruction Renal infection Renal failure (any cause)
Cardiovascular	Coarctation
Endocrine	Congenital adrenal hyperplasia Hyperaldosteronism Hyperthyroidism Pheochromocytoma Neuroblastoma
Respiratory disease	Bronchopulmonary dysplasia (mechanism unknown)
Neurological disease	Raised intracranial pressure (any cause)
Drugs	Corticosteroids Methylxanthines Phenylephrine (in eyedrops)

## CARDIOVASCULAR ASPECTS OF NEONATAL DISEASES

### Respiratory distress syndrome

#### *Persistent ductus arteriosus (PDA)*

Patency of the ductus arteriosus is associated with worse RDS, and delayed closure of the ductus can result in the need for continuing ventilation, but clear evidence of reduced long term morbidity or mortality from prophylactic or therapeutic intervention is not available.<sup>669</sup> Antenatal prostaglandin synthetase inhibitor administration predisposes to postnatal delayed closure of the ductus and makes the ductus less responsive to indometacin.<sup>670</sup> The efficacy of antenatal steroid administration in reducing incidence and severity of RDS may in part be due to increasing ductal sensitivity to postnatal constricting influences. Cautious fluid regimens in babies with RDS are associated with a lower incidence of PDA. Etamsylate<sup>671</sup> given to reduce intracerebral hemorrhage has been found to be associated with a lower incidence of PDA. Prophylactic duct closure with indometacin reduces but does not abolish the occurrence of later symptoms;<sup>672</sup> similar effects are described for ibuprofen.<sup>673</sup> The failure to demonstrate better outcomes following prophylactic use of indometacin<sup>674,675</sup> or ibuprofen<sup>676</sup> indicates the need for caution but long term outcome information following treatment only of babies at increased risk of symptomatic PDA is not available.

Prediction in the first 3 days of life of high risk of future symptomatic PDA is possible if a duct more than 1.5 mm in diameter is seen on color flow Doppler<sup>677</sup> or if low velocity continuous left to right shunting is demonstrated by pulsed wave Doppler.<sup>678</sup> The typical clinical features of PDA may be hard to detect in a baby with respiratory disease and PDA may cause no murmur or more usually just a systolic one. Other features of PDA in the context of the preterm include apnea, hypotension, heart failure, NEC and metabolic acidosis. When ventilator requirements are increasing after apparently passing the peak of RDS and a continuous murmur is present, the diagnosis is easy; when features are less obvious, the possibility of left to right shunting through a PDA must be remembered. The ECG is not helpful and chest X-ray is often noncontributory. If there is clinical doubt, echocardiography imaging, M mode<sup>679</sup> and Doppler examination are required<sup>680</sup> looking for the features mentioned above and also for mean and diastolic velocities in the left pulmonary artery.<sup>681</sup>

Symptomatic PDA should be vigorously treated with fluid restriction, correction of anemia and cautious use of diuretics, which may derange electrolytes. If these measures do not rapidly control the situation, indometacin has long been known to be effective in closing the ductus in approximately 70% of premature infants.<sup>682</sup> Intravenous indometacin (0.2 mg/kg) for 3 doses 8–24 h apart should be used; an infusion over at least 30 min is preferable to a bolus injection because of effects on blood pressure and cerebral circulation<sup>683</sup> although even slow infusions reduce cerebral oxygen delivery.<sup>684</sup> Less than three doses may be used if the Doppler velocity across the ductus can be shown to evolve to a closing pattern after the initial dose.<sup>685</sup> It is possible that ibuprofen may be less active on the cerebral circulation and just as effective at closing the ductus<sup>686,687</sup> although pulmonary hypertension and chronic lung disease may be more common than after indometacin use, therefore at present it has no clear advantage over indometacin.<sup>688</sup> Fluid retention and elevation of creatinine are temporary adverse effects of indometacin; thrombocytopenia is usually considered a contraindication to its use, as are renal failure and NEC. A repeat course may be used if the beneficial effect is transient although an asymptomatic murmur which reappears after natural or pharmacological ductal closure is more likely to be arising from the pulmonary artery branches than from the ductus.<sup>689</sup> A 5-day course of indometacin<sup>690</sup> or a 6-day low dose course<sup>691</sup> is effective at closing the ductus with a lower relapse rate. Biochemical evidence of renal dysfunction is less on the low dose regimen. The effect on cerebral hemodynamics of prolonged indometacin treatment has not been studied. Two unsuccessful short courses, unacceptable side-effects or a definite contraindication mean that surgical ligation or clipping of the ductus should be carried out. This can be done in the neonatal nursery with low mortality and morbidity. Transcatheter<sup>692</sup> and thorascopic<sup>693</sup> closure of the ductus is now reported in babies under

2000 g but not in those under 1000 g. Whether or not echocardiography is regarded as mandatory before using prostaglandin synthetase inhibitor drugs, it certainly is before surgical ligation to confirm the diagnosis and to rule out structural congenital heart disease and systemic to pulmonary collateral arteries which can be found in preterm infants<sup>694</sup> and which cause a continuous murmur.

### ***Persistent pulmonary hypertension of the newborn (PPHN)***

Pulmonary hypertension may complicate a variety of neonatal respiratory illnesses (Table 12.54). Diagnosis is helped by recognizing risk factors and by excluding structural heart disease. Lower saturations in the feet than the right hand are characteristic if the ductus arteriosus is open (this is also a feature of structural heart lesions with obstruction of the aortic arch).

Management in general consists of treating predisposing and aggravating factors aggressively, ensuring adequate alveolar recruitment and systemic blood pressure and normalizing acid–base balance. Consideration should then be given to the use of vasodilators. Oxygen and inhaled nitric oxide<sup>695</sup> are the only specific pulmonary vasodilators. The optimum dosage of nitric oxide is unclear but may be 20 parts per million (ppm)<sup>696</sup> and there may be disadvantages to initiating therapy at a lower dose.<sup>697</sup> There are benefits in tailoring ventilatory modes to the individual patient which may be additive to the effects of nitric oxide.<sup>698</sup> Plasma expansion and inotropes may both be needed. ECMO is effective in PPHN but exact indications for its use are unclear, as newer treatment protocols are more effective than those used when ECMO was first introduced. Intravenous magnesium sulfate, prostacyclin and tolazoline may be effective and the latter drug has also been used by inhalation. These treatments have not been extensively evaluated in randomized controlled trials. All infused drugs will lower systemic as well as pulmonary vascular resistance, so blood pressure must be invasively and continuously monitored when they are used. Modest hyperventilation to a carbon dioxide tension of 3–4 kPa or administration of alkali lower pulmonary vascular resistance but have adverse effects on cerebral perfusion and are seldom used.

### **Asphyxia**

#### ***Persistent pulmonary hypertension***

This may also be a feature of perinatal asphyxia, with or without meconium aspiration pneumonitis (see above).

#### ***Myocardial ischemia and infarction***

Electrocardiographic<sup>699</sup> and pathological<sup>700</sup> studies indicate that myocardial ischemia is common in neonates stressed by asphyxia. Even in mild cases there may be the murmur of tricuspid regurgitation which may be associated with ischemic ECG changes. In severely asphyxiated infants, hypotension from myocardial dysfunction may need inotrope support, and any type of arrhythmia can occur. Discrete areas of myocardial infarction can occur secondary to thromboembolic phenomena pre- or postnatally; this is rare but has a high mortality.<sup>701</sup>

### **Infection**

Generalized and pulmonary bacterial and viral infections in the newborn may predispose to PPHN. Myocarditis is a feature of disseminated viral infections, and heart failure, shock and arrhythmias may result. Shock may also be caused by peripheral vasodilation and capillary leakage in severe bacterial sepsis. Endocarditis is increasingly being recognized in already sick newborn infants.<sup>702</sup> Clinical features are nonspecific. There is rarely underlying structural heart disease. The diagnosis is suggested by multiple septic lesions appearing over time or recurrent bacteremia or fungemia, particularly in the presence of intravenous long lines. Ultrasound scanning can make, but not exclude, the diagnosis. Masses within the heart chambers or in great vessels can be vegetations in association with infection, non-infected thrombus (usually related to presence of an indwelling catheter at that site at some time) or tumors. Prolonged appropriate multiple antimicrobial therapy is indicated for endocarditis.

### **Metabolic diseases**

There are many inborn errors of metabolism and storage diseases which may be associated with cardiomyopathy. Hypertrophic cardiomyopathy seen in the newborn infants of diabetic mothers is worth specific mention because although it is frequently asymptomatic it may cause severe heart failure with gross cardiomegaly and ECG changes. The possibility of cardiac dysfunction in the respiratory problems encountered in infants of diabetic mothers needs careful individual assessment, as in some it will be a major contributory factor. This cardiomyopathy is self-limiting, resolving completely in 6–12 months.<sup>703</sup> Inotropes and vasodilators should be avoided in this condition because they may aggravate left ventricular outflow obstruction. Dilated cardiomyopathy may present symptomatically in the newborn period and a vigorous search for familial, infective and metabolic causes is indicated.

### **GENERAL MANAGEMENT OF NEONATAL HEART DISEASE**

All the principles for care of the newborn infant apply to the baby with definite or suspected cardiac disease. These principles should not be neglected because of a desire to get the correct diagnosis or to transfer the infant elsewhere.

### **Ductal manipulation**

The major resuscitative decision with respect specifically to heart disease is whether or not to use prostaglandin. In an unwell baby with poor systemic perfusion the possibility of critical left heart obstruction must always be borne in mind and unless it can be confidently excluded a trial of prostaglandin is appropriate. A cyanosed infant who is well does not need prostaglandin urgently but if there is metabolic acidosis or respiratory distress for which no primary respiratory cause is apparent prostaglandin should be commenced. Pharmacological duct closure with indometacin is never as urgent and if any doubt exists about the diagnosis, echocardiography is essential, as indeed it is before surgical intervention.

### **Heart failure**

Fluid restriction in the short term, optimal oxygenation and the treatment of anemia are important. Digoxin use is time honored but controversial in the treatment of heart failure when associated with left to right shunt. Diuretics, usually furosemide with or without a potassium sparing diuretic, are particularly effective in relieving symptoms. Vasodilators in neonatal heart failure are relatively untried, although angiotensin-converting enzyme inhibitors are widely used in infants.<sup>704,705</sup> Aggressive drug therapy for heart failure is appropriate in order to allow adequate nutrition.

### **Hypotension/low output states**

There is no single objective method of assessing clinically the adequacy of the circulation in a newborn infant. Decisions to provide circulatory support are not based on any one parameter alone. Normal ranges for blood pressure can be derived from healthy infants but they do not determine what is an adequate or beneficial blood pressure and there are no randomized trials assessing the outcomes of sick infants treated with different target ranges for blood pressure.

Clinical assessment of end organ perfusion is more important than aiming at a particular blood pressure.<sup>706</sup> If the urine output is good, there is no metabolic acidosis and there is good peripheral perfusion, the circulation is likely to be adequate whatever the blood pressure. However, preterm infants with higher blood pressure tend to have better clinical outcomes than those with lower blood pressure and, perhaps because it is easily measured, treatment decisions are strongly influenced by blood pressure measurements.

The broad consensus is that if the mean arterial blood pressure is around the gestational age in weeks then it is likely to be adequate;<sup>707</sup> ensuring optimal circulating volume should precede or accompany inotrope support.<sup>708</sup> However, in the majority of cases hypovolemia is unlikely to be the explanation and repeated boluses of colloid for

hypotension in preterm infants may be harmful. Early intervention with dopamine or dobutamine<sup>709,710</sup> should be considered. Echocardiography is helpful if doubt about the need for inotrope support exists and central venous pressure measurements may help.

A small number of infants remain hypotensive despite maximal inotropic support and volume replacement. Some of these infants respond well to small doses of hydrocortisone. It is not clear to what extent newborn infants can increase cardiac output by increasing myocardial contractility rather than heart rate. Bradycardia, be it sinus or due to atrioventricular block, resulting in circulatory compromise should be treated by identifying and removing the cause, aided if necessary by drugs such as atropine and isoprenaline or by pacing. Primary tachyarrhythmias such as atrial flutter and atrioventricular re-entry tachycardia (see Ch. 21) can be hard to distinguish from reactive sinus tachycardia but must be recognized and treated if compromising cardiac output. The rare cases of cardiac tamponade from pericardial fluid or air require drainage.

### Arrhythmias

Management of these in newborn babies is governed by the same principles as throughout infancy and is discussed in Chapter 21.

### Drug therapy

Recommended drugs and dosages for the treatment of neonatal cardiovascular disease are given in Table 12.63.

### Interventional cardiac catheterization

Rashkind balloon atrial septostomy still forms part of the emergency management of a number of conditions, particularly transposition of the great arteries (TGA). If diagnostic catheterization is not needed, a balloon atrial septostomy can be performed by an experienced operator under ultrasound control in the neonatal nursery. Balloon valvuloplasty is used in some centers for both critical aortic and critical pulmonary valve stenosis.<sup>711</sup> Balloon dilatation of neonatal coarctation is generally not as effective as surgery. The role of ductal stenting in duct-dependent lesions is being explored.<sup>712</sup> Transcatheter ductal closure is not yet feasible in babies under about 1500 g.<sup>692</sup>

### Surgery

Cardiac surgery in the newborn can be palliative or corrective, closed or open. Surgical treatment for particular conditions is discussed in Chapter 21 and it must be remembered that local practices vary a great deal. In general there is a trend towards performing corrective open procedures at increasingly younger ages. Whatever approach is taken, results are better when infants come to operation well resuscitated and stable.

## STRUCTURAL HEART DISEASE IN THE PRETERM INFANT

Respiratory pathology and infective processes are so common in the preterm infant that cardiac disease can be forgotten or masked. It is extremely important to bear in mind the possibility of structural and functional cardiac disease as the cause of or a contributory factor to symptoms and signs in the premature infant. In many cases pharmacological or surgical management is possible with ultimate good outcome. Preterm babies may go into heart failure at an earlier postnatal age with a given condition, such as VSD, than a term baby for reasons that are not entirely clear.

## CARDIOVASCULAR ASPECTS OF CHRONIC PULMONARY DISEASE IN THE NEWBORN

The role of PDA in prolonging acute respiratory failure in RDS has been discussed above. Chronic lung disease will make clinical features of a left to right shunt of any sort very hard to recognize but treatment of the cardiac abnormality may help the respiratory condition. Chronic respiratory failure may cause right heart failure; it is important to avoid hypoxemia in such infants and to treat intercurrent infections and secretion retention vigorously.

## GASTROINTESTINAL PROBLEMS AND JAUNDICE OF THE NEONATE

### EMBRYOLOGY AND MALFORMATIONS

The gut is derived from the embryonic yolk sac which differentiates in early life into the fore-, mid- and hindgut. The foregut gives rise to the pharynx, thyroid, thymus, parathyroid glands, respiratory tract, esophagus, stomach, upper duodenum, liver and pancreas. The midgut gives rise to the lower half of the duodenum, small intestine and large intestine as far as the distal third of the transverse colon. The rest of the large bowel arises from the hindgut. Agenesis of a complete segment is rare; rather, constriction (atresia) of a small portion is more common and can occur at any level because normal development includes luminal obliteration by mucosal growth, followed by recanalization.<sup>713</sup> Atresia is more common at sites where the development of the gut is complex, like the respiratory diverticulum of the foregut (see below).

Between 4 and 6 weeks of fetal life the cranial portion of the foregut differentiates into a complicated branchial arch system which is transitory and obliterated by 7 weeks. Failure of obliteration may result in a persistent sinus, fistula or epithelial lined cyst (e.g. neurenteric cyst). The partitioning of the foregut into the pharynx and trachea may also be incomplete and various types of tracheoesophageal fistula with or without esophageal atresia will result. Abnormal development of the lower end of the foregut may result in a diaphragmatic hernia whilst failure of esophageal differentiation causes achalasia of the cardia or more rarely an esophageal web.

The stomach is relatively immune to embryological malformation. However, the terminal portion of the foregut and cranial end of the midgut undergo major growth in length with consequent herniation from the umbilical cavity (Fig. 12.33).<sup>714</sup> As it returns to the abdomen there is a complex counterclockwise rotation (ultimately 270 degrees) resulting in the fixation of the cecum in the right iliac fossa and the passage of the transverse colon and mesentery over the second and third parts of the duodenum. The first possible failure is that of the endoderm of the yolk sac to separate from the notochord during the third week which

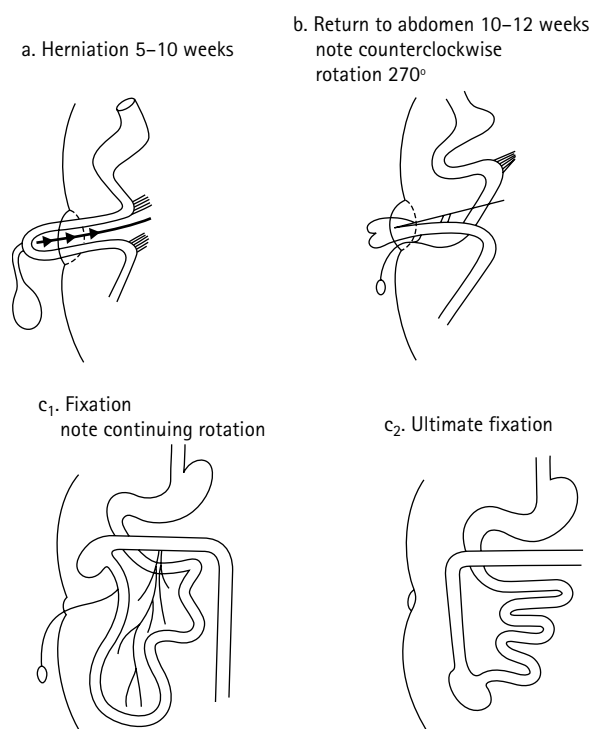

Fig. 12.33 The course of events leading to fixation and final position of the gut within the abdomen. (From Leberthal et al 1988<sup>714</sup>)

results in a variety of reduplications of the intestine. Incomplete failure of the vitellointestinal duct to regress in the fifth week results in a Meckel's diverticulum and complete failure results in an umbilical fistula. Finally failure in herniation return and fixation of the intestine between the fifth and twelfth weeks may cause major defects such as exomphalos and malrotation.

The cloaca is divided by a membrane at 6 weeks into the sagittally oriented rectum posteriorly and the urogenital sinus. Anomalies in rectal differentiation cause a variety of defects ranging from imperforate anus and rectovaginal fistulae to sacral sinus formation. Because rectal differentiation is contemporaneous with that of esophageal differentiation, defects in both structures are often found in the same patient.

The liver is derived from an outpouching of the ventral portion of the duodenum at 4 weeks and defects in its development are rare (Fig. 12.34).<sup>714</sup> Defects in the development of the biliary tree from the cystic duct are more common with either cystic dilation (choledochal cyst) or failure of canalization (biliary atresia) being the commonest disorders. Defects in pancreatic development are also rare but because the final gland is produced by the fusion of a dorsal pancreas from an outpouching of the duodenum just cranial to the hepatic diverticulum and a ventral pancreas from an outpouching in the caudal angle between the gut and hepatic diverticulum (Fig. 12.34) failure of this fusion process may result in an anular pancreas. Cellular differentiation of all the organs of the gut occurs early and is complete in most cases by the end of the first trimester. Intestinal epithelial cells of the first trimester human fetus resemble immature crypt cells of the adult intestine. Morphogenesis of the intestinal epithelium (including differentiation of crypts and villi as well as the intracellular organelles) is completed by about 22 weeks' gestation. Thus, the anatomical development of the gut is complete by the birth of even the 24-week infant and the limiting factor in feeding is the maturation of functional activity.

## ONTOGENY OF GUT FUNCTION

### Carbohydrate absorption

The absorption of carbohydrates seems to pose no problem even for premature neonates. Human milk and most formula milks usually contain only lactose, thus pancreatic digestion is relatively unimportant and the low levels of amylase detected in the duodenal juice of premature and term infants do not matter. More modified milks contain such elements as corn syrup, amylose or maltodextrins in order to reduce their osmolality; however, glucoamylase and sucrase-isomaltase activity should be adequate for their digestion. The disaccharidases develop in close association with the enterocyte itself and disaccharidase activity first appears with the villus formation. Lactase, however, develops later in comparison with sucrase-isomaltase activity (8–10 months' gestation) but lactose intolerance is very rarely seen in the very low birth weight infant, presumably because of enzyme induction.

Intestinal absorption of nutrients and electrolytes is dependent on the development of appropriate cellular active transport processes.

Studies of everted fetal intestinal sacs have shown that cotransport of glucose/galactose by the sodium-glucose linked transporter (SGLT1) is present as early as 10 weeks and there is a three-fold increase in the uptake by 18 weeks. Studies of glucose-evoked potential difference across the duodenum in neonates have confirmed the presence of active glucose transfer in premature neonates, although the number of monosaccharide transporters is reduced in the premature compared with the term infant. Thus carbohydrate digestion/absorption is adequate in the premature infant.

### Protein absorption

Protein digestion is initiated in the stomach and gastric peptic activity increases rapidly after birth (from 2 to 50% adult reference levels by 2 months in term infants). Gastric acid secretion (which is necessary for full peptic activity, the optimal pH for pepsin being 4–5) does not occur at maximal activity in the preterm infant for about 1 month. It is, however, rapidly buffered by milk because of the overall decreased secretory mass in these infants.

Although tryptic activity is low at birth, pancreatic enzyme induction results in high levels by the first week of life in term/preterm infants. Brush border oligopeptidase activity is similar to that found in adults by the early part of the second trimester and protein digestion appears adequate. Active absorption of L-alanine and L-leucine has also been demonstrated in everted sacs from both 10- and 18-week fetuses. Peptides as well as amino acids can be absorbed by the enterocyte which further enhances the efficiency of protein absorption.

### Fat absorption

Lipid digestion is more complex and requires more adaptive mechanisms to ensure maximal absorption of this major source of energy by preterm infants. Four major lipases exist:

1. lingual lipase – this is often bypassed by nasogastric tubes although nonnutritive sucking may increase the contribution of this enzyme;
2. gastric lipase (first demonstrated as having a role in the gastric aspirates of infants with esophageal atresia);
3. pancreatic lipase (this shows rapid substrate induction);
4. bile salt-stimulated lipase (present in high quantities in human milk, irrespective of prematurity and milk volume).

Together, these contribute more than sufficient lipolytic activity even in the preterm infant. Unfortunately, bile salt production in such infants barely reaches the critical micellar concentration and this becomes the rate-limiting factor in fat digestion. However, the palmitic acid of human milk fat is predominantly esterified at the triglyceride 2 position which matches the stereospecificity of pancreatic lipase reducing the need for bile salts. Milk manufacturers tend to compensate for the inefficient fat absorption of their milks by supplementing them with medium chain triglycerides (at the expense of increasing osmolality). The products of fat digestion are absorbed, resynthesized as triglycerides and secreted into the lymphatic system as chylomicrons. Medium chain triglycerides (8–10 carbon chain length) are absorbed without bile salts, and pass to the liver in the portal system.

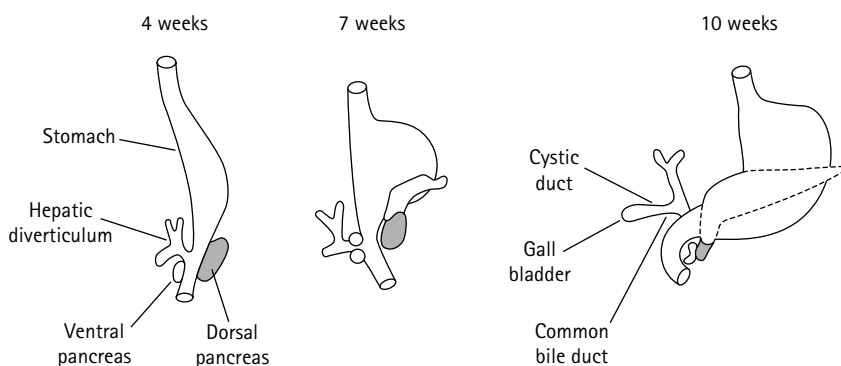

Fig. 12.34 The development of the liver/pancreas from an outpouching of the ventral portion of the duodenum. (From Leberthal et al 1988<sup>714</sup>)

## Salt and water absorption

Salt and water absorption by the enterocyte is present in the early stages of cellular differentiation. It has been shown that adenylate cyclase and Na/K ATPase activities, both closely related to the electrolyte transport processes, develop concomitantly with the brush border translocation mechanisms. Equilibrium dialysis studies of colonic transport mechanisms in the premature infant have demonstrated that the sodium chloride exchange mechanisms are highly active (presumably under the influence of the high levels of aldosterone seen in these infants). Basic transport processes clearly function in early life.

## Intestinal motility

The limiting factor in feeding premature infants is intestinal motility, the ontogeny of which lags behind digestion and absorption. The ability to suck is not present until about 34 weeks' gestation (although it can occur earlier) but this can be bypassed by tube feeding. Gastric emptying, although poor at birth, is fully functional by 24 h postnatally. It is controlled by duodenal receptors in similar fashion in both premature and mature infants by nutrient density and specific constituents of the meal and is inhibited by pathological processes (e.g. RDS and asphyxia). Small intestinal motor activity is divided into fasting and postprandial motor patterns. The fasting migrating motor complex does not fully develop until about 34 weeks' gestation (in association with the onset of sucking).<sup>715</sup> Postprandial activity does not occur until later and seems to be a learned phenomenon increasing with the increasing nutritional density of the feeds. Before 34 weeks a highly propulsive activity, the fetal motor complex, is seen which allows the intestine to function and feeding to be effective. Before 26 weeks, only small nonpropagated contractions are seen and so enteral feeds may not be tolerated initially. More mature motor function may be induced by feeding, allowing many infants of lower gestation to tolerate enteral feeding. The development of colonic motility has not been studied but appears to be adequate although regular glycerin suppositories may be needed initially. It is also clear that the gut motor function is critically dependent upon the well-being of the infant. Thus, sick infants will show delayed maturation (or regression) of gut motor activity and it is this which causes the functional ileus seen in such infants. More rarely disorders of the nervous system of the gut may present with a true pseudo-obstruction and disordered distal migration of the myenteric nerves can give rise to aganglionic segments as in Hirschsprung disease.

## Postnatal development

There are three elements of postnatal development of the gastrointestinal tract that are of fundamental importance in the consideration of neonatal and later childhood intestinal disease.<sup>716</sup> First is the huge capacity for postnatal growth of small and large intestine. The small intestine increases in length from 4 mm at 4 weeks' gestation to 250–300 cm at term, and the colon is 30–40 cm at term. The postnatal growth of the intestine is at least ten-fold, with the small intestine reaching 4–6 m, and the colon 1.5–2.0 m.<sup>717</sup> Second, there is increasing evidence that postnatal modelling events, either as part of normal growth or as a response to injury or inflammation, may proceed under very similar regulation to embryonic development.<sup>716</sup> This will soon be the source of therapeutic development. Last is the central role of the intestinal immune system – the intestine is the largest immune organ in the body. Very recent environmental and cultural changes in human life have resulted in changes in tolerance to dietary antigens and the enteric flora, and may be the cause of the rapid rise in inflammatory bowel diseases and atopic diseases.<sup>716</sup>

## PROBLEMS

The common problems of feeding intolerance, feeding difficulties, vomiting, diarrhea, constipation and gastrointestinal bleeding in the neonatal period will be considered, and then the specific problems of necrotizing enterocolitis (NEC) and intestinal failure, principally due to short bowel syndrome.

### Feeding intolerance (Table 12.68)

This is a common problem in the neonatal nursery, becoming manifest as increasingly large aspirates and failure to tolerate milk in the

Table 12.68 Feeding disorders

Etiology	Investigations
a. 'Feeding intolerance'	
Prematurity	History and examination
Ileus	Nursing observation
Sepsis	Abdominal distention
Major clinical deterioration	Septic screen
Necrotizing enterocolitis	Distention – abdominal wall crepitus, tenderness
	Abdominal X-ray
	Proctoscopy
Asphyxia	
Drugs	
All causes of vomiting	
b. 'Feeding difficulties'	
Maternal factors	History and examination
Poor milk supply	Nursing observation
Cracked nipples/breast abscess	
Tension/anxiety	
Poor ability to suck	
Tachypnea/RDS	
Anatomical abnormality	
Micrognathia	
Macroglossia	
Cleft palate	
Asphyxia	
Bulbar/suprabulbar palsy	Jaw jerk positive
Moebius syndrome	
Myopathies	Absent reflexes
	Electromyogram nerve conduction studies
Familial dysautonomia	Jewish race
	Histamine prick test
	Pupillary response to metacholine

tube-fed infant. Care must be taken to check for blood or bile in the aspirate. The former suggests a gastritis and the latter functional or surgical obstruction. Prematurity is the usual cause for failure to tolerate feeds although most infants after the age of 28 weeks will tolerate continuous tube feeds which are started gradually at 1 ml/h and increased, as tolerated, to full requirements over the course of the first week. In their Cochrane review of ten randomized trials, Premji & Chessell<sup>718</sup> concluded that the evidence to date could not reliably discern between the clinical benefits and risks of continuous versus intermittent milk feeding of preterm infants. A further Cochrane review concluded that the ideal rate of advancement of feeds for preterm infants remains unclear.<sup>719</sup> Hourly intermittent bolus feeds are then introduced and by about 34 weeks' gestation, with the onset of suckling, the infant will tolerate 3- to 4-hourly feeds and is ready for the introduction of orogastric feeding. Attempts to introduce these steps too quickly will result in an increase in the volume of stomach contents aspirated before the next feed (or hourly if continuously fed). Continuous feeds should be continued in infants with short bowel syndrome or other causes of intestinal failure, together with very slow advancements and ongoing parenteral nutrition. Experienced nurses are normally able to distinguish any increase in aspirate due to overly aggressive feeding changes from that occurring unexpectedly and indicating pathology in the gastrointestinal tract. A Cochrane review of 15 randomized trials concluded that non-nutritive sucking by preterm infants aided the transition to bottle feedings and gave better bottle-feeding performance.<sup>720</sup> Most of the causes of vomiting in the neonatal period could present in this manner but most commonly such an increase in aspirate heralds the onset of ileus secondary to sepsis, a major deterioration in the child's general condition or NEC. Asphyxia may be complicated by gastric stasis and is the

commonest organic cause of poor feeding postnatally in the term infant. Failure to start oral feeding for more than 1 week indicates a poor prognosis. Drugs used postnatally, especially phenobarbitone and diazepam, can delay gastric emptying and enteral feeding may not be possible in the ventilated and paralyzed infant. Other drugs have been assessed in randomized trials for improvement of motility in preterm infants with feeding intolerance, but some, such as erythromycin,<sup>721</sup> do not have current evidence to support such use, and others, such as cisapride,<sup>722</sup> have been withdrawn from use due to side-effects.

### Feeding difficulties (Table 12.68)

It may be difficult to establish feeding even in the term infant. Breast problems such as cracked nipples or a breast abscess may prevent breast-feeding, the gold standard route of feeding for both preterm and term infants, but the baby will quickly accept bottle-feeding. Maternal anxiety, however, may prevent the establishment of breast-feeding and can also lead to clumsy or inappropriate methods of bottle-feeding (resulting usually in overfeeding and vomiting but occasionally in inadequate feeding and failure to thrive). A recent Cochrane review evaluated 34 eligible randomized controlled trials containing nearly 30 000 mother–infant pairs, and concluded that there was clear evidence that professional support and lay support could prolong duration of breast-feeding and promote exclusive breast-feeding respectively.<sup>723</sup>

Disorders of sucking and swallowing can occur. Anatomical abnormalities such as micrognathia, macroglossia and cleft palate often result in poor sucking and slow feeding. Neurological conditions other than asphyxia tend to present with uncoordinated sucking and swallowing causing oral or nasal regurgitation, sometimes accompanied by the signs of a suprabulbar palsy with tongue thrust and a positive jaw jerk. The rare congenital Moebius syndrome with bilateral facial palsy (and other cranial nerve palsies) due to congenital agenesis of the cranial nerves also results in a poor suck and uncoordinated swallowing. Unilateral nerve lesions do not usually cause problems and where present should be distinguished from myopathies such as mitochondrial myopathy which may cause dysphagia in the neonatal period. The Riley–Day syndrome (familial dysautonomia) may also present in the neonatal period with disorders of swallowing but usually dysphagia occurs later in childhood. Where there is excessive drooling of saliva in association with swallowing difficulties a tracheoesophageal fistula should be considered although the usual clinical picture (coughing, excessive saliva, cyanotic and apneic spells) is quite distinctive and is rapidly diagnosed within a few hours of birth by a plain X-ray with a nasogastric tube inserted.

### Vomiting

Vomiting is common in newborn infants. Assessment should always include the overall clinical condition and other symptoms and signs, as well as the volume, frequency and contents of the vomitus (causes and investigations in Table 12.69).

### Possetting

Possetting (the regurgitation of small amounts of milk after feeds) is common in the neonatal period and is easily distinguished from pathological vomiting by experienced mothers and midwives. Regurgitation and vomiting both indicate underlying disorders in the newborn period (vomiting is a more serious problem). Rumination is a rare disorder, possibly familial. The baby regurgitates small amounts of food into the mouth which is then chewed with apparent self-gratification. It usually presents after the neonatal period.

### Feeding disorders

Feeding disorders are the commonest cause of vomiting in the first month of life after leaving hospital. Greedy babies swallow air. This leads to excessive possetting or vomiting and can usually be recognized by experienced health visitors. Overfeeding or the improper preparation of the bottles is more difficult to spot and commonly presents as vomiting to casualty departments. A careful history of type, amount and constitution of feed is vital in every case of vomiting. With correction of mother's mistakes

Table 12.69 Vomiting

Etiology	Investigations
<i>Feeding disorders</i>	
Overfeeding	Feeding history and observation
Air swallowing	
Maternal stress	Family history
<i>Esophageal disorders</i>	
Tracheoesophageal fistula/frothy vomit day 1	CXR/AXR with large nasogastric tube
Hiatus hernia	Barium swallow/pH study
<i>Gastric disorders</i>	
(Gastritis)	
Maternal debris	Stomach washout
Blood – hemorrhagic disease of the newborn	Clotting screen
Maternal stress illness	History
Pyloric stenosis	Test feed Ultrasound/barium meal
<i>Small intestinal disorders</i>	
Congenital	
Duodenal atresia	AXR
Extrinsic duodenal obstruction	AXR
Malrotation	AXR
Volvulus	AXR
Meconium ileus	AXR (calcification)
Intestinal duplication	AXR
Acquired	
Pseudo-obstruction/sepsis	Full blood count, septic screen
NEC	AXR – free or intramural gas
Proctocolitis	Stool cultures
Food allergy	Dietary manipulation
Incarceration/strangulation	Inspection
Inguinal herniae	AXR
<i>Extraintestinal disorders</i>	
Intracranial lesions	
Asphyxia, meningitis	
Intracranial hemorrhage	
Hydrocephalus/SOL	
Renal disorders	
Urinary tract infection	MSU/bag urine
Obstructive uropathy	Renal ultrasound
Metabolic disorders	
Galactosemia	Urine sugar
Hyperammonemias	Urine amino acids
Phenylketonuria	Urine amino acids
Organic acidemias	pH urine
Congenital adrenal hyperplasia	Electrolytes
Drugs	Theophylline

AXR, abdominal X-ray; CXR, chest X-ray; MSU, mid stream urine; NEC, necrotizing enterocolitis; SOL, space-occupying lesion.

the symptoms rapidly resolve. However, maternal anxiety or depression is often a coexistent factor in such cases and contributes to the fussy eating and vomiting in these babies. Evidence of affective disorder or postnatal depression in the mother should be sought during history taking and a full family history often reveals predictable stressors such as death of a sibling or other close relative, or a previous stillbirth or neonatal death.

### Organic causes of vomiting

**Vomiting in the first week of life.** Vomiting at this time may be due to difficulties in establishing appropriate feeding. However, more specific organic causes must be excluded by appropriate means. All causes of

vomiting (Table 12.69) may present at any time, but in this early period, consideration of the vomitus and baby together with an abdominal X ray can narrow the differential diagnosis. For example:

1. Vomitus
  - Frothy
    - tracheoesophageal fistula
  - Blood
    - maternal – swallowed
    - hemorrhagic disease
    - gastric erosions/stress ulcers
  - Bile
    - intestinal obstruction
    - intestinal perforation/peritonitis
    - intestinal pseudo-obstruction
  - Milk only
    - feeding disorder
    - gastroesophageal reflux
    - food allergy
2. Baby well: abdomen normal
  - AXR – fluid level
    - duodenal/intestinal atresia
    - meconium ileus
    - large bowel obstruction/Hirschsprung disease
  - AXR – no fluid levels
    - gastroesophageal reflux
    - milk allergy
3. Baby sick
  - Abdomen normal: AXR –  $\pm$  fluid levels + watery diarrhea
    - sepsis/UTI
    - increased intracranial pressure/meningitis
    - renal tract disorders
    - metabolic disorders
  - Abdomen distended/tender: AXR – fluid levels (watery or bloody diarrhea)
    - necrotizing enterocolitis
    - obstruction/perforation
    - volvulus
    - intussusception.

The commonest cause for vomiting in the first 2 days of life is neonatal gastritis due to irritation from swallowed liquor and debris from the birth canal. One or two stomach washouts will identify the debris (and the altered maternal blood) and cure the problem. The baby remains well throughout. If the baby is sick, other signs are present or the vomiting persists, then fuller investigations are required. Clearly a septic screen comprising full blood count (FBC), clotting studies, blood cultures, mid stream specimen of urine (MSSU) and possibly lumbar puncture (LP)] is indicated in a baby who is unwell, and all vomiting babies need urea and electrolytes checked. Hematemesis may require transfusion and treatment with vitamin K or fresh frozen plasma (FFP) as indicated. Stress ulceration is rare but usually settles with i.v. ranitidine or omeprazole.

Bile-stained vomiting is a more sinister sign and usually indicates NEC, obstruction or some other surgical condition. Request for a surgical opinion should always be considered. The higher the obstruction, the earlier the presentation; thus duodenal atresia, jejunal atresia, malrotation and volvulus and high duplications all present in the first 2 days of life with marked vomiting and intolerance of feeds. Low obstructions due to Hirschsprung disease, milk plug functional obstruction and anal atresia may present more insidiously with a period of constipation before vomiting starts towards the end of the first week. Meconium ileus due to cystic fibrosis presents at any time in the first week (usually in the first few days). Acquired obstruction obviously tends to present later but one should always examine the abdomen carefully for signs of strangulated herniae and intussusception and the presence of anal atresia. These conditions are discussed in more detail in Chapter 37.

The abdominal X-ray is pivotal in making the initial diagnosis. Fluid levels indicate both the obstruction and the level of obstruction. Duodenal atresia causes a classic double bubble whilst high obstructions reveal

small bowel fluid levels with no gas in the rectum. Colonic disorders may have many fluid levels but often require contrast enemas to distinguish between long segment Hirschsprung disease, meconium ileus of cystic fibrosis (although abdominal calcification may be seen following intra-uterine perforation) and the even more rare true pseudo-obstruction (visceral myopathy or neuropathy). Free abdominal gas indicates an intestinal perforation that is usually due to NEC but occasionally spontaneous or associated with an atretic segment. Volvulus secondary to malrotation is dramatic with large dilated loops (the American football sign) or may be inferred from the abnormal distribution of the bowel gas in malrotation (although this usually requires upper gut contrast studies for accurate delineation). When fluid levels are less marked and the infant is sick or jaundiced, ileus due to sepsis is likely.

Surgical disorders when identified will require prompt transfer to a unit specializing in neonatal surgery. An intravenous infusion of 10% dextrose should be started and the infant kept warm in the incubator. The stomach should be aspirated hourly and the aspirate replaced as normal saline intravenously. If the infant is shocked, resuscitation with 10–20 ml/kg of fluid is required. If the infant is sick, parenteral antibiotics must be started whilst awaiting the result of the septic screen. In cases of tracheoesophageal fistula, a large bore double lumen tube (Replogle tube) is passed into the proximal pouch. Air is passed into one lumen and aspirated with any secretions from the other. Continuous drainage in this way prevents apnea and aspiration episodes. The infant is nursed prone with a slight head tilt.

*General disorders.* Nongastrointestinal causes for vomiting must always be borne in mind. Sepsis will cause an ileus, as already described. Urinary tract infection without bacteremia, however, has long been recognized to present with gastrointestinal symptoms, most commonly with vomiting. Obstructive renal disease may also present in this way in the absence of infection. Urine culture and microscopy must always be performed. Plasma urea and electrolytes are also important to identify acidosis (renal and metabolic disease) and alkalosis (pyloric stenosis occasionally presents early in the neonatal period). Intracerebral asphyxial insults may cause vomiting acutely due to raised intracranial pressure, and meningitis may present as vomiting at any age. Other cerebral causes of vomiting such as hydrocephalus, space-occupying lesions and the diencephalic syndrome rarely present in this fashion in the neonatal period. Metabolic disorders are a cause of vomiting in the neonatal period and should always be considered if metabolic acidosis (and/or hypoglycemia) is present, or if a baby appears septic but has a metabolic alkalosis (urea cycle disorders). Galactosemia may present as early as the first day and the urine must always be tested for reducing substances. Usually the infants with metabolic disorders start vomiting after milk feeding has been established and they have been exposed to a reasonable protein load (e.g. the hyperammonemias, disorders of amino acid metabolism and the nonketotic hypoglycemias). The presence of constipation with vomiting in a dysmorphic infant may suggest the presence of idiopathic hypercalcemia; vomiting with dehydration and electrolyte disturbance (sometimes with diarrhea) may be due to congenital adrenal hyperplasia. The organic acidemias must be excluded by specific assays (dicarboxylic aciduria) on acute phase urines collected when the patient is symptomatic and, where possible, acidotic. After the first week of life acquired metabolic disorders such as diabetic ketoacidosis and Munchausen syndrome by proxy may rarely have to be considered.

**Persisting vomiting/vomiting after the first week of life.** Babies presenting after the first week of life tend to have acquired problems although lower intestinal obstructions, malrotation and, in the very low birth weight baby, NEC, may present later. Vomiting is one of the commonest presentations to a pediatric unit and consideration of the baby's clinical state again allows a fairly rapid differentiation of causes:

- Baby well: abdomen normal
  - possetting
  - feeding disorder
  - gastroesophageal reflux
  - gastrointestinal food allergy
  - pyloric stenosis
  - urinary tract infection

- Baby unwell: abdomen distended
  - late obstruction
  - peritonitis/appendicitis
  - intussusception
  - NEC.

Persistent vomiting even in a relatively well baby, and especially if accompanied by poor growth, may indicate a more serious underlying disorder. If investigations are normal, a feeding disorder is excluded and the vomiting still persists then the differential diagnosis usually rests between a dietary food intolerance and gastroesophageal reflux.

**Gastroesophageal reflux (GOR).** GOR may present with vomiting in the first month of life. It must be remembered that GOR is a physiological condition, associated with transient relaxation of the lower esophageal sphincter, and should only be investigated and treated if there is GOR-associated disease present (GORD) – esophagitis, strictures, chronic aspiration, failure to thrive. In the term baby, GORD can be investigated with upper gastrointestinal endoscopy, pH meter or radiolabeled milk scan, although many would use an empirical trial of treatment first. The role of contrast studies is not for diagnosis but rather to rule out anatomical lesions (malrotation) or esophageal strictures. Infants at risk of GORD include those with repaired esophageal atresia, those with bronchopulmonary dysplasia, and those with severe neurodevelopmental problems. Infants with severe neurodevelopmental problems develop a generalized gastrointestinal dysmotility, manifest by GOR and duodenogastric reflux, leading to bilious vomiting, and may be intractable. In the premature infant recurrent consolidation due to aspiration from GOR may lead to a disorder indistinguishable from bronchopulmonary dysplasia. GOR may also be a major cause of apneic spells resistant to methylxanthine therapy. Esophageal pH studies may confirm this, although they undoubtedly underestimate postprandial reflux in the preterm baby where the decreased acid production of the stomach is readily buffered for prolonged periods by the milk feed. Sometimes it is more practical to again treat such infants empirically. Treatment includes pharmacological, surgical and nonpharmacological, nonsurgical options such as positioning and feed thickeners. The role of the last group of measures has recently been systematically reviewed, and it was concluded that commonly used conservative measures do not have any proven efficacy in GORD in infancy.<sup>724</sup> Positioning at 60 degree elevation in seats was found to increase reflux compared to prone positioning, and thickened formulas reduced vomiting but not reflux.<sup>724</sup> The supine position is currently recommended for infants due to reduced risk of SIDS. There are no high quality randomized trials of drug or surgical therapy confined to infancy with GOR as a primary outcome, so systematic review is currently unhelpful. Antacids and alginates, prokinetic agents such as domperidone, antisecretory agents such as ranitidine, and proton pump inhibitors such as omeprazole are all used in the treatment of GORD in infancy, although few are licensed for this. Fundoplication, increasingly by the laparoscopic route, is reserved for persisting and severe GORD. Severe gastrointestinal dysmotility may require nasojejunal or transgastric jejunal feeding, with gastric (nasogastric or gastrostomy tube or gastric port) access for aspiration, drainage and medication administration.

**Gastrointestinal food allergy.** Food allergy is becoming increasingly common in children and may present in the first weeks of life, even in solely breast-fed babies.<sup>725</sup> Sensitization can occur due to minute doses of antigens (usually glycoproteins) passing into breast milk. Symptoms such as vomiting follow food ingestion, due to an abnormal immunologically mediated reaction within the gastrointestinal tract. These reactions can be type I immediate hypersensitivity, which will present with vomiting, or type IV delayed hypersensitivity, which presents with poor growth, diarrhea and rectal bleeding. For acute allergy, careful history will reveal the ingestion of an allergen, such as cows' milk protein, followed by vomiting, and occasionally pallor, diarrhea and rarely acute anaphylaxis. There is often a family history of atopy and atopic eczema may be present. The best investigation is exclusion, causing relief of symptoms, and challenge, which may need to be in a controlled environment. The presence of specific IgE antibodies and positive skin-prick tests are not valuable for delayed reactions. Treatment is elimination of cows' milk, usually by substitution with an extensively hydrolyzed protein feed or amino acid based feed (Neocate, SHS, Liverpool).

### Neonatal diarrhea (Table 12.70)

Diarrhea is a relatively uncommon symptom in the neonatal period although most breast-fed children will have loose yellow seedy stools. Mothers and midwives are very clear when the stools are pathological, usually because they are watery with little or no solid matter, are increased in frequency or contain blood and mucus. The commonest cause of loose stools is phototherapy but this causes no harm as long as the fluids are increased appropriately. Loose stools may occur with nasojejunal tube feeding. The commonest serious causes of diarrhea are gastroenteritis and NEC and the latter should always be considered in infants with diarrhea. Usually, however, the characteristic bloody/mucousy stool together with the abdominal distension and X-ray signs give the diagnosis.

Outbreaks of viral gastroenteritis are not unknown in the neonatal unit and the infants respond to the normal management of such infections. Stools should be sent for cultures and electron microscopy for viruses. A full infection screen should be performed to exclude systemic causes of diarrhea. Diarrhea always causes loss of water and electrolytes, and dehydration can rapidly occur; the newborn are more susceptible

Table 12.70 Neonatal diarrhea

Etiology	Investigations
<i>Iatrogenic</i>	
Phototherapy	
Nasojunal tube feeding	
Narcotic withdrawal	Drug history – maternal, neonatal
<i>Infective</i>	
Gastroenteritis	
Viral	Stool electron microscopy
Bacterial	Culture
Systemic infection	Infection screen
<i>Surgical</i>	
Necrotizing enterocolitis	Abdominal X-ray
Appendicitis	
Hirschsprung disease	Rectal examination, biopsy
<i>Congenital enteropathy</i>	
Lactase deficiency	Stool sugars – Clinitest, chromatography
Sucrase-isomaltase deficiency	Biopsy
Glucose-galactose malabsorption	
Congenital Na/H exchange deficiency	
Congenital chloridorrhea	Stool electrolytes/osmolality
Congenital microvillus atrophy	
Tufting enteropathy	
Abetalipoproteinemia	Fasting cholesterol/lipids + biopsy
Acrodermatitis enteropathica	Plasma zinc
<i>Acquired enteropathy</i>	
Food allergy	Family history, eosinophilia on biopsy
Immunodeficiency (SCID)	Immunoglobulins, lymphopenia
<i>Metabolic disorders</i>	
Congenital adrenal hyperplasia	Electrolytes
Dicarboxylic aciduria	Venous pH, urine organic acids
<i>Drugs</i>	
Antibiotics	
Prostaglandins	
Theophylline	
<i>Pancreatic insufficiency</i>	
Cystic fibrosis	
Shwachman–Diamond syndrome	

SCID, severe combined immunodeficiency.

to this, due to gut immaturity. The baby should be rehydrated with oral rehydration therapy (ORT) by oral or nasogastric tube, or intravenous fluids as necessary. Once replacement of deficit has occurred, reinstitution of feeds should occur, with maintenance fluids and ongoing losses replaced with ORT or i.v. fluids. Complications of diarrhea include electrolyte disturbance with acidosis, nosocomial spread of the disease (the infants should be isolated), secondary lactose intolerance (check for stool pH and reducing sugars), and secondary cows' milk protein intolerance.

Other causes of diarrhea are all rare, and may present as intractable or protracted diarrhea, defined as watery diarrhea for more than 2 weeks. It is often associated with malabsorption and undernutrition. Many of these infants eventually will be found to have a specific diagnosis,<sup>726</sup> but a group remains in which no primary cause can be determined. Congenital disorders of the enterocyte usually cause loose stools in the neonatal period although they may present later with intractable diarrhea since the pathological nature of the stools is not always appreciated initially. An antenatal ultrasound may have shown distended fluid-filled bowel loops. Food allergy, particularly the delayed type, may present as diarrhea. The more specific entity of cows' milk colitis, however, presents with bloody diarrhea and must be differentiated from NEC and other conditions (intussusception, Meckel's diverticulitis and volvulus). Diagnosis rests on the resolution of the symptoms after appropriate substitution of the feed. Where the infant's size and condition permit, a rectal biopsy may show eosinophils in the inflammatory infiltrate. Autoimmune enteropathy and immunodeficiency, especially severe combined immunodeficiency (SCID) and IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy and X-linkage), may present with diarrhea and even a protein-losing enteropathy in the neonatal period. Lymphopenia on the blood film and other coexistent signs of infection (such as an interstitial pneumonia on chest X-ray) should alert one to this diagnosis. Similarly, abnormalities of the urea and electrolytes or acidosis should suggest the possibility of a metabolic disorder and one should always inquire jointly of the mother's and baby's drug history. Intractable or protracted diarrhea of infancy may helpfully be divided into those entities having normal villous-crypt axis (transport defects, acrodermatitis enteropathica, enzyme deficiency) and those with villous atrophy (congenital enterocyte disorders, autoimmune enteropathy, IPEX syndrome, allergic enteropathy and infectious and postinfectious enteropathies).<sup>726</sup>

Nutritional management remains the cornerstone of treatment of intractable diarrhea, and the majority require parenteral nutrition, with very careful and slow introduction of enteral feeds.<sup>726</sup> In many cases, home parenteral nutrition or intestinal transplantation are the only long term therapeutic options.

### Neonatal constipation (Table 12.71)

The failure to pass meconium in the first 24 h in a term baby is a significant symptom and should prompt a search for the underlying cause. In a preterm baby, however, failure to open the bowels is not uncommon and many neonatal units use glycerin suppositories (chips) from day 1 to encourage bowel actions and facilitate tolerance of enteral feeds. After prematurity, the most common organic cause of constipation in the first weeks of life is Hirschsprung disease and this must be excluded by rectal examination followed by suction biopsy in all term infants when constipation follows on failure to pass meconium within the first 48 h. Hirschsprung disease has an incidence of 1 in 5000 live births, and has complex inheritance; multiple genes have been found to be involved.<sup>727</sup> Neonatal constipation should always be taken seriously; failure to open the bowels at least every other day is outside the range of normality. Clinical findings and simple investigations as outlined in Table 12.71 should allow one to identify most organic causes.

The management of simple constipation in the neonatal period is similar to that at an older age. Correction of a feeding disorder and provision of an adequate amount of extra water to slake thirst (especially in hot weather) will correct most cases. If this proves insufficient, intermittent suppositories are occasionally successful but more usually infants will need a stool softener (lactulose 2.5 ml b.d.) for a period of time to regularize the bowel habit. Impaction, if present, must be relieved before a regular bowel habit is restored.

Table 12.71 Neonatal constipation

Etiology	Investigation
1. Ileus	
Prematurity	Abdominal X-ray
Major insult – sepsis	Abdominal X-ray
Asphyxia	Abdominal X-ray
2. Pseudo-obstruction	
Neuropathy	Abdominal X-ray, barium meal and follow through
Myopathy	Rectal biopsy
3. Meconium plug	
4. Low bowel obstruction	
Meconium ileus/cystic fibrosis	Immunoreactive trypsin
Hirschsprung disease	Rectal examination, barium enema
Colonic atresia	
5. Anorectal anomalies	
Imperforate anus – anal atresia, anorectal atresia	Rectal examination
Rectal atresia	
Anal stenosis/stricture	
Rectal stenosis/stricture	
6. Metabolic disorder	
Hypothyroidism	Thyroxine, thyroid stimulating hormone
Hypercalcemia	Calcium
Salt- and water-losing states	Urea and electrolytes
Renal tubular acidosis	Urine pH
7. Overfeeding	

### Gastrointestinal bleeding

Gastrointestinal bleeding in the newborn is a potentially serious problem.<sup>728,729</sup> It can present in four ways – hematemesis, hemochezia (bright red blood passed per rectum), melena or occult bleeding. The initial assessment should rapidly address the need for resuscitation, and whether bleeding is ongoing. Recognition of shock should not rely on hypotension, a late and ominous finding in infancy. Differentiation of upper from lower gastrointestinal bleeding will guide the order of investigations and the therapy. Hematemesis is a clear guide of upper bleeding, melena suggests a source far from the rectum, and hemochezia can occur with small intestinal or colonic bleeding. Diagnostic techniques include upper and lower gastrointestinal endoscopy using neonatal endoscopes, scintigraphy (Meckel's scan), ultrasonography, other imaging, and rarely laparoscopy or laparotomy.

Swallowed maternal blood explains many cases of bleeding in the newborn.<sup>728,729</sup> Small amounts of fresh blood or coffee-ground material in vomitus is not rare, and if self-limiting the prognosis is good. The common sources of upper gastrointestinal bleeding in the newborn are nasopharyngeal bleeding, swallowed maternal blood, esophagitis, gastritis and stress ulcer; rarer causes include vitamin K deficiency, bleeding disorders, duplication cyst, trauma from tubes, food allergy and vascular malformations. The common sources of lower gastrointestinal bleeding in the newborn are anal fissure, enteritis, intussusception, NEC, food allergy and an upper source; rarer causes include vitamin K deficiency, bleeding disorders, pseudomembranous colitis, duplication cyst, Meckel's diverticulum, Hirschsprung's enterocolitis, ischemia and vascular malformations. Treatment of all moderate and severe cases includes assessment, resuscitation, appropriate venous access, consultation with a pediatric surgeon, then identification and treatment of the cause.

### Necrotizing enterocolitis

Necrotizing enterocolitis (NEC) is a much feared condition in every neonatal unit, and has a much higher incidence in the very low birth

weight infant, with an incidence of 2–5% in the UK, where a survey by the British Paediatric Surveillance Unit to the end of 1994 reported over 300 new cases, with a total mortality of 22%.<sup>730</sup> In the USA, NEC is reported to occur in 4–13% of VLBW infants.<sup>731</sup> In high risk groups, such as those of birth weight < 1 kg, up to 25% of survivors experience long term adverse sequelae.<sup>732</sup> The etiology is unknown but is likely to be multifactorial with superinfection by gas-forming bacteria and failure of the mucosal barrier in the immature gut playing important roles. Other contributing elements include inadequate oxygen transport to the gut mucosa and substrate in the form of enteral feeds.<sup>733</sup> Precipitating factors include hyperosmolar feeds, perinatal asphyxia, polycythemia and umbilical vessel catheterization. A clear association has emerged between the presence of reversed end-diastolic flow in the umbilical artery in utero in the severely growth retarded infant and the development of NEC in the first weeks of life.

The prevention of NEC in the neonatal unit has been addressed in eight Cochrane reviews.<sup>718,719,734–739</sup> None of those concerning feeding strategies<sup>718,719,734,735</sup> contains enough high quality randomized trials of sufficient power to demonstrate superiority of one feeding regimen over another. Similarly, a review found only one small randomized trial of arginine supplementation to parenteral feeds to prevent NEC, with insufficient power to support this action.<sup>736</sup> Three randomized trials (involving 2095 newborn) of oral immunoglobulin usage were reviewed by Foster & Cole,<sup>737</sup> who concluded that the evidence did not currently support this strategy. Five eligible randomized trials (involving 456 infants) of enteral antibiotic prophylaxis were reviewed by Bury & Tudehope,<sup>738</sup> who concluded that a larger single randomized trial was needed to assess benefit and harm. A review of three randomized trials suggested restricted fluid intake for preterm infants could prevent NEC, although

one was of low methodological quality.<sup>739</sup> Bell<sup>733</sup> has reviewed other proposed strategies for the prevention of NEC, including significant risk reduction by the use of antenatal corticosteroids<sup>740</sup> and feeding with breast milk.<sup>741</sup> Schanler<sup>742</sup> has recently summarized three randomized trials of probiotic usage in more than 1100 preterm infants to prevent NEC, and also showed a significant risk reduction but some unanswered questions.

The disease presents with increasing aspirates (usually bile-stained) or vomiting (usually bilious but occasionally blood-stained). Diarrhea follows (or occasionally precedes) the failure to tolerate feeds and may be watery or contain mucus and visible blood and pus. The baby is often unwell, lethargic and having apneic episodes. Examination reveals a tense distended tender abdomen which is quiet (or silent if perforation has taken place). Tenderness and/or guarding suggest peritonitis has supervened and in the later stages there may be edema and inflammation of the abdominal wall (producing a 'peau d'orange' appearance in the skin) or an underlying abdominal mass. Blood cultures are positive in 18–60% of cases and septic or hypovolemic shock may be a complication and the infant may collapse and die. Diagnosis is classically made on the plain abdominal X-ray. This initially shows separation of the bowel loops due to ascites with fluid levels. Then the periluminal tramlines indicating intramural gas appear (Fig. 12.35a) especially in the cecum, ascending and descending colon and sigmoid. Later signs include gas in the portal tree (Fig. 12.35b) and gas under the diaphragm following perforation. In the early stages the diagnosis may also be suggested by the presence of a proctocolitis using an auroscope as a proctoscope.

A pancolitis is usually found at postmortem. The histology reveals a characteristic hemorrhagic inflammatory infiltration. The differential diagnoses include generalized sepsis, meconium ileus, malrotation

Fig. 12.35 (a) Necrotizing enterocolitis. Double lumen to the colon can be seen clearly at the hepatic flexure and triple lumen in the descending colon – both effects caused by intramural gas. (b) Gas tracts ramifying throughout the liver in portal vessels and periportal tissue. Arterial catheter is adequately sited. The venous catheter passes into the right hepatic vein.

and volvulus, hemorrhagic disease of the newborn, cows' milk colitis and intussusception and the even rarer neonatal appendicitis. The other causes of abdominal distention (Table 12.72) must also be considered, especially spontaneous perforation of the gut and other causes of ascites.

Management is initially medical and conservative.<sup>743</sup> Oral feeds should be stopped and the stomach placed on free drainage. A septic screen is performed and it is customary to give broad spectrum intravenous antibiotics. Blood counts, clotting screen, urea and electrolytes and albumen are checked and appropriate supportive management given as indicated. Intravenous feeding through a central line should be instituted for 10 days and the bowel rested. Afterwards feeds should be introduced slowly. Expressed breast milk or a preterm formula is used, although a protein hydrolysate may be needed as lactose and cows' milk protein intolerance are often seen in the recovery phase in these infants. Surgery is required for the acute complications of perforation, ongoing necrosis, progressive shock and bleeding, or if there is failure to improve with medical therapy. Later complications (stricture formations with subacute small bowel obstruction, blind loop syndrome and rectal bleeding) may also require surgery, as may a recurrence which occurs in 10% of patients. Short bowel syndrome (see below) may occur.

### Neonatal intestinal failure

*Intestinal failure* is defined as a reduction of functional gut mass below that needed to allow sufficient digestion and absorption of fluids and nutrients for growth in infants and children.<sup>744</sup> In neonatal practice, this will be severe congenital or early onset disorders needing protracted or indefinite parenteral nutrition. Intestinal failure is usually divided into three groups:<sup>744,745</sup> an anatomical reduction giving short bowel syndrome (SBS), neuromuscular disease of the gastrointestinal tract such as chronic intestinal pseudo-obstruction syndrome (myopathy or neuropathy) or long segment Hirschsprung syndrome, and lastly the congenital enterocyte disorder such as microvillous inclusion disease and intestinal epithelial dysplasia. Short bowel syndrome is by far the predominant cause of neonatal intestinal failure and is therefore considered in more detail below. The small intestine is only 115 cm length at 27 weeks and is 250 cm at term. There is maximal growth in the first year of life and adults have a mean of 6.2 m. The capacity for small intestinal growth is highest in preterm infants. There is regional gut function, with the stomach acting as a reservoir, then the jejunum has most nutrient absorption but is very porous for water and electrolytes. The ileum is involved mainly in fluid and electrolyte absorption, with less general absorption of nutrients except for specific absorption of vitamin B<sub>12</sub> and bile acids. The ileocecal valve acts as a barrier to colonic bacteria and in the colon there is absorption of sodium, water and some carbohydrate and fat.

The early management of intestinal failure in the neonatal unit is vital. This includes:

- careful charting of input and output;
- use of a stoma bag to measure effluent if applicable;
- replacement of stoma losses in terms of fluid and electrolytes;
- meticulous checking of growth, recording of growth and consultation of the results;
- checking of urinary sodium levels, even when serum levels are normal;
- a very slow increase in enteral feeds, be it expressed breast milk, protein hydrolysate or elemental feed;
- use of continuous enteral feeding via a pump;
- treatment of gastric hyperacidity with H<sub>2</sub> receptor agonists or proton pump inhibitors.

*Short bowel syndrome* is defined functionally, rather than anatomically; it exists where there is malabsorption in the presence of a shortened small intestine. Intestinal adaptation begins with gut resection and there is epithelial hyperplasia to increase surface area and later muscular hypertrophy. This will result in improved digestive and absorptive function, and the ileum has the best adaptive capacity. This process will not occur without enteral nutrition. The consequences of a major loss of small bowel include malabsorption of nutrients, vitamins and minerals, gastric acid hypersecretion, functional pancreatic insufficiency, water and electrolyte losses, hyperoxaluria, biliary lithiasis, liver disease and bone disease. The relative degree of jejunal, ileal and colonic loss in this syndrome determines the pathophysiological effects and thus the management. By far the commonest cause of short bowel syndrome is NEC, but many other prenatal (vascular accidents, atresias, volvulus, abdominal wall defects) and postnatal (volvulus, thrombosis) etiologies exist.

The development and refinement of parenteral nutrition, techniques and equipment for prolonged central venous access, new enteral formula development and the back-up of intestinal and/or liver transplantation have changed this disorder from one that was fatal 30 years ago to one where infants may have a prolonged life span into adult life.<sup>745</sup> Management of short bowel syndrome is a gradually changing multi-stage process.<sup>744,745</sup> There has to be institution of appropriate parenteral nutrition and restoration of fluid and electrolyte balance. When the infant is stabilized, enteral feeding should be initiated. The aim is to increase enteral feeds within the limits of tolerance until weaned from TPN. If parenteral nutrition will be prolonged, management at home should be considered, with appropriate training and support. Once a child has adapted, parenteral nutrition should be stopped and the child maintained on a combination of oral and/or enteral tube feeding. The child will continue to need to be monitored for growth and complications. Given that it is a relatively rare and highly complex problem, assessment and management must involve tertiary center pediatric gastroenterologists and pediatric surgeons.

There are few randomized trials of components of management of short bowel syndrome. Other medical management includes treating hypergastrinemia, cycling TPN, and treatment of small bowel bacterial overgrowth. Surgical management includes stricturoplasties, tapering procedures and consideration of small bowel and/or liver transplant if vascular access or chronic liver disease become problematic. Complications include macro- and micro-nutrient deficiency, intestinal failure-associated liver disease,<sup>746</sup> central venous catheter thrombosis and infection, and small bowel bacterial overgrowth. Prognosis depends upon presence of the ileocecal valve, length and quality of remaining bowel, number of anastomoses, and small bowel bacterial overgrowth. Intestinal failure and short bowel syndrome are discussed further in Chapter 19.

### BILIRUBIN METABOLISM<sup>747,748</sup>

Bilirubin is one of the end products of heme catabolism and in normal circumstances has to be processed by the liver for its excretion. In early neonatal life there is a much greater production of bilirubin.

The hemoglobin mass at birth is high (and further increased by such factors as delayed clamping of the cord) and contains approximately 80% fetal hemoglobin. This is replaced within 4 months by adult hemoglobin. This obligatory red cell turnover is the major factor in the excess bilirubin production (each 1 g Hb produces 600  $\mu\text{mol}$  of bilirubin). To this must be added the bilirubin produced by bruising, cephalhematoma and shunt bilirubin (bilirubin produced by heme pigments in the reticuloendothelial system that are never incorporated into hemoglobin: approximately 20% of the total bilirubin production).

Heme is metabolized to biliverdin by heme oxygenase (Fig. 12.36)<sup>749</sup> which is found in the liver, spleen and macrophages and whose activity is increased many-fold in the face of such an increased substrate load. The biliverdin is rapidly reduced to bilirubin by biliverdin reductase using NADPH as a proton donor. The end product, bilirubin XIIa, is insoluble because of the hydrogen bonding between the two pyrrole rings (a process facilitated by the ionization of the molecule that occurs below pH 7.4) (Fig. 12.37).<sup>750</sup> The insoluble bilirubin is tightly bound to albumin (binding capacity 0.5–1.0 mmol bilirubin per mol albumin). At a bilirubin concentration of 340 mmol/L the molar ratio exceeds 1:1 and dissociation of the bilirubin occurs readily. Because of its fat solubility (increased at low pH) this bilirubin is readily deposited in the tissues.

Bilirubin is transported through the hepatocyte membrane by a carrier-mediated process and is then carried to the endoplasmic reticulum after binding to cytosolic glutathione-S-transferases (ligandins). These also have low concentrations at birth but increase to adult levels by 5–10 days of age. In the endoplasmic reticulum the bilirubin is conjugated with a uridine moiety to bilirubin monoglucuronide by the enzyme glucuronyltransferase, properly termed UGT1A1, which is essential for efficient biliary excretion of bilirubin. UGT1A1 also has a low activity at birth but following induction by the high bilirubin load, adult levels are reached by 14 days of age irrespective of gestation (a birth-related event). The activity of this enzyme can be induced by phenobarbitone or other microsomal enzyme-inducing drugs. The bilirubin monoglucuronide is

further converted to bilirubin diglucuronide by UGT1A1 and then transported across the canalicular membrane by an energy-dependent carrier-mediated system, using various export pumps, including MRPR2, MDR3 and the bile salt export pump.<sup>748</sup> Conjugated bilirubin is excreted into the duodenum. Degradation by intestinal bacteria produces urobilinogen, most of which is reabsorbed from the intestine and undergoes enterohepatic recirculation. A minor fraction is excreted in the urine. The oxidation product urobilin/stercobilin contributes color to normal urine and stools.

The excretory mechanisms described above result in a high concentration of bilirubin in the bile. In the adult this consists mostly of bilirubin IXa, a pigment which cannot be excreted without conjugation which alters its involuted hydrogen-bonded conformation. However, the other bilirubin isomers can be excreted directly in the bile since they are naturally water soluble. The major photochemical effect of phototherapy makes use of this fact. Under blue light (420–480 nm) bilirubin IXa is converted by photoisomerization to Z-lumirubin (Fig. 12.38).<sup>751</sup> There is a 180 degree rotation of a terminal pyrrole which prohibits intramolecular hydrogen bonding, thus disrupting the tertiary structure of the bilirubin IXa isomer, and exposes the carboxyl radical, thus creating a polar water-soluble pigment which can be excreted in the bile.

The newborn infant is unable to cope with the normal bilirubin load and thus a degree of jaundice is to be expected. This is recognized by the term physiological jaundice of the newborn. Postnatally there is a rapid rise in the bilirubin due to a combination of high bilirubin load and decreased hepatic excretion. Following the initial rise there is a slow fall due to the slow development of hepatic carrier proteins (induction of ribosomal enzyme complexes). The maximum allowable level of physiological jaundice is not clear. A level as low as 210  $\mu\text{mol/L}$  by the third day of life has been claimed to indicate the need for further investigation but, in practice, most clinicians probably would not investigate the cause of jaundice unless the patient required phototherapy or other clinical features were present, the most important of which is the postnatal age of patient.

Fig. 12.36 The pathway of bilirubin production, transport and metabolism. (From Garcia 1972,<sup>749</sup> reprinted with permission.)

Fig. 12.37 Primary structure of bilirubin above, and below tertiary structure with hydrogen bonds shown as shaded lines. This folded structure serves to mask the polar carboxyl residues and renders the bilirubin molecule water insoluble/fat soluble. (From Schmidt 1978<sup>750</sup>.)

Fig. 12.38 Photoisomerization by light converts the stable isomer of bilirubin to the thermodynamically unstable Z-lumirubin (From McDonagh et al 1982<sup>751</sup>.)

NEONATAL JAUNDICE (Table 12.73)

Early jaundice (< 10 days)

First 24 hours (hemolytic disease of the newborn, HDN)

This is by far the most dangerous form of jaundice in the newborn as the bilirubin levels can rise rapidly into the toxic range. The most common cause is rhesus hemolytic disease although with current obstetric management it is now rare in resource rich countries. Sensitization of the mother (usually by small fetomaternal transfusions in previous pregnancies and particularly deliveries) will result in the production of anti-D IgM and IgG. The latter is responsible for rhesus disease in the

Table 12.73 Neonatal jaundice

Mechanism	Cause	Investigation
<b>1. Early jaundice (&lt; 10 days)</b>		
<b>a. First 24 h</b>		
Immune hemolysis	Rhesus disease	Direct Coombs' test
	ABO incompatibility	Maternal/infant blood group
Non-immune hemolysis	Rare blood group antibodies	
	Glucose-6-phosphate dehydrogenase (G6PD) deficiency	Family history
	Pyruvate kinase (PK) deficiency	G6PD assay
	Congenital spherocytosis	PK assay
Sepsis		Blood film

neonate which is characterized by a (often highly) positive Coombs' test and extravascular hemolysis in the spleen. ABO incompatibility, now the most common cause for HDN (mother usually blood group O, infant blood group A or B) in the UK, occurs in 15% of pregnancies. It is particularly common in those of African origin. Again the IgG antibody is the important hemolysin but in this case the Coombs' test is often negative (possibly due to the decreased number of A and B sites on the fetal erythrocyte). Laboratory investigation is notoriously unreliable at predicting infants at risk from ABO hemolytic disease but microspherocytosis on the blood film is a useful diagnostic pointer to the condition. Red blood cell destruction occurs primarily by extravascular mechanisms and is more rapid in ABO incompatibility with the antibody disappearing within 2–3 days. Occasionally minor blood group antibodies (anti-Kell, anti-Duffy) cause hemolytic disease and these are usually Coombs' positive.

Hemolysis also occurs in the absence of blood group incompatibility. Sepsis is said to cause jaundice at this age and should always be excluded. In fact, it rarely turns out to be responsible for such early jaundice but congenital infections, e.g. rubella, syphilis and toxoplasmosis, can present this way. The most common non-immunological cause of hemolytic jaundice within 24 h is congenital hemolytic anemia due to a red cell metabolic defect [e.g. glucose-6-phosphate dehydrogenase (G6PD) deficiency or pyruvic kinase (PK) deficiency] or structural defect (congenital spherocytosis, elliptocytosis and pyknocytosis). In these cases there is often a family history. G6PD deficiency occurs more commonly in patients of Mediterranean, African or Oriental origin. Appropriate hematological investigations and enzyme assays usually provide a rapid diagnosis.

### After 24 hours

Sixty-five percent of normal neonates exhibit clinical jaundice (85  $\mu\text{mol/L}$  or 5 mg/dL). In most patients excessive jaundice at this stage is due to exacerbation of the normal physiological jaundice of the newborn. The 95th percentile for term infants is 190  $\mu\text{mol/L}$  (11.5 mg/dl) for bottle-fed and 240  $\mu\text{mol/L}$  (14.5 mg/dl) for breast-fed infants. The more premature the infant the more immature the liver although this may be balanced by decreased bilirubin production since exchange transfusion is rarely required despite the almost obligatory use of phototherapy in infants of less than 30 weeks' gestation. Excessive production of bilirubin from severe bruising or cephalhematomata, polycythemia or ingestion of maternal blood commonly causes jaundice in this period.

The most important cause to consider is acquired bacterial infection or rarely congenitally transmitted infections (CMV, rubella, toxoplasmosis, syphilis). Direct involvement of the liver by the infective process is one reason for the jaundice, as is increased bilirubin breakdown with disseminated intravascular coagulation. However, it is likely that the nature of the hyperbilirubinemia is multifactorial.

Inadequate calorie intake and decreased glucose production will lead to a reduction in glycogen and energy available for the production and conversion of the uridine diphosphoglucuronic acid required for the conjugation of the bilirubin glucuronyltransferase. Acidosis may increase bilirubin levels but, more importantly, increases bilirubin toxicity due to the alteration of the equilibrium between free bilirubin and its acid salt, thus decreasing the maximum tolerable level of bilirubin. Dehydration probably increases the bilirubin levels by prolonging gut transit and therefore increasing the enterohepatic circulation. In such conditions as failure to pass meconium, pyloric stenosis and cystic fibrosis with meconium ileus, there will be an increase in the hydrolysis of the conjugated bilirubin by the alkaline duodenal juices and the mucosal beta-glucuronidases of the small intestine, thus increasing the bilirubin returned to the blood via the enterohepatic circulation.

In most cases of neonatal jaundice, the bilirubin levels will fall below the phototherapy range before the end of the second week of life. However, in the premature infant phototherapy may be required for longer. One group of patients that presents with severe early neonatal jaundice that continues beyond the first 10 days (and may also present later) are the rare patients with congenital nonhemolytic hyperbilirubinemias. The most important of these, Crigler–Najjar syndrome, presents as two variants:

1. the autosomal recessive type I with absence of uridine diphosphoglucuronyltransferase (UDPGT) in the liver, characterized by persistent severe unconjugated hyperbilirubinemia;
2. the autosomal dominant type II with defective rather than absent UDPGT activity in which the bilirubin levels are lower (< 340  $\mu\text{mol/L}$ ). This latter variant (known also as Arias syndrome) may present much later in life and for this reason is said to merge diagnostically into the commonest of the unconjugated hyperbilirubinemias, Gilbert syndrome, which is more common in men and usually presents after puberty. The other familial conjugated hyperbilirubinemias (Dubin–Johnson and Rotor syndrome) hardly ever present at birth.

### Management of early jaundice

**Investigation and treatment of cause.** It is important that the etiology of the hyperbilirubinemia should be established. A careful obstetric

and family history (e.g. spherocytosis) is important. A full blood count, direct Coombs' test, grouping of mother and baby and testing the urine for reducing substances are the usual minimum of investigations required. If infection is suspected a septic and TORCH (congenital infection) screen can be added. Where the hemolysis remains unexplained further hematological investigation (e.g. enzyme assays for G6PD deficiency and PK deficiency) will be needed. In most cases no treatment for the cause of the hemolysis will be available though it behoves the pediatrician to ensure that the mother is given anti-D globulin where indicated. Advice on drugs to be avoided in the future must be made available to the patients with G6PD deficiency. Infection should be treated as indicated.

**Treatment of jaundice. Phototherapy.** The aim of therapy is to keep the level of bilirubin below the toxic level. Phototherapy must be started early enough to prevent the expected rise in bilirubin but not at a level which causes unnecessary work for the nursing staff and, more importantly, an unnecessary separation of mother and baby. Most units have their own chart for plotting bilirubin levels and action lines to indicate the levels at which phototherapy (and exchange transfusion) are indicated. Where a rapidly rising bilirubin is expected such as hemolytic disease and jaundice at less than 24 h, phototherapy should be started straight away and the sequential bilirubin results should be graphed. At a later stage the need for phototherapy is more debatable. As a general rule the more premature the infant the lower the levels of bilirubin that are tolerated and thus a good guiding figure is that phototherapy is indicated when the bilirubin rises above a level given by the formula: birth weight in kg  $\times$  100. In term babies, phototherapy should be given when the bilirubin rises above 300  $\mu\text{mol/L}$ .

There are many potential complications to phototherapy:

1. Equipment failure/design drawbacks: the lamps must produce radiation in the blue range of 450–460 nm with a minimum irradiance of flux of 4  $\mu\text{W}/\text{m}^2/\text{nm}$ . The new generation of phototherapy units is much more efficient than the old (although the blue light is off-putting for the parents). It seems prudent to protect the eyes since changes of premature aging have been induced by phototherapy in newborn monkeys but no detrimental effect is recorded in the human infant.
2. Dehydration: this is by far the most important complication and is the result of increased insensible water loss through the skin and increased stool water content. Increasing the fluid intake of infants under phototherapy by 15 ml/kg/day will correct this.
3. Loose stools: Z-lumirubin excreted in the bile is a highly polar, nonphysiological substance which has a direct secretory effect on intestinal mucosa leading, inevitably, to loose stools. These are not troublesome and frank diarrhea never results. The increased fluid intake is the only therapeutic manipulation required. (Lactose intolerance, however, may also occur.)
4. Parental anxiety: the separation of mother and baby and the terrible color given to the infant by the effective blue lamps are naturally upsetting to parents and a sympathetic explanation of what is happening is mandatory. The best way of minimizing this anxiety is to pay scrupulous attention to the need for phototherapy and to minimize the duration of such therapy.
5. Other effects have been noted experimentally (copper retention, abnormal porphyrin metabolism and damage to DNA in cell cultures) but they do not seem relevant in clinical practice. Bronzing or discoloration of the skin can also occur when phototherapy is used in patients with a cholestatic element to their jaundice.

**Exchange transfusion.** The exchange transfusion of blood via an umbilical artery or vein is the most efficient way of removing bilirubin (and other noxious substances). It is employed when bilirubin levels reach the toxic range determined both by the gestational age and the clinical state of the baby. Sicker babies with their attendant metabolic derangements such as acidosis are transfused at lower levels. Acceptable criteria for exchange transfusion would be a serum bilirubin of 340  $\mu\text{mol/L}$  (term babies), 300  $\mu\text{mol/L}$  (infants < 2500 g), 250  $\mu\text{mol/L}$  (infants < 1500 g) and 170  $\mu\text{mol/L}$  (infants < 1000 g). In practice, however,

most exchange transfusions in the smaller infants (<1500 g) are performed for reasons other than jaundice (usually a septic child in extremis or for disseminated intravascular coagulation). Most physicians would not immediately exchange an asymptomatic term baby even with severe physiological jaundice greater than 340  $\mu\text{mol/L}$  assuming there was a fairly prompt response to phototherapy (usually given with double lamps in such situations). The commonest indication for exchange transfusion is a rapidly rising bilirubin in the first 24 h of life in babies with hemolytic disease of the newborn (p. 288). The technique is described on page 288. The complications are listed in Table 12.74 together with suitable avoiding action.

**Other methods.** Attention to clinical detail (for example the correction of acidosis, treatment of infection and maintenance of hemodynamic stability) is valuable. In the small premature infant judicious use of 20% albumen (4–5 ml/kg) will buy time under phototherapy and often obviate the need for a formal exchange transfusion. In the rarer congenital nonhemolytic disorders (Crigler–Najjar type II and Rotor syndrome) hepatic enzyme inducers such as phenobarbitone (1–8 mg/kg/24 h) are used in addition to prolonged daily phototherapy to control the bilirubin levels.

### Prolonged jaundice

Any jaundice beyond 10 days in a term infant is pathological but preterm infants (especially very low birth weight infants) often have jaundice that persists beyond this time for which no cause is found. It is probably wise, however, to investigate all these patients in the same way so that rarer conditions presenting in premature infants are not missed. The basic investigation is the estimation of the percentage of conjugated bilirubin; the majority of patients will have an unconjugated hyperbilirubinemia (conjugated bilirubin <25% of total). Conjugated hyperbilirubinemia (>25% of total) is an indication of intra- or extrahepatic cholestasis and is accompanied by bilirubinuria and dark urine (conjugated bilirubin >25  $\mu\text{mol/L}$ ). Early diagnosis, supportive care and specific therapy is mandatory.<sup>752</sup>

### Prolonged unconjugated hyperbilirubinemia

**Breast milk jaundice.** The usual cause of such prolonged jaundice is breast milk jaundice but to diagnose this without estimating the percentage of conjugated bilirubin would be negligent. The bilirubin is usually less

than 200  $\mu\text{mol/L}$ , but can rise to values up to 400  $\mu\text{mol/L}$  (usually less than 20% conjugated); the patient, however, is well and no treatment is necessary.<sup>753,754</sup> The jaundice usually settles by about 6 weeks although it may occasionally continue up to 4 months. Discontinuation of breast-feeding leads to a rapid fall in the bilirubin. The etiology of this condition long remained obscure and was thought to be due to various constituents of the milk. Breast milk consists of milk constituents which are parceled in maternal breast milk membrane prior to their secretion from the acini of the gland. This membrane is a protein structure and has a functional activity in its own right, e.g. enzymatic (breast milk lipase) and transport (membrane-bound iron). Both of these greatly increase the nutritional efficiency of milk. In patients with breast milk jaundice a beta-glucuronidase has been shown to be present in mother's milk and in the infant's feces (the activity in the stool disappearing with the cessation of breast-feeding coincident with a fall in unconjugated hyperbilirubinemia). It seems likely, therefore, that breast milk jaundice is due to the breast milk beta-glucuronidase causing deconjugation of the bilirubin diglucuronide and intestinal absorption of the fat-soluble bilirubin through the intestinal mucosa, increasing the enterohepatic circulation of bilirubin (Fig. 12.36) and thus increasing the level of unconjugated bilirubin in the blood.<sup>749</sup> It is relevant at this point to contrast this with the mechanism seen in the very rare Lucy Driscoll syndrome in which there is a definite inhibitor of bilirubin glucuronide in mother's milk (recoverable in the infant's serum) and which results in the development of jaundice in all of the mother's offspring (despite her apparent good health). This entity may present in the first few days of life and is occasionally severe enough to require exchange transfusion.

**Hypothyroidism.** It is mandatory to exclude hypothyroidism as a cause of persistent unconjugated hyperbilirubinemia although in countries with a neonatal screening program for hypothyroidism this is hardly ever a presenting symptom.

**Intestinal stasis.** The second most common cause now for persistent unconjugated jaundice is an increased enterohepatic circulation of bilirubin. In the normal situation 25% of the conjugated bilirubin reaching the duodenum is deconjugated and reabsorbed. This may be increased in situations of stasis where the alkaline intestinal juices and the mucosal bilirubin diglucuronidases (together with bacterial organisms in conditions of overgrowth) have longer to act on this substrate. Thus surgical conditions such as Hirschsprung disease, intestinal atresia, pyloric stenosis and the meconium ileus of cystic fibrosis are often complicated by jaundice. Cystic fibrosis may also cause unconjugated jaundice due to hepatic involvement, and such involvement may explain why other conditions can present in this fashion (i.e. sepsis, galactosemia and fructosemia).

**Hemolytic causes.** Finally, the hemolytic anemias, especially rhesus hemolytic disease and more consistently the rare hemolytic congenital hyperbilirubinemias, will be a cause of prolonged unconjugated jaundice. The management of all such jaundice is the identification and treatment of the underlying disorder as indicated in Table 12.73.

### Prolonged conjugated hyperbilirubinemia

This discussion will center on the presentation of the child with prolonged conjugated jaundice to the general pediatrician. The more complicated perspective of the specialist referral center will be dealt with in the section on liver disease (Ch. 19). The main aim of the general pediatrician is to recognize that a cholestatic syndrome is present. The signs listed in Table 12.75 should alert the physician to the presence of such a syndrome. Whilst jaundice is the usual presenting symptom, other complications, especially bruising and other evidence of defective hemostasis, hypoalbuminemia or hypoglycemia may also be presenting features. (One should never diagnose hemorrhagic disease of the newborn, especially in a jaundiced child, without checking the liver function tests and percentage conjugated bilirubin.) Clues that suggest an underlying disorder are shown in Table 12.75.

The management of prolonged cholestatic jaundice is aimed at identifying conditions requiring immediate treatment and supportive therapy and then distinguishing between intra- and extrahepatic cholestasis. Blood cultures and a septic screen together with a screen

Table 12.74 Complications of exchange transfusion

Infection	Sepsis	Strict aseptic technique
	CMV	Fresh blood
	Hepatitis	Appropriate screening donors
Hypothermia		Warm blood/baby
Cardiovascular instability	Transient hypovolemia	Small aliquots (10–20 ml)
	Hypervolemia	Meticulous recording of exchanges
	Cardiac dysrhythmia	Cardiac monitoring
Electrolyte disorders	Hyperkalemia	Monitor electrolytes and blood sugar before and after exchange
	Hypoglycemia	
	Hypocalcemia	Check citrate concentration of donor blood
Complications of catheter	Acidosis	
	Embolic	Minimize duration of catheterization
	Hemorrhage (late portal vein thrombosis)	
Inadequate exchange		Use 170–200 ml/kg over 100 min for full exchange

**Table 12.75** Clinical features that alert one to the presence of conjugated hyperbilirubinemia

<b>a. Evidence of hepatic disease</b>	
Jaundice	Urine – Yellow, not colorless from birth. Dark later with bilirubin <sup>++</sup> on Stick test Stools – Pale yellow to white (may be green)
Hepatomegaly	
Pruritus	
Splenomegaly, ascites, edema	
Evidence of bleeding tendency	–Bruising Bleeding
Failure to thrive	
Investigations –	Increased bilirubin, conjugated bilirubin >80% Increased alanine aminotransferase Increased aspartate transaminase Increased $\gamma$ -glutamyltransferase Increased $\alpha$ -fetoprotein Prolonged prothrombin time Low albumin Low blood sugar
<b>b. Features of underlying etiology</b>	
Maternal history, skin lesions	– Congenital infections
Purpura, choroidoretinitis	– Congenital infections
Cataracts	Galactosemia (urine positive for reducing substances) Lowe syndrome (aminoaciduria)
Multiple congenital	– Trisomy 13, 18, 21 abnormalities
Ascites, bile-stained hernia	– Spontaneous perforation of bile ducts
Cystic mass below the liver	– Choledochal cyst
Situs inversus, midline, liver	– Extrahepatic biliary atresia
Malposition of the viscera	– Biliary hypoplasia
Systolic murmur, dysmorphic facies	
Cutaneous hemangioma	– Hepatic/biliary hemangiomata
Marked splenomegaly	– Lysosomal storage disorder
Hypoglycemia	– Pituitary deficiency
<b>c. Features indicating the nature of the cholestasis</b>	
Incomplete stool pallor	– Intrahepatic cholestasis plus low birth weight, moderate hepatomegaly
Complete stool pallor:	– Intrahepatic cholestasis
< 10 days transient	
> 10 days permanent	– Extrahepatic cholestasis Plus normal birth weight, firm hard hepatomegaly

for intrauterine infections (TORCH, VDRL) should be sent in all infants. Parenteral antibiotics should be started if the infant appears unwell. Urine should be tested for reducing substances and sent for sugar chromatography to exclude galactosemia and fructosemia. It is also sensible to exclude galactose and fructose from the diet until the results of this are known. It should be remembered that all infants less than 2 weeks of age (and babies with renal tubular disorders, e.g. Lowe syndrome) can have reducing substances in the urine. Furthermore, infants with liver disease can both have sugar in the urine and present with septicemia. Initial investigations should include urine for amino acid chromatography to identify particularly tyrosinemia, and blood for alpha1-antitrypsin phenotyping and serum immunoreactive trypsin (if available), or fecal elastase. Endocrinological disorders and other rare metabolic disorders should be considered and investigated as seems appropriate to the infant. Liver function tests are not discriminatory but serum alpha-fetoprotein is particularly raised in tyrosinemia. A hemorrhagic diathesis should be

treated with vitamin K (1 mg i.v.) and fresh frozen plasma if bleeding continues. Other supportive measures for liver failure may be needed.

The next step is to distinguish between intra- and extrahepatic cholestasis. The color of the stool is a useful guide (Table 12.75). Incomplete stool pallor together with evidence of intrauterine growth retardation suggests a prenatal hepatitis causing intrahepatic cholestasis. Complete stool pallor lasting longer than 2 weeks, especially if accompanied by a large hard liver or a conjugated bilirubin level of > 80%, suggests extrahepatic biliary obstruction and referral to a specialist to exclude biliary atresia is required without delay. Where the diagnosis is less clear cut or delay in referral is experienced, a hepatobiliary ultrasound (to exclude a choledochal cyst) or technetium-99m HIDA cholescintigraphy (to demonstrate hepatic uptake and functional bile flow) may all be considered. The gold standard for the diagnosis of intra- and extrahepatic cholestasis remains, however, the percutaneous liver biopsy (see Table 12.75). This will also provide for the differentiation between neonatal hepatitis syndrome and bile duct paucity. Paucity of the bile ducts may be further differentiated into syndromic (Alagille syndrome – characteristic facies, butterfly wing vertebra, peripheral pulmonary artery stenosis and retinopathy) and nonsyndromic. Neonatal hepatitis is the end result of many hepatic insults. In some cases, however, no cause can be found and the final diagnosis is idiopathic neonatal hepatitis. These entities are discussed further in Chapter 19.

Management of neonatal liver disease is supportive and, where possible, definitive.<sup>753</sup> Nutritional support aims to provide sufficient energy and nutrients to combat maldigestion and malabsorption, and specialized formulas are used. Fat soluble vitamin supplementation is required for all cholestatic infants. Management is discussed further in Chapter 19.

## HEMATOLOGICAL PROBLEMS OF THE NEWBORN

### DEVELOPMENTAL HEMOPOIESIS

#### Hemopoietic stem cells and hemopoiesis

Hemopoiesis is the process which generates life-long production of cells of all the hemopoietic lineages. The principal lineages and current views of the organization of hemopoiesis are shown in Figure 12.39. The most primitive cells are the pluripotent hemopoietic stem cells. These stem cells are characterized by their astonishing capacity to choose between one of two destinies depending on the genes they express: they either undergo self-renewal (i.e. they maintain exactly the same pluripotent characteristics after cell division) or alternatively they differentiate. At an early stage in this process of differentiation stem cells commit themselves, via a distinct pattern of gene expression, to producing cells of the lymphoid lineage (lymphoid stem cells) or nonlymphoid lineage (myeloid stem cells).

Myeloid stem cells are able to further differentiate into hemopoietic progenitor cells of all the remaining lineages (erythroid, megakaryocyte, eosinophil, granulocyte, monocyte and basophil) as shown in Figure 12.39. By coordinated expression of many genes in response to a range of stimuli, including hemopoietic growth factors, these cells develop into mature peripheral blood cells. The process of hemopoiesis outlined here is broadly similar in adults, children, neonates, the fetus and the embryo. However, there are differences in the regulation of this process and its cellular components during development which contribute to the nature and management of the neonatal hematological problems described in this section.

#### Sites of hemopoiesis

While virtually all hemopoiesis in children and adults takes place in the marrow, the principal sites of hemopoietic activity change during development. The first signs of hemopoiesis in humans occur in the third week of gestation in the yolk sac; by 5 weeks' gestation the majority of hemopoietic stem cells arise from the embryonic dorsal aorta in the aorto-gonad-mesonephros (AGM) region.<sup>755</sup> Soon afterwards these hemopoietic stem cells migrate to the liver. By the eleventh week,

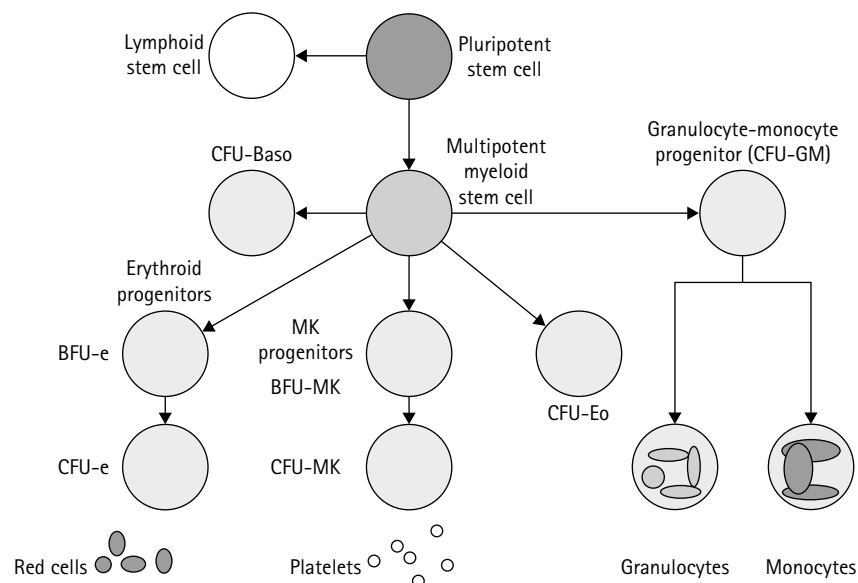

Fig. 12.39 Hemopoiesis: a schematic outline. BFU-e, burst-forming unit erythrocyte; BFU-MK, burst-forming unit megakaryocyte; CFU-baso, colony-forming unit basophil; CFU-e, colony-forming unit erythrocyte; CFU-Eo, colony-forming unit eosinophil; CFU-MK, colony-forming unit megakaryocyte; MK, megakaryocyte.

hemopoiesis begins in the bone marrow although the fetal liver remains the principal site of hemopoiesis until the end of the third trimester.

### Erythropoiesis

A number of characteristics of erythropoiesis in the newborn are relevant to our understanding of the normal changes in hemoglobin (Hb) during this period and to identifying significant abnormalities of erythropoiesis in neonates.

#### (i) Erythropoiesis is switched off at birth

Production of new red blood cells and the rate of Hb synthesis fall dramatically after birth and remain low for the first 2 weeks of life. The exact mechanisms for these changes are unknown but probably reflect the sudden increase in tissue oxygenation at birth and downregulation of erythropoietin production. Although erythropoiesis begins to increase after the first 2 weeks, this starts at the erythroid progenitor stage of differentiation and the rise in Hb is not apparent until many weeks later and reaches a maximum only by 3 months of age when a healthy infant should be able to produce up to 2 ml packed red cells/day. Studies in preterm neonates have suggested that over the first 2 months of life the maximal rate of red cell production is  $\leq 1$  ml/day since preterm babies receiving erythropoietin are unable to maintain their Hb if  $> 1$  ml of blood/day is venesected for diagnostic purposes.

#### (ii) Neonatal red cells have a reduced life span

Calculated actuarial red cell life spans for preterm infants are 35–50 days compared to 60–70 days for term infants and 120 days for healthy adults.<sup>756</sup> The reasons are unclear and are likely to mainly reflect changes in the red cell membrane.

#### (iii) Neonatal red cell membranes and intracellular metabolism are different from adult red cells

Differences in the red cell membranes of neonates include: increased resistance to osmotic lysis, increased mechanical fragility, increased total lipid content and an altered lipid profile, increased insulin-binding sites and reduced expression of blood group antigens such as A, B and I. There are also numerous differences in metabolism between neonatal and adult red blood cells both in the glycolytic and pentose phosphate pathways which lead to an increased susceptibility to oxidant-induced injury, although the clinical implications of these differences remain unclear.

#### (iv) The principal hemoglobin at birth is hemoglobin F

Knowledge of the normal evolution of embryonic, fetal and 'adult' Hbs during development is essential to our understanding of hemoglobinopathies and how they present in neonates. The first globin chain produced is epsilon globin, followed almost immediately by alpha- and gamma-globin chain production. HbF (alpha<sub>2</sub>gamma<sub>2</sub>) is therefore produced from very early in gestation (4–5 weeks) and is the predominant Hb until after birth. Adult Hb (Hb A: alpha<sub>2</sub>beta<sub>2</sub>) is also produced from an early stage (6–8 weeks' gestation) but remains at low levels (10–15%) until 30–32 weeks. After this time the rate of HbA production increases at the same time as HbF production falls, resulting in an average HbF level at birth of 70–80%, HbA of 25–30%, small amounts of HbA<sub>2</sub> and sometimes a trace of Hb Barts (beta<sub>4</sub>) (Table 12.76).

After birth and over the first year of life HbF falls in healthy term and preterm babies (to 2% at age 12 months) with a corresponding increase in HbA. In term babies there is little change in HbF in the first 15 days after birth but it declines steeply thereafter as neonatal erythropoiesis starts. In preterm babies who are not transfused, HbF may remain at the same level for the first 6 weeks of life before HbA production starts to increase. It is this delay in HbA production which can make the diagnosis of beta-globin disorders difficult in the neonatal period. By contrast, the fact that alpha-globin chains are absolutely essential for the production of both HbF and HbA, means that alpha-thalassemia major causes severe anemia from early in fetal life.

Table 12.76 Composition of embryonic, fetal and adult Hbs

Hb	Globin chains		Gestation
	Chromosome 16 $\alpha$ -gene cluster	Chromosome 11 $\beta$ -gene cluster	
<i>Embryonic</i>			
Hb Gower 1	$\zeta$ 2	$\epsilon$ 2	From 3 to 4 weeks
Hb Gower 2	$\alpha$ 2	$\epsilon$ 2	
Hb Portland	$\epsilon$ 2	$\gamma$ 2	From 4 weeks
<i>Fetal</i>			
HbF	$\alpha$ 2	$\gamma$ 2	From 4 weeks
<i>Adult</i>			
Hb A	$\alpha$ 2	$\beta$ 2	From 6 to 8 weeks
HbA <sub>2</sub>	$\alpha$ 2	$\epsilon$ 2	From 30 weeks

### (v) Regulation of erythropoiesis in the fetus and newborn: role of erythropoietin

The principal cytokine regulating erythropoiesis in the fetus and newborn is erythropoietin. Since erythropoietin does not cross the placenta, erythropoietin-mediated regulation of fetal erythropoiesis is predominantly under fetal control. The only known stimulus to erythropoietin production under physiological conditions is hypoxia with or without anemia. This explains the high erythropoietin levels in fetuses of mothers with diabetes or hypertension or those with IUGR or cyanotic congenital heart disease where the fetus and newborn are polycythemic rather than anemic; erythropoietin is also increased in fetal anemia of any cause including hemolytic disease of the newborn.<sup>757</sup>

### Platelet production in the fetus and neonate

Platelets first appear in the fetal circulation at 5–6 weeks' postconceptional age. During the second trimester the platelet count rises to  $175\text{--}250 \times 10^9/\text{L}$ .<sup>758</sup> The principal cytokine regulating platelet production is thrombopoietin. Thrombopoietin stimulates megakaryocyte progenitors and mature megakaryocytes. In neonatal thrombocytopenia thrombopoietin levels rise when the platelet count and/or circulating megakaryocyte progenitors are low (e.g. early onset thrombocytopenia associated with maternal PET and/or IUGR) while thrombopoietin levels remain low where thrombocytopenia is secondary to increased platelet destruction (e.g. idiopathic thrombocytopenic purpura; ITP). Although thrombopoietin is detectable in all healthy neonates, the ability to upregulate thrombopoietin is reduced in the fetus and newborn which limits their capacity to increase platelet production at times of need, e.g. during neonatal sepsis.<sup>759</sup>

### Neutrophil production (granulopoiesis) in the fetus and neonate

There are few circulating neutrophils in first trimester blood (around 1% of circulating nucleated cells). The number of granulocytes in fetal blood remains low ( $0.1\text{--}0.2 \times 10^9/\text{L}$ ) throughout the second trimester gradually rising to over  $2 \times 10^9/\text{L}$  by term, with slightly lower numbers in preterm neonates (Table 12.77). The principal difference between granulopoiesis in the newborn and later in infancy is the diminished size of the neutrophil storage pool, particularly in preterm infants and most markedly so in those with IUGR or exposure to maternal hypertension. (The neutrophil storage pool reflects the available reserve of neutrophils which the fetus or neonate can mobilize in response to infection.) This may explain the frequency of bacterial infection in such infants. In healthy term and preterm neonates the ratio of immature band forms to mature neutrophils is normal. This has led to widespread use of 'I/T' (immature/total) ratios as an indicator of neonatal sepsis. However, there are several important limitations to their value. In particular,

Table 12.77 Representative normal hematological values at birth and over the first 2 months of life in term babies

	Birth	2 weeks	2 months
Hb (g/dl)	14.9–23.7	13.4–19.8	9.4–13
Hematocrit	0.47–0.75	0.41–0.65	0.28–0.42
Mean cell volume (fl)	100–125	88–110	77–98
Reticulocytes ( $\times 10^9/\text{L}$ )	110–450	10–85	35–200
White blood cells ( $\times 10^9/\text{L}$ )	10–26	6–21	5–15
Neutrophils ( $\times 10^9/\text{L}$ )	2.7–14.4	1.5–5.4	0.7–4.8
Monocytes ( $\times 10^9/\text{L}$ )	0–1.9	0.1–1.7	0.4–1.2
Lymphocytes ( $\times 10^9/\text{L}$ )	2.0–7.3	2.8–9.1	3.3–10.3
Eosinophils ( $\times 10^9/\text{L}$ )	0–0.85	0–0.85	0.05–0.9
Basophils ( $\times 10^9/\text{L}$ )	0–0.1	0–0.1	0.02–0.13
Nucleated red blood cells ( $\times 10^9/\text{L}$ )	<5	<0.1	<0.1
Platelets ( $\times 10^9/\text{L}$ )	150–450	150–450	150–450

These data are obtained from a number of sources and have been chosen to represent data most useful for interpreting the significance of hematological results.

preterm infants born to mothers with chorioamnionitis frequently have markedly increased numbers of all types of immature granulocytic cells on their blood film including metamyelocytes, myelocytes, promyelocytes and blast cells; this appearance in the first few days of life is not usually indicative of sepsis, instead reflecting the normal hematological response of a neonate to preterm delivery. The most useful diagnostic clue to the coincident presence of sepsis is a marked peak in the numbers of band forms compared to other granulocytic cells.<sup>760</sup> The regulation of granulopoiesis is not fully understood. Various cytokines, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF), stimulate granulocyte production in vitro and in vivo but their exact physiological role is unclear.<sup>760</sup>

### Other leukocytes

All types of leukocyte found in adult blood are also seen in the fetus and the newborn. Monocytes circulate from 4–5 weeks' gestation and eosinophils and basophils from 14–16 weeks' gestation, each cell type being present in low numbers and increasing slowly to the normal values at term (Table 12.77). There are few studies of lymphopoiesis in the human fetus. There appears to be no lymphopoiesis in the yolk sac, but both T lymphocytes and B lymphocytes are found in small numbers in the fetal liver by 8 weeks' gestation. Shortly thereafter T lymphocytes are detectable in fetal blood and thymus, with marrow T lymphocyte production established during the second trimester. By term T lymphocytes form 40–45% of circulating mononuclear cells with a CD4:CD8 ratio of around 5.0, slightly higher than in adult blood (3.1:1). B lymphocytes are found in fetal blood and bone marrow from around 12 weeks' gestation and constitute 4–5% of circulating mononuclear cells by term.<sup>761</sup>

## HMATOLOGICAL VALUES AT BIRTH

### Practical issues: establishing normal values and identifying artefacts

One of the most important aspects of neonatal hematology is knowledge of what is normal in the neonatal period and the factors that impact upon the importance of a laboratory result. These include:

1. *Site of sampling:* capillary or skin puncture samples yield higher Hb levels (2–4 g/dl higher) and hematocrits (up to 20% higher) than venous or arterial samples collected simultaneously.<sup>762</sup>
2. *Quality of the blood sample:* common problems include clotted or partially clotted samples particularly when the baby is polycythemic; and poorly preserved white cell morphology due to excess ethylenediaminetetraacetic acid (EDTA) if there is delay in samples reaching the laboratory or a high blood:anticoagulant ratio.
3. *Gestational age-related changes in hematological values:* while there are no significant differences in Hb, hematocrit, white blood cell (WBC) count or platelet count with gestational age from 24 weeks to term, the normal mean cell volume (MCV) is higher in preterm infants (Tables 12.77 and 12.78); the number of reticulocytes is twice as high in preterm compared to term infants (6% at 24–25 weeks versus 3.2% at term); and the numbers of circulating nucleated red cells in healthy preterm infants are around twice as high ( $\leq 20 \times 10^9/\text{L}$ ) as in term babies.
4. *Postnatal changes in hematological values:* the marked changes after birth in almost all hematological parameters over the first few weeks of life make it essential to know the postnatal age of a baby to make a sensible interpretation of the hematological results.
5. *Effect of timing of cord clamping and other aspects of delivery on hematological values in the newborn:* Since the placental blood vessels in a term baby contain 50–200 ml of blood, delaying clamping of the cord and holding the baby below the level of the placenta to allow emptying of this blood into the baby's circulation can increase the blood volume by 50–60% with a consequent increase in Hb (to  $> 19$  g/dl versus 15–16 g/dl with early clamping of the cord); similar differences are seen in preterm babies.<sup>764</sup>

**Table 12.78** Representative normal hematological values at birth in preterm babies

	24–25 weeks	26–27 weeks	28–29 weeks	30–31 weeks
Hb (g/dl)	19.4 ± 1.5	19.0 ± 2.5	19.3 ± 1.8	19.1 ± 2.1
Hematocrit	0.63 ± 0.04	0.62 ± 0.08	0.60 ± 0.07	60 ± 0.08
Mean cell volume (fl)	135 ± 0.02	132 ± 14.4	131 ± 13.5	127 ± 12.7
Reticulocytes (× 10 <sup>9</sup> /L)	279 ± 23	454 ± 15	347 ± 12	278 ± 10
Platelets (× 10 <sup>9</sup> /L)	150–450	150–450	150–450	150–450

Data adapted from Brugnara & Platt 2003.<sup>763</sup>

### Normal values for red blood cells and blood volume

Normal values at birth for Hb, hematocrit and MCV are shown in Tables 12.77 and 12.78 for term and preterm babies respectively. In term babies the Hb, hematocrit and red cell indices fall slowly over the first few weeks reaching a mean Hb of 13–14 g/dl at 4 weeks of age and 9.5–11 g/dl at 7–9 weeks of age. For preterm infants changes in the first few weeks of life are often difficult to interpret because of their variable clinical course and transfusion requirements. However, studies of well preterm infants carried out in the 1970s show a more rapid and steeper fall in Hb reaching a mean of 6.5–9 g/dl at 4–8 weeks' postnatal age.<sup>763</sup> The reticulocyte count and numbers of nucleated red cells also fall rapidly after birth as erythropoiesis is suppressed. The reticulocyte count starts to increase in term babies at 7–8 weeks of age and in preterm babies at 6–8 weeks of age.

Normal blood volume at birth varies with gestational age as well as the timing of the clamping of the cord. In healthy term infants average blood volume is around 80 ml/kg. The blood volume is higher in preterm infants with an average of 106 ml/kg. Term and preterm babies have adequate stores of iron, folic acid and vitamin B<sub>12</sub> at birth. However, stores of both iron and folic acid are lower in preterm infants and are depleted more quickly, leading to deficiency after 2–4 months if the recommended daily intakes are not maintained (see p. 227 and Ch. 16). In general, even term neonates with a normal Hb at birth will have depleted their iron stores by the time they have doubled their birth weight.

### Normal values for white cells

The neutrophil and monocyte count vary over the first few days of life even in healthy babies. For the first 12 h they increase then fall to a nadir at 4 days of age. Normal values for neutrophils at birth are also affected by other factors including antenatal history, perinatal history, ethnic origin, site of blood sampling and whether or not the baby has been crying. The neutrophil count is higher in capillary samples and after vigorous crying; it is lower in neonates with IUGR, those born to mothers with hypertension or diabetes and in neonates of African origin.<sup>757,760</sup> Some cell types not found in healthy adults are seen in healthy preterm babies – these include blast cells, other early myeloid cells, nucleated red cells and even occasional megakaryocytes.

### Normal platelet count and platelet function

Blood platelet counts at birth in term and preterm neonates are within the normal adult range.<sup>765</sup> Many studies have found impaired function of neonatal platelets *in vitro* in term and preterm infants; the most consistent abnormalities are reduced aggregation in response to epinephrine (adrenaline), ADP and thrombin. However, these abnormalities do not appear to be of major clinical significance: there is no increased bleeding tendency in neonates with normal platelet counts and coagulation parameters and the bleeding time tested with adult and neonatal devices is normal in term and preterm infants (≤ 135 s).

## RED CELL DISORDERS

### Anemia

Anemia is the commonest hematological abnormality in the newborn. The cause is often multifactorial. Nevertheless a logical approach and appropriate use of straightforward investigations, as outlined below and summarized in figure 12.40, reveal the cause in most babies. The general management of neonatal anemia, including red cell transfusion, is outlined on page 290.

**Definition.** Anemia is defined as an Hb concentration below the normal range for a population of age- and sex-matched individuals. Normal values for term and preterm infants at birth are shown in Tables 12.77 and 12.78; from this it can be seen that, regardless of gestation, any neonate with a Hb of < 14 g/dl at birth on a properly taken blood sample would be considered anemic.

### Physiological impact of anemia in the neonate

Anemia is one of the main factors, together with cardiopulmonary function and the position of the Hb–oxygen dissociation curve, which influences tissue oxygenation. The clinical significance of anemia in the newborn does not therefore depend solely upon the Hb concentration. The two most important factors determining the position of the Hb–oxygen dissociation curve are the HbF and 2,3-DPG concentrations within the red blood cells: a high HbF and low 2,3-DPG both cause the curve to be shifted to the left, i.e. the affinity of Hb for oxygen is increased so less oxygen is released to the tissues. This is the situation just after birth and will be more marked in preterm babies with higher HbF concentrations. Over the first few months of life 2,3-DPG levels rise and HbF levels fall so the Hb–oxygen dissociation curve gradually shifts to the right, i.e. the oxygen affinity of Hb falls and oxygen delivery to the tissues increases. This increase in oxygen delivery ameliorates the effects of the falling Hb over the first months of life.

### Pathogenesis and causes of neonatal anemia

Anemia in the neonatal period has distinct physiological features compared to older children and a distinct pathogenesis. Interpretation of diagnostic investigations has to be made on a background of changes in the red cell membrane, red cell enzymes and Hb production which vary with gestational and postnatal age. Furthermore, anemia in the neonate may be attributable to pregnancy-related or pre-existing disorders in the mother. Anemia results from one or more of the following mechanisms:

1. inappropriately reduced red cell production (see below);
2. increased red cell destruction/reduced red cell life span (p. 288);
3. blood loss (p. 289);
4. a combination of these mechanisms (anemia of prematurity, p. 290).

Using this approach the principal causes of anemia in the term and preterm neonate are shown in Table 12.79 and a diagnostic approach to identifying these causes is shown in Figure 12.40.

### Anemia due to reduced red cell production

The main diagnostic clues are a combination of a low reticulocyte count (< 20 × 10<sup>9</sup>/L) together with a negative direct antiglobulin test (Coombs' test). The most important causes are red cell aplasia due to parvovirus B19 and Diamond–Blackfan anemia (DBA). Reduced red cell production may also be due to abnormal red cell development, usually congenital dyserythropoietic anemia (CDA) or part of a global failure of hemopoiesis, e.g. in CMV infection, Pearson syndrome or congenital leukemias (see p. 292).

### Anemia due to parvovirus B19 and other congenital infections

Parvovirus B19 causes selective red cell aplasia when maternal infection occurs during the first or second trimester. The anemia and reticulocytopenia are severe and may present as hydrops fetalis; the leukocyte and platelet count are usually, but not always, normal.<sup>766</sup> The diagnosis of fetal/neonatal parvovirus B19 may be very difficult to make and should

syphilis, rubella and herpes simplex; in these cases the reticulocytopenia is less marked or absent and the blood film often shows abnormal 'viral' lymphocytes, thrombocytopenia and/or neutropenia.

**Management.** Antenatally diagnosed parvovirus with early hydrops can be treated with intrauterine transfusions. Neonates with red cell aplasia secondary to parvovirus B19 should be treated with red cell transfusion; those who fail to recover should be given intravenous immunoglobulin (IVIG) to help eradicate persistent viral infection.<sup>766</sup>

### ***Congenital red cell aplasia, including Diamond–Blackfan anemia***

The principal cause of congenital red cell aplasia is DBA. The incidence is 5–7 cases/million live births. Most cases present at 2–3 months of age when transfusion-dependent anemia becomes apparent. Around 25% of cases present at birth and rare cases present in utero in the second trimester with anemia and/or hydrops. Around 50% of patients also have a distinct facial appearance and/or short stature, thumb abnormalities, genitourinary and cardiac abnormalities. Mutations of the RPS19 gene

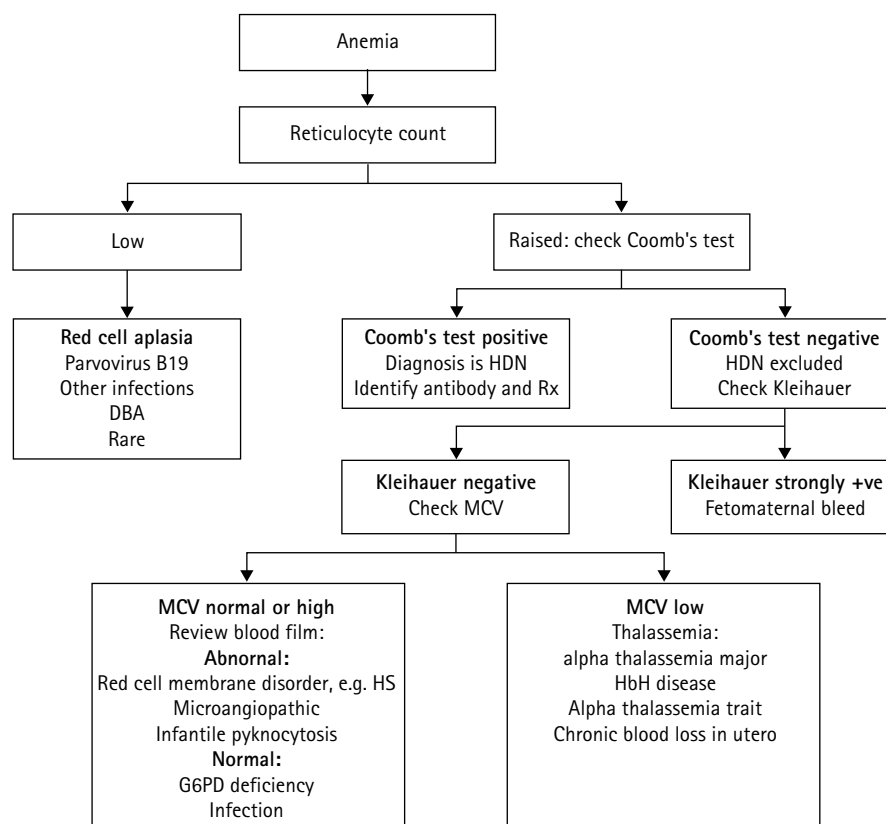

Fig. 12.40 Diagnostic approach to neonatal anemia. G6PD; glucose-6-phosphate dehydrogenase; DBA, Diamond–Blackfan anemia; HDN, hemolytic disease of the newborn; HS, hereditary spherocytosis; MCV, mean cell volume.

are found in 25% of cases of DBA; this causes a defect in ribosome biogenesis. The genetic basis of DBA in the remaining families is currently unknown although the majority of cases are familial and at least two other genetic loci have been identified.<sup>768</sup> Red cell adenosine deaminase activity (measured pre-transfusion) is elevated in some patients and family members and may help diagnosis in patients without an RPS19 mutation.

Other inherited/congenital disorders which may present with anemia due to reduced red cell production include CDA and Pearson syndrome. Most types of CDA present in childhood but a significant number do present with transfusion-dependent anemia in the neonatal period. Most affected babies are normally grown with no dysmorphic features, have a normocytic anemia with normal white cells and platelets but a low reticulocyte count. The genetic basis is unknown but most cases are autosomal recessive. Pearson syndrome, which is caused by mutations in mitochondrial DNA, presents in neonates who are SGA and thrive poorly in the first few weeks of life due to anemia and exocrine pancreatic dysfunction. The anemia is normocytic and associated thrombocytopenia and neutropenia are common; abnormal leukocyte vacuolation may be seen in the peripheral blood and highly characteristic vacuolation of early erythroid cells on the marrow aspirate should prompt blood to be sent for mitochondrial DNA analysis to establish the diagnosis. The other inherited bone marrow failure syndromes, e.g. Fanconi anemia, rarely present at birth.

**Management.** Management of these disorders is discussed in detail in Chapter 23. In the neonatal period the main issues are making the diagnosis and judicious use of red cell transfusion (see p. 290). Steroids are rarely used for DBA in the neonatal period as they are only indicated in transfusion-dependent children and have significant side-effects in this age group.

### Anemia due to increased red cell destruction/reduced red cell life span (hemolytic anemia)

Recognition of neonatal anemia due to hemolysis is clinically extremely important even if the anemia is mild and apparently trivial. This is because transient or mild hemolysis in the neonatal period may be the first sign of an underlying problem with more serious manifestations later on in childhood (e.g. red cell enzymopathies or hemoglobinopathies) or problems which might affect future siblings (e.g. alloimmune anemia due to maternal red cell antibodies).

The principal diagnostic clues suggesting hemolysis are: increased numbers of reticulocytes, unconjugated hyperbilirubinemia, a positive Coombs' test (if immune) and characteristic changes in the morphology of the red cells on a blood film (e.g. hereditary spherocytosis). The main types of neonatal hemolytic anemia are listed in Table 12.79. It is usually straightforward to distinguish the cause. The first step should be a Coombs' test, which will be positive only in the presence of immune hemolytic anemia.

### Immune hemolytic anemias including hemolytic disease of the newborn (HDN)

By far the most common cause of Coombs'-positive hemolysis is hemolytic disease of the newborn (HDN) due to transplacental passage of maternal IgG alloantibodies to red cell antigens. Maternal autoimmune hemolytic anemia occasionally causes a positive Coombs' test in the neonate; however, both hemolysis and anemia in the baby are extremely rare.

Alloantibodies which can cause HDN include anti-D, anti-c, anti-E, anti-Kell, anti-Kidd (J<sup>k</sup>), anti-Duffy (F<sup>b</sup>) and antibodies of the MNS blood group system, including anti-U. Anti-D remains the most frequent alloantibody to cause significant hemolytic anemia; it affects 1 in 1200 pregnancies and still results in around 50 deaths per year in the UK.<sup>769</sup> Anti-Kell antibodies also cause severe fetal and neonatal anemia since they inhibit erythropoiesis as well as producing hemolysis. Although ABO incompatibility between mother and fetus is present in approximately 25% of pregnancies, hemolysis is relatively uncommon. This is because the majority of naturally occurring anti A and B antibodies are

of the IgM subclass that do not cross the placenta. In addition, neonatal red cell A and B antigens are not fully glycosylated and are therefore weakly antigenic at birth; there is also widespread expression of A and B antigens on other cells throughout the body thereby 'mopping up' any antibody that crosses the placenta. Nevertheless ABO HDN occurs around 1 in 150 births. It affects neonates born to women of blood group O and is confined to the 1% of such women with high titer IgG antibodies. Hemolysis due to anti-A is more common than anti-B. The main clinical feature is hyperbilirubinemia which may be severe. Anemia is usually mild or absent and where there is significant anemia it is usually associated with anti-B antibodies. HDN is a rare cause of 'blueberry muffin' baby.

**Management of HDN due to Rh or Kell alloantibodies.** The antenatal diagnosis and management of pregnancies affected by red cell alloimmunization are discussed in Chapter 11. Close cooperation between obstetric, pediatric and hematology teams is essential for good management.<sup>769</sup> All neonates at risk of HDN should have cord blood taken for Hb, bilirubin and a Coombs' test and should remain in hospital until hyperbilirubinemia and/or anemia have been properly managed. Phototherapy should be given to all Rhesus-alloimmunized infants from birth as the bilirubin can rise steeply after birth and this expectant approach will prevent the need for exchange transfusion in some infants.

Exchange transfusion is required for:

1. severe anemia (Hb < 10 g/dl at birth) or;
2. severe and/or rapidly increasing hyperbilirubinemia as indicated by standard graphs.

Blood for exchange transfusion should be Group O, Rh D-identical with the neonate, Kell-negative and < 5 days old. Current recommendations state that the blood should be CMV-negative but universal leukocyte depletion in the UK means that CMV-untested blood is likely to be of equivalent safety to CMV-negative blood even in the newborn.<sup>770</sup> The blood should be irradiated if the baby has received intrauterine transfusion; irradiation of blood for exchange is not essential otherwise but may be carried out in some centers if it can be performed without delay. Packed red blood cells are suitable for neonatal exchange transfusion provided they have a hematocrit of < 0.6. The technique for exchange transfusion is described on page 98. There is some evidence that IVIG may be helpful in preventing exchange transfusion in neonates with immune hemolytic anemia. It is postulated that this exogenous source of antibodies might block destruction of antibody-coated red cells in the reticuloendothelial system. A recent Cochrane review concludes that studies so far are of limited applicability and high quality large studies are needed.<sup>771</sup> 'Late' anemia is seen in some babies with milder hemolytic disease who do not require exchange transfusion and in babies who have had earlier exchange transfusion. This presents at a few weeks of age and is due to ongoing hemolysis and postnatal suppression of erythropoiesis. Such babies may require 'top-up' transfusion (see p. 290) but irradiated blood must be used for infants who have previously received intrauterine transfusion to prevent the risk of transfusion-associated graft versus host disease.

### Non-immune hemolytic anemia presenting in neonates

Causes of non-immune hemolysis in neonates are shown in Table 12.79. The main diagnoses to consider are:

- red cell membrane disorders;
- red cell enzymopathies;
- hemoglobinopathies.

A number of congenital and primary infections can also cause hemolytic anemia in the neonatal period including CMV, toxoplasmosis, congenital syphilis, rubella, herpes simplex and, rarely, malaria (see also Ch. 28).

**Red cell membrane disorders.** Red cell membrane disorders can usually be identified by the characteristic shape of red cells on a blood film. Hereditary spherocytosis (HS) occurs in 1 in 5000 births. HS is autosomal dominant but around 25% of cases are sporadic due to new mutations; it is genetically heterogeneous – mutations in spectrin, ankyrin, protein 4.1 and protein 3 have all been reported. The usual presentation

of HS in neonates is unconjugated hyperbilirubinemia. Most affected neonates are not anemic at birth but may become anemic during the first month of life due to increased splenic function and the physiological shutdown of erythropoiesis at birth.<sup>772</sup> The blood film in HS shows moderate numbers of spherocytes; the appearance is identical to that of ABO HDN but the two disorders are distinguishable by the negative Coombs' in HS. Recent guidelines for the diagnosis and management of HS have been published.<sup>773</sup> Hereditary elliptocytosis is a more complex disorder caused by mutations in the genes for spectrin, ankyrin or Band 4.1. In the common, autosomal dominant form, heterozygotes have no clinical manifestations (i.e. no anemia and no jaundice) apart from elliptocytes on the blood film. More important clinically are neonates who have more than one mutation in a red cell membrane protein (they may be homozygous or compound heterozygotes) as they present with the disease hereditary pyropoikilocytosis (HPP). In HPP hemolytic anemia is severe in the neonatal period and many infants require transfusion. The diagnosis of HPP should be easily made by examining blood films from the baby and both parents; a useful diagnostic clue is the low MCV at birth (< 70 fl).

**Management.** Babies with chronic hemolysis secondary to red cell membrane abnormalities should be given folic acid (i.e. all affected babies except hereditary elliptocytosis heterozygotes who have no significant hemolysis). Red cell transfusion may be required in the neonatal period and, especially in HPP, sometimes indefinitely until the child is old enough to undergo splenectomy. It is important to carry out definitive diagnostic investigations on pretransfusion blood samples to minimize diagnostic confusion due to transfused cells.

**Red cell enzymopathies.** Red cell enzymopathies present in neonates with unconjugated bilirubinemia with or without anemia and, unlike the membrane disorders, usually do not have characteristic changes on the blood film. The most common is G6PD deficiency, which has a high prevalence in individuals from central Africa (20%) and the Mediterranean (10%). G6PD deficiency, which is X-linked, predominantly affects boys although female carriers may have milder symptoms. In neonatal G6PD deficiency jaundice usually presents within the first few days of life and is often severe; anemia is uncommon and the blood film is usually completely normal and so the diagnosis must be made by assaying G6PD on a peripheral blood sample. This predominance of jaundice over hemolysis probably results from hepatic dysfunction caused by G6PD deficiency in the liver.<sup>774</sup> In addition there is an association between the degree of hyperbilirubinemia and co-inheritance of Gilbert syndrome due to a polymorphism in the promoter of the gene uridine diphosphate glucuronyltransferase (UGT1A). The second most common red cell enzymopathy in neonates, pyruvate kinase deficiency, is more heterogeneous varying from anemia severe enough to cause hydrops fetalis to a mild unconjugated hyperbilirubinemia; the blood film is sometimes distinctive but often shows nonspecific changes of nonspherocytic hemolysis.<sup>775</sup> Neonatal hemolytic anemia may be the only presenting feature of triosephosphate isomerase deficiency, the devastating neurological features of this disorder only becoming apparent 6–12 months later. Persistent hemolysis should therefore always be investigated.

**Management.** The most important management issues in these disorders are making the diagnosis and issuing parents of babies with G6PD deficiency with the appropriate information about which medicines, chemicals and foods may precipitate hemolysis (Table 12.81). If transfusion is required, conventional guidelines for neonatal transfusion can be followed. Folic acid supplements are not required in most cases of G6PD deficiency but are necessary in any baby with chronic hemolysis, e.g. pyruvate kinase deficiency.

**Hemoglobinopathies.** Hemoglobinopathies, with the exception of alpha-thalassemia major, do not usually present in the neonatal period. Alpha-thalassemia major (all four alpha-globin genes deleted) occurs predominantly in families of south-east Asian origin and presents with mid-trimester fetal anemia or hydrops fetalis, which is fatal within hours of delivery. The only long term survivors of alpha-thalassemia major received intrauterine transfusions. The diagnosis is made by Hb electrophoresis or high performance liquid chromatography (HPLC; which

Divicine (broad beans)
Methylene blue

\*Acceptable in acute malaria.

\*\*Some sulfonamides do not cause hemolysis in most G6PD deficient patients, e.g. sulfadiazine.

†To be avoided in some types of G6PD deficiency (can be taken by patients with the common, African A- form of G6PD deficiency).

shows mainly Hb Barts); the blood film shows hypochromic, microcytic red cells with circulating nucleated red cells. Symptoms and signs of the major beta-globin hemoglobinopathies (sickle cell disease and beta-thalassemia major) are rare in neonates although modern techniques (e.g. HPLC, isoelectric focusing) allow the diagnosis to be made on neonatal blood samples where family studies indicate that both parents are carriers. Many countries and regions with a high prevalence of hemoglobinopathies, including the UK, have neonatal screening programs to facilitate early diagnosis which is particularly important in sickle cell disease in order to start penicillin prophylaxis as soon as possible.

**Management.** Transfusion for hemoglobinopathies is rarely required in the neonatal period. It is important to carry out diagnostic investigations on pretransfusion samples and analysis of parental samples is also essential. Folic acid should be given, until transfusion dependence occurs, as all patients have chronic hemolysis and penicillin prophylaxis should be commenced in babies with all forms of sickle cell disease.

### Anemia due to blood loss

Anemia due to blood loss may occur during fetal life, at the time of delivery or postnatally (Table 12.79). In neonatal inpatients the most common cause of anemia is blood loss secondary to iatrogenic blood letting.

### Blood loss prior to birth, including twin-to-twin transfusion

This usually follows twin-to-twin transfusion, fetomaternal transfusion or trauma but may be spontaneous. The degree of anemia is variable and the clinical presentation depends on the amount and rate of blood loss. The most useful diagnostic tests are a blood film and a Kleihauer test on maternal blood to quantitate the number of HbF-containing fetal red blood cells in the maternal circulation. Where there is chronic blood loss the baby is often well but may present with cardiac failure; the blood film is hypochromic/microcytic. Where the baby has bled acutely just prior to delivery, it will have signs of circulatory shock and the maternal Kleihauer will show a large fetomaternal bleed; in this situation the Hb may be normal at delivery but fall rapidly as hemodilution occurs and the blood film is normochromic/normocytic with large numbers of nucleated red cells. Twin-to-twin transfusion occurs only in monochorionic twins with monochorial placentas. In this situation

fetal–fetal transfusion may occur in up to one third of cases producing a discordance in birth weight and Hb (> 5 g/dl). Diagnosis is usually made antenatally by detection of markedly different amniotic fluid volumes between the twins in the second trimester.

### Blood loss at or after delivery

This is usually due to obstetric complications, such as placenta previa, placental abruption or incision of the placenta during Cesarean section. Such babies are often extremely unwell with circulatory shock, anemia worsening rapidly after birth, large numbers of circulating nucleated red cells and disseminated intravascular coagulation. Similar hematological changes occur after massive internal bleeding in the baby, e.g. subarachnoid or retroperitoneal bleeding, and may be particularly severe where there is damage to the liver. While most cases of internal bleeding will be associated with traumatic delivery, it is important to search for any underlying bleeding disorder in such babies (see p. 293).

### Anemia of prematurity

The normal fall in Hb after birth is greater in preterm compared to term neonates and has been termed ‘physiological anemia of prematurity’ since it does not appear to be associated with any abnormalities in the baby. The pathogenesis is not fully elucidated but contributory factors include:

- reduced red cell life span;
- inappropriately low erythropoietin;
- nutritional deficiency (iron and folic acid);
- rapid growth rate.

The nadir of Hb in a well term infant is as low as 9.4–11 g/dl at 8–12 weeks of age (Table 12.77); for a preterm infant the nadir in Hb occurs earlier (4–8 weeks of age) and is lower (6.5–9 g/dl). The diagnosis is usually straightforward – a well preterm baby has a slowly falling Hb with a completely unremarkable blood film showing normochromic/normocytic red cells, slightly low reticulocytes ( $20 \times 10^9/L$ ) and no nucleated red cells.

*Management.* This is discussed in detail below. The most important aspects are minimizing the severity of anemia and judicious use of red cell transfusion. Erythropoietin may have a role in some babies (see below).

### A simple diagnostic approach to neonatal anemia

Red cell disorders associated with anemia present in three main ways: with a low Hb (anemia), with jaundice and with hydrops. A diagnostic algorithm to help in identifying the cause of neonatal anemia and the most useful investigations is shown in Figure 12.40. Hematological causes of neonatal jaundice and of hydrops are shown in Tables 12.80 and 12.82.

### Management of neonatal anemia

There are two facets to management:

1. identifying the underlying cause of the anemia where possible; and
2. deciding whether or not to transfuse.

A brief summary of the indications for red cell transfusion is outlined (Table 12.83). Management of neonatal anemia associated with specific hematological disorders is discussed in the relevant sections (Ch. 23). With increasing recognition of potential transfusion hazards, prevention of neonatal anemia has become extremely important.

### Red cell transfusion for neonatal anemia

The threshold levels of anemia which should trigger red cell transfusion in neonates remain controversial. There are several useful reviews and guidelines produced by professional bodies; almost none are evidence based. Nevertheless, compliance with transfusion guidelines reduces transfusion requirements and donor exposure.<sup>776,777</sup> A pragmatic approach is to use the published guidelines to produce local, consensus-based neonatal transfusion protocols which can be enforced and monitored to maintain a consistent and sensible transfusion policy for all neonates (Table 12.83). The red cells used should be packed

**Table 12.82** Hematological causes of neonatal jaundice

A.	Red cell membrane disorders
	Hereditary spherocytosis
	Hereditary pyropoikilocytosis
	Other: e.g. homozygous hereditary elliptocytosis
B.	Red cell enzymopathies
	G6PD deficiency
	Pyruvate kinase deficiency
	Other: e.g. glucose phosphate isomerase deficiency
C.	Hemoglobinopathies
	Alpha-thalassemias
	Gamma-thalassemias
	Other: sickle cell syndromes (occasionally)
D.	Immune
	Hemolytic disease of the newborn
	Maternal autoimmune hemolytic anemia
	Drug induced
E.	Infection
	Bacterial
	Viral, e.g. CMV, rubella, herpes simplex
	Protozoal, e.g. toxoplasma, malaria, syphilis

**Table 12.83** Indications for ‘top up’ red cell transfusion in preterm infants: based on a summary of national consensus-based guidelines

1.	Severe pulmonary disease (babies on mechanical ventilation) Hb < 13 g/dl
2.	Acute blood loss with shock
3.	Stable newborn with clinical signs of anemia (e.g. tachycardia, poor weight gain) Hb 8–10.5 g/dl (threshold varies in different national guidelines)
4.	Stable newborn without signs of anemia Hb < 7 g/dl

These guidelines can be used as the basis to produce more specific local neonatal transfusion protocols which may specify different thresholds for transfusion depending upon other important clinical variables, e.g. the postnatal age of the infant, the  $FiO_2$ , whether the baby is on CPAP, whether there are associated major complications, e.g. septic shock, NEC, planned surgery.

cells (hematocrit 0.5–0.7) which are ABO and Rh D-compatible with the mother and the baby and which are < 35 days old. Specially prepared satellite packs should be used wherever possible to allow multiple-transfused neonates to receive blood from the same donor.

### Prevention of neonatal anemia, including the role of erythropoietin and hematinics

Approaches to preventing or minimizing neonatal anemia include:

1. limiting iatrogenic blood loss by appropriate use of blood tests;
2. iron and folate supplementation for all preterm infants;
  - iron 3 mg/kg/day from 4–6 weeks of age (a pragmatic approach is to give 1 ml of sodium iron edetate – ‘Sytron’ – once daily)
  - folic acid 15 mcg daily or 500 mcg once weekly;
3. judicious use of erythropoietin.

There have been many controlled trials of erythropoietin for prevention of neonatal anemia. The subject has been extensively reviewed<sup>778,779</sup> and is only briefly summarized here. Erythropoietin is able to reduce red cell transfusion requirements in preterm infants. However, in most studies only the relatively well infants with low transfusion requirements benefit from this as, even in high doses, the erythropoietin-mediated increase in red cell production is unable to increase sufficiently to cope with the need for frequent phlebotomy and multiple transfusions in sick preterm infants. The use of erythropoietin in the first week of life has been associated with an increase in retinopathy of prematurity and therefore is not currently recommended.<sup>779</sup> Erythropoietin has a useful role where

red cell transfusions cannot be used (e.g. preterm babies of Jehovah's witnesses). Hb does not start to rise until about 10–14 days after erythropoietin has been commenced and iron supplements should be started as soon as possible to prevent the rapid development of iron deficiency in erythropoietin-treated infants.

## Polycythemia

For both term and preterm infants polycythemia can be defined as a central venous hematocrit of  $>0.65$ ; above this level there is an exponential rise in blood viscosity. Clinical manifestations include lethargy, hypotonia, hyperbilirubinemia and hypoglycemia. Polycythemia may also be a contributory factor in neonatal seizures, stroke, renal vein thrombosis and NEC. Causes of polycythemia include:

- IUGR;
- maternal hypertension;
- maternal diabetes;
- endocrine disorders: thyrotoxicosis, congenital adrenal hyperplasia;
- chromosomal disorders – trisomy 21, 18 or 13;
- twin-to-twin transfusion;
- delayed clamping of the cord.

Treatment of neonatal polycythemia is controversial. A recent meta-analysis suggested no proven benefit of partial exchange transfusion in terms of long term neurological outcome or early neurobehavioral assessment although there may be an earlier improvement in symptoms. There is also a suggestion of increased risk of gastrointestinal symptoms, in particular NEC, in exchanged neonates.<sup>780</sup> If partial exchange transfusion is felt to be necessary then a crystalloid solution such as normal saline should be used.<sup>781</sup> The aim of exchange transfusion is to reduce the hematocrit to 0.55. The formula for calculating the volume to be exchanged in ml is:

$$\frac{\text{Blood volume} \times \text{Observed PCV} - \text{Desired PCV}}{\text{Observed PCV}}$$

Controlled studies show no evidence to support the use of fresh frozen plasma or albumin for this procedure, both of which carry the risk of transfusion-transmitted infection.<sup>781</sup>

## WHITE CELL DISORDERS

### Neutropenia

#### *Definition and causes of neonatal neutropenia*

Neutropenia is fairly common in preterm neonates but is uncommon in term infants. Since normal values are dependent on age and gestational age, a pragmatic approach is to consider a neutrophil count at birth of  $<2 \times 10^9/L$  as abnormal and worth monitoring and a neutrophil count during the first month of life of  $<0.7 \times 10^9/L$  as significant enough to merit further investigation. Causes of neonatal neutropenia are shown in Table 12.84. In preterm neonates the commonest cause is neutropenia in association with IUGR and/or maternal hypertension. The second most frequent cause in preterm infants, and the most common cause in term infants, is neutropenia secondary to bacterial or viral infection.

#### *Immune neutropenias*

Although uncommon, immune neutropenia may be severe in the newborn. Both autoimmune and alloimmune neutropenia occur. Autoimmune neutropenia is secondary to maternal autoimmune disease [e.g. systemic lupus erythematosus (SLE)] and is self-limiting. Alloimmune neutropenia occurs where fetal neutrophils express paternally derived neutrophil-specific antigens not present on maternal neutrophils and against which the mother produces IgG neutrophil alloantibodies. The causative antibodies are usually anti-NA1 or anti-NA2. It is said to occur in 3% of all deliveries but it seems likely that most cases are so mild they do not present to medical attention. The more severe cases present in the first few days of life with fever and infections of the respiratory tract, urinary tract and skin, particularly due to *Staphylococcus aureus*. The neutropenia is self-limiting, usually resolving within 1–2 months, and the mainstay of treatment is antibiotics.

**Table 12.84** Causes of neonatal neutropenia

1. Immune	Alloimmune Autoimmune
2. Infection	Acute, perinatal bacterial infection, e.g. group B streptococcus Congenital infections, e.g. CMV Postnatal bacterial infections Postnatal viral infections, e.g. CMV
3. Necrotizing enterocolitis	
4. Placental insufficiency	Maternal hypertension Intrauterine growth restriction Maternal diabetes
5. Genetic	Trisomies: 21, 13 and 18 Kostmann syndrome Shwachman syndrome Pearson syndrome Reticular dysgenesis Metabolic disorders, e.g. hyperglycinemia; isovaleric, propionic and methylmalonic acidemia
6. Marrow replacement	Congenital leukemia

#### *Non-immune neutropenias*

The commonest non-immune cause in preterm infants is neutropenia secondary to IUGR and/or maternal hypertension; it may also occur in infants of diabetic mothers. The exact pathogenesis is unknown. Neutrophil production secondary to reduced numbers of neutrophil progenitors (CFU-GM) is found and most affected neonates have associated thrombocytopenia and increased erythropoiesis (polycythemia and/or increased circulating nucleated red cells).<sup>757</sup> The hematological abnormalities appear secondary to fetal tissue hypoxia. Increased erythropoietin is likely to play a role, perhaps by enhancing erythropoiesis at the expense of neutrophil and platelet production. Neutropenia secondary to IUGR/maternal hypertension reaches its nadir on day 2/3 of life and recovers spontaneously by day 7–10. The severity is directly related to the severity of the IUGR/maternal hypertension. Attempts have been made to prevent or ameliorate sepsis in neutropenic infants by the use of growth factors (recombinant G-CSF or GM-CSF) either therapeutically or prophylactically, or by direct infusion of donor granulocytes. Despite a number of small double-blind placebo-controlled trials none of these approaches has currently been shown to be of clinical benefit.<sup>782,783</sup>

Other non-immune causes of neutropenia are listed in Table 12.84. The most important is neutropenia secondary to infection. Any bacterial infections cause acute neutropenia – where this is short lived (6–12 h) it is a normal response, but neutropenia lasting  $>12$  h in the setting of acute bacterial infection is a poor prognostic sign. Examination of the blood film is often helpful in differentiating neutropenia secondary to infection from that due to viral infection or IUGR. The classic signs of acute bacterial infection are the presence of an increased percentage of band neutrophils and toxic granulation of immature and mature neutrophils followed after 1–2 days by a mature neutrophilia and after 3–5 days by eosinophilia. By contrast, there is no increase in band cells or toxic granulation in viral infections; instead atypical 'viral' lymphocytes are seen. Rare causes of neonatal neutropenia include Kostmann disease and bone marrow failure syndromes. These should be sought where the neutropenia is prolonged, there is a relevant family history, there is consanguinity or if the baby has typical dysmorphic features.

## Hemopoietic stem cell disorders including leukemias and myeloproliferative disorders

### *Congenital leukemias*

Congenital leukemia is rare but the diagnosis is usually straightforward. The most common types are acute monoblastic leukemia and acute megakaryoblastic leukemia; around 25% of cases occur in babies with Down syndrome (see Ch. 14). Both have similar presentations but can be differentiated by cytogenetic and immunophenotypic studies on bone marrow and blood leukemia cells. The usual presentation is with clinical signs of anemia and skin lesions caused by focal infiltration by leukemic cells. Congenital leukemia may present as a 'blueberry muffin' baby or hydrops fetalis. The prognosis in infants without Down syndrome is extremely poor; few are cured by chemotherapy and bone marrow transplantation may be the best option.<sup>784</sup>

### *Hematological abnormalities in neonates with Down syndrome and other trisomies*

Hematological abnormalities are more common in neonates with chromosomal disorders, including Down syndrome, trisomy 13 and trisomy 18, all of which may be associated with pancytopenia. Most babies with Down syndrome have a normal blood count; the remaining 10% have one of three hematological presentations:

1. acute leukemia (see p. 334);
2. transient abnormal myelopoiesis (TAM);
3. mild pancytopenia with subtle myelodysplastic changes.

TAM presents with leukocytosis and an abnormal blood film with circulating blast cells. In most cases no treatment is required and TAM almost always resolves by the age of 2–3 months.<sup>785</sup> In some cases affected infants may present with severe hepatic or pulmonary impairment due to fibrosis or infiltration with hemopoietic cells. These babies may respond to low dose cytarabine chemotherapy. The majority of cases of TAM spontaneously resolve but 20–30% of babies go on to develop acute megakaryoblastic leukemia (AMKL) within the first four years of life. This disease is of considerable scientific interest as virtually 100% of affected babies with TAM and AMKL harbor mutations in the X-linked hemopoietic transcription factor GATA-1. This, alongside the tight association between trisomy 21 and TAM/AMKL, makes it an excellent biological model with which to try to understand the stepwise acquisition of molecular and cellular abnormalities underlying the development of leukemia in all children.<sup>786</sup> Large national prospective studies are under way to try to acquire knowledge of the natural history of hemopoietic abnormalities in Down syndrome and evaluate markers that may predict which children are likely to develop leukemia in later infancy/childhood.

### **Abnormal leukocytes in neonatal systemic disease**

The blood film often provides clues to other underlying disorders in the newborn. As well as classic features of acute bacterial and viral infections (see p. 322), characteristic changes can be seen in fungal infection where vacuolation of the neutrophils and monocytes may be prominent and fungi may be seen within the phagocytic cells. In NEC, neutrophil and monocyte vacuolation is also common. A number of metabolic and storage disorders produce changes in the appearance of leukocytes which can be seen on carefully examined blood films:

- leukocyte vacuolation in Pearson syndrome;
- giant neutrophil granules in Chediak–Higashi syndrome;
- Alder Reilly leukocyte granules in Hunter syndrome, Hurler syndrome and Sanfilippo syndrome;
- lymphocyte vacuolation in Wolman disease, alpha-mannosidosis, sialidosis and Sanfilippo syndrome.

## HEMOSTASIS AND THROMBOSIS

### **Normal hemostasis**

Hemostasis involves a complex balance between activators and inhibitors of the coagulation cascade and a system to break down and limit

clot size (fibrinolysis).<sup>787</sup> There are five main components: blood vessels, platelets, coagulation factors, coagulation inhibitors and fibrinolysis.

### *Blood vessels*

Local damage to the vasculature leads to release of tissue factor and exposure of procoagulants in the subendothelium including collagen and von Willebrand factor (vWF). This results in platelet adhesion followed by coagulation. Key inhibitors of coagulation are also present on the endothelial surface including antithrombin, protein C and protein S. Hence endothelium is responsible for directing coagulation to the site of injury and then limiting the extent of thrombus formation via inhibitors.

### *Platelets*

Platelets aggregate at sites of injury and are vital for primary hemostasis. They also provide a phospholipid surface essential for the coagulation cascade. Both quantitative and qualitative defects can lead to bleeding disorders.

### *Coagulation factors*

Traditional versions of the coagulation cascade based on *in vitro* clotting tests delineated intrinsic and extrinsic pathways and sequential activation of coagulation factors. It has become clear that the process *in vivo* is quite different and a new pathway has been proposed (Fig. 12.41). Clotting factors generally exist as inactive precursors and require activation to take part in coagulation. The key initiating event is exposure of tissue factor in response to endothelial damage. Tissue factor activates factor VII to form a complex, TF–VIIa, which cleaves factor X to its active form Xa. Xa can convert prothrombin to thrombin with low efficiency but this generation of small amounts of thrombin then activates feedback loops to increase coagulation factor activation. Factor VIII (activated by thrombin) and factor IX (activated by TF–VIIa and factor XI) form a complex VIIIa–IXa known as tenase. Tenase generates activated factor X with great efficiency. Thrombin also activates factor V, and a Xa–Va complex is formed which cleaves prothrombin to form thrombin. Thrombin generation leads to conversion of fibrinogen to fibrin with subsequent crosslinking by factor XIII.

### *Inhibitors of coagulation*

Upon localized initiation of clotting, spread throughout the vasculature is prevented by inhibitors. Protein C is activated by thrombin. Once

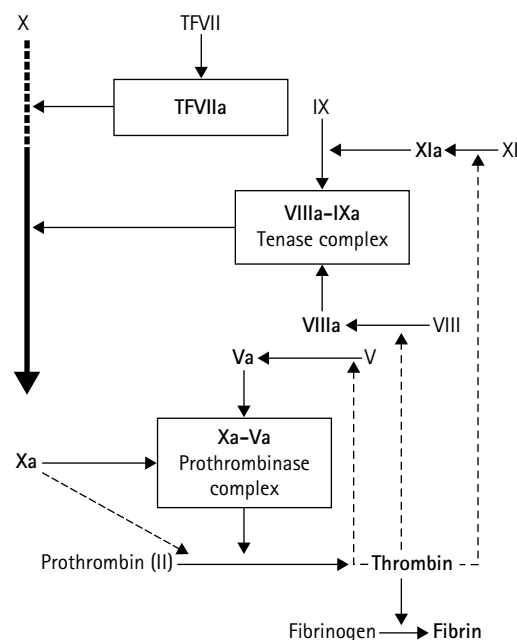

Fig. 12.41 Coagulation cascade. Thick dashed arrows indicate low efficiency pathways. Thin dashed arrows indicate feedback activation loops. Boxes indicate complexes on phospholipid surface.

activated, protein C forms a complex with protein S which increases its activity 10-fold. The activated protein C complex (APC) cleaves and inactivates factors V and VIII. A mutation in factor V (factor V Leiden) at the cleavage site, preventing factor V inactivation by APC, is associated with thrombophilia. Antithrombin and heparin cofactor II are both potent direct inhibitors of thrombin; levels of these proteins are low at birth but rarely cause thrombosis.<sup>788</sup>

### Fibrinolysis

Fibrinolysis limits fibrin deposition at the site of injury. The key enzyme is plasmin. This is produced by the action of tissue plasminogen activator whose activity is catalyzed by fibrin itself. Fibrin breakdown is accompanied by the production of degradation products (FDPs) and D-dimers.

### Coagulation in the fetus and newborn

Coagulation proteins are synthesized from the fifth week of gestation onwards and do not cross the placenta.<sup>788</sup> Levels gradually rise towards birth but many do not attain adult values during the neonatal period. Birth may cause activation of coagulation, hence levels in preterm infants may be significantly higher than those found in fetuses of the same gestational age. Normal values vary with gestational and postnatal age (Table 12.85).<sup>789-791</sup>

## Diagnostic approach to bleeding in neonates

### Clinical presentation of bleeding disorders

Neonates exhibit patterns of bleeding distinct from those in older children. Bleeding from the umbilical cord stump, venepuncture sites, cephalhematomas after vacuum extraction, intracranial and pulmonary hemorrhage can occur. Bleeding post circumcision is a relatively common presentation of hemophilia in the neonate, but hemarthroses are extremely rare. The most likely cause of bleeding in neonates depends on gestational age and whether the child is clinically well or unwell. A thorough clinical assessment is essential and should include sites and severity of bleeding, predisposing factors, drug history (infant and maternal) including vitamin K and a family history of possible coagulation disorders.

### Screening tests for bleeding disorders

Initial screening tests should comprise:

1. *prothrombin time* (PT) – measures activity of factors II, V, VII and X;
2. *activated partial thromboplastin time* (APTT) – measures factors II, V, VIII, IX, X, XI and XII;
3. *thrombin time* (TT) – prolonged by quantitative and qualitative disorders of fibrinogen, the presence of inhibitory factors such as fibrin/FDPs and the presence of heparin;
4. fibrinogen level;
5. platelet count.

Table 12.85 Reference values for (a) healthy full-term infants and (b) preterm infants during the neonatal period

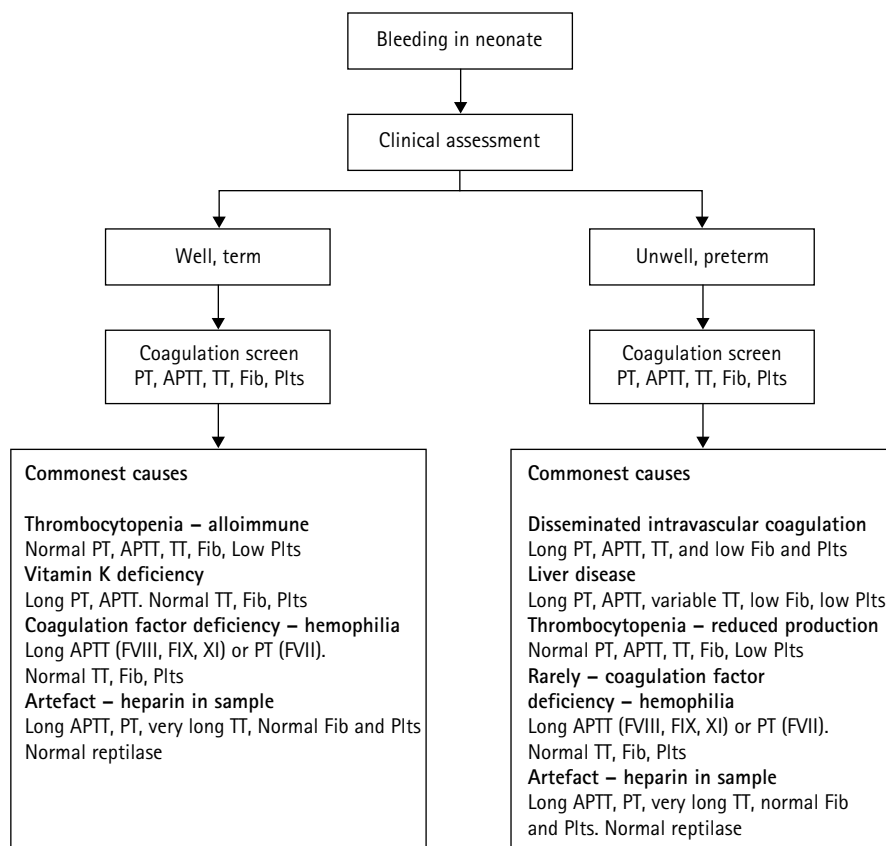

Fig. 12.42 Diagnostic algorithm for bleeding in neonates. APTT, activated partial thromboplastin time; Fib, fibrinogen; Plts, platelets; PT, prothrombin time; TT, thrombin time.

Results of these tests along with clinical history can guide subsequent investigation. Bleeding times are generally unhelpful. A diagnostic algorithm is shown in Figure 12.42.

### Interpretation of laboratory coagulation tests

Coagulation testing in neonates is often difficult. Since testing is done on plasma, the high hematocrit in many neonates means the blood volumes required for testing are relatively large even when using specially adapted microtechniques. Activation of coagulation during sampling is common when venepuncture is difficult and invalidates results. Samples from indwelling lines are frequently heparin contaminated. Laboratories may use various tests to distinguish the presence of heparin in a sample including measuring the degree of correction of the thrombin time with protamine or normal patient plasma. A *reptilase time* (so named because snake venom is used in the test) can also be very helpful; it assesses the same components as a TT but is unaffected by heparin. In coagulation factor assays, the lower limit of the normal range in neonates often overlaps with those seen in deficiency states (especially seen with factor II, factor X and factor XI). In such circumstances demonstrating heterozygote levels of factor activity in parents is useful.

### Inherited coagulation disorders

Inherited coagulation disorders are rare but often present in the neonatal period so a high index of suspicion is needed. The commonest are the X-linked disorders factor VIII (hemophilia A) and factor IX (hemophilia B) with a frequency of 1 in 10 000 and 1 in 60 000 male births respectively. Most other factor deficiencies are autosomal recessive. All produce prolongation of coagulation screening tests with the exception of factor XIII deficiency and, rarely, von Willebrand disease (vWD). Therefore a normal coagulation screen in a child with unexplained bleeding does not exclude all inherited coagulation disorders and further specialized tests may be needed.

This section addresses neonatal aspects of inherited coagulation abnormalities. A comprehensive discussion of these conditions is provided elsewhere (Ch. 23).

### Factor VIII deficiency

**Clinical presentation.** This may be diagnosed or suspected antenatally in families with a history of hemophilia. One third of cases represent new mutations and are therefore unsuspected at birth. They may present with intracranial hemorrhage, subgaleal or cephalhematomas, bleeding post circumcision or from venous or arterial puncture sites. The hemorrhage may be life threatening. Prolonged bleeding from the umbilical cord is less common. Large bruises may occur and the diagnosis may be made during investigations of possible non-accidental injury.

**Diagnosis.** Coagulation tests show a very prolonged APTT with normal PT, TT, platelets and fibrinogen. The definitive diagnosis is made by measurement of factor VIII clotting activity which is < 50%; all other factors, including vWF antigen, are normal. Disease severity is classified according to factor VIII activity with levels < 1% indicative of severe disease.

**Management.** Adequate family support is vital and early liaison with a hemophilia center is essential. Treatment should be with recombinant factor VIII concentrate for bleeding episodes. The best mode of delivery is controversial; there is no evidence that elective Cesarean section eliminates bleeding; spontaneous vaginal delivery is acceptable but vacuum extraction should be avoided due to the high rate of subgaleal bleeds and cephalhematomas. There is debate as to whether known hemophilic newborns should be given prophylactic factor VIII following delivery to reduce the risk of intracranial bleeding, currently estimated to have an incidence of around 3–5%. Large prospective cohort studies are needed.<sup>792</sup> Known or suspected hemophilic newborns should always have a cord blood sample taken for a coagulation screen and factor VIII level as this avoids possible iatrogenic bruising or bleeding

secondary to difficult venepuncture in the first few days of life. Vitamin K should be given at birth but the intramuscular route avoided because of hematoma formation.

### **Factor IX deficiency**

This has an identical clinical phenotype to factor VIII deficiency and can only be distinguished by specific factor assays. Unlike factor VIII, factor IX is vitamin K dependent and hence its activity also falls in liver disease and vitamin K deficiency. However there is seldom diagnostic confusion as the latter diseases produce prolongation of other screening tests and characteristic clinical features. Treatment of bleeding is with recombinant factor IX concentrate.

### **von Willebrand disease**

This is a complex group of conditions caused by quantitative or qualitative defects in vWF. Neonatal presentation is rare as levels of vWF are elevated at birth.<sup>788</sup> However, one of the most severe forms, type 3 vWD, may present in the neonatal period. In this case factor VIII levels are very low, vWF is virtually absent and the patient presents in a similar way to hemophilia A. Clues to the diagnosis are the absence of X-linked inheritance and poor response to factor VIII concentrates. Quantification of vWF makes the diagnosis. Treatment of bleeding is with a viridically treated intermediate purity factor VIII concentrate containing the high molecular weight multimers of vWF. Desmopressin (DDAVP) can be used in older children with mild to moderate vWD but should be avoided in neonates and younger children due to the risk of hyponatremic convulsions.

### **Factor XIII deficiency**

Factor XIII deficiency presents with umbilical stump bleeding and/or intracranial hemorrhage. Routine coagulation screens are normal. Diagnosis is made by measuring clot lysis in 5 M urea solution; molecular tests for the common mutations are also available. Treatment is with factor XIII concentrate.

### **Other rarer inherited coagulation factor deficiencies**

These can present in the neonatal period with bleeding or unexplained prolongation of coagulation tests. The majority are autosomal recessive. Factor XI deficiency can produce hemophilic-type bleeding and is commoner in Ashkenazi Jews. Factor VII deficiency can produce a very severe bleeding disorder with a high incidence of intracranial hemorrhage. Recombinant factor VII concentrate can be used but is expensive and has a very short half-life. Factor XII deficiency produces a markedly prolonged APTT but no clinically apparent bleeding disorder. Dysfibrinogenemias are rare and can produce both hemorrhage and thrombosis.<sup>793</sup>

## **Acquired disorders of coagulation**

### **Vitamin k deficiency (hemorrhagic disease of the newborn)**

Vitamin K is essential for the production of active forms of factors II, VII, IX, X and protein C and S. Placental transfer of vitamin K occurs but is insufficient to build up adequate stores in the neonate and without supplementation levels fall during the first few days of life. Untreated vitamin K deficiency can lead to hemorrhagic disease of the newborn. It can be classified according to age of onset into classic, early and late.

**Classic.** This presents at 2–7 days old, generally in breast-fed term healthy infants. The incidence in babies not receiving supplementation is 0.4–1.7/100 births. Causes include: low vitamin K content in breast milk (< 5 mcg/L compared to 50–60 mcg/L in formula milk), poor oral intake and a sterile gut. It can be prevented by vitamin K supplementation at birth.

**Early.** This presents within the first 24–48 h and is associated with severe vitamin K deficiency in utero. The usual cause is maternal medication that interferes with vitamin K, e.g. anticonvulsants (phenobarbital, phenytoin), antituberculous therapy and oral anticoagulants. It cannot be prevented by vitamin K supplementation at birth.

**Late.** This occurs from 2 weeks to 6 months of age. It is usually associated with disorders that reduce vitamin K absorption, e.g. alpha1-antitrypsin deficiency, biliary atresia, liver disease and malabsorptive

states. Breast-fed babies are also at risk. It is prevented by a single intramuscular dose or repeated oral doses of vitamin K. Prolonged vitamin K supplementation should be given to all babies with chronic liver disease or other risk factors.

Bleeding manifestations include gastrointestinal, cutaneous and intracranial bleeding. Gastrointestinal bleeding in newborns can be differentiated from melena secondary to swallowed maternal blood by the Apt test which distinguishes fetal from adult hemoglobin, although this test is no longer widely available. Isolated prolongation of the PT is the earliest laboratory sign of vitamin K deficiency, followed by prolongation of the APTT. Low levels of vitamin K dependent factors are seen, and inactive forms (proteins induced by vitamin K absence; PIVKAs) can be measured. Treatment is with 1 mg vitamin K subcutaneously or intravenously (not i.m. due to risk of hematoma) which will usually correct the coagulopathy within a few hours; fresh frozen plasma (FFP) at a dose of 10–15 ml/kg may be given for active bleeding prior to vitamin K taking effect. In the presence of life-threatening bleeding, prothrombin complex concentrate may be more effective in restoring adequate clotting factor levels but there are few data in neonates.<sup>793</sup>

**Vitamin K supplementation at birth.** Vitamin K supplementation prevents classic and late vitamin K deficiency bleeding. Controversy surrounds the best mode of administration. Studies by Golding et al<sup>794</sup> suggested a link between intramuscular vitamin K at birth and later childhood malignancies. These studies have been criticized on methodological grounds. No link between oral vitamin K and malignancy has been reported but disadvantages of oral vitamin K include unnoticed regurgitation, unpredictable absorption and the need for repeated dosing. In one study there were no cases of vitamin K deficiency bleeding in 320 000 infants given 1 mg i.m. vitamin K at birth, but 32 cases of late disease in 1 200 000 infants given 1 mg orally at birth, 1 week and 1 month of age.<sup>795</sup> A systematic review<sup>796</sup> concludes that:

1. intramuscular vitamin K has been proven to prevent classic disease;
2. oral vitamin K has been proven to improve biochemical parameters of vitamin K deficiency in the first week of life;
3. the efficacy of oral supplementation in preventing late disease is unproven.

### **Disseminated intravascular coagulation (DIC)**

The pathophysiology of DIC is complex but involves widespread uncontrolled activation of the coagulation cascade with subsequent consumption of clotting factors and a combination of thrombotic and hemorrhagic manifestations. The initial trigger is usually the release of tissue factor and cytokines from damaged endothelium or monocytes. A number of neonatal disorders resulting in severe hypoxia and/or acidosis can precipitate DIC including peripartum hemorrhage, severe birth asphyxia, meconium aspiration and sepsis. Clinically DIC is seen in sick neonates and presents with generalized bleeding. The PT, APTT and TT are prolonged; platelets and fibrinogen are low. Although D-dimers are of some use in monitoring DIC they should be interpreted with caution as they are not specific and can be found in healthy neonates with no evidence of coagulopathy.<sup>793</sup> The mainstay of management is treatment of the underlying cause. In the presence of uncontrolled bleeding, platelet infusion and FFP or cryoprecipitate may be needed. Platelets should be maintained above  $50 \times 10^9/L$  and fibrinogen  $> 1 g/L$ .

### **Other acquired coagulation disorders**

Serious liver disease can cause a severe coagulopathy compounded by hepatocyte immaturity, vitamin K deficiency and DIC. Platelets may be low due to impaired production, increased consumption and splenic sequestration. Coagulopathy can be seen with metabolic defects such as hyperammonemia. Extracorporeal membrane oxygenation often causes coagulation and platelet disturbances due to consumption of clotting factors and platelets and heparinization. Consumptive coagulopathy with thrombocytopenia can be seen with giant hemangioendotheliomas (Kasabach–Merritt syndrome).

## Neonatal thrombocytopenia

### *Incidence of neonatal thrombocytopenia*

Thrombocytopenia (platelets  $< 150 \times 10^9/L$ ) is relatively common in neonates, occurring in 1–5% of all newborns, in 22–35% of neonates admitted to NICUs and in up to 50% of neonates who are preterm and sick.<sup>797</sup> Severe thrombocytopenia (platelets  $< 50 \times 10^9/L$ ) occurs in 0.2% of neonates.

### *Causes and natural history of neonatal thrombocytopenia*

Neonatal thrombocytopenia usually presents in one of two patterns: early (within 72 h of birth) and late (after 72 h of life). Early thrombocytopenia is more common; the principal causes are shown in Table 12.86. The most frequent cause of early thrombocytopenia in preterm infants is 'placental insufficiency'; this is self-limiting, usually within 10 days, and is rarely severe except in neonates with profound IUGR. It is caused by reduced platelet production. The most important cause of early neonatal thrombocytopenia from a clinical viewpoint is neonatal alloimmune thrombocytopenia (NAITP) (see below). The most common and clinically important causes of late thrombocytopenia are sepsis and NEC.<sup>797</sup>

### *Neonatal alloimmune and autoimmune thrombocytopenia (NAITP)*

NAITP is the platelet equivalent of hemolytic disease of the newborn. Fetal and neonatal thrombocytopenia result from transplacental passage of maternal platelet-specific antibodies; in 80% of cases these are anti-HPA-1a antibodies and in 10–15% anti-HPA-5b. Although NAITP is uncommon, affecting 1:1000 pregnancies, it is frequently severe and occurs in the first pregnancy in almost 50% of cases. Intracranial hemorrhage occurs in 10% of cases with long term neurodevelopmental sequelae in 20% of survivors. Diagnosis is made by demonstrating platelet antigen incompatibility between mother and baby. Therapy for NAITP remains controversial (reviewed in Ouwehand et al<sup>798</sup>). Antenatal management may include fetal blood sampling, fetal transfusion with HPA-compatible platelets and/or maternal IVIG therapy; each approach has evidence to support it. All severely affected babies should receive HPA-compatible platelets until a stable platelet count  $> 50 \times 10^9/L$  is achieved.

Neonatal autoimmune thrombocytopenia occurs secondary to transplacental passage of maternal platelet autoantibodies, usually maternal ITP. Thrombocytopenia affects the infants of 10% of affected mothers;

**Table 12.86** Causes of neonatal thrombocytopenia

Early (< 72 h)	<i>Placental insufficiency (PET, IUGR, diabetes)</i>
	NAITP
	Birth asphyxia
	Perinatal infection (group B strep, <i>Escherichia coli</i> , <i>Listeria</i> )
	Congenital infection (CMV, toxoplasmosis, rubella)
	Maternal autoimmune (ITP, SLE)
	Severe rhesus HDN
	Thrombosis (renal vein, aortic)
	Aneuploidy (trisomy – 21, 18, 13)
	Congenital/inherited (TAR, Wiskott–Aldrich)
	Late (> 72 h)
Congenital infection (CMV, toxoplasmosis, rubella)	
Maternal autoimmune (ITP, SLE)	
Congenital/inherited (TAR, Wiskott–Aldrich)	

CMV, cytomegalovirus; HDN, hemolytic disease of the newborn; ITP, idiopathic thrombocytopenic purpura; IUGR, intrauterine growth restriction; NAITP, neonatal alloimmune thrombocytopenia; NEC, necrotizing enterocolitis; PET, pre-eclampsia; SLE, systemic lupus erythematosus; strep, streptococcus; TAR, thrombocytopenia with absent radii.

thrombocytopenia is usually mild and intracranial hemorrhage occurs in 1% or less. In affected babies with severe thrombocytopenia treatment with IVIG is usually effective.

### *Management of neonatal thrombocytopenia*

The antenatal management of immune thrombocytopenias is described in chapter 11. For other forms of neonatal thrombocytopenia therapy mainly depends upon the appropriate use of platelet transfusion. Evidence-based guidelines for neonatal platelet transfusion therapy are yet to be defined; consensus guidelines are available, most of which recommend platelet transfusion for sick neonates where the platelet count is  $< 50 \times 10^9/L$ ; for stable, relatively well preterm and term infants platelet counts of  $30\text{--}50 \times 10^9/L$  do not appear to be associated with an increased risk of hemorrhage: this approach conforms to the current UK guidelines.<sup>777</sup>

### *Thrombosis in neonates*

Neonates and infants have the highest rate of thrombotic problems within the pediatric population. Most thromboses occur in sick or preterm neonates and are due to acquired risk factors, especially the presence of an indwelling central line. Inherited deficiencies of coagulation inhibitors can lead to dramatic thrombosis in otherwise healthy neonates.

### *Inherited thrombotic disorders*

**Protein C deficiency.** Homozygous or compound heterozygous protein C deficiency usually presents within the first few days of life with purpura fulminans. This is characterized by a rapidly progressive hemorrhagic necrosis of the skin accompanied by dermal vessel thrombosis which is most pronounced in the extremities. Babies may also show evidence of intrauterine thrombosis with cerebral and ophthalmic damage at birth. Occasionally isolated vessel thrombosis may occur. Diagnosis is made by the characteristic clinical picture in conjunction with very low levels of protein C in the patient and heterozygote levels in the parents. Treatment is with FFP or protein C concentrate. Oral anticoagulation is used in the medium to long term to prevent recurrence but its introduction must be covered by infusion of a source of protein C and very careful monitoring is needed to prevent subtherapeutic levels which are associated with recurrence of thrombosis.

**Protein S deficiency.** This presents in a similar way to protein C deficiency. Treatment is with FFP.

**Antithrombin deficiency.** This is very rare in the homozygous state. Myocardial infarction, aortic thrombosis and cerebral thrombosis have all been reported in neonates. Antithrombin concentrate is commercially available.

**The role of thrombophilia screening in neonatal thrombosis.** Homozygous protein C, S and antithrombin deficiency are the only inherited thrombophilic mutations shown to directly cause neonatal thrombotic problems. Many studies have documented the presence of other thrombophilic mutations such as factor V Leiden and the prothrombin 20210A promoter mutation in neonatal thrombotic disease, both venous and arterial, but whether these mutations are causative and the role they play in the natural history of these disorders is uncertain. In order to justify testing for these defects it must be shown that the result influences treatment or prognosis. At present there is insufficient evidence to support routine testing but ongoing international registries of pediatric thrombosis are currently collecting data and the position may become clearer in the future.<sup>793</sup>

### *Acquired thrombotic problems*

Risk factors for thrombosis include the presence of a vessel catheter, shock syndromes (septic, hypoxemic or hypovolemic) and, rarely, the presence of maternal lupus anticoagulant.

**Catheter-related thrombosis.** This is the commonest cause of neonatal thrombosis, being responsible for  $> 80\%$  of venous and  $> 90\%$  arterial thrombosis. Symptomatic thrombosis occurs in 1% of neonates with indwelling vascular catheters, but postmortem studies suggest rates of asymptomatic thrombosis up to 20–30%. Arterial thrombosis can

lead to peripheral gangrene and renal hypertension. Venous thrombosis can cause portal hypertension and varices. Neonatal thrombosis is increasingly recognized as a risk factor for post-thrombotic syndrome, often presenting much later in childhood with skin changes, chronic edema and limb pain or dysfunction.<sup>799</sup> The gold standard for diagnosis of venous thrombosis is contrast angiography, although Doppler ultrasound or magnetic resonance angiography may also be useful. Injection of contrast down a catheter lumen (lineogram) may miss significant thrombosis. The optimal treatment in the neonatal setting is controversial and large randomized trials are urgently needed.<sup>800</sup> Because of differences between the neonatal coagulation system and those of older children and adults extrapolation of guidelines from older age groups to neonates is difficult. In general treatment depends on the severity and extent of thrombosis. The first step is prompt removal of the catheter. If signs progress or have not resolved by 24 h, heparin is the drug of choice but requires a dosing regimen adapted for neonates. Duration of therapy is generally shorter than for older children with 10–14 days of initial treatment followed by re-imaging and discontinuation unless there is new or extending thrombus at this time.<sup>793</sup> Local or systemic thrombolysis with tissue plasminogen activator (tPA) can be considered where there is associated organ dysfunction or limb viability is threatened but can cause high rates of bleeding including intracranial hemorrhage and needs specialist advice and monitoring. Prevention of thrombosis is paramount, e.g. correct catheter positioning, prompt removal once unnecessary. Prophylactic low dose heparin prolongs catheter patency but its role in preventing thrombosis is unproven.<sup>801</sup>

**Non-catheter-related thrombosis.** The commonest non-catheter-related thrombosis is renal vein thrombosis. Nearly 80% present in the neonatal period and thrombosis may occur in utero. One quarter are bilateral. Presentation is with a flank mass, hematuria, proteinuria, thrombocytopenia and reduced function of the involved kidney. Predisposing factors include reduced renal blood flow, increased viscosity, hyperosmolar states and hypercoagulability; therefore risk factors are sepsis, maternal diabetes, polycythemia, dehydration and prothrombotic mutations. Treatment is supportive. Heparin and thrombolysis are reserved for extensive bilateral cases. Long term outlook is variable.

**Neonatal stroke.** Neonatal stroke is rare. Causes include bacterial meningitis, hypoxic-ischemic damage and birth trauma. Many cases are idiopathic. Some studies show an increased prevalence of thrombophilia in affected neonates, particularly factor V Leiden.<sup>802</sup> Maternal or neonatal anticardiolipin antibodies have also been linked to neonatal stroke; these are often transient and their causal role is not yet established. This is a rapidly evolving field. It is likely that thrombophilia plays a role in neonatal stroke but additional risk factors are probably also needed.

## NEONATAL NEUROLOGY

### NEUROLOGICAL ASSESSMENT

#### Introduction

Clinical examination of the neonatal nervous system is, of necessity, dominated by assessment of motor function. Over time the emphasis has shifted from examination of primitive reflexes to the assessment of the newborn's spontaneous behavior and the way that the baby interacts with adults and deals with stimuli. The following description is based on the work of many pioneers such as Saint-Anne Dargassies,<sup>803</sup> Amiel-Tison & Grenier,<sup>804</sup> Prechtl and his colleagues,<sup>805–808</sup> Brazelton<sup>809,810</sup> and Dubowitz and her colleagues.<sup>811,812</sup>

#### State

Normal babies show different states of alertness (Table 12.87).<sup>805,809</sup> The fetus exhibits similar states, apart from crying. Babies born before 36 weeks' gestation spend a great deal of time asleep and fall asleep easily when awakened. Preterm sleep states are less easily characterized than at term. Term babies spend about 50 min of each hour asleep, 50% of the time in quiet sleep. Babies who are continually in one state may be abnormal. One example is the baby who is 'hyperalert' due to withdrawal

Table 12.87 Normal neonatal states of Prechtl and Brazelton

Prechtl & Bientema <sup>805</sup>	
State 1	Eyes closed, regular respiration, no movements
State 2	Eyes closed, irregular respiration, no movements
State 3	Eyes open, no gross movements
State 4	Eyes open, gross movements, no crying
State 5	Crying
Brazelton <sup>809</sup>	
State 1	Deep sleep, regular breathing, no movements
State 2	Light sleep, irregular respiration, rapid eye movements, eyes closed
State 3	Drowsy, eyes open or closed, some activity – smooth
State 4	Alert, minimal motor activity
State 5	Eyes open, considerable motor activity
State 6	Crying

symptoms after maternal drug abuse, who spends little time asleep and more time crying than is usual. Inability to rouse a baby from sleep is pathological and a baby who is persistently in state 1 is in a coma.

#### Crying and consolability

During an examination most babies will cry but are consolable. Soundless or hoarse crying can result from a congenital abnormality such as vocal cord palsy, or from an acquired problem such as trauma from intubation or damage to the recurrent laryngeal nerve during thoracic surgery. High pitched or excessive crying can indicate cerebral irritability due to neonatal encephalopathy. Asymmetrical crying facies is usually due to agenesis or hypoplasia of the depressor anguli oris muscle and needs to be differentiated from facial palsy. Asymmetrical crying facies can be a marker of congenital heart disease although it is usually an isolated malformation.

#### Posture, spontaneous movement and tone

Normal muscle offers a resistance to stretch felt by the examiner as tone. Tone increases with gestational age and is high in term babies. Term babies lie with their limbs flexed and adducted, unlike preterm babies who adopt an extended posture (Fig. 12.43). Asymmetrical tone does not always indicate asymmetrical pathology in the newborn period.

A term newborn makes smooth, spontaneous symmetrical limb movements which stop when the baby's attention is diverted.<sup>808</sup> Finger movements are elegant and varied, involving the thumb which can be abducted away from the palm by term.<sup>808</sup> In general, the movements of the newborn have a writhing quality, which changes to fidgety after 6–9 weeks of age. Fidgety movements persist until around 6 months of age, when intentional and anti-gravity movements start to dominate. The repertoire of movement is varied and not stereotyped. A persistently adducted thumb (cortical thumb) is abnormal, and brain damaged babies often have fistled hands and a paucity of fine finger movements.

#### Jitteriness

The normal term newborn is in a state of hypertonicity, with brisk reflexes tending to clonus. This 'transient spasticity' gradually relaxes over the first 8–10 months in a caudocephalad direction. The high tone can lead to the clinical sign of jittering. Jittering is a high frequency, generalized, symmetrical tremor of the limbs which is stilled by flexion or by inducing the baby to suck on a finger. Jittering is common in the first 2 or 3 days in term babies but if it is excessive or persistent deserves investigation. Repetitive chewing movements or tongue thrusting are not part of jitteriness and imply seizures. Jitteriness is stimulus-sensitive whereas seizures are not and in seizures the movements have a fast and slow component whereas in jittering the tremor is symmetrical.

#### Limb tone and power

Before passive movements are used to assess tone it may be possible to observe spontaneous movements of the limbs against gravity. Failure to

Fig. 12.43 Comparison between low tone in preterm baby (normal) (left) and the high flexor tone of a healthy term baby (right).

move part or whole of a limb may be due to pain or paralysis. Limb tone is influenced by the tonic neck reflex in newborns which means it is important to have the head in the midline before beginning to elicit the response to passive movements. Passive movements involve gentle flexion of the upper and lower limbs, then rapid extension and observation of recoil.

#### **Trunk and neck tone and power**

Normal term babies have sufficient power in their neck muscles to lift their heads slightly when prone or supine. Preterm babies can manage to turn their heads from side to side but have much less power with complete head lag when pulled to sit. In order to judge tone in the neck and trunk, babies should be pulled to sit by holding them at the shoulders and then allowing them to fall back again. If the head is unsupported it will gradually fall forwards or backwards: normal term babies will be able to raise their heads to the vertical again from either direction. There is balance between the neck flexors and extensors during pull-to-sit and back-to-lying maneuvers at term so that the head is held in line with the body during both phases. Immature babies usually have better control in back-to-lying. To assess truncal tone, lie the child on his back and try to push his bottom towards his head using his thighs (Fig. 12.44).<sup>813</sup> With the baby lying on his side, hold the lumbar region and pull both legs backwards with the other hand grasping the ankles. Trunk flexion should always exceed extension. Arching of the trunk is abnormal; backwards arching of the whole back and neck is called opisthotonos. Opisthotonos is an important sign of neurological abnormality in the newborn.

#### **Reflexes**

##### **Tendon and Babinski reflexes**

Eliciting tendon reflexes is of less value in the newborn period than later in childhood. Knee and biceps jerks can usually be obtained.

Reflexes at term are very brisk due to the high tone, and a few beats of clonus at the ankle are usual. The plantar reflex of Babinski is always extensor and is best omitted as the stimulus often results in a withdrawal response.

##### **Primary neonatal reflexes**

Whilst the multiplicity of these responses and the timing of their appearance and disappearance is fascinating it is only necessary to have a working knowledge of a few. The reflexes have parallels in animals: the Moro reflex enables young primates to hold on to their mothers. Primitive reflexes normally habituate after repeated performance: this 'conditioning' is apparent even in fetal life. Persistence of neonatal reflexes can considerably inhibit normal movement in children with cerebral palsy.

##### **Moro**

This reflex is elicited by allowing the previously supported head of a baby to fall backwards slightly, whereupon the baby extends and adducts both upper limbs, opening the hands (Fig. 12.45). Babies of greater than 33 weeks' gestation subsequently abduct their arms. The Moro response is present from 28 weeks of gestation and usually disappears by 4 months. Persistence beyond 6 months is always abnormal.

##### **Asymmetric tonic neck reflex**

Starting with the baby supine and the head in the midline the head is slowly turned to one side. This results in increased extensor tone in the arm on the side to which the head is turned and increased flexor tone in the arm on the opposite side (fencing posture). A persistent asymmetric tonic neck reflex can dominate the movement patterns of children with cerebral palsy for many months, even years.

Name	D.O.B./Time	Weight	E.D.D.	E.D.D.	States			State	Comment	Asymmetry
Hosp. No.	Date of exam	Height	L.N.M.P.	U/snd.	1. Deep sleep, no movement, regular breathing	2. Light sleep, eyes shut, some movement	3. Dozing, eyes opening and closing			
Race	Sex	Age	Head circ.	Gestational assessment	Score	Weeks				
<b>Habituation ( state 3)</b>										
<b>Light</b> Repetitive flashlight stimuli (10) with 5 sec. gap Shutdown = 2 consecutive negative responses	No response	A. Blink response to first stimulus only B. Tonic blink response C. Variable response	A. Shutdown of movement but blink persists 2-15 stimuli. B. Complete shutdown 2-5 stimuli	A. Shutdown of movement but blink persists 6-10 stimuli B. Complete shutdown 6-10 stimuli	A. Equal response to 10 stimuli. B. Infant comes to fully alert state C. Startles + major responses throughout

<b>Movement and tone</b>										
<b>Posture</b> (at rest- predominant)	*									Abnormal postures: A. Opisthotonus. B. Unusual leg extension. C. Asymm. tonic neck reflex
<b>Arm recoil</b> Infant supine. Take both hands, extend parallel to the body; hold approx. 2 secs. and release.	No flexion within 5 sec.	Partial flexion at elbow >100° within 4-5 sec.	Arms flex at elbow to <100° within 2-3 sec.	Sudden jerky flexion at elbow immediately after release to <60°	Difficult to extend; arm snaps back forcefully					
<b>Arm traction</b> Infant supine; head midline; grasp wrist, slowly pull arm to vertical. Angle of arm scored and resistance noted at moment infant is initially lifted off and watched until shoulder off mattress. Do other arm.	Arms remain fully extended	Weak flexion maintained only momentarily	Arm flexed at elbow to 140° and maintained 5 sec.	Arm flexed at approx. 100° and maintained	Strong flexion of arm <100° and maintained					
<b>Leg recoil</b> First flex hips for 5 secs, then extend both legs of infant by traction on ankles; hold down on the bed for 2 secs and release	No flexion within 5 sec.	Incomplete flexion of hips within 5 sec.	Complete flexion within 5 sec.	Instantaneous complete flexion	Legs cannot be extended; snap back forcefully					
<b>Leg traction</b> Infant supine. Grasp leg near ankle and slowly pull toward vertical until buttocks 1-2" off. Note resistance at knee and score angle. Do other leg.	No flexion	Partial flexion, rapidly lost	Knee flexion 140-160° and maintained	Knee flexion 100-140° and maintained	Strong resistance; flexion <100°					
<b>Popliteal angle</b> Infant supine. Approximate knee and thigh to abdomen; extend leg by gentle pressure with index finger behind ankle.	180-160°	150-140°	130-120°	110-90°	<90°					
<b>Head control (post. neck m.)</b> Grasp infant by shoulders and raise to sitting position; allow head to fall forward; wait 30 sec.	No attempt to raise head	Unsuccessful attempt to raise head upright	Head raised smoothly to upright in 30 sec. but not maintained.	Head raised smoothly to upright in 30 sec. and maintained	Head cannot be flexed forward					
<b>Head control (ant. neck m.)</b> Allow head to fall backward as you hold shoulders; wait 30 sec.	Grading as above	Grading as above	Grading as above	Grading as above						
<b>Head lag</b> Pull infant toward sitting posture by traction on both wrists. Also note arm flexion	*									
<b>Ventral suspension</b> Hold infant in ventral suspension; observe curvature of back, flexion of limbs and relation of head to trunk	*									
<b>Head raising in prone position</b> Infant in prone position with head in midline	No response	Rolls head to one side	Weak effort to raise head and turns raised head to one side	Infant lifts head, nose and chin off	Strong prolonged head lifting					
<b>Arm release in prone position</b> Head in midline. Infant in prone position; arms extended alongside body with palms up	No effort	Some effort and wriggling	Flexion effort but neither wrist brought to nipple level	One or both wrists brought at least to nipple level without excessive body movement	Strong body movement with both wrists brought to face, or 'press-ups'					
<b>Spontaneous body movement</b> during examination (supine). If no spont. movement try to induce by cutaneous stimulation	None or minimal Induced	A. Sluggish B. Random, incoordinated. C. Mainly stretching	Smooth movements alternating with random, stretching, athetoid or jerky	Smooth alternating movements of arms and legs with medium speed and intensity	Mainly: A. Jerky movement B. Athetoid movement C. Other abnormal movement				1 2	

Fig. 12.44 The Dubowitz score. (From Dubowitz & Dubowitz 1981,<sup>811</sup> courtesy of Spastics International Publishers Ltd.)

(Continued)

**Placing and stepping**

By stimulating the dorsum of the foot, usually by bringing it into contact with the edge of the couch, a mature baby can be induced to 'step' over the edge. With the feet in contact with a solid surface the baby will 'walk'.

**Rooting, sucking and swallowing**

Stroking the upper lip of a baby of 28 weeks' gestation and above results in the baby 'searching for the nipple' and tests the sensation in the distribution of the 5th cranial nerve. Sucking involves the motor activity of cranial nerves V, VII, XII; swallowing involves IX and X. The sensory input for the sucking reflex

<b>Tremors</b> Mark: Fast (>6/sec.) or Slow (<6/sec.)	No tremor	Tremors only in state 5-6	Tremors only in sleep or after Moro and startles	Some tremors in state 4	Tremulousness in all states			
<b>Startles</b>	No startles	Startles to sudden noise. Moro, bang on table only	Occasional spontaneous startle	2-5 spontaneous startles	6+ spontaneous startles			
<b>Abnormal movement or posture</b>	No abnormal movement	A. Hands clenched but open intermittently. B. Hands do not open with Moro	A. Some mouthing movement. B. Intermittent adducted thumb	A. Persistently adducted thumb. B. Hands clenched all the time	A. Continuous mouthing movement. B. Convulsive movements			
<b>Reflexes</b>								
<b>Tendon reflexes</b> Biceps jerk Knee jerk Ankle jerk	Absent		Present	Exaggerated	Clonus			
<b>Palmar grasp</b> Head in midline. Put index finger from ulnar side into hand and gently press palmar surface. Never touch dorsal side of hand	Absent	Short, weak flexion	Medium strength and sustained flexion for several secs.	Strong flexion; contraction spreads to forearm	Very strong grasp. Infant easily lifts off couch			
<b>Rooting</b> Infant supine; head midline. Touch each corner of the mouth in turn (stroke laterally)	No response	A. Partial weak head turn but no mouth opening B. Mouth opening, no head turn	Mouth opening on stimulated side with partial head turning	Full head turning, with or without mouth opening	Mouth opening with very jerky head turning			
<b>Sucking</b> Infant supine; place index finger (pad toward palate) in infant's mouth; judge power of sucking movement after 5 sec.	No attempt	Weak sucking movement: A. Regular B. Irregular	Strong sucking movement, poor stripping A. Regular B. Irregular	Strong regular sucking movement with continuing sequence of 5 movements. Good stripping	Clenching but no regular sucking			
<b>Walking (state 4, 5)</b> Hold infant upright, feet touching bed, neck held straight with fingers	Absent		Some effort but not continuous with both legs	At least 2 steps with both legs	A. Stork posture; no movement. B. Automatic walking			
<b>Moro</b> One hand supports infant's head in midline, the other the back. Raise infant to 45° and when infant is relaxed let his head fall through 10°. Note if jerky. Repeat 3 times	No response, or opening of hands only	Full abduction at the shoulder and extension of the arm 	Full abduction but only delayed or partial adduction 	Partial abduction at shoulder and extension of arms followed by smooth adduction A. Abd>Add B. Abd=Add C. Abd<Add 	A. No abduction or adduction; extension only B. Marked adduction only 		J	S
<b>Neurobehavioural items</b>								
<b>Eye appearances</b>	Sunset sign Nerve palsy	Transient nystagmus. Strabismus. Some roving eye movement	Does not open eyes	Normal conjugate eye movement	A. Persistent nystagmus B. Frequent roving movement C. Frequent rapid blinks			
<b>Auditory orientation (state 3, 4)</b> To rattle. (Note presence of startle)	A. No reaction B. Auditory startle but no true orientation	Brightens and stills; may turn toward stimuli with eyes closed	Alerting and shifting of eyes; head may or may not turn to source	Alerting; prolonged head turns to stimulus; search with eyes	Turning and alerting to stimulus each time on both sides		S	
<b>Visual orientation (state 4)</b> To red woollen ball	Does not focus or follow stimulus	Stills; focuses on stimulus; may follow 30° jerkily; does not find stimulus again spontaneously	Follows 30-60° horizontally; may lose stimulus but finds it again. Brief vertical glance	Follows with eyes and head horizontally and to some extent vertically, with frowning	Sustained fixation; follows vertically, horizontally, and in circle			
<b>Alertness (state 4)</b>	Inattentive; rarely or never responds to direct stimulation	When alert, periods rather brief; rather variable response to orientation	When alert, alertness moderately sustained; may use stimulus to come to alert state	Sustained alertness; orientation frequent, reliable to visual but not auditory stimuli	Continuous alertness, which does not seem to tire, to both auditory and visual stimuli			
<b>Defensive reaction</b> A cloth or hand is placed over the infants face to partially occlude the nasal airway	No response	A. General quietening B. Non-specific activity with long latency	Rooting; lateral neck turning; possibly neck stretching.	Swipes with arm	Swipes with arm with rather violent body movement			
<b>Peak of excitement</b>	Low level arousal to all stimuli; never > state 3	Infant reaches state 4-5 briefly but predominantly in lower states	Infant predominantly state 4 or 5; may reach state 6 after stimulation but returns spontaneously to lower state	Infant reaches state 6 but can be consoled relatively easily	A. Mainly state 6. Difficult to console, if at all B. Mainly state 4-5 but if reaches state 6 cannot be consoled			
<b>Irritability (states 3,4,5)</b> Aversive stimuli: Uncover Undress Pull to sit Prone Ventral susp. Moro Walking reflex	No irritable crying to any of the stimuli	Cries to 1-2 stimuli	Cries to 3-4 stimuli	Cries to 5-6 stimuli	Cries to all stimuli			
<b>Consolability (state 6)</b>	Never above state 5 during examination, therefore not needed	Consoling not needed, Consoles spontaneously	Consoled by talking, hand on belly or wrapping up	Consoled by picking up and holding; may need finger in mouth	Not consolable			
<b>Cry</b>	No cry at all	Only wimpering cry	Cries to stimuli but normal pitch	Lusty cry to offensive stimuli; normal pitch	High pitched cry, often continuous			

**Notes** \* If asymmetrical or atypical, draw in on nearest figure  
Record any abnormal signs (e.g. facial palsy, contractures, etc.)

Fig. 12.44 Continued

comes from the hard palate, not the tongue or cheek. Coordination between sucking and swallowing exists from 28 weeks' gestation but the strength to sustain it and to synchronize breathing is only adequate after 32-34 weeks' gestation. Sucking gradually builds up from bursts of three at a time to eight or more, with a reduction in the interburst interval. If sucking is absent, test the gag reflex by gently stroking the soft palate with a cotton bud.

### Palmar and plantar

The palmar reflex results from stroking the palmar surface of the hand, eliciting a grasp that is often strong enough to lift the baby from the crib. It is present from 26 weeks' gestation and persists up to 4 months. Stroking the ball of the foot results in curling of the toes in a similar manner to the palmar response.

Fig. 12.45 The fully developed Moro reflex, abduction phase.

## Special senses

### Examination of the eyes and vision

Babies can usually be induced to open their eyes by holding them face to face and spinning them round, or they often open their eyes when sucking. The eyes are in alignment, although a slightly dysconjugate horizontal position is not abnormal in the first 6 weeks. Vertical or skew deviation is always abnormal and has been seen in association with periventricular hemorrhage. Sunsetting should be noted although it is not as reliable a sign of raised intracranial pressure as later in childhood. The 'doll's eye' maneuver induced by rotating the head from side to side results in reflex deviation of the eyes to the opposite side. It is normally present even in preterm babies, and absence of this reflex indicates severe brainstem damage. Pupil reactions to light are present after 30 weeks' gestation. Visual fixation of a suitable target such as a red woolly ball or a target of broad concentric rings is present from 32 weeks' gestation, and by 34 weeks babies track briefly. By term, babies can reliably fix and track an object held 20–30 cm away from the face, and persistent failure to follow a suitable object should give rise to concern. Blinking in response to a bright light is a subcortical response and has been recorded in anencephalic and holoprosencephalic babies. Tracking in infancy is not a guarantee of later intact visual function and may be subcortically mediated.<sup>814</sup> Optokinetic nystagmus is present from 36 weeks and preferential looking towards gratings of varying thickness can be used to assess acuity. Visual cortical function is achieved by 6 weeks.<sup>815</sup> Visual evoked potentials are discussed below, in the investigation section.

### Hearing

Babies from 28 weeks' gestation onwards can be shown to respond to noise, usually by turning the head or increased body movements. For electrophysiological methods of assessing the auditory pathway, see investigation section below.

### Smell

There is no doubt that babies, including preterm babies, can detect smells. Babies of all gestations have been found to respond to odors such as peppermint, or breast pads soaked in their own mother's breast milk.

## Sensory testing

### Withdrawal

Babies respond to pinprick stimuli with gross body movements or grimacing and there is no doubt that even very preterm babies feel pain. The classic withdrawal response of flexion of the lower limb and extension of the opposite leg in response to pricking the sole of the foot requires motor integrity also, and habituates easily.

## Occipitofrontal head circumference and fontanelles

Examination is not complete without measuring and charting the occipitofrontal circumference and noting the presence and tension of the fontanelles. An extremely large anterior fontanelle can indicate hypothyroidism; a non-existent fontanelle can mean craniosynostosis. Useful information can be obtained by palpation of the sutures which can be widely spaced (diastasis) or overlapping. During the first 3 months of life the head grows at least 0.5 cm a week, and insufficient head growth is an ominous sign.

## INVESTIGATION OF THE NEWBORN NERVOUS SYSTEM

### Imaging

Ultrasound is the imaging procedure of first choice in the newborn. The method is relatively cheap, portable and safe, enabling repeated examinations. Intracranial hemorrhage can be identified fairly reliably. The cystic lesions of periventricular leukomalacia can be imaged down to a resolution of 1–2 mm, although ultrasound detects only about a third of cases of periventricular leukomalacia when compared to MRI. Ultrasound is insensitive for the detection of lesions of the extracerebral space and in the posterior fossa. Several atlases of cranial ultrasound pictures exist.<sup>816</sup>

MRI provides exquisite anatomical information but requires careful supervision and attention to detail particularly when it involves babies requiring artificial ventilation, in order to ensure that all ferrous metal components are excluded for safety. MRI is the method of choice for imaging the neonatal brain and avoids the radiation exposure of CT. CT should be reserved for emergencies and occasions when there is concern about intracranial bleeding. For those who wish to learn more about MRI the books by Rutherford<sup>817</sup> and Barkovich<sup>818</sup> are useful resources.

### Examination of CSF

Lumbar puncture is often easier with the baby sitting up in the newborn period, and this position results in a more stable oxygen level. The spinal cord of the newborn extends to L3 so that the L3/L4 space is the best one to choose. A blood sample for plasma glucose estimation should be collected before performing the lumbar puncture as the stress response raises the blood sugar level. The CSF glucose value is usually 70–80% of the plasma glucose and should be at least 50% of it. A proper styleted lumbar puncture needle should be used as there have been cases of epidural tumors resulting from the implantation of a tiny core of skin during neonatal lumbar puncture with an unstyleted needle. In the neonatal period CSF may be xanthochromic because of jaundice or old intraventricular hemorrhage. The cell count is higher than later in childhood. In preterm neonates the red and white cell counts can each be up to 30/mm<sup>3</sup> (Table 12.88). A study with careful documentation showed that the mean value was 7 white cells/mm<sup>3</sup> with two standard deviations from the mean being 21.<sup>820</sup> Martin-Ancel suggested that the upper limit of normal at term is 5 white cells/mm<sup>3</sup> although these workers found that counts of up to 30 occurred in babies without evidence of CNS infection.<sup>821</sup> There is some consensus emerging that the upper limit of normal white cell count in the CSF of a term baby should be set at 21 white cells/mm<sup>3</sup>, and a recent study found that this led to a sensitivity of 79% and a specificity of 81% for the diagnosis of meningitis, although 12% of the cases would still have been missed; choosing 1 as the upper limit was over-sensitive.<sup>819</sup>

In general the Gram stain will reveal organisms when the CSF white cell count is high in a baby who has not been treated with antibiotics; when no organisms are seen it is important to think of viral meningitis and to start treatment with aciclovir. Red cell counts of more than 1000/mm<sup>3</sup> make the interpretation of CSF results impossible: applying correction factors using the ratio of white cells to red cells has been shown to be inaccurate. The only course of action is to repeat the lumbar puncture after 12 h.

### Estimation of intracranial pressure (ICP)

ICP usually refers to pressure within the CSF space, and when subtracted from the arterial pressure gives the cerebral perfusion pressure. Rising

Table 12.88 Normal values for csf in neonates

Type of baby	Red cell count (per cubic mm)	White cell count (per cubic mm)	Protein (g/L) (mmol/L)	Glucose
Preterm < 7 days	~ 30	9 (0–30)	1 (0.5–2.9)	3 (1.5–5.5)
Preterm > 7 days	~ 30	12 (2–50)	0.9 (0.5–2.6)	3 (1.5–5.5)
Term < 7 days	< 10	5 (0–21)*	0.6 (0.3–2.5)	3 (1.5–5.5)
Term > 7 days	< 10	3 (0–10)	0.5 (0.2–0.8)	3 (1.5–5.5)

\*See text; more than 21 white cells/mm<sup>3</sup> has a sensitivity of 79% and a specificity of 81% for the diagnosis of meningitis in the newborn, but on occasion babies can have a positive CSF culture with white cell counts lower than this.<sup>819</sup>

ICP results in a reduction in cerebral perfusion unless the usual reflex elevation in systemic blood pressure occurs (the Cushing response). The Cushing response may be inadequate in the newborn.<sup>822</sup>

### Normal value of ICP in the newborn

Measured directly with pressure transducers at lumbar puncture the pressure is 0–5.5 mmHg.

### Electroencephalography

Conventional multichannel EEG recordings are difficult to obtain in newborn babies but provide the most complete information. The montage of electrodes is hard to apply and maintain and many babies requiring investigation are in ICUs which are electrically noisy. Continuous monitoring is possible with several types of cerebral function monitor (CFM) which display amplitude integrated and compressed EEG (aEEG) at the cot side. Modern digital technology now allows multichannel EEG recordings to be made and stored at the cotside, with simultaneous

video and physiological monitoring. Cotside aEEG is increasingly used as a tool with which to support the diagnosis of encephalopathy and/or seizures, and to assist with prognosis although at least one formal EEG is recommended. Guidance on the interpretation of aEEG patterns is available.<sup>823</sup>

### Maturation of EEG

The EEG of very preterm babies is markedly discontinuous (Fig. 12.46) with a pattern of high voltage slow activity with suppressed EEG activity termed 'trace alternant'. This pattern can still be seen during normal sleep in mature babies, but with increasing gestation there is a reduction in amount and duration of trace alternant activity. There is also a pattern, called 'delta brush', of fast waves superimposed on delta waves which can be misinterpreted as convulsive activity. A persisting severe abnormality of the background EEG activity predicts later adverse outcome in both preterm and term babies.<sup>824–826</sup>

Fig. 12.46 Maturation of the normal EEG in preterm babies: (a) 25 weeks; (b) 29 weeks; (c) 35 weeks; (d) 40 weeks.

## Investigation of the visual pathway

Visual evoked potentials (VEP) are produced within the occipital cortex as a result of repeatedly applying an appropriate visual stimulus so that the minute electrical response to it, which will be identical each time, can be extracted from the random background electrical noise (EEG) by computerized averaging. Stroboscopic or flashing red lights are used which can penetrate closed eyelids. The electrical response 'matures' with advancing gestation and can be detected from 25 weeks. Study of VEPs has been found to be of value in predicting outcome after birth asphyxia<sup>827</sup> and is a sensitive test for the integrity of the visual pathway. Absent VEPs predicted cortical blindness in preterm babies with extensive cystic leukomalacia.<sup>828</sup>

## Investigation of the auditory pathway

Neural pathways for hearing are established and can be tested within hours of birth. The fetus responds to low frequency sounds applied to the maternal abdomen from 19 weeks of gestation, with a gradual increase in the range of frequency response and sensitivity.<sup>829</sup> Young children who are fitted with hearing aids early have an excellent chance of developing normal speech, but the current average age for the acquisition of hearing aids is often almost 2 years. Universal neonatal hearing screening was established in all regions of England and in Scotland by the end of 2005, and so far the yield of babies diagnosed with bilateral permanent deafness is around 1 per 1000. This program replaced the previous 8 month health visitor 'distraction' test, which had proved unsatisfactory and has been phased out. The new program identifies cases far earlier than before, with a median age of 10 weeks. Newborn hearing screening is carried out with automated auditory evoked potentials or by the study of automated oto-acoustic emissions; the auditory response cradle proved unreliable and is not used for the national screening program ([www.library.nhs.uk/screening](http://www.library.nhs.uk/screening)).

## CONVULSIONS IN THE NEWBORN

### Diagnosis and incidence

Convulsions are more frequent on the first day of life than at any other time, although the diagnosis is easily missed because their manifestations can be extremely subtle.<sup>830</sup> Subtle seizures are the most common type, occurring in 75% of the cases described by Scher et al<sup>831</sup> (Table 12.89). Repetitive lip smacking, cycling or swimming movements, deviation of the eyes and apnea can all be epileptic in origin but are sometimes difficult to distinguish from normal movements or jittering.

Continuous monitoring has shown that electrical seizures occur more frequently in the newborn than clinically suspected seizures, and conversely that stereotyped repetitive activity which looks like a seizure is not always associated with EEG change.<sup>833,834</sup> This phenomenon of electro-clinical dissociation is more prevalent in the neonatal period than later in life. Recognition of seizure activity may be particularly important in babies who are paralyzed as prolonged seizures (> 30 min in animals) are accompanied by an increase in cerebral metabolic rate which outstrips

Table 12.89 Types of seizure in the newborn (adapted from Volpe<sup>832</sup>)

Type	Clinical manifestation
Subtle	Eye signs – eyelid fluttering, eye deviation, fixed open stare, blinking Apnea Cycling, boxing, stepping, swimming movements of limbs Mouthing, chewing, lip smacking, smiling
Tonic	Stiffening. Decerebrate posturing
Clonic	Repetitive jerking, distinct from jittering Can be focal or multifocal
Myoclonic	Rapid single repetitive contraction of muscle groups Sleep myoclonus is benign.

the available energy supply and leads to cerebral damage. Changes in cerebral energy metabolites and cerebral blood flow velocity have been seen even in the brief seizures characteristic of the human neonate.<sup>835</sup>

The incidence of seizures in term babies is reported at between 1.6 and 14 per 1000 deliveries. Higher incidences were reported prior to the introduction of low-phosphate milks, and half the babies in early series were hypocalcemic. More recent series give an estimate of around 5 per 1000; in most series a quarter of the cases are amongst babies of less than 30 weeks' gestation and a half are less than 37 weeks.<sup>836</sup> The incidence of clinically diagnosed seizures in VLBW babies varies from 50 to 130 per 1000.<sup>837,838</sup>

## Etiology

### Intracranial injury

The majority of cases of seizures in term babies are associated with hypoxic–ischemic encephalopathy (HIE) (Table 12.90).<sup>830,839–842,844</sup> Newer imaging methods have revealed focal cerebral artery infarction (stroke) to be more common than previously suspected, with the left middle cerebral artery the most commonly affected.<sup>845,846</sup> A thrombophilia screen (looking for inherited disorders such as factor V Leiden) should be carried out in cases of neonatal stroke. Intracranial hemorrhage is the commonest cause of seizure in the preterm neonate.

### Maternal drug withdrawal

Methadone withdrawal is more likely to produce seizures than heroin, but modern treatment for neonatal abstinence syndrome is aimed at preventing seizure, which has now become rare. Withdrawal from maternal selective serotonin reuptake inhibitors (SSRIs) such as paroxetine is probably increasing as a cause of neonatal seizure.

### Metabolic causes

The metabolic causes of hypocalcemia, hypoglycemia, hyponatremia and hypomagnesemia now account for less than 10% of cases of neonatal seizure but remain important because they are readily treatable. Hypomagnesemia coexists with hypocalcemia about half the time, and recognition is important because administration of calcium can cause the serum magnesium to drop further. Pyridoxine dependency can be a difficult diagnosis to make; the disorder is autosomal recessive and the fits are intractable until an infusion of 100 mg pyridoxine is given, ideally under EEG monitoring. The response may take up to half an hour. Pyridoxine is necessary for the manufacture of gamma-aminobutyric acid, which is the major inhibitory neurotransmitter, and hence in the familial form of the disease replacement needs to be life-long. Temporary deficiency has also arisen following vomiting and incorrectly designed formula baby milks. Inborn errors of metabolism such as nonketotic hyperglycinemia can cause seizure and these should be suspected if the onset is late and related to milk feeds. Preterm babies can develop transient hyperammonemia and hyperlactemia causing seizures. 'Fifth day fits' were commonly reported in the 1970s and 1980s, but this condition is now rarely diagnosed.

### Infection

Infection accounts for about 8% of cases of neonatal seizure and evidence of bacterial or viral infection should always be sought, including congenital infections such as CMV.

### Inherited and congenital disorders

Benign familial convulsions are dominantly inherited and occur in the first 3 weeks of life. The fits can be very frequent but they are usually brief and the prognosis is excellent. The diagnosis rests on excluding other causes and the presence of a positive family history. The chromosomal defect has recently been mapped to the long arm of chromosome 20. Benign neonatal sleep myoclonus may give rise to dramatic manifestations in otherwise entirely healthy newborns who have an excellent prognosis.

Sometimes neonatal seizures are the first manifestation of a congenital neurological disorder and these are more likely if the fits are intractable. The condition called 'early infantile epileptic encephalopathy'

Table 12.90 Causes of neonatal convulsions

	1	2	3	4	5*	6†	7
Number of cases in report	–	–	71	131	100	40	100

\*This series included >31 week gestation infants only.

†This series was limited to cases presenting in the first 48 hours of life.

Blanks occur where no cases were recorded in a particular study.

Data in column 1 are from Levene & Trounce,<sup>839</sup> column 2 from Goldberg,<sup>840</sup> column 3 from Andre et al,<sup>841</sup> column 4 from Bergman et al,<sup>842</sup> column 5 from Estan & Hope,<sup>843</sup> column 6 from Lien et al,<sup>844</sup> column 7 from Mizrahi & Kellaway.<sup>850</sup>

presents as severe tonic spasms and many of these babies have cerebral malformations. Cases of Aicardi syndrome (female children with infantile spasms, agenesis of the corpus callosum and a characteristic EEG) would also fall into this group. The phakomatoses occasionally present in the neonatal period, and syndromes such as Zellweger or Smith–Lemli–Opitz can cause neonatal seizures.

## Investigations of seizures

These follow from the possible causes listed above. Information regarding the pregnancy, labor and delivery is vital. Essential laboratory investigations include estimation of calcium, magnesium, glucose, acid–base balance and sodium in the blood together with a full infection screen including a lumbar puncture, specimens for virology and a congenital infection screen. A cranial ultrasound scan should be included as a first line investigation. If the cause is not revealed, second line investigations include MRI, samples to look for maternal ‘street’ drugs, urinary and blood amino acid estimation, chromosomal analysis, blood ammonia, measurement of organic acids and consideration of a trial of pyridoxine. The value of an EEG examination has already been discussed. Information about the background interictal EEG is useful in prognosis, particularly if the EEG is made at 12–48 hours of age.<sup>826,847</sup>

## Treatment

### General guidelines

Treatment is best given intravenously as intramuscular absorption is erratic and the neonate has little muscle mass. Facilities to site and maintain intravenous lines and to institute artificial ventilation are necessary, as many of the available drugs depress respiration and ventilation can become inadequate due to frequent convulsions. The high total body water of the neonate means a large volume of distribution hence the loading doses are relatively large. Most of the antiepileptic drugs (AEDs) are protein bound and can interact with other drugs and bilirubin. Many AEDs act by enhancing the inhibition of the gamma amino butyric acid (GABA) receptors, particularly the chloride permeable GABA<sub>A</sub> receptors. The neonatal neurone has a high chloride content and consequently the developing brain has a different response to GABA compared to the adult brain; in other words GABA becomes excitatory rather than inhibitory. Recently, it has been discovered that the neonatal brain continues to express a Na<sup>+</sup>K<sup>+</sup>2Cl<sup>−</sup> (NKCC1) cotransporter after birth, explaining the high intracellular chloride levels which

have been observed at this time.<sup>848</sup> This provides an elegant explanation for the observation that standard AEDs do not work well in newborn babies and leads to the intriguing possibility that drugs which act on the NKCC1 transporter would work better. Recently, there has been the exciting observation that bumetanide, which is widely used as a diuretic and has a good safety profile, suppresses seizures in rat pups, and anecdotal case reports are likely to follow. In the meantime, the best current advice is to use phenobarbital in an adequate dose with an early blood level, and to follow with intravenous phenytoin if seizures are not controlled.<sup>849,850</sup> Midazolam is a popular third line antiepileptic drug and has a good safety profile, albeit evidence for effect on electrographically determined seizures in the newborn is lacking.<sup>851</sup> Thiopental coma did not improve the outcome in a controlled clinical trial<sup>852</sup> and in resistant cases lidocaine may be the best alternative, although it accumulates and should not be continued for more than 48 hours.<sup>853</sup>

### Phenobarbital

It is reasonable to give 30 mg/kg of phenobarbital as a loading dose to a baby who is already ventilated, otherwise use 15 mg/kg. Gilman et al achieved seizure control with phenobarbital alone in 77% of cases using a rapid sequential method in which they gave 15–20 mg/kg initially then further doses of 5–10 mg/kg every 30 min up to a maximum of 40 mg/kg and serum level of over 40 mg/L.<sup>854</sup> The half-life of phenobarbital is very long and there have been concerns about toxic effects on the developing brain, including apoptosis.

### Sodium valproate

Hepatotoxic effects, hyperammonemia and hyperglycemia may limit the use of this drug in the newborn. Valproate proved effective in six intractable cases of neonatal seizure.<sup>855</sup>

### Duration of treatment

Concern about the effects of anticonvulsant treatment on the developing brain means that most neonatologists would only discharge a baby on maintenance phenobarbital if the neurological examination was abnormal, discontinuing treatment before discharge in those who were neurologically normal. As many as 56% of babies developed subsequent epilepsy in one series<sup>856</sup> although 30% is probably a more realistic figure.<sup>830,831</sup> For babies who are discharged on anticonvulsants consider discontinuation of treatment if the baby is seizure-free at 9 months.

## Prognosis

This is related to the cause of the seizures. Following hypoxic–ischemic encephalopathy at term about 25% of those who fit will have sequelae. Many surviving preterm babies who suffered seizures have a disability, and a more precise prognosis in this group can be obtained by considering the findings on MRI. The prognosis after hypocalcemic seizure and in familial neonatal seizure is excellent. Symptomatic hypoglycemia and meningitis have a 50% chance of sequelae in the survivors. A normal background interictal EEG at term is a good prognostic factor. The value of a normal neurological examination at discharge in providing early reassurance should not be underestimated either; in one series 11 of 14 babies with seizures who were normal at 4 years were assessed as normal at this stage. However, this apparently normal group of Oxford children then had problems with spelling and memory in adolescence.<sup>857</sup>

## INFECTION OF THE NERVOUS SYSTEM IN THE NEWBORN

### Neonatal meningitis

#### *Incidence and cause*

Meningitis is more common during the first month of life than at any other time: the incidence has been estimated as 0.25–0.5 per 1000 in normal weight babies and 1–2 per 1000 in those below 2.5 kg at birth. Gram negative organisms are more often implicated than later in childhood. The commonest causative organisms are *Escherichia coli* and group B streptococcus (GBS). The incidence of GBS meningitis has fallen in Australia and New Zealand since the widespread introduction of GBS screening and intrapartum antibiotic prophylaxis.<sup>858</sup> There are no plans to introduce GBS screening in the UK. *Listeria monocytogenes* neonatal meningitis has become very rare in the UK since the Government issued advice to pregnant women about avoiding soft cheese and cook-chill food in the late 1980s. A wide variety of different organisms have been reported, particularly in the LBW baby. Staphylococci have a predilection for ventriculoperitoneal shunts. Table 12.91 lists 10 important causative bacteria.

#### *Clinical signs and diagnosis*

The diagnosis can be difficult and if infection is considered as a cause for a baby's symptoms then a lumbar puncture must be performed. Examples of babies who should have LP performed include those who are shocked or who present later with subtle signs such as apnea or lethargy. Seizures are an indication for LP, and the investigation should be part of a septic screen done for prolonged rupture of membranes. Babies developing hydrocephalus deserve to have at least one LP even if the etiology is thought to be posthemorrhagic hydrocephalus, as ventriculomegaly can result from low grade staphylococcal infection. Cerebral ultrasound scans may reveal intraventricular strands. The yield of positive CSF cultures is relatively low, around 1% in most series, but the observation that the organism will not always be grown from the blood culture remains true, and there is still no substitute for lumbar puncture as part of a

septic screen in a symptomatic baby.<sup>819</sup> As previously discussed, the definition of what constitutes a normal neonatal CSF remains elusive but in a 'clean' tap at term more than 21 white cells/mm<sup>3</sup>, and certainly more than 30 are suspicious. If a high number of white cells are found but no organisms are seen on Gram staining in a baby not previously treated with antibiotics, then think of viral meningitis and start aciclovir pending further results including polymerase chain reaction (PCR) for herpes simplex.

#### *Treatment*

Antibiotics alone do not treat meningitis, and the importance of supportive treatment must not be underestimated. Babies are often shocked, requiring measures such as artificial ventilation, inotropic support, frequent monitoring of their acid–base state, careful fluid balance and maintenance of nutrition. There is no convincing evidence that adjunctive therapy such as steroid or immunoglobulin administration, exchange transfusion or monoclonal antibody treatment helps in neonatal meningitis.

Most treatment is started without knowledge of the infecting organism. Third generation cephalosporins offer excellent penetration into CSF with wide spectrum of activity including Gram negative organisms. Of those available, cefotaxime is probably the best choice and the outcome of neonatal meningitis has improved since the introduction of third generation cephalosporins. Before the organism is identified a broad spectrum of coverage with good CSF penetration can be achieved with cefotaxime, penicillin and gentamicin. The combination of ampicillin and an aminoglycoside is still chosen by some authorities. Vancomycin should be considered in preterm babies at high risk of *Staphylococcus epidermidis* infection. Antibiotics should be continued for 2–3 weeks, longer with Gram negative infections than for GBS. Recent advice to stop antibiotic treatment 2–3 days after the C-reactive protein returns to normal seems sensible. A repeat lumbar puncture should be carried out if there is a failure of clinical response and/or a failure of the laboratory indices of infection to return to normal. An intraventricular tap may be required if the ventricles are seen to enlarge on serial ultrasound scans, and intraventricular therapy should be considered via a surgically implanted reservoir in this situation.

#### *Prognosis*

The mortality of neonatal meningitis has fallen since the introduction of neonatal intensive care and the use of cephalosporins. In England and Wales, the mortality has fallen from 29% in 1985 to 10% in 1996–97.<sup>859</sup> The 1985–87 cohort have been followed up, and neurodevelopmental sequelae continue to be a problem in the survivors, with only 63% reported to have an entirely normal outcome. Deafness is the most common disability, and 10% had a severe disability (usually cerebral palsy).

### Viral and protozoal infections

These may be acquired in utero or postnatally and can cause severe neurological impairment. The acronym TORCH has been used to summarize the infections *Toxoplasma*, rubella, CMV and herpes, to which should be added human immunodeficiency virus and varicella zoster.

#### *Rubella*

Rubella infection in the first 16 weeks of pregnancy can result in a severely damaged baby with cataracts, sensorineural deafness, congenital heart disease, microcephaly, hepatosplenomegaly and thrombocytopenia. The condition is preventable by achieving high immunization coverage.

#### *CMV*

CMV can present in a dramatic form with jaundice and petechiae, the 'blueberry muffin' baby. Most babies who are symptomatic at birth will be handicapped. Only 1% of babies born with congenital CMV infection are symptomatic, however, most babies being clinically unaffected by the infection. Perhaps 6% have significant hearing loss at follow-up.<sup>860</sup>

Table 12.91 Bacterial causes of neonatal meningitis

Organism	Incidence
<i>Escherichia coli</i>	34%
Group B streptococci	30%
Other Gram negative bacilli	8%
<i>Listeria monocytogenes</i>	6%
Staphylococci	4.5%
Other streptococci	4%
<i>Pneumococcus</i>	3%
<i>Pseudomonas</i>	3%
<i>Haemophilus</i>	2%
<i>Meningococcus</i>	2%

**Varicella zoster**

Varicella zoster can result in severe damage with cicatricial skin scarring, cataracts and seizures. Sequelae are more likely following infection in the first trimester, when the risk was 1/11 in one study.<sup>861</sup> Transmission later in pregnancy can result in zoster or chickenpox in the newborn. If the maternal infection occurs within -5 to +5 days of delivery, the fetus will be unprotected by maternal antibody and should be treated with aciclovir and zoster immune globulin.

**Herpes simplex virus**

Herpes simplex virus can result in severe illness in newborns, and there is not always a clear history of a primary maternal genital infection because the lesions can be hidden on the cervix. There is a high incidence of meningitis and encephalitis. The infection should be treated with aciclovir. Herpes can be difficult to diagnose but the virus can be identified on electron microscopy, or a search for viral DNA can be made with a specific PCR test.

**Human immunodeficiency virus**

This retrovirus can cause meningitis and encephalopathy. Vertical transmission occurs in 13–45% of cases, a risk which can be reduced by zidovudine and by Cesarean section delivery. Neurological manifestations of HIV include encephalopathy and microcephaly.

**Toxoplasma gondii**

This protozoan can cause neurological sequelae when acquired in uterine life and the diagnosis is important because the condition is treatable. The organism is mainly acquired from cat litter or consumption of undercooked meat, and the infection may produce only mild symptoms in the mother. Birth prevalence is about 0.5 per 1000 in the UK. The classic triad of hydrocephalus, chorioretinitis and intracranial calcification is extremely rare, with only four such cases reported in the UK between 1975 and 1980. Specific IgM antibody can be demonstrated in the baby who should be treated with pyrimethamine + sulfadiazine followed by spiramycin. The prognosis of symptomatic congenital toxoplasmosis is poor, with 50% suffering impaired vision and 85% mental retardation.

**Spirochetal and fungal infections**
